Chapter 11 - Intravenous Drug Delivery Systems

Peter S. A. Glass
Steven L. Shafer
J. G. Reves

INTRODUCTION

For anesthetic drugs to be effective, they must reach their site of action. In 1628, William Harvey proved in *Exercitatio Anatomica de Motu Cordis et Sanguinis in Animalibus* that venous blood was transported to the arterial circulation and thus to the organs of the body by the heart. It was recognized almost immediately that this meant that drugs given into veins could be rapidly carried to the entire body. Indeed, in 1657, Christopher Wren injected opium intravenously by means of a quill and bladder (Fig. 11-1A) in dogs and humans, rendering them unconscious. It is doubtful that Wren recognized this unconsciousness as "anesthesia" as we think of it today. Eight years later, Sigismund Elsholtz gave an opioid solution for the purpose of rendering subjects insensitive, but it was not until 1874 that Pierre-Cyprien Ore administered chloral hydrate intravenously for a surgical procedure. This landmark occasion followed the unsuccessful attempts by the Russian surgeon Pirogoff to administer ether intravenously in 1846, shortly after Crawford Long and William Morton had independently demonstrated the efficacy of ether insufflation for surgery. [1]

Intravenous methods of anesthetic drug delivery have depended on a steady improvement in technology. The quill and bladder used by Wren were not significantly improved on until Alexander Wood employed a needle and syringe to give intravenous medications in 1853. The hollow hypodermic needle was developed by Frances Rynd and a functional syringe, by Charles Pravaz. [1] Contemporary needles, catheters, and syringes are descendants of these early devices. The latest technologic development in intravenous anesthesia has been the introduction of computerized pharmacokinetic model-driven continuous-infusion devices (Fig. 1B) , first published by Helmut Schwilden [2] in 1981. Schwilden demonstrated the ability to attain desired plasma levels of an intravenous anesthetic drug by using a computer-controlled infusion pump driven by the published pharmacokinetics of the drug. These efforts have resulted in the release in Europe of the first commercial targetcontrolled infusion (TCI) device, developed by Zeneca, specifically for the administration of propofol. The March 1998 issue of the journal *Anaesthesia* was devoted entirely to a review of TCI, with a focus on the "Diprifusor" and the role of TCI devices in clinical practice.

The ultimate development will be devices for the closed-loop administration of intravenous drugs during anesthesia. Systems have been developed for closed-loop administration of sodium nitroprusside [3] [4] [5] [6] [7] and muscle relaxants. [8] [9] [10] [11] [12] [13] [14] The drug effect is easily measured for vasoactive drugs and muscle relaxants, facilitating closed-loop control. The lack of an obvious readily available measure of mental status has hindered the development of closed-loop anesthetic delivery systems. Clinical assessment of anesthetic depth requires integration of the patient's physiology, the drug dosing history, the level of noxious stimulation, and measurement of the patient's response to stimulation (hemodynamics, movement, electroencephalogram [EEG], tearing, and so on). It seems unlikely that a closed-loop device will perform this complex heuristic assessment in the near future. However, increasing understanding of the physiology involved in providing anesthesia and the development of monitoring devices for specific components of the anesthetic state have resulted in increasing efforts to develop such closed-loop devices. Schwilden has developed closed-loop systems for infusion of methohexital [15] [16] and propofol [17] on the basis of the median EEG frequency. Other closed-loop systems have been based on auditory evoked potentials [18] or the bispectral index [19] developed by Aspect Medical Systems. [20]

The development of new techniques has coincided with the development of new drugs. Rapid intravenous induction became popular with the introduction of sodium thiopental in 1934. The pharmacokinetics of thiopental prevented its becoming popular for the maintenance of anesthesia. During the past 30 years, numerous intravenous hypnotics

Figure 11-1 Intravenous drug delivery, past and future. (A) A depiction of the first intravenous injection of opium, utilizing the quill and bladder. (B) The future of intravenous drug delivery, in which drugs are delivered with the aid of a small, sophisticated infusion pump, which permits dosing in terms of plasma drug concentration rather than amount.

(methohexital, 1957; propanidid, 1957; althesin, 1971; etomidate, 1973; propofol, 1977), anxiolytics (diazepam, 1966; midazolam, 1978), and analgesics (fentanyl, 1959; ketamine, 1966; sufentanil, 1979; alfentanil, 1980; remifentanil, 1996) have been introduced. The general trend in the introduction of these newer agents has been to provide drugs with shorter and shorter times for recovery from drug effect. The newer intravenous agents propofol, etomidate, alfentanil, sufentanil, and remifentanil have all been shown to provide a rapid onset of anesthesia, a stable maintenance phase, and a rapid recovery.

Before a review of intravenous anesthesia delivery techniques and devices, it is essential that the relevant pharmacokinetics and pharmacodynamics be understood so that intravenous drugs may be given to their best advantage. Therefore, we develop these concepts and then show how intravenous anesthesia delivery systems can be used to ration-ally dose the intravenous drugs used in clinical practice.

PHARMACOKINETIC CONSIDERATIONS

One objective of anesthetic administration is to produce the clinically desired *time course of anesthetic effect.* Often, this includes rapid onset, smooth maintenance, and rapid recovery after termination of the anesthetic. Conventional pharmacokinetic models assume that a bolus of drug is instantaneously mixed into the plasma, producing an immediate peak in the plasma concentration. The concentration then continuously declines until the next bolus. Except for a transient perioperative stimulus (intubation, incision, bowel traction), it is unlikely that the patient's anesthetic requirements follow the saltatory time course of anesthetic effect seen with repeated bolus injections. Thus, the technique of intermittent boluses results in excessive drug effect at the time of the bolus, inadequate drug effect before the next bolus, or both (Fig. 11-2) . The technique of giving the entire anesthetic as an initial bolus, as was popular several years ago with massive doses of opioids for cardiac surgery, represents the reductio ad absurdum of the intermittent bolus technique. This technique produces a needlessly huge initial peak and, depending on the dose, grossly excessive or possibly subtherapeutic levels later in the case. Fortunately, opioids are enormously forgiving drugs in paralyzed patients whose lungs are mechanically ventilated.

The oscillating effect produced by intermittent bolus injection may be clinically undesirable when drugs that depress hemodynamics are used or when prompt emergence is desirable. To produce a time course of drug effect that follows the time course of anesthetic requirement, it is necessary to use a continuous infusion that is titrated to perceived anesthetic requirement. Ideally, just enough drug is given to achieve the therapeutic blood or plasma drug concentration, which is then titrated until the end of surgery (Fig. 11-3) . This method of drug delivery avoids the peaks and valleys in drug concentration seen with intermittent drug boluses. Theoretical advantages of continuous infusions over intermittent bolus injections include fewer periods of poor anesthetic control, a reduction in the total amount of drug used, and a more rapid recovery from anesthesia. These advantages have been documented by several investigators. [21] [22]

The goal of intravenous administration is to administer anesthetic drugs so that the resulting plasma concentration produces the desired time course of drug effect. By use of pharmacokinetic models, it is possible to calculate the dose of drug needed to produce the desired time course of plasma concentration. The medical literature is replete with articles describing pharmacokinetic models for every drug administered in the course of providing anesthesia. Anesthesiologists have found little use for these models. In this chapter, we demonstrate how pharmacokinetic models *can* be used to develop rational dosing guidelines for use with intravenous infusion delivery systems. We first review some basic pharmacokinetic concepts and define the relevant pharmacology terminology. The reader can find more detail about pharmacokinetics in Chapter 2 .

Pharmacokinetic models are mathematical descriptions of how the body "disposes" of drugs. The parameters describing this disposing process are estimated by administering a known dose of the drug and measuring the resulting plasma

Figure 11-2 Pharmacokinetic simulation of (upper curve) a single large bolus (50 mug/kg) and (lower curve) of a smaller bolus (8 mug/kg) followed by small intermittent boluses (1.5 mug/kg), using fentanyl as an example. The single large bolus results in plasma drug concentrations far in excess of those required, whereas the intermittent scheme results in plasma concentrations that periodically fall below those required. Ideally, the plasma drug concentration should be just within the therapeutic range, which can be best accomplished by an appropriately administered continuous infusion.

concentrations. A mathematical model then relates the input, I(t), with the concentrations, C(t). These models can take many forms. Figure 11-4 shows the concentrations in the plasma over time after a single intravenous bolus of drug at time 0. The drug concentrations continuously decrease after the bolus, and the rate of decrease is approximately proportional to the amount of drug in the plasma. Typically, it is convenient to describe this behavior by use of exponential models. The curve might have a single exponent, in which case the plasma concentrations over time might be described by the function $C(t) = A\ e^{-kt}$, where A is the concentration at time 0, and k is a constant that describes the rate that the concentrations decrease. The relationship appears to be a straight line when graphed as the log of concentration versus time. The pharmacokinetics of intravenous anesthetic drugs are more complex because after a bolus of any anesthetic drug, one observes a period of rapid decrease before the terminal "log-linear" portion (e.g., the part that is a straight line when graphed as log concentration versus time is reached). We can model this by taking several

Figure 11-3 Landscape of surgical anesthesia. The stimuli of surgery are not constant; therefore, the plasma concentration of the anesthetic drug should be titrated to match the needs of the patient. ICU, intensive care unit.

Figure 11-4 Steps involved in pharmacokinetic model-driven infusion. Typically, pharmacokinetic models are derived from experiments in which plasma drug concentrations are measured at intervals after bolus administration of the drug. Nonlinear regression is used to fit a mono-, bi-, or tri-exponential curve to the resulting concentration versus time data. There is an algebraic relationship between the exponential decay curves and a 1-, 2-, or 3-compartment pharmacokinetic model. The BET infusion scheme is derived from the 2-compartment model by use of contour integration. A BET infusion results in the maintenance of a constant specified plasma drug concentration. Practical implementation of the BET scheme using real infusion pumps and infusion rates that change only at discrete intervals of time results in a plasma drug concentration profile that approximates that resulting from a BET infusion. V_1, volume of the central compartment.

monoexponential (i.e., one-exponent) curves and adding them together. The result is a polyexponential curve. For example, the concentrations after an intravenous bolus might be described by an equation with two exponents, $C(t) = A\ e^{-alpha\ t} + B\ e^{-beta\ t}$, or an equation with three exponents, $C(t) = Ae^{-alpha\ t} + B\ e^{-beta\ t} + C\ e^{-gamma\ t}$.

There are many uses of intravenous anesthetic drugs besides single boluses. A more general way to think of pharmacokinetics is to decompose the input into a series of bits (boluses) and consider each bit of drug separately. The general pharmacokinetic model of drug disposition commonly used in anesthesia treats each bit of administered drug to a polyexponential decay over time. The formal mathematical description of treating each bit of drug to a polyexponential decay over time is the relationship

where C(t) is the plasma concentration at time t and I(t) is the drug input (i.e., a bolus or infusion). The summation after the * (described later) is the function describing how the drug is disposed of (hence its name, the "disposition" function). Note that this is again a sum of exponentials, as described in the prior paragraph. Pharmacokinetic modeling is the process of estimating the parameters within this function. The integer n is the number of exponentials (i.e., compartments) and is usually two or three for the drugs used in anesthesia. Each exponential term is associated with a coefficient A_i and an exponent $lambda_i$. The lambda values are the inverse of the half-lives (half-life = 0.693/lambda), with the smallest lambda representing the longest (terminal) half-life. The A values are the relative contribution of each half-life to overall drug disposition. If a drug has a very long terminal half-life but a coefficient that is much smaller than the other coefficients, then the long half-life is likely to be clinically meaningless. The * means the mathematical process called convolution, which can be thought of as multiplication, but for functions rather

than for simple numbers. For a bolus at time 0, convolution simply is multiplication. For infusions, the math implied by the $*$ gets more complicated, but the A's and lambda's estimated are the same.

Constructing pharmacokinetic models represents a trade-off among accurately describing the data, having confidence in the results, and achieving mathematical tractability. It is usually the case that adding exponentials (i.e., increasing n) to the model provides a better description of the data. However, adding exponential terms usually decreases our confidence in how well we know each coefficient and exponential. Additionally, each exponential greatly increases the mathematical burden of pharmacokinetic models. This is why most models of anesthetic drugs are limited to two or three exponential terms.

The pharmacokinetic model shown has some useful characteristics, accounting for its enduring popularity in pharmacokinetic analysis. Most important, the model describes the observations from studies reasonably well, obviously the sine qua non for models. Second, these models have the useful characteristic of linearity. Consider the aforementioned equation for two values of I (the drug input), one exactly twice the magnitude (over the same time course) of the other. The equation predicts that C(t) will be twice as large for twice the input. Simply stated, if you double the dose (e.g., a bolus twice as large or an infusion twice as fast), then you double the concentrations.

More generally, linearity implies that the system (i.e., the body acting to produce a plasma drug concentration output from a drug dosage input) behaves in accordance with the principle of superposition. The superposition principle states that the response of a linear system having multiple inputs can be computed by determining the response to each individual input and then summing the individual responses. In other words, when the body treats each bit of drug to a polyexponential decay over time, the disposing of each bit of drug does not influence the disposing of other bits of drug.

The third reason for the continuing popularity of these models is that they can be mathematically transformed from the admittedly unintuitive exponential form shown earlier to a more easily intuitive compartmental form, as shown in Figure 11-5 .The fundamental parameters of the compartment model are the volumes of distribution (central, rapidly, and slowly equilibrating peripheral volumes) and clearances (systemic, rapid, and slow intercompartmental). The central compartment (compartment 1) represents a distribution volume and includes the rapidly mixing portion of the blood and the first-pass pulmonary uptake. The peripheral compartments are composed of those tissues and organs that show a time course and extent of drug accumulation (or dissipation) different from that of the central compartment. In the three-compartment model, the two peripheral compartments may correspond roughly to splanchnic and muscle tissues (rapidly equilibrating) and fat stores (slowly equilibrating). The sum of the compartment volumes is the apparent volume of distribution at steady state (Vd_{SS}) and is the proportionality constant relating the plasma drug concentration at steady state to the total amount of drug in the body. The intercompartmental rate constants (k_{12}, k_{21}, and so on) describe the exchange of drug between the central and the peripheral compartments. The elimination rate constant (k_{10}) encompasses processes acting through biotransformation or elimination that irreversibly remove drug from the central compartment.

Despite the physiologic flavor of compartmental models, compartmental models are simply mathematical transformations of the polyexponential disposition functions that are computed entirely from observed plasma concentrations. Thus, physiologic interpretation of the volumes and clearances, with the possible exception of systemic clearance and Vd_{SS} (the algebraic sum of the volumes), are entirely speculative.

The last reason that these models have been popular is that they can be used to design infusion regimens. If we abbreviate the disposition function

Figure 11-5 Three-compartment model (including the effect site) schematizing the basic pharmacokinetic processes that occur after intravenous drug administration. V_1, central compartment volume, usually expressed in liters or liters per kilogram. I (mug/kg/min or mug/kg), the dosing scheme as a function of time; k_{10}/min, rate constant reflecting all processes acting to irreversibly remove drug from the central compartment; k_{ij}/min, intercompartmental rate constants.

as simply D(t), then we can rewrite the relationship among concentration, dose, and the pharmacokinetic model D(t) as

where $*$ is the convolution operator, as noted earlier. In the usual pharmacokinetic study, we know I(t) (what we gave the patient), and we measured C(t). Our goal is to find D(t), the pharmacokinetic disposition function. Pharmacokinetic analysis can be thought of as a simple rearrangement of the above equation to solve for D(t):

where the horizontal bar means deconvolution, which is like division, but of functions rather than of simple numbers. When we design dosing regimens from known pharmacokinetic models and a desired course for the plasma concentration over time, then the known values are D(t) (the pharmacokinetics) and C_T (t) (the desired target concentrations), and the drug dosing scheme is

Thus, knowing the desired concentration time course and the pharmacokinetics, we can design an infusion rate to achieve any result. Unfortunately, such a solution might require some negative infusion rates, which is obviously impossible. Because we cannot suck drug out of the body (i.e., give negative infusions), we must restrict ourselves to those plasma concentrations over time that can be achieved with nonnegative infusion rates. The fundamental point is that given desired target concentrations, C_T (t), one can calculate the necessary infusion rates, I(t), from the pharmacokinetics, D(t), by use of the same set of tools used to calculate the

pharmacokinetics, D(t), when we know the infusion rates, I(t), and measured plasma concentrations, C(t).

The standard pharmacokinetic model has one glaring shortcoming. It assumes that after a bolus injection there is complete mixing within the central compartment, so that the peak concentration occurs precisely at time 0. It actually takes about 30 to 45 seconds for the drug to make its transit from the venous injection site to the arterial circulation. This model misspecification of 30 to 45 seconds may not seem significant, but it can cause some problems when one is trying to relate the drug effect after a bolus to the drug concentrations in the body. Researchers are modifying the standard polyexponential pharmacokinetic models to provide more accurate models of plasma drug concentration in the 1st minute after bolus injection.

PHARMACODYNAMIC CONSIDERATIONS

Although the plasma concentration after an intravenous bolus peaks nearly instantaneously, no anesthesiologist would induce a healthy patient with an intravenous bolus of hypnotic and immediately intubate the patient's trachea. The reason, of course, is that although the plasma concentration peaks almost instantly, additional time is required for the drug concentration in the brain to rise and induce unconsciousness. This delay between peak plasma concentration and peak concentration in the brain is called hysteresis. Hysteresis is the clinical manifestation of the fact that the plasma is not the site of anesthetic action, only the mechanism of transport. It is at the biophase that intravenous anesthetic drugs exert their pharmacologic effect. Physically, the biophase is the immediate milieu in which the drug acts on the body, including membranes, receptors, and enzymes.

The concentration of drug in the biophase cannot be measured for two reasons. First, it is usually inaccessible, at least in human subjects. Second, even if we could take tissue samples, the drug concentration in the microscopic environment of the receptive molecules would not be the same as the concentration grossly measured in, say, homogenated brain and cerebrospinal fluid. Although it is not possible to actually measure drug concentration in the biophase, by use of rapid measures of drug effect we can characterize the time course of drug effect. Knowing the time course of drug effect, we can characterize the rate of drug flow in and out of the biophase (or "effect site") by use of mathematical models. [23] [24] Knowing the rate of equilibration between the plasma and the biophase, we can characterize the apparent drug concentration in the biophase in terms of the steady state-plasma concentration that would produce the same effect.

Just as shown for the plasma pharmacokinetics earlier, if we know the time course of drug input and the time course of drug concentration, we can compute how the biophase disposes of drug, that is, the disposition function of the biophase. [25] [26] The direct input to the biophase is not the drug infusion, I(t), but is the arterial plasma concentration over time, $C_{plasma}(t)$. We can estimate the disposition function of the biophase, $D_{biophase}(t)$, on the basis of the plasma drug concentrations and the biophase concentrations:

where the horizontal bar is deconvolution, the inverse operation of deconvolution. Of course, $C_{biophase}(t)$ is an unknown quantity because we cannot directly measure drug concentrations in the biophase. As an alternative, we can postulate that drug concentration in the biophase relates to drug effect through one of several pharmacodynamic models. In this sense, the biophase concentrations over time can be thought of as a function of the observed effect over time, E(t), and several additional pharmacodynamic parameters, P, that relate concentration to effect. The parameters, P, are simultaneously estimated with D(t). We can rewrite the relationship stated earlier in terms of the time course of drug effect:

where F is the function relating the effect-site concentration to drug effect, according to parameters P. Just as developed for plasma pharmacokinetics, we assume that the effect site

treats each bit of drug to an exponential decay over time. However, the data almost never justify more than a single exponential term, and so the disposition function of the effect site is

where k_{e0} is the rate constant for transfer of drug from the site of drug effect to the environment. The monoexponential disposition function implies that the effect site is simply an additional compartment in the standard compartmental model, connected to the plasma compartment(see Fig. 11-5) . The effect site is the hypothetical compartment that relates the time course of plasma drug concentration to the time course of drug effect, and k_{e0} is the rate constant of drug elimination from the effect site. By definition, the effect compartment receives such tiny amounts of drug from the central compartment that it has no influence on the plasma pharmacokinetics.

If a constant plasma concentration is maintained, then the time required for the biophase concentration to reach 50 percent of the plasma concentration ($t½k_{e0}$) can be calculated as $0.693/k_{e0}$. After a bolus dose, the time to peak effect-site concentration is a function of both the plasma pharmacokinetics and k_{e0} . For drugs with a very rapid decline in plasma concentration after a bolus (e.g., adenosine, which has a half-life of several seconds), the effect-site concentration peaks within several seconds of the bolus, regardless of the k_{e0} . For drugs with a rapid k_{e0} and a slow decrease in concentration after bolus injection (e.g., pancuronium), the peak effect-site concentration is determined more by the k_{e0} than by the plasma pharmacokinetics. The time to peak effect and the $t½k_{e0}$ for several intravenous anesthetics are listed in Table 11-1 .

This delay in onset has important clinical implications. After a bolus, the plasma concentration peaks nearly instantly and then steadily declines. The effect-site concentration starts at zero and increases over time until it equals the descending plasma concentration. The plasma concentration continues to fall, and after that moment of identical concentrations, the gradient between the plasma and the effect site favors drug removal from the effect site, and the effect-site concentrations decrease. The rate at which the effect site rises toward the peak after a bolus dictates how much drug must be injected into the plasma to produce a given effect.

TABLE 11-1 -- The $t½k_{e0}$ and Time to Peak Drug Effect Following a Bolus Dose

DRUG	TIME TO PEAK EFFECT (MIN)	$t½\ k_{e0}$ (MIN)
Fentanyl	3.6	4.7
Alfentanil	1.4	0.9
Sufentanil	5.6	3

Remifentanil	1.6	1.3
Propofol	2.2	2.4
Thiopental	1.7	1.5
Midazolam	2.8	4
Etomidate	2	1.5

t½k_{e0} , rate constant for the transfer of drug from the site of drug effect to the environment.

For alfentanil, the rapid plasma-effect-site equilibration (large k_{e0}) causes the effect-site concentration to rise rapidly, producing a peak in about 90 seconds. At the time of the peak, about 60 percent of the alfentanil bolus has distributed into the peripheral tissues or has been eliminated from the body. For fentanyl, the effect site rises much more slowly and peaks 3 to 4 minutes after the bolus. [27] At the time of the peak, more than 80 percent of the initial bolus of fentanyl has been distributed into the tissues or eliminated. As a result of the slower equilibration with the effect site, relatively more fentanyl than alfentanil must be injected into the plasma, which slows the rate of drug offset from a fentanyl bolus compared with an alfentanil bolus.

This suggests that the k_{e0} must be incorporated into dosing strategies. For a rapid onset of effect, a drug with a short k_{e0} should be chosen. For example, for a rapid-sequence induction, alfentanil or remifentanil may be the opioid of choice when given as part of the rapid induction sequence because the peak opioid effect-site concentration coin-cides with endotracheal intubation. However, for a slower induction, in which a nondepolarizing neuromuscular blocking drug is used, it may be appropriate to choose an opioid with a slower onset of drug effect to coincide with the peak effect of the muscle relaxant. In this case, a bolus of fentanyl or sufentanil at the time of induction may be appropriate. The time to peak effect for the commonly used opioids is shown in Figure 11-6 . Knowing the k_{e0} (or time to peak effect) also improves titration of the drug by identifying the time at which the clinician should make the assessment of drug effect. For example, midazolam has a slow time to peak effect, and repeat bolus doses should be spaced at least 5 to 7 minutes apart to avoid inadvertent overdosing.

Figure 11-6 The simulated onset and time to peak effect of commonly used opioids based on their k_{e0} and pharmacokinetic parameters. k_{e0} , rate constant for transfer of drug from the site of drug effect to the environment.

To summarize:

1. If we know $D_{plasma}(t)$, the plasma pharmacokinetics, and I(t), the drug given to the patient, we can calculate the resulting concentrations, $C_{plasma}(t)$, as the convolution of $D_{plasma}(t)$ with I(t).

2. If we know $D_{biophase}(t)$, the biophase pharmacokinetics, and $C_{plasma}(t)$, the input to the biophase, we can calculate the resulting concentrations in the biophase as the convolution of $D_{biophase}(t)$ with $C_{plasma}(t)$.

It follows that we can relate the biophase concentration to drug input by the relationship

From this relationship, it follows that we can calculate the infusion rate necessary to produce any desired concentration time course in the biophase, $C_T(t)$, the target concentration, as

where the horizontal line represents deconvolution, provided we restrict our choice of $C_T(t)$ to those biophase concentrations that can be achieved without negative infusion rates. [25] [26]

Having established that we can produce almost any desired concentration time course in the effect site, what concentration should we choose? The pharmacokinetics and pharmacodynamics of the inhalational anesthetics are greatly simplified by the equilibrium established at the alveolar gas/blood interface, permitting the measurement of the minimum alveolar concentration (MAC) associated with 50 percent likelihood of movement in response to noxious stimulation. [28] Considerable effort has gone into developing a concept equivalent to MAC for intravenous anesthetic drugs.

Because of the difficulty measuring the concentration of intravenous drugs, early investigators related infusion rate to clinical effects, such as the response to skin incision. These studies defined the minimum infusion rate (MIR) necessary to prevent a somatic response to surgical skin incision in 50 percent of patients. This simple approach is pharmacokinetically naive. It ignores the accumulation of drug in the plasma that necessarily occurs over time during intravenous infusions. The result is that MIR is a time-dependent measure of dose adequacy. Additionally, the variability in MIR reflects both pharmacokinetic and pharmacodynamic variability between individuals, whereas the variability in MAC measures only pharmacodynamic variability between individuals.

Because MIR depends on the patient's pharmacokinetics, and MIR changes over time, investigators have developed more general measures to relate intravenous drugs to drug effect. The most common approach is to report pharmacodynamics in terms of C_{50} . The C_{50} is, by definition, *the concentration that produces 50 percent of the maximum possible drug effect.* There are many ways of thinking about C_{50} . It might be the drug concentration that prevents response (e.g., movement, hypertension, and catecholamine release) to a particular stimulus (e.g., incision, intubation, and sternal spreading) in 50 percent of patients. In this case, each combination of stimulus and response may have a unique C_{50} . For example, Ausems and colleagues [29] defined the C_{50} for several noxious stimuli for alfentanil in the presence of 66 percent nitrous oxide. When C_{50} is defined as the drug concentration that produces a given response in 50 percent of the patients, it is also the concentration associated with a 50 percent probability of response in a given patient. Note that defining C_{50} as the concentration that produces a given effect in 50 percent of individuals implicitly assumes that the effect can be achieved in all individuals. Some drugs exhibit a ceiling effect. For example, there appears to be a ceiling on the ability of opioids to suppress response to noxious stimulation. When a ceiling exists in drug effect, even at infinite concentrations, some patients may not exhibit the drug effect. In this case, the C_{50} is not the concentration that causes the drug effect in 50 percent of patients but is the concentration associated with the drug effect in half of whatever fraction of patients are able to show the drug effect.

Several studies have been performed to establish appropriate concentrations for intravenous anesthetics. The C_{50} for skin incision for alfentanil, fentanyl, and remifentanil in the presence of 70 percent nitrous oxide have been defined (Table 11-2) . The C50 values for loss of consciousness and skin incision have also been defined for the hypnotics thiopental, [30] [31] propofol, [32] [33] [34] and midazolam [35] (see Table 11-2). Defining the C_{50} , like MAC, provides a measure of relative potency between the intravenous anesthetics.

Another means of evaluating the relative potency of an intravenous anesthetic during anesthesia is to define the plasma concentration of the intravenous anesthetic (once it has equilibrated with the biophase) required to reduce the MAC of a volatile anesthetic by a set percentage. The MAC reduction of isoflurane by fentanyl, [36] sufentanil, [37] alfentanil, [38] and remifentanil [39] have all been defined. The concentrations of these opioids that provide a 50 percent MAC reduction are listed in Table 11-2 .

Another interpretation of C_{50} is the concentration that produces 50 percent of the maximum possible physiologic response. For example, the C_{50} for an EEG response is the drug concentration that provides 50 percent of the maximal EEG effect. The C_{50} for EEG response has been measured for the opioids alfentanil, [40] fentanyl, [40] sufentanil, [41] remifentanil, [42] [43] and trefentanil. [44] It has also been determined for thiopental, [30] [45] [46] etomidate, [47] propofol, [48] and benzodiazepines [49] (see Table 11-2) .

The EEG is a surrogate measure of anesthetic effect. The utility of the EEG as a surrogate measure of opioid drug effect comes from the consistency between the relative potency of the opioids based on the C_{50} for EEG response and the relative potency based on clinical measures, such as the C_{50} for ablation of response to a noxious stimulation and the C_{50} for 50 percent MAC reduction. Although the C_{50} values for all combinations of stimuli and measures have not been experimentally determined for each opioid, these can be accurately estimated by scaling the values of C_{50} determined experimentally for other opioids by the relative potency. For example, the C_{50} of alfentanil for spontaneous ventilation is about 40 percent of the C_{50} for the EEG response (Table 11-1) . Knowing this, we can estimate the C_{50} for spontaneous ventilation of sufentanil (which has not yet been determined experimentally) as 0.2 to 0.3 ng/mL, that is, 40 percent of the C_{50} for EEG response (0.7 ng/mL).

To be entirely independent of dosing history, the C_{50} must be determined at steady state. This is rarely possible

TABLE 11-2 -- Steady-State Concentrations or Predefined Effects [a]

DRUG	C_{50} FOR EEG DEPRESSION [b]	C_{50} FOR INCISION OR PAINFUL STIMULUS [c]	C_{50} FOR LOSS OF CONSCIOUSNESS [d]	C_{50} FOR SPONTANEOUS VENTILATION [e]	C_{50} FOR 50% ISOFLURANE MAC REDUCTION	MEAC
Alfentanil (ng/mL)	500-600	200-300	--	175-225	50	10-30
Fentanyl (ng/mL)	6-10	4-6	--	2-3	1.67	0.5-1
Sufentanil (ng/mL)	0.5-0.75	(0.3-0.4)	--	(0.15-0.2)	0.145	0.025-0.05
Remifentanil (ng/mL)	10-15	4-6	--	2-3	1.23	0.5-1
Thiopental (mug/mL)	15-20	35-40	8-16	--	--	--
Midazolam (ng/mL)	250-350	--	125-250	--	--	--

MEAC, minimum effective plasma concentration providing postoperative analgesia.

[a] Values in parentheses are estimated by scaling to the alfentanil C_{50} (see text for details).

[b] C_{50} for EEG depression is the steady-state serum concentration that causes a 50% slowing of the maximal EEG.

[c] C_{50} for skin incision is the steady-state plasma concentration that prevents somatic or autonomic response in 50% of patients.

[d] C_{50} for loss of consciousness is the steady-state plasma concentration for absence of a response to a verbal command in 50% of patients.

[e] C_{50} for spontaneous ventilation is the steady-state plasma concentration associated with adequate spontaneous ventilation in 50% of patients.

because most anesthetic drugs do not reach steady state during a continuous infusion until many hours have passed. However, if the drug has rapid equilibration between the plasma and the effect site and the investigator waits long enough after starting the infusion, this choice can be reasonably satisfactory. For example, Ausems and colleagues [29] [50] used a continuous infusion but chose a rapidly equilibrating drug, alfentanil, for their experiments and waited sufficiently long before taking measurements to ensure that the plasma and effect-site concentrations were nearly in equilibrium.

One alternative to performing a true steady-state experiment is to simply measure the plasma drug concentrations in non-steady-state conditions and to calculate C_{50} from these values. This is a poor choice because the extent of equilibration between the site of drug effect and the plasma influences the value of C_{50} . Thus, if C_{50} is based on non-steady-state plasma drug concentrations, it has exactly the same dependence on dosing history and time of measurement that taints the use of MIR.

A second alternative to performing a true steady-state experiment is to use mathematical modeling to calculate the effect-site concentrations of drug at the time of the measurement, as proposed by Hull et al [23] and Sheiner et al. [24] The relationship between the effect site and the plasma concentrations is represented graphically in Equation 5 and mathematically in Equation 9. Calculating effect-site concentrations is nothing more than attempting to determine the steady-state plasma concentrations that would produce the observed drug effect. Sometimes, when the C_{50} reflects effect-site concentrations, it is represented as Ce_{50} , to distinguish it from values of C_{50} that are based on plasma concentrations, which are then termed Cp_{50} . However, the distinction is artificial. In both cases, the C_{50} is intended to represent the steady-state plasma drug concentration associated with a given drug effect.

A third alternative to performing a steady-state experiment is to establish a pseudo-steady state by use of computer-controlled drug delivery. This has become the present state-of-the-art method for determining the C_{50} for anesthetic drugs, and many of the C_{50} values referenced earlier were determined at pseudo-steady state by use of computer-controlled drug delivery. Typically, this requires maintaining a constant plasma concentration steady state for four to five plasma-effect-site equilibration half-lives (e.g., 10-15 minutes for fentanyl). Such a long delay is not necessarily required when computer-controlled drug delivery is used. For example, Glass et al [51] used computer controlled infusions to target initially higher plasma target concentrations to provide more rapid achievement of the desired effect-site concentration. This can be automated by having the computer actually target the concentration in the effect-site rather than the plasma, rapidly establishing plasma-effect-site equilibration. [25] [26]

Thus, there are several ways to establish C_{50} in terms of steady-state concentrations. C_{50} can be estimated through mathematical effect-site modeling or can be measured experimentally by use of computer-controlled drug delivery to quickly establish a pseudo-steady state. Regardless, when C_{50} is referenced to steady-state plasma concentrations, it is superior to MIR because it is independent of the dosing history and the pharmacokinetic variability.

When C_{50} is defined in terms of the concentration associated with a response in half of a population, then that same C_{50} is the concentration associated with a 50 percent probability of response in the typical individual. However, the individual patient is not the typical individual but rather will have his or her own value for C_{50} . Expressed in clinical terms, different patients have different anesthetic requirements for the same stimulus. For example, the minimal effective analgesic concentration of fentanyl is 0.6 ng/mL but varies from 0.2 to 2.0 ng/mL between patients. [52] The minimal effective analgesic concentration of alfentanil [53] [54] and sufentanil [55] similarly varies between patients by a factor of five to ten times. This range encompasses both variability in the intensity of the stimulus and variability of the individual

patient. However, this wide range reflects the clinical reality that must be accounted for when dosing regimens are designed. Because of this variability, intravenous anesthetics should be titrated to each patient's unique anesthetic requirement for the given stimulus.

Pharmacodynamic Drug Interactions in Providing Anesthesia

A common residency experience for the authors, and perhaps for the reader as well, was the attempt to administer "pure" techniques: pure inhalational anesthesia (e.g., isoflurane/oxygen), pure nitrous/narcotic anesthesia (nitrous oxide/fentanyl/oxygen), pure ketamine anesthesia, and so on. We rapidly discovered that pure anesthetics required huge doses of drugs to achieve anesthetic conditions that were often unsatisfactory. The only benefit of struggling with pure techniques is the appreciation one gets for the essential role of drug interactions in the practice of anesthesia.

Drug interactions cause the C_{50} of one drug to shift in response to administration of a second drug. We have already referred to the ability of opioids to reduce MAC, a clinically useful drug interaction with a long history. In 1901, George Crile suggested that opioids should be administered with supplemental drugs for intravenous anesthesia. In 1959, DeCastro and Mundeleer introduced the term "neurolept anesthesia," consisting of a tranquilizer, opioid, and nitrous oxide. Today, the concept and term coined by John Lundy, "balanced anesthesia," is used to describe the concurrent administra-tion of several anesthetic drugs so that no single drug is given in a dosage sufficient to produce toxicity during or after surgery. Contemporary anesthesia consists of at least two components--analgesia and loss of consciousness. Combining an opioid with a volatile anesthetic provides both components. The interaction of volatile anesthetics and opioids in producing the anesthetic is complex but predictable. In addition, because two drugs are being used to provide anesthesia, recovery to an awake state is dependent on both drugs. Thus, to provide adequate anesthesia and appropriate recovery, it is important to incorporate both the pharmacodynamic interactions that occur between these drugs and their relative offset, as demonstrated by their context-sensitive decrement times.

Drug interactions are species dependent. Thiopental and opioids show relative antagonism to analgesic end points in rats, [56] [57] whereas their effects are synergistic in humans. [58] Just as C_{50} must be defined for very specific end points, drug interactions must also be clearly defined in terms of end points. For example, Kissin et al [57] observed that "the combination of a barbiturate and an opioid gives different outcomes for different end-points of anesthesia." Often, we differentiate between analgesic end points (i.e., analgesia to noxious stimulation) and hypnotic end points (e.g., sedation and loss of consciousness). In a study of morphine-midazolam interactions on sedation and loss of righting reflex in rats, Kissin et al [59] observed that the conventional bifurcation into hypnotic and analgesic end points may be inadequate. Both sedation and loss of righting reflex appear to be "hypnotic" end points, but they were associated with different degrees of synergy between morphine and analgesia. Kissin et al concluded that "differences in the outcomes of midazolammorphine interactions regarding sedation and hypnosis (loss of righting reflex) suggest that underlying mechanisms for these two effects are different. Therefore, they should not be regarded as only increasing depths of the same action."

The MAC of volatile anesthetics appears additive when several inhalational anesthetics are administered concurrently. [60] [61] In other words, 30 percent MAC of drug A combined with 40 percent MAC of drug B produce the same effect as 70 percent MAC of A or B. The additivity of MAC suggests a uniform mechanism of action for the inhalational anesthetics, although the "unitary theory" of inhalational anesthesia has fallen into disfavor. [62] [63] The intravenous anesthetics encompass categories of drugs (hypnotics, opioids, psychotomimetics, anxiolytics, neuroleptics, local anesthetics, and so on) with different receptors and mechanisms of action. In the absence of a uniform mechanism of action, there is no reason to anticipate simple additivity, for example, that maintaining 30 percent C_{50} of drug A plus 40 percent C_{50} of drug B will produce the same effect as 70 percent C_{50} of either drug A or drug B.

The assumption of balanced anesthesia is that combinations of drug will be synergistic in anesthetic effect (however defined) but not in toxicity. Such synergism has been demonstrated for a variety of drug combinations but not for others. [64] In an interesting set of studies, Glass and colleagues [34] observed minimal synergy between propofol and fentanyl for a hypnotic end point, loss of consciousness (Fig. 11-7) , but profound synergy between propofol and fentanyl for an analgesic end point, loss of response to skin incision (Fig. 11-8) More profound synergy for analgesic end points than hypnotic end points has also been demonstrated for the interaction between propofol and alfentanil [33] and sevoflurane and fentanyl. [65] Thus, when anesthetic regimens are designed that rely on synergy to produce the anesthetic state, it is important to distinguish the desired end point--loss of consciousness or ablation of response to noxious stimulation. Different combinations of drugs may be required to achieve each end point.

Mean alveolar concentration is defined as the steady-state alveolar concentration of anesthetic gas that inhibits movement to incision in 50 percent of patients. It is an excellent measure of potency. MAC is also a useful guideline for clinical

Figure 11-7 The interaction of propofol and fentanyl in providing loss of consciousness. The solid lines represent the concentrations of propofol and fentanyl when administered together that are required to prevent a response to a verbal command in 50% of patients at each decade of age.

Figure 11-8 The interaction of propofol and fentanyl in preventing a somatic response at skin incision. The solid line represents the concentrations of propofol and fentanyl when administered together that are required to prevent purposeful movement in 50% of patients at skin incision. The dashed line represents the concentration of propofol and fentanyl when administered together that is required to prevent purposeful movement in 95% of patients at skin incision.

dosage, provided the clinician remembers that it is the concentration *in 50 percent of patients* that inhibits a movement response and that it is defined in terms of an analgesic end point--loss of movement in response to noxious stimulation. To establish the interaction between volatile anesthetics and opioids, the reduction in MAC can be utilized. When such studies are performed, it is important that both the volatile anesthetic and the opioid be maintained at stable concentrations and have equilibrated with their effect site. For the volatile anesthetic, this is readily achieved by use of a calibrated vaporizer. For the opioid, targetcontrolled delivery devices as described in this chapter are used to maintain constant opioid concentrations within the effect compartment.

Probably the most commonly used combination of anesthetics is isoflurane and fentanyl. McEwan et al [36] demonstrated that the MAC of isoflurane is reduced by 50 percent at a fentanyl concentration of 1.7 ng/mL (Figure 11-9) This corresponds with a fentanyl loading dose of 4 mug/kg followed by 1.75 mug/kg/h. Because the minimum effective analgesic concentration of fentanyl is 0.6 ng/ml, [52] and because clinically significant respiratory depression may occur with plasma fentanyl concentrations above 2 ng/mL, [66] the steepest reduction in MAC occurred within the useful analgesic range for fentanyl (i.e., 0.6-2 ng/mL). In other words, just maintaining fentanyl within an analgesic range reduces MAC by 50 percent. The study by McEwan et al also demonstrated that beyond a fentanyl plasma concentration

Figure 11-9 The interaction of isoflurane and fentanyl in preventing a somatic response at skin incision (i.e., MAC reduction of isoflurane). The solid line represents the concentrations of isoflurane and fentanyl when administered together that are required to prevent purposeful movement in 50% of patients at skin incision. The dashed line represents the 95% confidence interval of the MAC at each combination of fentanyl and isoflurane. MAC, minimum alveolar concentration.

of 5 ng/mL, a plateau is seen with a maximum MAC reduction of approximately 80 percent. The maximum reduction in isoflurane was to a concentration of ±0.3 percent, that is, a value close to the MAC awake for isoflurane. [67]

Alfentanil, [38] sufentanil, [37] and remifentanil [39] produce similar reductions in isoflurane MAC, with an initial steep reduction at lower concentrations and a plateau effect at higher concentrations. Remifentanil is a new esterase-metabolized opioid. [51] [68] The MAC reduction of isoflurane by remifentanil has been published and is illustrated in Figure 11-10 . [39] The results of this drug interaction are identical to those with the other opioids tested. Again, even with these very high plasma concentrations (>30 ng/mL), a ceiling effect was observed, and the MAC of isoflurane was not reduced lower than 0.2 to 0.3 percent. The interactions between propofol and fentanyl [34] (Fig. 11-8) and propofol and alfentanil [33] have also been studied. The reduction of the C_{50} of propofol by these opioids is almost identical to their interaction with isoflurane in preventing a somatic response at skin incision.

Adequate anesthesia provides for loss of consciousness (a hypnotic end point) and reduction in response to noxious stimulation (an analgesic end point). Loss of consciousness is achieved at hypnotic concentrations well below the concentration that suppresses response to noxious stimulation (e.g., MAC). If a slightly higher dose of hypnotic is combined with an analgesic dose of opioid, the profound interaction between opioids and hypnotics reduces or ablates the response to noxious

stimulation. There is very little advantage in administering the opioid to higher concentrations once the ceiling effect is reached. This occurs at a concentration of 3 to 5 ng/mL for fentanyl and remifentanil, 200 to 400 ng/mL for alfentanil, and 0.25 to 0.5 ng/mL for sufentanil.

Figure 11-10 The interaction of isoflurane and remifentanil in preventing a somatic response at skin incision (i.e., MAC reduction of isoflurane). The solid line represents the concentrations of isoflurane and remifentanil when administered together that are required to prevent purposeful movement in 50% of patients at skin incision.

Additionally, keeping the opioid dose within an analgesic range prevents the very slow recovery that is associated with high opioid concentrations.

Although these principles are likely true for all patients, there is still variability in sensitivity from patient to patient, as well as variability in the level of stimulation associated with different surgical procedures. Thus, each patient is an experiment, with the clinician learning the individual patient's C_{50} for the combination of drugs employed during the administration of each anesthetic. Despite this variability, dosing guidelines still have an important role to play in the practice of anesthesia. The concentration ranges for the intravenous anesthetics for anesthesia, sedation, and analgesia are given in Table 11-3 . These ranges should be viewed as starting estimates on which subsequent titration can be based. They also provide a means of estimating whether the patient is having a typical response or an atypical response. If the patient's dosing requirements deviate greatly from established guidelines, it is reasonable to stop and wonder whether something else might be going on with either the patient or the drug delivery system.

DESIGNING DOSING REGIMENS

Bolus Dose Calculations

The definition of concentration is amount divided by volume. We can rearrange the definition of concentration to find the amount of drug required to produce any desired concentration for a known volume:

where C_T is the desired or "target" concentration. Many introductory pharmacokinetic texts suggest using this formula to calculate the loading bolus required to achieve a given concentration. The problem with applying this concept to the anesthetic drugs is that there are several volumes: V_1 (central compartment), V_2 and V_3 (the peripheral compartments), and Vd_{SS}, the sum of the individual volumes. V_1 is usually much smaller than Vd_{SS}, and so it is tempting to say that the loading dose should be something between $C_T \times V_1$ and $C_T \times Vd_{SS}$.

Consider the dose of fentanyl required to attenuate the hemodynamic response to intubation when combined with thiopental. The C_{50} for fentanyl, combined with thiopental for intubation, is approximately 3 ng/mL. The V_1 and Vd_{SS} for fentanyl are 13 L and 360 L, respectively. The aforementioned equations can thus be interpreted as suggesting that an appropriate dose of fentanyl to attenuate the hemodynamic response is between 39 mug (3 ng/mL × 13 L) and 1080 mug (3 ng/mL × 360 L). A fentanyl bolus of 39 mug achieves the desired concentration in the plasma for an initial instant, but the plasma levels almost instantly decrease below the desired target. The levels in the effect site will never be close to the desired target concentration of 3 ng/mL. A fentanyl bolus of 1080 mug, not surprisingly, produces an enormous overshoot

TABLE 11-3 -- Plasma Drug Concentration Ranges

DRUG[a]	STIMULUS					
	SKIN INCISION	***MAJOR SURGERY***	***MINOR SURGERY***	***SPONTANEOUS VENTILATION***	***AWAKENING***	***ANALGESIA OR SEDATION***
Alfentanil (ng/mL)	200-300	250-450	100-300	<200-250	--	50-100
Fentanyl (ng/mL)	3-6	4-8	2-5	<1-2	--	1-2
Sufentanil (ng/mL)	1-3	2-5	1-3	<0.2	--	0.02-0.2
Remifentanil (ng/mL)	4-8	4-8	2-4	<1-3	--	1-2
Propofol (mug/mL)	2-6	2.5-7.5	2-6	--	0.8-1.8	1.0-3.0
Methohexital (mug/mL)	5-10	5-15	5-10	--	1-3	2-5
Thiopental (mug/mL)	7.5-12.5 (with N_2O) 35-45 (without N_2O)	10-20	10-20	--	4-8	7.5-15.0
Etomidate (ng/mL)	400-600	500-1000	300-600	--	200-350	100-300
Midazolam (ng/mL)	--	50-250 (combined with an opioid)	50-250 (combined with an opioid)	--	150-200 (reduced to 20- 70 in the presence of an opioid)	40-100
Ketamine (mug/mL)	--	--	1-2	--	--	0.1-1

[a] Drug levels are when combined with 65-70% nitrous oxide (N_2O) unless otherwise stated. Effective plasma concentrations may differ markedly, depending on premedication and intraoperative drug combinations.

in the plasma levels that persists for hours (Fig. 11-11) Additionally, it is clearly absurd to use equations to calculate the fentanyl dose if the resulting recommendation is "pick a dose between 39 and 1080mug."

The usual dosing guidelines for bolus dose, presented earlier, are designed to produce a specific plasma concentration. Because the plasma is not the site of drug effect, it is illogical to base the calculation of the initial bolus on a desired plasma concentration. As pointed out previously, by knowing the k_{e0} of an intravenous anesthetic, we can design a dosing regimen that yields the desired concentration at the site of drug effect. If we do not want to overdose the patient, we should select the bolus that produces the desired peak concentration in the effect site.

The decline in plasma concentration between the initial concentration after the bolus (amount/V_1) and the concentration at the time of peak effect can be thought of as a dilution of the bolus into a larger volume than the volume of the central compartment. This introduces the concept of Vd_{pe}, the apparent volume of distribution at the time of peak effect, [25] [69] (Table 11-4) or pseudo-equilibration between the plasma and the site of drug effect. [70] The size of this volume can be readily calculated

from the observation that the plasma and effect-site concentrations are the same at the time of peak effect:

where C_{pe} is the plasma concentration at the time of peak effect.

Figure 11-11 Pharmacokinetic simulation demonstrating the limitations of infusion regimens based on simple pharmacokinetic parameters, using fentanyl as an example. These infusion schemes were designed to achieve a plasma fentanyl concentration of 3 ng/mL. The upper curve shows that a regimen using a loading dose based on the volume of distribution followed by a constant infusion based on clearance results in a transient period of extremely high plasma concentrations. If the same maintenance infusion is given but the loading dose is based on the volume of the central compartment, distribution of drug to the peripheral compartments causes the plasma concentration to fall below the desired level until the compartments reach steady-state concentrations, as shown in the lower curve. Cp, plasma drug concentration.

TABLE 11-4 -- Volume of Distribution at the Time of Peak Effect

DRUG	V_1 (L)	VD_{PE} (L)
Fentanyl	12.7	75
Alfentanil	2.19	5.9
Sufentanil	17.8	89
Remifentanil	5.0	17
Propofol	6.7	37

V_1 , volume of the central compartment; Vd_{pe} , apparent volume of distribution at the time of peak effect.

Returning to the goal of selecting the dose required to produce a certain drug effect, without producing an overdose, by definition, the plasma concentration at the time of peak effect is the bolus amount/Vd_{pe} . This can be rearranged to calculate the size of the initial bolus:

The Vd_{pe} for fentanyl is 75 L. Producing a peak fentanyl effect-site concentration of 3.0 ng/mL requires 225 mug, which produces a peak effect in 3.6 minutes. This is a much more reasonable dosing guideline than the previous recommendation of picking a dose between 39 and 1080 mug. Table 11-4 lists V_1 and Vd_{pe} for fentanyl, alfentanil, sufentanil, remifentanil, thiopental, and propofol. Table 11-1 lists the k_{e0} , $t½k_{e0}$ /2 k_{e0} , and time to peak effect of the commonly used intravenous anesthetics.

Maintenance Infusion Rate

By definition, the rate at which drug exits from the body is the systemic clearance, Cl_S , times the plasma concentration. To maintain a given target concentration, C_T , drug must be delivered at the same rate that drug is exiting the body. Thus, the maintenance infusion rate is

For drugs with multicompartmental pharmacokinetics, which includes all of the intravenous drugs used in anesthetic practice, drug is distributed into the peripheral tissues as well as cleared from the body. The rate of distribution into tissues changes over time as the tissues equilibrate with the plasma. Equation 14 is correct only after the peripheral tissues have fully equilibrated with the plasma, which requires many hours. At all other times, this maintenance infusion rate underestimates the actual infusion rate to maintain a target concentration.

However, in some situations, this simple maintenance rate calculation may be acceptable. For example, if an infusion at this rate is used along with a bolus dose based on Vd_{pe} , and the drug has a long delay between the bolus and peak effect, then much of the distribution of drug into the tissues may have occurred by the time the effect-site concentration reaches the target concentration. In this case, the maintenance infusion rate calculated as clearance times target concentration may be fairly accurate because Vd_{pe} is sufficiently higher than V_1 to account for much of the distribution of drug into peripheral tissues. Unfortunately, most drugs used in anesthesia have sufficiently rapid equilibration between the plasma and the effect site that Vd_{pe} does not adequately encompass the distribution process, making this approach fairly unsuitable.

Another example for calculating infusion rates for drugs with multicompartmental pharmacokinetics is the two-step approach proposed by Wagner. [71] In this method, two infusions, Q_1 and Q_2 , are administered in sequence. The loading infusion, Q_1 , is selected on the basis of a combination of convenience and degree of overshoot in plasma concentration that will be clinically acceptable. The second infusion, Q_2 , is calculated as C_T times Cl_S , exactly as noted earlier. The Wagner two-step approach does not consider the time course of drug effect and thus is probably not appropriate for most anesthetic drugs.

Having offered to the reader several simple approaches that do not work very well, we now turn to approaches that are mathematically sound. Because the net flow of drug into peripheral tissues decreases over time, the infusion rate required to maintain any desired concentration must also decrease over time. If the initial bolus has been based on Vd_{pe} , no infusion need be administered until the effect-site concentrations peak. After the peak in effect-site concentration, the correct equation to maintain the desired concentration is (unfortunately)

This equation indicates that a high infusion rate is initially required to maintain C_T . Over time, the infusion rate gradually decreases (Fig. 11-4) At equilibrium (t

), the infusion rate decreases to $C_T V_1 k_{10}$, which is the same as $C_T Cl_S$. Few anesthesiologists would choose to mentally solve such an equation during administration of an anesthetic. Fortunately, there are a few simple techniques that can be used in place of solving such a complex expression.

Figure 11-12 is a nomogram in which the Equation 15 has been solved, showing the infusion rates over time necessary to maintain any desired concentration of fentanyl, alfentanil, sufentanil, and propofol. This nomogram is complex, so we will review it in detail. The Y axis represents the C_T , selected in "pharmacodynamic considerations." The X axis is the time since the beginning of the anesthetic (i.e., since the initial bolus). Envision a horizontal line drawn from the target concentration (on the Y axis) across the graph to the right edge. The correct rate is given by the diagonal line that most closely intersects with this imaginary horizontal line (desired

target concentration) at the desired point in time. Each diagonal line is associated with a particular infusion rate. The suggested target initial concentrations are based on the work of Vuyk and colleagues [33] with propofol and alfentanil and are scaled to fentanyl and sufentanil based on their relative potencies. [69]

For example, to maintain a fentanyl concentration of 1.5 ng/mL, the appropriate rates are 4.5 mug/kg/h at 15 minutes, 3.6 mug/kg/h at 30 minutes, 2.7 mug/kg/h at 60 minutes, 2.1 mug/kg/h at 120 minutes, and 1.5 mug/kg/h at 180 minutes. Of course, you can select different times of rate adjustment, depending on clinical convenience and your assessment of how accurately the intravenous drug needs to be titrated.

Figure 11-12 Nomogram for calculating the maintenance infusion rates to maintain a stable concentration of fentanyl, alfentanil, sufentanil, or propofol. The Y axis is the desired concentration. The X axis is the time relative to the initial bolus. The diagonal lines show the infusion rates at different times required to maintain the desired concentration selected on the Y axis.

Recovery from Anesthesia

Recovery from anesthesia is similarly determined by the pharmacokinetic principles that determine the rate of decrease of drug from the effect compartment, once drug administration is terminated, as well as by the pharmacodynamics of the drug. Although the terminal elimination half-life is often interpreted as a measure of how short or long lasting a drug is, the rate at which drug decreases is dependant both on elimination and on redistribution of the drug from the central compartment. The contribution of both redistribution and elimination toward the rate of decrease of drug concentration varies according to the duration for which the drug has been administered. [69] [72]

In 1985, Schwilden [73] developed a mathematical model to relate the time course of offset of the inhalational anesthetics to the duration of anesthetic drug delivery. Similarly, Fisher and Rosen [74] demonstrated how accumulation of muscle relaxants in peripheral volumes of distribution resulted in slowed recovery with increasing duration of administration.

Figure 11-13 Context-sensitive half-times as a function of infusion duration (the "context") derived from pharmacokinetic models of fentanyl, sufentanil, alfentanil, propofol, midazolam, and thiopental.

They introduced two measures of the time course of recovery, the time for twitch tension to recover from 5 to 25 percent and the time for twitch tension to recover from 25 to 75 percent.

Since then, the time for the plasma concentration to decrease by 50 percent from an infusion that maintains a constant concentration (e.g., the infusion given by Equation 15) has been termed the "context-sensitive half-time" [72] (Fig. 11-13) , with the context being the duration of the infusion. The 50 percent decrease was chosen both for tradition (e.g., half-lives are the time for a 50 percent decrease with a one-compartment model) and because, very roughly, a 50 percent reduction in drug concentration appears necessary for recovery after administration of most intravenous hypnotics at the termination of surgery. Depending on the circumstances, decreases other than 50 percent may be clinically relevant. Additionally, sometimes it is the plasma concentration that is of interest, and sometimes it is the effect-site concentration that is of interest. A more general term is the context-sensitive "decrement time," [75] in which the decrement in concentration is specifically noted, as is the compartment where the decrease is modeled (plasma effect site). For example, the relationship between infusion duration and time required for a 70 percent decrease in fentanyl effect-site concentration is the "context-sensitive 70 percent effect-site decrement time."

Context-sensitive effect-site decrement times for varying percent decreases in alfentanil, fentanyl, and remifentanil concentration are illustrated in Figure 11-14 To determine when an infusion should be terminated (to enable awakening of the patient at the end of surgery), the clinician needs to bear in mind the decrease in concentration necessary for recovery, the duration of the infusion (the context), and the context-sensitive effect-site decrement time required for the necessary decrease.

Context-sensitive decrement times provide a clinically useful framework for understanding the relationship between infusion duration and time course of recovery. The context-sensitive half-time is fundamentally different from the elimination half-life. With a monoexponential decay, each 50 percent decrease in concentration requires the same amount of time, and this time is independent of how the drug was given. This is not true for the context-sensitive

Figure 11-14 Context-sensitive effect-site decrement times for alfentanil, fentanyl, sufentanil, and remifentanil showing the time required for decreases of a given percentage (labeled for each curve) from the maintained effect-site concentration after termination of the infusion.

decrement times. First, as the name is intended to imply, the time for a 50 percent decrease is absolutely dependent on how the drug was given, with infusion duration being the context to which the name refers. Also, small changes in percent decrement can result in surprisingly large increases in the time required. As can be seen from Figure 11-14 , in some situations, the time required for a 60 percent decrease in drug concentration can be more than twice the time required for a 50 percent decrease.

Context-sensitive decrement times are based on the assumption that the plasma or effect site is maintained at a constant concentration. This is rarely the case clinically, but maintenance of constant concentrations is a necessary assumption to provide a unique mathematical solution to the time required for a given percent decrement in plasma or effect-site concentration. Because plasma and effect-site concentrations are rarely kept constant, it is important that the context-sensitive decrement times be used as general guidelines for interpreting the pharmacokinetics of intravenous drugs and not as absolute predictions for any given case or infusion regimen. Automated drug delivery systems can provide more precise predictions of the time required for the plasma or effect-site concentration to decrease to any desired concentration, based on the actual drug dosing in the individual patient. This provides the clinician with guidance for the most appropriate time to terminate the infusion.

The context-sensitive decrement times focus on the role of pharmacokinetics in recovery from anesthesia. Pharmacodynamics plays an important role in recovery as well. Bailey [76] used integrated pharmacokinetic/pharmacodynamic models to define the "mean effect time" as the average time to responsiveness after maintenance of anesthesia at the 90 percent probability of unresponsiveness. The mean effect time demonstrates that when drugs have a very shallow concentration-versus-response relationship, the concentrations must fall a great distance to provide adequate emergence. This delays recovery from anesthesia. In contrast, recovery is hastened by a steep concentration-versus-response relationship, in which emergence from anesthesia occurs after a small decrease in concentration.

Pharmacodynamic drug interactions play a role in the recovery from anesthesia. Interaction relationships predict that the same anesthetic state can be achieved by different ratios of two drugs. One way of selecting the best ratio might be the combination that offers the most rapid recovery. For example, when an opioid is combined with a hypnotic, recovery from anesthesia depends on the opioid and the hypnotic concentrations, the rate of decrease of both drugs, and the relative synergy between loss of response to noxious stimulation (i.e., the state maintained during anesthesia) versus the relative synergy for loss of consciousness. Although the time course of decrease in opioid and hypnotic concentrations can be approximately described by their respective context-sensitive decrement times for both drugs (Fig. 11-15) , the influence of relative synergy for different end points must be captured by separate models of the interaction of the drugs for adequate anesthesia and emergence from anesthesia.

Vuyk et al [77] modeled the predicted time to awakening when propofol is combined with fentanyl, sufentanil, alfentanil, or remifentanil on the basis of the interaction

between

Figure 11-15 The interaction between hypnotic and opioid for prevention of movement to a noxious stimulus and for awakening and adequate spontaneous ventilation at the end of a surgical procedure. From this it can be seen that the time to recover at the end of a procedure is dependent on the concentration of both drugs used during surgery and the time for both to decrease below that required for consciousness and adequate spontaneous ventilation (i.e., their context-sensitive decrement times).

propofol and these opioids to provide adequate anesthesia and the interaction between propofol and opioids on emergence from anesthesia, as seen in Figures 11-16 and 11-17 The recovery times vary according to the selection of opioid and the relative balance of opioid and propofol during maintenance of anesthesia. For example, in the upper right of Figure 11-16 is a simulation of emergence from a propofol/fentanyl anesthetic of 15 minutes' duration. The simulations assume a steady concentration of fentanyl and propofol throughout the anesthetic, similar to the underlying assumption of context-sensitive decrement times. The curve in the lower plane is the interaction curve between fentanyl and propofol, ranging from no fentanyl and 10 mug/mL of propofol on the left to 1.8 mug/mL of propofol and 5.33 ng/mL of fentanyl on the right. In theory, any point along this curve would provide equivalent maintenance of anesthesia. When the infusion is turned off after 15 minutes of anesthesia, the concentration of both drugs decreases. The decreasing concentrations of propofol and fentanyl when the infusion is turned off can be found by the upward lines drawn from different points on the interaction curve, with the distance away from the lower plane representing time. Taken together, these upward lines represent a "recovery surface." The line drawn on the recovery surface shows the points at which the fentanyl-propofol interaction model predicts emergence.

Figure 11-16 shows that after 15 minutes of maintaining 1.8 mug/mL of propofol and 5.33 ng/mL of fentanyl (right edge of interaction curve), it takes approximately 20 minutes for the concentrations of both drugs to decrease enough to permit emergence. However, if one maintains concentrations of 3.0 mug/mL of propofol and 1.5 ng/mL of fentanyl (toward the middle of the interaction curve), then emergence can be expected just 10 minutes after the infusions are turned off. Examination of the curves for 60, 300, and 600 minutes of fentanyl/propofol anesthesia suggests that the fentanyl target concentration that provides the most rapid emergence is approximately 1.0 to 1.5 ng/mL, which requires a propofol concentration of approximately 3.0 mug/mL to maintain adequate anesthesia. This is consistent with the earlier observation that most of the MAC reduction benefit of fentanyl occurs within the analgesic range, and exceeding this range is of little benefit during anesthesia. In similar simulations, Vuyk and colleagues demonstrated that maintaining alfentanil and sufentanil concentrations in excess of the analgesic range (i.e., approximately 80 ng/mL for alfentanil and 0.15 ng/mL for sufentanil) is of little clinical benefit but can be expected to delay recovery from anesthesia. A second conclusion from these simulations is that if the patient demonstrates inadequate anesthesia, to prevent prolongation of recovery, it is preferable to increase the hypnotic concentration than to increase the opioid concentration beyond the analgesic range.

The situation is different for remifentanil, owing to its unusual pharmacokinetic properties (Fig. 11-17) The extraordinary clearance of remifentanil results in a very rapid offset of opioid drug effect when a remifentanil infusion is terminated. In Figure 11-17 , the lower plane again shows equivalent anesthetic states during maintenance with an opioid, remifentanil, and propofol. High doses of remifentanil permit a modest reduction in the dose of propofol necessary for adequate anesthesia. However, the recovery surfaces show that high doses of remifentanil, with a modest reduction in propofol dose, permit considerably faster emergence from anesthesia. For example, it takes approximately 12 minutes to awaken from 600 minutes of anesthesia maintained with 3 mug/mL of propofol and 2.5 ng/mL of remifentanil (Fig. 11-17 , lower left graph). If the remifentanil concentration is increased to 5 ng/mL, the propofol concentration can be reduced to 2 to 2.5 ng/mL, and emergence can be anticipated within 6 minutes of discontinuation of the infusions. It is unclear whether such a technique places patients at increased risk for awareness because a propofol concentration of 2 mug/mL is below the C_{50} value for wakefulness. [32] [34] Thus, a technique utilizing high doses of opioids with low doses of hypnotics depends on the opioid/hypnotic interaction to maintain unconsciousness.

Figure 11-16 Simulation of the interaction of propofol and fentanyl in preventing a somatic response at skin incision and time to recovery. On the X axis is fentanyl concentration, and on the Y axis, the propofol concentration. The curve in the lower plane shows the propofolfentanyl interaction required to provide adequate anesthesia. When the infusion is turned off, the concentrations of each drug decrease, as shown on the Z axis. The curve drawn on the recovery surface shows the time to emergence from anesthesia for combinations of fentanyl and propofol after an anesthetic of 15 minutes' (A), 60 minutes' (B), 180 minutes' (C), or 600 minutes' (D) duration. Note that the optimal combination for the most rapid recovery is a propofol concentration of 3.0-3.5 mug/mL of propofol combined with 1.5 ng/mL of fentanyl. As the concentration of propofol or fentanyl increases, the time for recovery increases. Also, the longer the duration of drug infusion, the longer recovery takes, especially if the optimal combination is not used.

The offset of isoflurane and sevoflurane is similar to that of propofol. The offset of desflurane is slightly quicker than that of propofol. We can draw some logical extrapolations from these propofol/opioid simulations to anesthetics consisting of volatile anesthetics combined with opioids. When fentanyl, alfentanil, or sufentanil is combined with a volatile anesthetic, the most rapid recovery occurs when the opioid concentration is maintained at an analgesic concentration equivalent to 1 to 2 ng/mL of fentanyl (Table 11-5) Concurrently, the volatile anesthetic should be administered to the lowest concentration required to provide adequate anesthesia but no less than an end-tidal concentration of 0.3 MAC, the MAC value for return of consciousness. If the patient demonstrates signs of inadequate anesthesia, it is

TABLE 11-5 -- Infusion Rates for Opioids to Achieve Preset Concentrations

DRUG	PLASMA TARGET CONCENTRATION (ng/m L)	BOLUS (mu g/kg)	INFUSION RATE mu g/kg/min)
Fentanyl	1	3	.020
	4	10	.070
Alfentanil	40	20	0.25
	160	80 [a]	1.00
Sufentanil	0.15	0.15	0.003
	0.50	0.50	0.010
Remifentanil	6	1 [a]	0.02
	12-20	1-2 [a]	0.4-1.0

[a] Give as a rapid infusion over 1-2 min.

Figure 11-17 Simulation of the interaction of propofol and remifentanil in preventing a somatic response at skin incision and time to recovery. Note that with remifentanil, the optimal combination is a propofol concentration of 2.5 mug/mL, and remifentanil, 5-7 ng/mL, and that increasing the duration of the infusion has minimal impact on recovery time if the optimal dose of remifentanil is not used. However, if the propofol dose is increased, recovery is prolonged.

preferable to increase the volatile anesthetic because this has less of an effect on prolonging wake-up time than does increasing the opioid (with the exception of remifentanil) and is more likely to ensure that awareness does not occur.

MANUAL INFUSION SCHEMES FOR INTRAVENOUS ANESTHETIC DRUG ADMINISTRATION

The following infusion schemes are developed from integrated pharmacokinetic-pharmacodynamic models. However, it is the patient's response, demonstrating adequate or inadequate anesthesia, that ultimately determines the rate of drug administration. Individuals vary markedly in their response to a given drug dose or concentration, and therefore it is essential to maintain an adequate drug level for each individual patient. Drug concentrations required to provide adequate anesthesia vary according to the type of surgery (e.g., surface surgery versus upper abdominal surgery). Thus, the infusion scheme should try to obtain higher or lower concentrations, depending on the planned surgery. The end of surgery requires lower drug levels, and therefore continuously titrating the infusion rate to a pharmacodynamic end point provides lower drug concentrations at the end of surgery and thus facilitates a rapid recovery. Common dosing schemes for administering intravenous anesthetics by infusion are given in Table 11-6 .

If the infusion rate proves to be insufficient to maintain adequate anesthesia, then both a further loading (bolus) dose and an increase in infusion are required to rapidly raise the plasma (biophase) drug concentration. Various interventions also require greater drug concentrations, usually for brief periods (e.g., laryngoscopy, endotracheal intubation, skin incision) (Fig. 11-3) Therefore, the infusion scheme should be tailored to provide peak concentrations during these brief periods of intense stimulation. An adequate drug level for endotracheal intubation is often achieved by the initial loading dose, but for procedures such as skin incision, a further bolus dose may be necessary. When the initial loading dose is based on the central compartment volume, a high initial infusion rate or several repeat doses are initially required to replace drug loss resulting from distribution.

TABLE 11-6 -- Manual Infusion Schemes[a]

DRUG	ANESTHESIA		SEDATION OR ANALGESIA	
	***LOADING DOSE* (mu *g/kg*)**	***MAINTENANCE INFUSION* (mu *g/kg/min*)**	***LOADING DOSE* (mu *g/kg*)**	***MAINTENANCE INFUSION* (mu *g/kg/min*)**
Alfentanil	50-150	0.5-3	10-25	0.25-1
Fentanyl	5-15	0.03-0.1	1-3	0.01-0.03
Sufentanil	1-5	0.01-0.05	0.1-0.5	0.005-0.01
Remifentanil	0.5-1.0	0.1-0.4	* [b]	0.025-0.1
Ketamine	1500-2500	25-75	500-1000	10-20
Propofol	1000-2000	50-150	250-1000	10-50
Midazolam	50-150	0.25-1.5	25-100	0.25-1
Methohexital	1500-2500	50-150	250-1000	10-50

[a] After the loading dose, an initially high infusion rate to account for redistribution should be used and then titrated to the lowest infusion rate that will maintain adequate anesthesia or sedation.
[b] For analgesia or during sedation, an initial loading dose is not required with remifentanil.

Opioids

Alfentanil

As shown by the work of Ausems et al, [22] the highest alfentanil concentrations (in combination with 70 percent nitrous oxide) are required for endotracheal intubation. The concentration of alfentanil required for skin closure is less than that required for skin incision or spontaneous ventilation. This allows the opioid to be gradually titrated downward toward the end of the procedure.

Several schemes have been advocated for the infusion of alfentanil when it is used as part of a nitrous-narcotic technique. [78] [79] [80] Most schemes vary in the sequence of the initial loading dose, although most provide 100 mug/kg within the first 10 minutes. Thus, the loading dose may be given as an initial rapid infusion of 50 mug/kg/min over 2 minutes or two 50-mug/kg doses given before endotracheal intubation and skin incision or as a slower infusion of 10 mug/kg/min over 10 minutes. The initial loading dose is followed by an infusion of 0.5 to 2 mug/kg/min. If the plasma concentration needs to be raised, an incremental bolus of 7 to 15 mug/kg with a 0.5- to 1-mug/kg/min increase in infusion rate is usually successful. For the aforementioned infusion scheme, alfentanil is usually combined with 66 percent nitrous oxide. If a hypnotic is used with alfentanil to induce anesthesia, the dose of the hypnotic can usually be markedly reduced. Alfentanil can be infused with nitrous oxide or combined with a hypnotic for a total intravenous technique. If combined with midazolam (loading dose, 0.05-0.2 mg/kg, and maintenance infusion, 0.05-0.15 mug/kg/min) or propofol (loading dose, 1-2 mg/kg, and maintenance infusion, 50-150 mug/kg/min), the loading dose and infusion rate of alfentanil can be reduced to 10 to 50 mug/kg followed by 0.5 to 1 mug/kg/min. If given with a potent inhalational anesthetic at 0.3 to 0.5 MAC, both the loading dose and the infusion rate can be reduced to approximately 30 to 50 percent of that used with nitrous oxide alone. When alfentanil is combined with a volatile anesthetic or forms part of a total intravenous anesthetic (TIVA) technique, alfentanil is dosed to achieve plasma concentrations of 75 to 150 ng/mL. When these doses are used, the infusion of alfentanil should be discontinued approximately 10 to 20 minutes before the expected end of surgery.

For cardiac anesthesia, in the absence of adjuvant anesthetic drugs, much larger infusion rates are required. An initial infusion of 40 mug/kg/min to loss of consciousness is followed by 10 mug/kg/min until cooling. On patient rewarming, the infusion rate can be restarted at 2.5 mug/kg/min. If inadequate anesthesia occurs, a bolus of 30 mug/kg usually ablates a response. Alfentanil has also been used for sedation in intensive care units. An initial loading dose of 25 mug/kg is followed by 0.25 to 0.5 mug/kg/min for 20 minutes and then titrated according to patient needs (0.1-2.0 mug/kg/min). A bolus of 3 mug/kg can be given when further supplementation is needed. In general, the doses of alfentanil, as listed earlier, should be reduced in elderly or debilitated patients.

Fentanyl

Infusion of fentanyl has classically been used for cardiac surgery. Again, various schemes have been advocated for the loading dose that vary from a bolus of 50 mug/kg to a rapid infusion of 4 to 5 mug/kg/min for 5 minutes or 2 to 3 mug/kg/min over 10 minutes. [79] [80] This is followed by continuous infusion of 0.1 to 1.0

mug/kg/min. These infusion schemes are designed to obtain a plasma fentanyl concentration of 20 to 40 ng/mL. Such a high dose of fentanyl has not demonstrated advantage over infusion schemes that provide fentanyl concentrations of 5 to 10 ng/mL and are combined with low-dose volatile anesthetic or propofol. This approach also facilitates fast tracking of cardiac patients. An initial loading dose of 10 to 20 mug/kg is followed by an infusion of 0.05 to 0.1 mug/kg/min. For noncardiac surgery in which a nitrous narcotic technique is used, the loading dose can be reduced to 5 to 15 mug/kg, followed by continuous infusion of 0.03 to 0.1 mug/kg/min to provide plasma concentrations of 3 to 10 ng/mL. [51] These concentrations combined with 66 percent nitrous oxide provide adequate anesthesia for intraabdominal and body surface surgery but may result in prolonged respiratory depression.

Analgesic concentrations of fentanyl are obtained at a plasma concentration of 1 to 2 ng/mL. [52] This concentration is optimal when combined with an intravenous hypnotic or potent inhalational agent or postoperatively for analgesia and is obtained after a loading dose of 1.5 to 3 mug/kg is administered,

followed by continuous infusion of 0.01 to 0.04 mug/kg/min.

Sufentanil

Sufentanil has been successfully used by infusion during cardiac anesthesia. [79] [80] For cardiac surgery, an initial loading dose of 15 mug/kg followed by an infusion of 0.75 mug/kg/min has been used. When combined with midazolam (midazolam loading dose, 100 mug/kg, and maintenance infusion, 1.0 to 2.5 mug/kg/min), the sufentanil dose is reduced to 2 mug/kg/min for 5 minutes, followed by 0.010 to 0.025 mug/kg/min thereafter. Even smaller doses of midazolam and sufentanil may be adequate for cardiac surgery. Very little has been published on the plasma concentrations or infusion rates of sufentanil required for noncardiac surgery. Several studies have established that in the concentration domain, sufentanil is approximately ten times more potent than fentanyl. Thus, for noncardiac surgery, infusion rates are based on achieving concentrations approximately one-tenth those of fentanyl. When combined with 70 percent nitrous oxide, a loading dose of 1 to 2 mug/kg of sufentanil followed by an infusion of 0.01 to 0.04 mug/kg/min can be used. As the analgesic component of a total intravenous technique or combined with a volatile anesthetic, an initial loading dose of 0.2 to 0.5 mug/kg followed by an infusion of 0.005 to 0.01 mug/kg/min of sufentanil is generally appropriate to achieve sufentanil concentrations within the analgesic range of 0.1 to 0.3 ng/mL.

Remifentanil

Remifentanil is the newest mu-agonist available for administration as an analgesic during surgery. Because of its metabolism by general body esterases, the drug is best administered as an infusion. Also, as a result of this unique metabolism, the decrease in concentration and dissipation of opioid effect are very rapid after termination of its administration. This enables the clinician to administer remifentanil at relatively higher analgesic concentrations than is possible with other opioids without the likelihood of prolonged respiratory depression. An initial loading infusion of 0.5 to 1 mug/kg/min is usually administered. Because the offset of the drug is so rapid, to ablate the response to endotracheal intubation, the infusion must be maintained at 0.2 to 0.5 mug/kg/min. When it is used in combination with a volatile anesthetic or propofol for noncardiac surgery, the infusion rate can then be reduced to 0.1 to 0.2 mug/kg/min. When it is used as a nitrous-narcotic technique, an infusion rate of 0.3 to 0.6 mug/kg/min is necessary. The infusion should be terminated only 5 to 10 minutes before the end of surgery. If postoperative pain is likely to be present, it is important that the clinician initiate other forms of pain management either before or on termination of the remifentanil infusion. For cardiac surgery, infusion rates of 1 mug/kg/min have been used successfully with marked ablation of the stress response. Infusion rates of 0.5 mug/kg/min combined with low-dose propofol or volatile anesthetic are also likely to be useful for cardiac surgery. Remifentanil, like all the other opioids, requires lower infusion rates to produce the same effect in elderly subjects. [43] [81] In general, by the age of 50 years, the remifentanil infusion rate should be reduced by half of that given to a 21-year-old patient. An 80-year-old patient requires a remifentanil infusion rate that is just ^{1} 1/3 of that required in a 21-year-old patient.

Hypnotics

Thiopental

Thiopental is rarely used by infusion for the maintenance of surgical anesthesia because the context-sensitive half-time is prolonged when an infusion of more than just a brief duration is used. Thiopental has been successfully used by infusion for short body surface procedures in combination with fentanyl. [82] An initial loading dose of 2 to 4 mg/kg is followed by an infusion of 200 to 300 mug/kg/min for the first 20 minutes and 30 to 70 mug/kg/min thereafter. For sedation, an initial loading dose of 2 to 4 mg/kg is followed by an infusion of 30 to 80 mug/kg/min. When thiopental is used by infusion, its metabolism results in the formation of pentobarbital. It is uncertain whether this is of clinical significance.

Methohexital

Methohexital (unlike thiopental) can be used effectively by infusion for the maintenance of anesthesia for surgical procedures of up to 2 hours' duration. A loading (induction) dose of 1 to 2 mg/kg is followed by an infusion of 50 to 150 mug/kg/min. Methohexital (at these infusion rates) is combined with 66 percent nitrous oxide and/or an opioid. For total intravenous anesthesia, alfentanil (10 mug/kg followed by 1 mug/kg/min) can be utilized with methohexital, 1.5 mg/kg, followed by a variable rate of infusion of 50 to 150 mug/kg/min. After premedication with morphine (0.15 mg/kg) or diazepam (10 mg orally), the MIR_{95} of methohexital (combined with 66 percent nitrous oxide and after a loading dose of 1.5 mg/kg) is 80 mug/kg/min. [83] Methohexital may also be used by infusion for sedation. A loading dose of 0.5 to 1 mg/kg given over 5 to 10 minutes followed by an infusion of 15 to 25 mug/kg/min usually provides an adequate level of sedation.

Etomidate

The use of etomidate by infusion is controversial (Ch. 9). Most infusions with etomidate for general anesthesia are designed to provide a plasma concentration of etomidate of 500 ng/mL. [84] This may be achieved with either a two-stage or a three-stage infusion scheme. In the two-stage scheme, etomidate is infused at 100 mug/kg/min for 10 minutes and then at 10 mug/kg/min. In the three-stage regimen, etomidate is infused at 100 mug/kg/min for 3 minutes, 20 mug/kg/min for 27 minutes, and 10 mug/kg/min thereafter. Etomidate is combined with nitrous oxide and usually an opioid given either intermittently or by continuous infusion. Etomidate plus fentanyl (loading dose 2-3 mug/kg, and maintenance infusion, 0.03-0.06 mug/kg/min) or alfentanil (loading dose, 10-20 mug/kg and maintenance infusion, 0.5-1 mug/kg/min) can be

combined to provide a total intravenous anesthesia. The etomidate infusion can usually be terminated 10 to 15 minutes before the anticipated end of the surgical procedure. Etomidate has been used by infusion for cardiac surgery. An initial loading dose (used for induction) is followed by an infusion of etomidate at 20 mug/kg/min. This results in a plasma level of 550 to 900 ng/mL. The use of etomidate for prolonged sedation is contraindicated, but it can be used for brief periods of sedation (i.e., for regional anesthesia). For sedation, a loading dose of 15 to 20 mug/kg/min for 10 minutes is followed by a maintenance infusion of 2.5 to 7.5 mug/kg/min.

Ketamine

Ketamine, although it possesses both hypnotic and analgesic properties as well as suitable pharmacokinetics, is not a popular agent for the maintenance of general anesthesia because of the psychotomimetic action of the currently available racemic mixture. When combined with a benzodiazepine, ketamine can provide suitable anesthesia (with or without nitrous oxide). The loading (induction) dose is 1 to 2 mg/kg followed by an infusion of 10 to 50 mug/kg/min. [85] In the absence of nitrous oxide and for more invasive surgery, higher infusion rates of 30 to 100 mug/kg/min may be necessary. Ketamine has also been used by infusion during cardiac surgery with similar infusion rates. An infusion of ketamine is also useful for analgesia and/or sedation. The loading dose can be reduced to 0.2 to 0.75 mg/kg and the infusion to 5 to 20 mug/kg/min. Ketamine has been successfully used with propofol for a TIVA technique. The ketamine infusion consists of a loading dose of 1 to 3 mg/kg followed by an infusion of 5 to 20 mug/kg/min. The propofol infusion is the same regimen used when propofol is combined with nitrous oxide.

Propofol

Propofol is best administered by continuous infusion. Plasma concentrations necessary during surgery and for awakening have been established (Table 11-6) .[32] [33] [34] [86] [87] To obtain a plasma level of 3 to 4 mug/mL, a four-stage infusion scheme can be utilized. This consists of a loading dose of 1 mg/kg over 20 seconds, followed by 170 mug/kg/min (10 mg/kg/h) for 10 minutes, then 130 mug/kg/min (8 mg/kg/h) for 10 minutes, and 100 mug/kg/min (6 mg/kg/h) thereafter. More simply, a loading dose of 1 to 2 mg/kg can be followed by an initial infusion of 150 to 200 mug/kg/min, which is then titrated to about 100 mug/kg/min. For short surgical procedures, generally higher average infusion rates are required, but for longer procedures, the average infusion rate is 100 to 150 mug/kg/min when combined with nitrous oxide.

When propofol is given with an opioid (rather than nitrous oxide) as part of a total intravenous anesthetic, the infusion rate of propofol remains similar to that required with nitrous oxide (i.e., an initial induction dose followed by a decreasing infusion rate of 150 to 100 mug/kg/min). Propofol has been combined with alfentanil (loading dose, 10-25 mug/kg, and maintenance infusion, 0.5-1 mug/kg/min), fentanyl (loading dose, 2-5 mug/kg, and maintenance infusion, 0.025-0.075 mug/kg/min), sufentanil (loading dose, 0.2-0.5 mug/kg, and maintenance infusion, 0.005-0.03 mug/kg/min), or remifentanil (loading dose, 1 mug/kg, and maintenance infusion, 0.1-0.4 mug/kg/min) for total intravenous anesthesia. The required infusion rate of propofol during anesthesia demonstrates a negative correlation with age, that is, elderly patients need lower infusion rates.

For sedation during regional or topical anesthesia, an initial loading infusion of 0.5 mg/kg is given over 5 minutes, followed by a maintenance infusion of 25 to 75 mug/kg/min. Propofol has been used for up to 2 weeks for continuous sedation of patients in intensive care units. [88] In critically ill patients, a loading dose may not be desirable, and therefore, an infusion can be started at 25 to 50 mug/kg/min. This rate is subsequently titrated to the desired level of sedation.

The bispectral monitor has recently been shown to correlate well with sedation and loss of consciousness [89] [90] [91] and thus has been introduced as a monitor for the hypnotic component of the anesthetic. Several studies have demonstrated that it may potentially facilitate the titration of the hypnotic component of the anesthetic, resulting in a decrease in the amount of hypnotic administered versus standard practice and shortening recovery time. [92]

Midazolam

Midazolam can be administered by infusion for sedation or for provision of the hypnotic component of a balanced anesthetic. [93] The effects of an opioid plus a benzodiazepine appear to be synergistic rather than additive for both loss of consciousness and anesthesia. [64] [94] The loading (induction) dose of midazolam can therefore be reduced to 0.05 to 0.1 mg/kg when combined with fentanyl (2-5 mug/kg) or alfentanil (10-25 mug/kg). The midazolam maintenance infusion rate during surgical anesthesia can then be titrated between 0.25 and 1 mug/kg/min with either fentanyl (maintenance infusion, 0.03-0.06 mug/kg/min) or alfentanil (maintenance infusion, 0.5-1.5 mug/kg/min). Nitrous oxide, if added to the aforementioned combinations, further decreases the required infusion rates of both midazolam and the opioid. For cardiac surgery, similar doses of midazolam can be combined with slightly larger doses of the chosen opioid. [95] For sedation, a loading dose of 0.02 to 0.1 mg/kg of midazolam is administered. This is best given as 10-mug/kg doses until the desired level of sedation is achieved. The maintenance infusion is then titrated between 0.25 and 1 mug/kg/min. At the termination of a prolonged (days') infusion, there is a possibility of a benzodiazepine withdrawal syndrome. Therefore, the infusion might need to be slowly tapered, or a long-acting benzodiazepine may need to be given.

INFUSION DEVICES

Manual Delivery

When an infusion of an intravenous anesthetic is administered, the infusion regimen can be controlled by a variety of mechanisms. These vary from the simple CAIR clamp or Dial-a-Flo (Abbott Laboratories) to complex computer-controlled infusion pumps. Simplicity of mechanical design, however, is not necessarily correlated with ease of use. This has prompted ongoing advances in infusion device technology.

Infusion devices can be classified as either controllers or positive displacement pumps. Explicit in their title, controllers contain mechanisms that control the rate of flow produced by gravity, whereas positive displacement pumps contain active pumping mechanisms.

The most commonly used pumps for the administration of intravenous anesthetics are positive displacement syringe pumps that utilize a screw mechanism. These pumps can be made extremely accurate and have the convenience of not requiring specialized tubing. Many of these pumps have included several new features that make infusion pumps more suitable for anesthetic delivery. An important advance has been the introduction of a calculator feature within the pump so that the clinician sets the weight of the patient, the drug concentration, and the infusion rate in dose/unit weight/unit time, and the pump then calculates the infusion in volume/unit time. These pumps also allow simple application of a stage infusion scheme (cf. Wagner [71]) by allowing a loading dose and a maintenance infusion rate to be programmed into the pump. Numerous syringe pumps also now include automated recognition of syringe size. Major advances have been made in pump technology and design, enabling intravenous anesthetics to be conveniently delivered. However, no commercially available device for the delivery of intravenous anesthetics approaches the convenience of the present-day vaporizer. It is therefore desirable to take intravenous drug delivery systems one step further beyond a "calculator" pump to a truly "smart" pump by utilizing truly automated drug delivery.

Automated Delivery

Automated drug delivery implies that some form of electronic and/or mechanical instrumentation performs dose rate adjustments independent of human intervention (in contrast to the manual devices described earlier). The desired target (e.g., drug concentration and clinical response) is still chosen by the clinician. Preprogrammed dosing (either bolus or infusion) is the simplest form of automated drug delivery. This consists of a preprogrammed infusion (usually calculated to provide a single target blood or effect concentration) that is automatically implemented by the microprocessor in the pump. Preprogrammed devices are limited in their application for intravenous anesthetic drugs because of their inability to allow the user to vary the target concentration. Generally, two methods may be applied for automated target anesthetic drug delivery: model-based (a form of open-loop control) and closed-loop systems.

Terms and Definitions

Both model-based and closed-loop systems require a set-point (Fig. 11-18) . [96] The set-point may best be defined as the quantifiable end point (e.g., plasma concentration or % T1 of the electromyogram) related to the clinical objective (level of anesthesia, neuromuscular blockade, and so on). Accordingly, the set-point is the value (i.e., target) that the automated system is attempting to maintain. The feedback signal is the measured (e.g., % T1 of the electromyogram) or predicted (e.g., predicted plasma concentration from pharmacokinetic

Figure 11-18 The components of a typical automated drug delivery system.

simulation) value that has resulted from the automated delivery process.

Although closed loop is the ideal means of automated drug delivery, as previously observed, there is no quantifiable signal that incorporates both the hypnotic and the analgesic requirements to provide an adequate anesthetic. Model-based drug delivery, therefore, provides an important alternative in circumstances in which the feedback signal cannot be measured and an appropriate model is available. A mathematical equation that can simulate the process that produces the set-point provides the model. Consequently, the accuracy of any model-based control system is dependent on how well the model represents the process under control. The control signal (which for automated drug delivery is the dosing scheme) is generated by a set of instructions known as an algorithm. An algorithm is ordinarily designed to keep the control variable as close as possible to the set-point value. The set-point and feedback values, in turn, act on the algorithm to generate the control signal. The control signal directs the actuator (i.e., the infusion pump), producing the intervention necessary to obtain the set-point (i.e., delivers the dosage regimen prescribed by the algorithm to the patient). This intervention results in a new feedback control signal, and the process repeats itself to maintain the patient at the target. In an adaptive control system, the algorithm is altered/adapted to the individual's unique response to the intervention produced by the actuator. For example, in a closed-loop system to control blood pressure, the algorithm may prescribe an increase in the infusion of sodium nitroprusside of 1 mug/kg/min when the blood pressure exceeds 5 mm Hg above the target. Although this may generally be an appropriate prescription, a change of this magnitude may cause a much greater drop in blood pressure than desired in a sensitive individual. After experience with the patient, an adaptive controller learns the individual's sensitivity and, utilizing this, changes the algorithm so that the control signal (dosing scheme) results in an intervention by the actuator that brings the feedback signal more closely to the target.

Target Control Infusion Systems

Devices

In 1968, Kruger-Thiemer [97] described the infusion regimen theoretically required to quickly achieve and maintain a constant plasma concentration of an intravenously administered

---

drug whose kinetics are described by a twocompartment model. This regimen has become known as the "BET scheme" and consists of an initial *B*olus of $C_T V_1$, an infusion at a rate of $C_T Cl_S$ to replace drug *E*liminated from the body, and an exponential decreasing infusion at a rate given by Equations 13 to 15 to replace drug

*T*ransferred to the peripheral tissues. The section on designing dosage regimens demonstrates that the bolus portion, calculated as $C_T V_1$, will likely be inadequate for reaching the desired effect-site concentration. Mathematically, the "ET" portion of the BET scheme is identical to the exponentially declining maintenance infusion rate shown in the section on designing dosing regimens. Precise implementation of this complex dosage regimen requires infusion rates that change continuously as a function of time until steady state is achieved.

More than a decade after publication of Kruger-Thiemer's classic paper, Schwilden and colleagues, [2] [98] [99] in Bonn, interfaced a microcomputer to an infusion pump and demonstrated clinical application of the BET infusion scheme. Many other groups have since implemented either the BET algorithm or modifications of this algorithm on microcomputers connected to infusion pumps. These algorithms are based on the same polyexponential equations or compartment models described previously and calculate the infusion rates theoretically required to obtain the desired plasma drug concentration (Fig. 11-4) . In implementing these algorithms, it is necessary to consider the physical limitations of the system. Drug cannot be removed from the system by the pump, and infusion rates must be positive or zero. Additionally, some pumps have limitations on precision and accuracy that can reduce the accuracy of the infusion.

Although there are minor differences in the approaches taken by different investigators using pharmacokinetic model-driven infusion systems, all are conceptually similar. Each consists of a microcomputer interfaced to an infusion pump (Fig. 11-19) The microcomputer executes a program that incorporates the pharmacokinetic model. In using the device, the anesthesiologist enters a target plasma or effect-site drug concentration (Fig. 11-20) This target concentration

Figure 11-19 The present CACI system used at Duke University Medical Center. It consists of a laptop computer electronically linked to an infusion pump. The desired drug plasma or effect-site concentration is entered via the keyboard.

is based on knowledge of the pharmacokinetic-dynamic relationship of the drug and the desired effect, as well as on the individual responses of the patient. At frequent intervals (e.g., every 9-15 seconds), the program compares the target concentration with the current prediction of the plasma or effect-site drug concentration, which is computed by real-time simulation of a pharmacokinetic model of the drug being infused. The computer calculates the infusion rate required to achieve the desired target concentration and transmits this rate to the pump, after adjusting the rate to reflect the physical capabilities of the pump. The pump then delivers drug to the patient at the desired rate.

At each step, the computer makes sure that the pump has delivered the drug it was instructed to give and checks for errors reported by the infusion pump (e.g., air in line, out of drug). The computer then calculates what the pump did during the previous interval and updates the internal pharmacokinetic model on the basis of the reported drug delivered. The cycle is completed when the computer calculates the infusion rate required over the next interval to reach the desired target concentration and transmits this rate to the infusion pump. Concurrently, the computer supplies the anesthesiologist with information about the state of the model, the state of the pump, any problems reported by the pump, the anticipated time course for elimination of drug from the patient, the total amount of drug delivered, the current infusion rate, and other information that may be of assistance in providing clinical care.

As a result of the increasing popularity of intravenous anesthesia and continuous-infusion techniques, the inherent reasonableness of pharmacokinetically based drug delivery, and the promising results achieved with automated administration of a variety of drugs by research groups around the world, pharmacokinetic model-driven infusion has now become a commercial device for the administration of propofol. This system consists of a commercial pump and the "Diprifusor" software that provides the control algorithm. This device is available in Europe and is awaiting approval in several countries, including the United States. It is expected that further devices consisting of standard infusion pumps, most of which already contain powerful microprocessors, will be equipped with the capability to perform pharmacokinetic model-driven infusions as a software-selectable option. Pharmacokinetic parameters for various drugs will be programmed into the device. Additionally, such devices will be able to target the concentration at the site of drug effect, rather than the plasma drug concentration, resulting in a system that is better adapted to the need for rapid titration in anesthesia. The user will use the pump's keypad or soft keys to select the drug to be infused and to enter pharmacokinetically relevant information about the patient, such as weight, age, and sex, and will ensure that the infusion setup is primed with drug at a specified concentration. Then, the keypad will be used to enter target concentrations in the same manner that the dial on a calibrated vaporizer is utilized in titrating the administration of an inhalation anesthetic. Alternatively, the pharmacokinetic model may be built into a future generation of anesthesia workstations. These workstations could then control many different brands of infusion pumps and could provide a common platform for implementing precise titration of intravenous anesthetics in the concentration domain.

Figure 11-20 Schematic illustration of pharmacokinetic model-driven drug delivery. The physician enters the target plasma or biophase drug concentration (Cp_d). An infusion device control algorithm uses a pharmacokinetic model for the drug being infused to determine what the infusion rate should be for the next infusion interval (e.g., 9-15 s). The infusion device delivers drug to the patient, and the infusion rate is fed into a simulation of the pharmacokinetic model to compute the current predicted plasma drug concentration (Cp_p). The variables computed in the simulation are available to the infusion algorithm, which then calculates the infusion rate necessary for the next 9-15 s to achieve the target concentration. On the basis of monitored and anticipated patient response, knowledge of approximate therapeutic plasma drug concentrations (e.g., Cp_{50}) and on Cp_p, the physician can titrate Cp_d as necessary.

Evaluation of Target-Controlled Drug Delivery

Acceptance of target-controlled drug delivery of intravenous anesthetics requires evaluation of both accuracy, defined as the difference between the predicted and the measured concentrations, and outcome of patients in whom automated drug delivery has been used. The sources of inaccuracy with pharmacokinetic model-driven devices include the software, the hardware, and the pharmacokinetic variability (Fig. 11-21) .

Inaccuracy in the software results from incorrect mathematical implementation of the pharmacokinetic model. Computer simulations can be used to test the infusion rates calculated by a software program, and thus software errors are fairly simple to identify and correct. [100] Inaccurate drug delivery from the infusion pump is small with present syringe-pump technology and thus contributes little to the overall inaccuracy of these devices. The major cause of inaccuracy is pharmacokinetic variability. There are two sources of this variability: (1) the pharmacokinetic model is always wrong and (2) the patient's pharmacokinetics are never those programmed into the model. The first source of variability reflects the fact that individuals are far more complex than implied by simple compartmental models, and thus no such model can precisely predict the concentrations, even if the pharmacokinetic parameters in the individual were known absolutely precisely. The second source of variability reflects that the parameters incorporated in TCI systems are average estimates in the population, and these estimates necessarily differ from the estimates that would best describe the model in any individual. Thus, the pharmacokinetic variability fundamentally precludes the possibility of precisely achieving the desired target concentration when automated drug delivery devices are used.

Optimization of Target-Controlled Drug Delivery

The performance of computer-controlled drug administration must be interpreted in terms of the therapeutic expectations of the clinician. Possible goals include accurately producing a desired concentration in the plasma, precisely titrating the plasma drug concentration, producing the desired drug effect, and producing the desired time course of

Figure 11-21 Major sources of potential error in pharmacokinetic model-driven drug delivery. In a commercial device, the computer functions would be incorporated into the infusion device itself.

drug effect. Over the past decade, investigators have addressed each of these goals and have refined the performance of automated drug delivery devices in light of these goals.

The ability of an automated drug delivery system to rapidly achieve and then maintain a selected target concentration is a logical measure of the performance of such a device. There are several ways of expressing the difference between the measured and the target concentrations. The most simple means is either to diagram a plot of the target and measured concentration of each sample in each individual patient (Fig. 11-22) or to diagram an XY plot of the measured to target concentration and observe how much the plots vary from the line of identity (Fig. 11-23) [66] The primary concern is how far the measured concentration is from the predicted one, and this is now most frequently described in terms of the performance error, which is the difference between the measured and the target concentrations as a percent of the desired target (i.e., [measured-target]/target * 100%). [101] The median value of the performance error for a patient or a population is referred to as the median performance error (MDPE) and represents the average overshoot or undershoot of the system. The median absolute performance error (MDAPE) is the median of the absolute value of all performance errors. The MDAPE is commonly used as a measure of the inaccuracy of an automated drug delivery device. An MDAPE of zero is perfect performance, and an MDAPE of 20 percent means that half the plasma concentrations will be within 20 percent of the target and half will be outside that range. A further assessment of accuracy is whether the system maintains a stable target concentration. This is best measured by the wobble of the system. Varvel et al [101] asked a group of clinicians to evaluate the performance of automated drug delivery devices and demonstrated that the MDAPE best predicted the adequacy of the performance of the automated delivery device, as judged by experienced clinicians.

As observed earlier, it is not reasonable to expect all performance errors to be zero percent. However, it would be desirable if positive and negative errors offset each other, so that the MDPE of an automated drug delivery device were zero percent. The MDPE does not indicate the range of performance errors (because positive and negative performance errors offset each other), but it does indicate whether the plasma concentrations achieved with the device tend to overshoot the desired target (+MDPE) or undershoot the desired target (-MDPE).

Table 11-7 summarizes the accuracy of pharmacokinetic model-driven devices administering several of the intravenous drugs in anesthetic. [29] [66] [102] [103] [104] [105] [106] [107] [108] [109] [110] It is clear from Table 11-7 that the expected performance of such devices, at best, tends to be around 20 to 30 percent MDAPE. The pharmacokinetics of propofol have probably been the most frequently tested. Coetzee et al [109] tested the accuracy of three parameter sets and found those of Marsh et al [110] and Tackley et al [111] to provide the best accuracy in adult patients (Fig. 11-24) . To demonstrate the actual impact of the three different pharmacokinetic parameters on propofol dosing, the infusion rates required to produce a set of target concentrations are plotted in Figure 11-25 . The pharmacokinetic parameter set of Marsh are those included in the Diprifusor software. Better accuracy has been obtained in

Figure 11-22 Individual plots of the target plasma fentanyl concentration (solid line) and measured concentration (dots) in four separate patients.

Figure 11-23 Plot of the measured to the predicted concentration of fentanyl administered via CACI in 24 patients. The solid line represents the line of identity, i.e., the target concentration is equal to the measured. The dashed lines represent a bias of ±30%.

children [110] because they may have less pharmacokinetic variability as a result of their general lack of chronic disease and more narrow distribution of weight at any given age (than found in adults).

Interest has focused on the impact of a second drug on the pharmacokinetics of the first. Several studies have shown that opioids may alter the pharmacokinetic parameters of propofol. [112] [113] [114] The exact mechanism for this is unclear but may be the result of alterations in cardiac output, reductions of hepatic blood flow, or first-pass pulmonary uptake of drug. It is unlikely to be related to any interaction with cytochrome P-450 systems because the pharmacokinetics of propofol are limited by liver blood flow and thus are unlikely to be affected by modest alterations in hepatic metabolic capacity. Although these drug interactions have not had a major impact on the utility of TCI devices, to enhance their accuracy, different pharmacokinetic sets should be determined for each of the commonly used drugs that result in a significant pharmacokinetic drug interaction.

The best performance with an automated drug delivery device is that reported by Crankshaw et al [103] [115] (Table 11-7) . The Crankshaw device is not based on a pharmacokinetic model but rather targets a single concentration by use of a series of preprogrammed infusion rates (i.e., this is a preprogrammed automated infusion device as described earlier). In a series of iterations with successive populations

TABLE 11-7 -- Accuracy of Target-Controlled Infusion Devices for Intravenous Anesthetics Using Different Pharmacokinetic Parameter Sets

MDPE, median performance error; MDAPE, median absolute performance error.

[a] MDAPE and MDPE were not calculated or only provide as a figure, and so the reported numbers are approximately inferred from the measure of performance reported by the authors.
[b] Not model-based (see text for details).
[c] Retrospectively applied to same data set.
[d] Prospectively tested.

Figure 11-24 The evaluation of 3 pharmacokinetic parameter sets for propofol. Plotted is the measured/predicted ratio for samples obtained during administration of propofol using a target-controlled infusion device programmed with the pharmacokinetics derived by Dyck, Marsh, or Tackley (*n* = 10 per group). A ratio of 1 means measured = predicted. Note that the pharmacokinetic parameters of Dyck provide a consistently positive bias.

of patients, the preprogrammed rates are adjusted by the ratio between the desired and the observed concentrations. Crankshaw et al demonstrated that after several honing iterations, the MDAPE can be decreased to 10 to 15 percent, which is superb performance. However, the device cannot achieve arbitrary targets at arbitrary times, as can the model-dependent devices, and so the very accurate performance comes at the cost of flexibility.

There are a variety of published parameter sets for most of the drugs used in anesthesia. If the pharmacokinetic parameters are highly biased, then one might expect large errors to occur in performance. Several studies in Table 11-7 show the importance of selecting the proper pharmacokinetic parameters (or at least the cost of selecting the wrong set). Shafer et al [107] examined the performance of a pharmacokinetic model-driven infusion device using the fentanyl pharmacokinetics described by McClain and Hug [116] and demonstrated

Figure 11-25 Infusion rates (mL/h) calculated to achieve propofol target concentrations of 4 (10 min), 3 (10 min), 4 (20 min), and 2 mug/mL (20 min) based on the 3 pharmacokinetic parameter sets of Dyck, Marsh, and Tackley.

an MDAPE of 61 percent and an MDPE of +61 percent. The large positive MDPE indicates that nearly all fentanyl concentrations greatly exceeded the target. The performance errors over time with the use of the McClain and Hug pharmacokinetics are shown in Figure 11-26 . Shafer et al also examined the performance of a pharmacokinetic model-driven infusion device by use of the fentanyl pharmacokinetic parameters described by Scott et al. [27] This second parameter set produced an MDAPE of 33 percent and an MDPE of +19 percent, as shown in the performance errors over time in Figure 11-26B . Although the measured concentrations tended to be higher than the target concentrations with the Scott and Stanski fentanyl parameter set, the performance was much better than obtained with the parameter set reported by McClain and Hug. This study demonstrated that selection of the proper parameter set influenced the performance of pharmacokinetic model- driven infusion. Raemer and colleagues [102] demonstrated the same for alfentanil, when they compared the performance of the alfentanil pharmacokinetic parameters reported by Maitre et al [117] with the alfentanil pharmacokinetic parameters reported by Scott et al. [27]

Glass et al [66] examined the performance of a pharmacokinetic model-driven infusion device by use of the same fentanyl pharmacokinetics described by McClain and Hug. [116] They demonstrated an MDAPE of 21 percent and an MDPE of +4 percent (i.e., an almost completely unbiased performance). It is important to realize that there were major differences in methodology between the study by Glass et al and that by Shafer et al, such as arterial versus venous samples, rapid sampling after changes in target concentration versus sampling only when a pseudo-steady state was achieved, and a different set of patients--cardiac versus noncardiac. It is these differences in methodology that result in differences in performance of pharmacokinetic model-driven infusion device using the same pharmacokinetic parameters being reported by different investigators.

With the goal of improving pharmacokinetic model- driven infusion device performance, Shafer et al recalculated

Figure 11-26 Performance errors over time for fentanyl by use of the pharmacokinetics reported by McClain and Hug (A) and Scott and Stanski (B) and a parameter set derived from these observations (C).

the optimal pharmacokinetic parameters of fentanyl directly from the observed concentrations that were obtained when fentanyl was administered via a pharmacokinetic model-driven infusion device by use of the initial pharmacokinetics of McLean and Hug. [116] Figure 11-26C shows the performance errors over time for the optimal fentanyl pharmacokinetics estimated for that population of patients (as compared with those of McLean and Hug [116] and Scott et al [27] in the same group of patients). The optimal pharmacokinetic parameter set still had a median residual error of 21 percent when retrospectively tested against the same group of patients. This represents the limit imposed by pharmacokinetic variability on the possible performance of any fentanyl parameter set for dosing to a similar adult population. In other words, it is unlikely that any fentanyl pharmacokinetic parameter set would produce less than 21 percent MDAPE.

Marsh et al [110] took the same approach to optimizing the performance of a pharmacokinetic model-driven infusion device administering propofol in children. They initially used a pharmacokinetic parameter set derived from adult subjects in their device and obtained an MDAPE of 25 percent and an MDPE of -18.5 percent. They subsequently derived new propofol pharmacokinetics for children and prospectively demonstrated that they had decreased the MDAPE to 16 percent, with a bias of less than 3 percent. This is highly accurate performance for a model-based device. Ginsberg et al [118] similarly derived a pharmacokinetic set for fentanyl in children, as did Fiset et al [119] for alfentanil.

Several other studies have also demonstrated that pharmacokinetic parameters vary with certain subsets of patients. For example, the pharmacokinetic parameters of propofol for patients presenting for open heart surgery are different from the previously verified pharmacokinetic parameters of the general population. These new pharmacokinetic parameters for fentanyl also vary both during bypass and after bypass. [120] The pharmacokinetics of intravenous

anesthetics may also be altered by age and possibly by gender. Not only is there interindividual variability, but there may also be significant intraindividual variability. Hill and colleagues [121] studied volunteers to learn the individual's own pharmacokinetics for morphine and alfentanil. These investigators then used that volunteer's unique pharmacokinetic values to subsequently control a pharmacokinetic model-driven infusion device. With this technique of personalized pharmacokinetics, they reduced the average error to just less than 20 percent. It appears that studies determining the pharmacokinetics of an individual to be used to infuse the same drug to the same individual later result in a bias and MAPE similar to those seen when an optimal pharmacokinetic set derived from the general population is used. The implication of these data is that although highly specific pharmacokinetic sets are desirable, they may not necessarily improve overall accuracy, and such systems can never be relied on to provide absolute accuracy.

It is unlikely that we will have the opportunity to conduct a full pharmacokinetic study on patients undergoing anesthesia. Bayesian forecasting is a statistical technique by which a few measured plasma concentrations from an individual can be incorporated into pharmacokinetic parameters to improve the performance of a pharmacokinetic model- driven infusion device. Maitre and Stanski [122] demonstrated the theoretical improvement in such devices when using bayesian forecasting for alfentanil. In this study, Maitre and Stanski demonstrated that measurement of a single plasma alfentanil concentration could potentially reduce the inaccuracy by half, to 14 percent average performance error. Unfortunately, a rapid assay does not exist for any of the intravenous drugs used in anesthetic practice. However, there are rapid assays for lidocaine, and at least one pharmacokinetic model-driven infusion device (STANPUMP, developed by Shafer and Maitre at Stanford) performs real-time bayesian forecasting using measured lidocaine levels for use in coronary care units.

In the absence of rapid assays for anesthetic drugs, the obvious method to decrease variability is to observe the drug effect and to adjust the target to the concentration that produces the desired level of drug effect. [25] [26] As discussed under "Pharmacodynamic Considerations," by knowing the rate constant k_{e0}, it is possible to model the concentration at the site of drug effect. Figure 11-27 (Figure Not Available) shows the plasma fentanyl concentrations that could theoretically be obtained over the course of a brief operation. Figure 11-27B (Figure Not Available) shows the fentanyl concentrations at the effect site for the same anesthetic shown in Figure 11-27A (Figure Not Available) . Even if the pump produced precisely the concentrations shown in Figure 11-27A (Figure Not Available) (i.e., had perfect performance), the lag between the plasma and the site of drug effect would, at best, produce a very slurred response because of the equilibration delay between the plasma and the effect site. Several pharmacokinetic model-driven infusion devices now simultaneously display both the plasma and the effect-site concentrations. Such devices permit the clinician to target the concentration in the effect site, rather than the plasma, in order to provide more precise control of drug effect.

Targeting the effect site rather than the plasma may make titration more precise by permitting the clinician to determine whether the levels are higher or lower than desired by observing drug effect. The next step is then to feed the measured drug effect directly back into the automated drug delivery device and to permit the model to be updated based on

Figure 11-27 (Figure Not Available) Simulated plasma fentanyl concentrations over time for a brief anesthetic, showing the rapid rise and fall and impression of precise titration that can be created by a target-controlled drug delivery device (A). (B) Effect-site concentrations for the same anesthetic course, demonstrating that precise control of plasma concentration does not necessarily translate into precise control at the site of drug effect. *(Adapted from Shafer and Gregg [25])*

---

observed measures of drug effect, thus providing a closed-loop system. [4] [7] [15] [16] [17] [18] [19] This is the same concept as using observed plasma concentrations for improving performance, except that assays are not available for most of the drugs used in anesthesia practice. Thus, several investigators have developed closed-loop target control of anesthesia. [15] [16] [17] [18] [123] As mentioned earlier, the ability to measure adequacy of anesthesia is limited; however, both median EEG frequency and auditory evoked responses, as well as the bispectral index, have been used successfully to provide closed-loop anesthesia in patients during surgery. Schwilden et al [15] [16] [17] used the EEG to adjust the infusion rates of anesthetic drugs with their automated drug delivery device. Their device does not maintain any drug target concentration either in the plasma or at the site of drug effect but rather uses a proportional controller to maintain a target median EEG frequency from 2 to 3 Hz. They found that this approach works well clinically for methohexital and propofol. Since then, it has become apparent that anesthesia may be composed of both hypnosis and analgesia. The bispectral index, which is a derived parame-ter of the EEG, has been shown to correlate well with level of sedation and loss of consciousness. Several investigators have started to implement closed-loop anesthesia using the bispectral index as the measure of effect, with the understanding that the analgesic component needs to be addressed separately. This approach moves automated delivery of anesthetic drugs away from pharmacokinetic models entirely and toward the closed-loop systems that have been developed and have been well described for the vasoactive drugs, nitroprusside in particular. [4] [5] [6] [7]

In summary, automated drug delivery devices appear to be able to achieve and maintain desired plasma concentrations with a median expected error of about 20 to 30 percent of the target. Although pharmacokinetic analysis after automated drug delivery results in a reduction in the median error to closer to 20 percent in adults and possibly lower in children, biologic variability sets a limit on the expected accuracy of these devices. More accurate performance could be obtained with bayesian feedback by use of rapid intraoperative assays, but this is unavailable for the intravenous drugs used in anesthetic practice. However, the equilibration delay between the plasma and the effect site is such that excessive focus on plasma concentrations may be unwarranted. Instead, learning about the pharmacokinetic/pharmacodynamic characteristics of the specific patient, by titrating to a readily measured drug effect, appears to be the most promising method for optimizing the performance of automated drug delivery devices to the clinical needs of the individual patient.

Outcome

The evaluation of outcome with TCI devices is more difficult than the evaluation of accuracy because of the difficulty of precisely measuring patient outcome. Because contemporary anesthetic practice produces very little morbidity, outcome measures are usually based on the process variables, such as blood pressure, heart rate, and duration of recovery room stay, rather than on substantive measures of patient morbidity. The evaluation of outcome with automated drug delivery devices requires a comparison of manual methods of administration with the same drug with automated drug delivery of intravenous anesthetics and volatile anesthetics. There have now been numerous studies evaluating automated drug delivery device administration of intravenous anesthetics for both brief and complex surgery, in children and in adults, in short-term sedation, in prolonged sedation (days), and in chronic pain management. Unfortunately, there have so far been very few comparative outcome studies between automated drug delivery devices and manual delivery systems.

Ausems et al [22] compared pharmacokinetic model-driven administration with intermittent bolus administration of alfentanil. Automated drug delivery produced fewer incidences of muscular rigidity, hypotension, and bradycardia on induction. Automated drug delivery during maintenance resulted in significantly fewer incidences of hemodynamic response, resulting in a greater percentage of anesthesia time within 15 percent of the desired blood pressure and heart rate. Recovery after TCI was associated with significantly less use of naloxone for adequate ventilation.

Pharmacokinetic model-driven infusion of fentanyl during cardiac surgery resulted in greater hemodynamic control with fewer additional drug interventions and significantly fewer episodes of either hypotension or hypertension than occurred with bolus dose administration. [108] A small study comparing manual alfentanil administration to pharmacokinetic model-driven infusion of alfentanil showed no statistical differences during maintenance or recovery. [124] Theil et al [95] compared double-blind manual administration of fentanyl/midazolam to pharmacokinetic model-driven infusion of these two anesthetics in a small group of patients presenting for cardiac surgery. Both systems were titrated simultaneously (one containing placebo), with the aim of maintaining hemodynamics within 20 percent of baseline values. Both systems were equally effective in providing hemodynamic control as dictated by the protocol. The most significant difference between the two modes of delivery was the greater variability in drug plasma concentrations in the manual group. This suggested that pharmacokinetic model- driven infusion maintained patients within a narrower therapeutic range. The advantages of this would be most important with drugs that have a narrow therapeutic window. This small comparative study, although it did not show many differences in outcome, demonstrated that targetcontrolled drug delivery was at least equal to manual drug delivery. Many pertinent outcome parameters, such as recovery times, were not measured in this study. Thus, there remains a need to establish which of the theoretical patient benefits will be realized with model-based target controlled delivery over manual delivery of intravenous drugs. With the introduction of a commercial TCI device for propofol, several more comparative studies have been performed. Struys et al [125] ($n = 90$), Russel et al [126] ($n = 160$), and Servin, in a large multicenter study ($n = 562$), found when they compared a manual infusion of propofol to TCI administration there were small differences between the two means of propofol administration. Interestingly, in the TCI groups, the maintenance infusion rate tended to be higher in the TCI groups but was associated with a lower incidence of movement by patients. Both Servin and Russel et al noted that there was a marked preference of the user for the TCI system, even though this was their first use of the device.

Pharmacokinetic model-driven infusion of propofol compares favorably with thiopental/isoflurane anesthesia for general surgery lasting several hours. [127] Induction, maintenance, and recovery were similar between the two groups. This implies that given the appropriate means for administration, intravenous anesthesia can be equal to inhalational anesthetics in providing the objectives of anesthesia, that is, rapid induction and recovery with stable maintenance.

In noncomparative studies, pharmacokinetic modeldriven infusion has been used to administer most of the potent opioids as well as the hypnotics. Different anesthetic techniques have also been tested with pharmacokinetic model-driven infusion devices, including nitrous-narcotic anesthesia, supplementation of volatile anesthetics, total intravenous anesthesia and sedation for monitored anesthesia care, and intensive care unit sedation. In all these studies, outcome, as measured by hemodynamics and recovery, has been within the expectations of normal clinical care. Etomidate, methohexital, midazolam, propofol, thiopental, alfentanil, fentanyl, remifentanil, and sufentanil have all been used with TCI. When these drugs were used with target-controlled drug delivery systems for total intravenous anesthesia or to supplement nitrous oxide or volatile anesthetics, hemodynamics were well maintained during induction and intubation, as well as during maintenance. Recovery milestones were reached that were at times comparable to those of similar drug combinations used in manual infusion schemes. In none of these numerous studies have authors commented on adverse outcome resulting from target-controlled drug delivery. The clinical experience with TCI devices is now enormous, with probably several hundred thousand patient exposures. It is thus likely that TCI will become a part of routine practice.

Most of the studies thus far published have targeted plasma/blood concentrations. Although systems are available to target the effect site, there have been no publications of the clinical utility when the effect site is targeted. As discussed earlier, targeting the effect site may even further enhance outcome with model-based target-controlled devices.

Target-controlled infusion devices have also been used to provide patient-controlled analgesia. Hill and colleagues demonstrated patient-controlled anesthesia devices using morphine, fentanyl, or alfentanil [121] [128] and the clinical utility of such devices. [129] [130] [131] [132] Van den Nieuwenhuyzen et al [53] demonstrated advantages of such a system with alfentanil over routine morphine patient-controlled anesthesia.

From the body of literature presently available, it appears that automated drug delivery of intravenous anesthetics is at least equal to manual delivery of these drugs. Intravenous drug administration using target-controlled drug delivery is analogous to inhalational vapor delivery using a calibrated vaporizer. Like the vaporizer, pharmacokinetic model- driven infusion facilitates drug delivery based on plasma or biophase concentration rather than on drug dosage. There is variability with the use of a calibrated vaporizer, including variability in the accuracy of drug delivery with vaporizers, slow equilibration between the fresh gas flow and the circuit at low flow rates, and variable uptake by the patient. This variability does not particularly complicate titration of the inhalational anesthetics. The variability with targetcontrolled drug delivery is of a similar magnitude. Just as with the vaporizers, the variability with target-controlled drug delivery does not particularly complicate titration of intravenous anesthetics. Indeed, the time-varying stresses of surgery and the variability in patient response require that the anesthesiologist titrate the administration of the potent inhalation anesthetics, using the calibrated vaporizer as a tool. These same factors require that the anesthesiologist vigilantly titrate the infusion of intravenous anesthetic drugs when using automated drug delivery as a tool.

Target-controlled drug delivery has advantages beyond a delivery system to simplify the clinical administration of intravenous anesthetics. Probably the most significant contribution of these delivery devices is their use in research. The pseudo-steady state that can be almost instantly achieved with these devices permits the plasma and effect site to rapidly come into equilibrium. This is critically important in studies examining the concentration-response relationships (i.e., the C_{50} values) for anesthetic drugs. [22] [30] [51] In addition, these systems enable interactions involving intravenous drugs to be clearly defined. [36] [37] [38] Closed-loop target delivery will eventually enable unbiased and more precise comparisons between drugs. Lastly, as noted earlier, targetcontrolled delivery has provided us with the ability to prospectively test pharmacokinetic parameter sets and modeling approaches and ultimately may provide the most suitable pharmacokinetic parameters for any intravenous drug delivery. [107] [110] [119] [133] Purely as a research tool, automated drug delivery has already had a major impact on anesthetic practice.

SUMMARY

In comparison with intermittent bolus administration, the continuous infusion of intravenous anesthetic drugs provides greater control of anesthetic depth, thus ensuring (1) better hemodynamic control with fewer incidences of hemodynamic instability, (2) lower total drug doses, and (3) more rapid return to an awake state. Improved drug administration techniques combined with several new intravenous anesthetic agents have provided greater impetus for the use of intravenous anesthesia in clinical practice. The devices for the administration of intravenous anesthesia are undergoing rapid evolution. The introduction of pumps designed specifically for continuous intravenous anesthetic drug delivery is likely to further enhance intravenous anesthesia. "Calculator" pumps enhance manual means of continuous intravenous drug administration. These pumps, although a major step forward for intravenous drug delivery, fall short of enabling the clinician to titrate drug concentration to drug effect.

Automated drug delivery provides this ability. There are several theoretical advantages of pharmacokinetic model- driven infusion over manual infusion systems, such as further improvements in hemodynamic control and a more predictable rapid awakening. The actual advantages of automated drug delivery of intravenous anesthetics over manual methods, or in comparison with inhalational anesthesia, are not yet fully established but, under all circumstances, are at least equal to them, with greater user preference for such devices. It also appears that pharmacokinetics used with pharmacokinetic model-driven infusion, although not yet optimal, are adequate for clinical use. The initial data, however,

indicate that pharmacokinetic model-driven infusion provides advantages as a system for intravenous drug delivery, but well-controlled studies with large patient populations are needed to fully establish its ultimate role in the clinical practice of anesthesia. The introduction of commercial TCI systems is a strong indication that automated drug delivery is now likely to become an everyday part of anesthesia practice.

Chapter 12 - Pharmacology of Muscle Relaxants and Their Antagonists

John J. Savarese
James E. Caldwell
Cynthia A. Lien
Ronald D. Miller

INTRODUCTION

History

In 1942 Griffith and Johnson [1] suggested that *d*-tubocurarine (dTc) is a safe drug to use during surgery to ensure good skeletal muscle relaxation. One year later, Cullen [2] reported that dTc had been given to 131 patients under general anesthesia to produce additional skeletal muscle relaxation greater than that provided by the anesthetic alone. In 1954, however, Beecher and Todd [3] published a clinical report in which a 6-fold increase in mortality rate was found in patients who received muscle relaxants versus those who did not receive muscle relaxants. This study created undeserved negative publicity and dampened growing enthusiasm for the clinical use of muscle relaxants, largely because the clinical pharmacology of the drugs was very imprecise in that era. At that time the value of supported or controlled ventilation was not adequately understood, the effects of residual neuromuscular blockade in the recovery room were not at all appreciated, the importance of antagonism of residual blockade was unknown, and the need for careful monitoring was not yet established. During subsequent years, as the clinical pharmacology of the neuromuscular blocking drugs has been refined, and as the drugs themselves have been improved, the use of muscle relaxants has become a vitally important aspect of modern anesthesia practice. The development of new synthetic relaxants has greatly increased the clinician's options for providing skeletal muscle relaxation. Safer, more efficient, and more precise practice patterns have evolved as a result of the development of both a vastly expanded knowledge base and greatly improved drugs and monitoring techniques.

Succinylcholine, introduced by Thesleff [4] and Foldes et al [5] in 1952, revolutionized anesthetic practice by providing intense neuromuscular blockade of very rapid onset and ultra-short duration, thereby greatly easing the maneuver of tracheal intubation. The synthetic and semisynthetic nondepolarizing drugs gallamine, dimethyltubocurarine, and alcuronium, introduced over the next decade, were alternatives to dTc. They were not considered as dramatic improvements or as replacements for dTc (see the sections on individual nondepolarizing relaxants), because they as well as dTc produced cardiovascular side effects and because they showed long durations of action similar to that of dTc. This extended neuromuscular blocking effect occurs as a result of little or no metabolism and dependence on organ-based (liver and kidney) elimination.

In 1967 Baird and Reid [6] first reported on the clinical administration of the synthetic aminosteroid pancuronium. Although also similar in duration of action to dTc, this drug provided an improved cardiovascular and autonomic side-effect profile--lack of ganglionic blocking and histaminereleasing properties--in addition to having a mild to moderate vagolytic effect. The resulting lack of hypotensive action and mild stimulation of heart rate and arterial blood pressure were considered significant improvements over dTc. The structure of pancuronium (see Fig. 12-4) also allows a small degree of liver metabolism via deacetylation of the acetoxy groups. This minor degree of destruction in the body was considered an advance with respect to dTc (which is not metabolized) because pancuronium was the first nondepolarizing relaxant in clinical practice that was intentionally designed to follow a theoretical metabolic pathway.

The nearly simultaneous introduction in the early 1980s of two new muscle relaxants of intermediate duration--atracurium [7] [8] and vecuronium [9] [10] --revolutionized clinical practice by providing relaxation with little or no dependence on the kidney for elimination; faster onset; a more rapid, measurable recovery; and faster and more complete antagonism of residual block than in the case of the longer-lasting drugs. The development of atracurium and vecuronium (1) encouraged tracheal intubation by the use of nondepolarizing relaxants, (2) made it more convenient to provide paralysis by continuous infusion of relaxants, and (3) most importantly, enabled significantly improved postoperative neuromuscular function, resulting in a measurably shorter period of risk of weakness in the postanesthetic care unit. (ch. 72).

The virtual lack of cardiovascular effect of vecuronium over a very wide dose-range established a benchmark for other relaxants. [11] The degradation of atracurium via the chemical mechanism of Hofmann elimination [12] removed any important influence of biologic disorders such as advanced age, organ failure, or biochemical abnormalities on the pattern of neuromuscular blockade.

The early 1990s witnessed the introduction in the United States of two long-acting muscle relaxants found to be free of side effects: pipecuronium [13] and doxacurium. [14] A short-acting relaxant hydrolyzed by plasma cholinesterase (mivacurium [15]) and an intermediate-duration substance with rapid onset (rocuronium [16]) were also added to the armamentarium. Mivacurium facilitates maintenance of relaxation by continuous infusion with rapid spontaneous recovery, making antagonism of residual blockade an option rather than a requirement. Rocuronium is the first nondepolarizer considered to be an acceptable substitute for succinylcholine in facilitating rapid intubation of the trachea. An atracurium isomer, cisatracurium, [17] introduced in 1996, does not release histamine, and retains the intermediate duration of action of atracurium, facilitated by the Hofmann elimination reaction. A new steroidal material, rapacuronium (ORG 9487), now in the latter stages of clinical trial, shows fast onset, approaching that of succinylcholine, enabling rapid tracheal intubation. It has a short-to-intermediate duration of action.

Clinical Use

Two philosophies govern the clinical administration of muscle relaxants. One end of the scale, first popularized by Cecil Gray and coworkers in Liverpool, England, in the early 1950s, employs nitrous oxide, oxygen, and large doses of muscle relaxants as the anesthetic prescription. With this type of anesthesia, patients are usually amnesic, but occasionally some recall may occur. [18] Awareness during surgery has been vividly described in an editorial [19] : a trained medical person under general anesthesia described being awake during a cesarean section. She specifically stated that when she moved she was given more muscle relaxant (pancuronium) rather than more anesthesia. This pattern of giving muscle relaxants, instead of analgesics or hypnotics, to prevent movement in response to surgical stimulation is completely unacceptable practice. Although this practice may be considered

as an essential part of general anesthetic technique in a patient who has an unstable circulatory status, in our opinion, muscle relaxants must not be given without adequate dosage of analgesic and hypnotic drugs, no matter how precarious the patient's physical state. As stated by Cullen and Larson, [20] "muscle relaxants given inappropriately may provide the surgeon with optimal [operating] conditions in ... a patient [who] is paralyzed but not anesthetized--a state that [is] wholly unsatisfactory for the patient."

A further quote from Cullen and Larson [20] expresses our philosophy concerning muscle relaxant administration: "Relaxants used to cover up deficiencies in total anesthetic management ... represent an ... inappropriate use of these valuable adjuncts to anesthesia." Muscle relaxants should be viewed as adjuncts, not as substitutes, for anesthesia. They should be given only to adequately anesthetized patients as an integral part of a prescription that includes hypnosis, analgesia, and amnesia as well as relaxation. Neuromuscular function must be monitored, and appropriate doses should be given in order to minimize the possibility of residual paralysis in the postanesthetic care unit.

The importance of proper monitoring of neuromuscular function calls for special emphasis (Ch. 39) . Recent developments in monitoring that are changing attitudes toward clinical practice include (1) the introduction of a new evoked response, double-burst stimulation [21] ; (2) the observation of significantly faster evolution of

blockade in the airway musculature (jaw, [22] larynx, [23] diaphragm [24]) as compared with that in the thumb; and (3) measurements emphasizing the longer time requirement for, and greater difficulty of, antagonism of residual blockade due to long-acting relaxants. [25] [26] There is also most likely overall reduced cost and greater safety in practice with the newer shorter-acting relaxants. Proper attention to careful monitoring will certainly lead to greater precision, safety, and economy of practice (see the section on economics of relaxation).

This chapter discusses the clinical pharmacology and clinical use of muscle relaxants in the operating room and in the intensive care unit, incorporating the overall philosophy that these drugs are adjuvants, not substitutes, for anesthesia and/or sedation and analgesia. Diseases of the neuromuscular system, with which anesthesiologists are often confronted, are discussed with respect to their influence on the actions of the relaxants. The economics of providing relaxation are discussed, and new outcome studies comparing relaxants of different duration are summarized. The latter two topics, namely, economics and outcome, are distinctly and directly related.

MONITORING NEUROMUSCULAR FUNCTION

Details of monitoring clinical neuromuscular function are described in Chapter 36 . In this section general concepts are presented.

Peripheral Nerve Stimulation

Stimulating a peripheral nerve (usually the ulnar nerve at the wrist or elbow) and visually observing contraction of the fingers (adductor pollicis and flexor digitorum muscles) is the most commonly advocated method of monitoring neuromuscular function clinically. This stimulation need not be restricted to the arm; any superficially located neuromuscular unit may be monitored. Stimulating the facial nerve or the motor nerves of a lower extremity, such as the peroneal nerve, and observing the magnitude of resultant muscular contraction can also be used for monitoring neuromuscular function. As will be discussed later in more detail, different neuromuscular units should be monitored to assess onset of and recovery from neuromuscular block (Table 12-1) .

Peripheral nerve stimulation can be used to detect both magnitude and type of neuromuscular blockade. Quantitative conclusions must be guarded, however. Because of the wide margin of safety of neuromuscular function, a reduction in the contractile response to peripheral nerve stimulation is not quantitatively proportional to the action of relaxants at the receptor. For example, Waud and Waud [27] demonstrated that the twitch response of the tibialis anterior muscle of the cat in response to a single supramaximal stimulus is not reduced unless more than 70 percent of the receptors are occupied by a nondepolarizing relaxant. Twitch is completely eliminated when 90 percent of the receptors are occupied. Furthermore, as Kopman [27A] demonstrated, regardless of a clinician's expertise, fade in the train-of-four (TOF) response is not reliably detected at TOF values above .40. This may lead to extubation of the trachea before adequate recovery of neuromuscular function. Despite these limitations, the response to peripheral nerve stimulation can be extremely useful. Four important questions can be answered by observing the response to peripheral nerve stimulation: (1) Is the neuromuscular blockade adequate? (2) Is the neuromuscular blockade excessive? (3) Can the neuromuscular blockade be antagonized? (4) Is the neuromuscular blockade adequately antagonized?

Whatever form of nerve stimulation is used, subtle slight degrees of neuromuscular blockade cannot be detected by observing the response of a peripheral muscle. Especially in light of recent claims that even a TOF ratio of .70 is inadequate to be considered "complete" recovery, detection of subtle degrees of neuromuscular block is important.

In order to detect subtle residual neuromuscular blockade, the neuromuscular junction must be stressed by a stimulus that is greater and longer in intensity than that used to elicit a single twitch. While a 5-second tetanic stimulus would accomplish this, tetanic stimuli are painful and are, therefore, of limited value in detecting shallow residual blockade in the unanesthetized patient.

There are multiple types of peripheral nerve stimulation. The specific pattern of stimulation used depends on the clinical purpose (e.g., monitoring of adequate relaxation versus adequate antagonism).

Muscle contraction is an all-or-none phenomenon. Each fiber either contracts maximally or does not contract at all. Therefore, when twitch height (adduction of the thumb, for example) is reduced, some fibers are contracting normally, and others are blocked and remain flaccid. The stronger the response, the fewer fibers exist in a blocked state. Fade of muscular contraction in response to tetanic stimuli suggests that some fibers are more susceptible to being blocked by relaxants and need a greater release of acetylcholine (ACh) to trigger their response.

TABLE 12-1 -- Tests of Neuromuscular Transmission

TEST	ACCEPTABLE CLINICAL RESULT TO SUGGEST NORMAL FUNCTION	APPROXIMATE PERCENTAGE OF RECEPTORS OCCUPIED WHEN RESPONSE RETURNS TO NORMAL VALUE	COMMENTS/DISADVANTAGES/ADVANTAGES
Tidal volume	At least 5 mL/kg	80	Insensitive as an indicator of peripheral neuromuscular function.
Single twitch strength	Qualitatively as strong as baseline	75-80	Uncomfortable, need to know twitch strength before relaxant administration. Insensitive as an indicator of recovery, but useful as a gauge of deep neuromuscular blockade.
Train-of-four (TOF)	No palpable fade	70-75	Still uncomfortable, but more sensitive as an indicator of recovery than single twitch. Useful as a gauge of depth of block by counting the number of responses perceptible.
Sustained tetanus at 50 Hz for 5 seconds	No palpable fade	70	Very uncomfortable, but a reliable indicator of adequate recovery.
Vital capacity	At least 20 mL/kg	70	Requires patient cooperation, but is the goal for achievement of full clinical recovery.
Double-burst stimulation	No palpable fade	60-70	Uncomfortable, but more sensitive than TOF as an indicator of peripheral function. No perceptible fade indicates TOF of at least recovery of 60%.
Sustained tetanus at 100 Hz	No palpable fade	50	Very painful, a "stress test" for the neuromuscular junction. It is not always possible to achieve or to demonstrate lack of fade at 100 Hz.
Inspiratory force	At least -40 cm H_2O	50	Sometimes difficult to perform without endotracheal intubation, but a reliable gauge of normal diaphragmatic function.
Head lift	Must be performed un-aided with patient supine at 180° and sustained for 5 sec-onds	50	Requires patient cooperation, but remains the standard test of nor-mal clinical function. Must be performed with the patient in a completely supine position.

Hand grip	Sustained at a level qualitatively similar to preinduction baseline	50	Sustained strong grip, though also requiring patient cooperation.Is another good gauge of normal function.
Sustained bite	Sustained jaw clench on tongue blade	50	Very reliable with patient cooperation.Corresponds with TOF of 85%.

Stimulus Variables

Because the interaction of nondepolarizing relaxants with ACh binding sites is competitive, neuromuscular blockade can be overcome by increasing, or intensified by reducing, the concentration of ACh. This basic concept is important in clinical monitoring of neuromuscular blockade. Another fundamental concept is the economy of ACh synthesis, storage, and release. The quantity of ACh released with each nerve action potential is inversely proportional to the number of action potentials reaching the nerve terminal per unit time, or the stimulus frequency. For this reason, low concentrations of nondepolarizing relaxants block responses to high-frequency peripheral nerve stimulation (e.g., 100 Hz), whereas relatively high concentrations of relaxant are required to abolish responses elicited by low-frequency stimulation (e.g., 0.1 Hz). The depth of blockade of evoked neuromuscular responses in the presence of nondepolarizing relaxants is directly proportional to the stimulus frequency. Thus, stimuli of increasing frequency are able to detect increasingly shallow degrees of neuromuscular blockade. With rapid rates of stimulation such as tetanus at 100 Hz, very subtle degrees of block can be detected because the response to this stimulus is diminished with only very slight clinical evidence of weakness.

The pattern of response during depolarizing neuromuscular blockade is the same during slow and high rates of stimulation. Therefore, twitch and tetanic response provide essentially the same information during this type of blockade.

While monitoring nondepolarizing blockade during a typical surgical procedure, the following pattern is advised: single twitch or TOF should be followed during onset of neuromuscular blockade. TOF should be monitored during maintenance of blockade and recovery until fade in the response is no longer perceptible. Double-burst stimulation, followed by tetanic stimulation at 50 to 100 Hz, may subsequently be employed to detect more subtle degrees of residual paralysis during the final stages of recovery. Inability to reliably detect shallow residual neuromuscular blockade with either of these stimulus patterns may be due to the second and third responses to TOF stimulation influencing the clinician's interpretation of the response as well as displacement of the thumb from its baseline position with repetitive stimulation. [27B] [27C] It is imperative to confirm adequacy of function following either spontaneous or pharmacologically augmented recovery with a reliable clinical test, such as head lift for 5 seconds. This test must be performed properly, with the patient's head being lifted unaided from a true horizontal (180-degree) position. If the clinician is concerned about even more shallow degrees of block and would like to be certain that the patient has a TOF ratio greater

than 85%, the ability of the patient to appose his incisor teeth should be tested. [27C]

Receptor Occlusion Techniques

Work on the subject of the fraction of receptors that may be occupied during responses to various tests of neuromuscular function was performed primarily by Waud and Waud. [27] [28] Although this approach is based on fundamental agonist-antagonist relationships, its main clinical value is that it allows estimation of the sensitivity of many of the tests used clinically (see Table 12-1) . Even though the number of receptors occupied by a relaxant cannot be counted, Waud and Waud estimated the fraction of receptors (without knowing the absolute number of receptors) that must be unblocked by relaxant for tests of neuromuscular function to be normal. The technique estimates the fraction of receptors blocked by a nondepolarizing muscle relaxant by determining a dose-response depolarization curve from various agonist doses (succinylcholine) both in the absence and in the presence of the nondepolarizing blocker or antagonist (dTc, pancuronium). The fraction of receptors unblocked by the nondepolarizing muscle relaxant or still available for neuromuscular transmission can be estimated from the dose ratio of the agonist and blocker. For example, in the presence of dTc, 100 nmol of succinylcholine might be required to produce the same degree of depolarization produced by 10 nmol without dTC. Because ten times more succinylcholine is required with dTc, 10 percent of the receptors are still free (or 90 percent of the receptors are blocked). All other tests permit a normal response with a significant number of receptors still blocked, even at a tetanic stimulus of 200 Hz. These results suggest that no test is available to determine whether all receptors are free of a relaxant.

Respiration

The ability of a patient to maintain sustained adequate ventilation and to protect the airway, particularly during stresses such as airway obstruction or vomiting, is a main concern when looking at adequacy of recovery of neuromuscular function. Despite the enormous number of relaxant studies in the literature, few correlate tests of neuromuscular function with adequacy of ventilation, and the conclusions are often incomplete.

Johansen et al [29] found head-lift and hand-grip strength to be 38 and 48 percent of control when both inspiratory and expiratory flow rates are greater than 90 percent of control. Furthermore, Ali et al [30] found inspiratory force to be only 70 percent of control when vital capacity and expiratory flow rate are greater than 90 percent of control. Pavlin et al [31] found that many of the recommended tests can return to normal while the pharyngeal and neck muscles necessary to protect the airway can still be partially paralyzed (Fig. 12-1) (Figure Not Available) . As a result, they recommend that patients should be considered to be partially paralyzed until they can lift their head for 5 seconds or achieve a maximum negative inspiratory pressure of 35 cm H_2O (Pavlin EG, Holle RH, Schoene RB, personal communication). A negative inspiratory force of 50 cm

Figure 12-1 (Figure Not Available) Levels of neuromuscular blockade from *d*-tubocurarine as measured by maximum inspiratory pressure (MIP) below which the indicated clinical maneuver could not be accomplished. Obviously, head lift and straight-leg raising are the most sensitive indicators of neuromuscular blockade. *(From Pavlin et al [31])*

H_2O was found to correlate well with recovery of peripheral muscle strength.

Most recently D'Honneur et al [31A] found that with a TOF ratio of 50 percent or greater in volunteers airway patency remained at baseline values. However, in two, more recent, studies with a TOF ratio less than 90 percent, 40 percent of volunteers aspirated, [31B] and the incidence of pulmonary complications is increased in patients who had a TOF ratio less than 70 percent postoperatively. [31C] Therefore, although clinicians cannot readily detect subtle degrees of block, and patients can sustain adequate respiration before the TOF ratio has reached 90 percent, it is imperative that neuromuscular blockers be chosen and dosed in a fashion that allows for prompt recovery. Recovery room personnel need to observe the patient closely until all evidence of residual neuromuscular blockade has dissipated, [32] and head-lift for 5 seconds is unequivocally demonstrated.

Pattern of Blockade in Muscles of the Airway

Several groups of investigators, most notably Donati et al [23] and Pansard et al, [24] have shown that the evolution of both depolarizing and nondepolarizing block proceeds more rapidly in the central muscles of the airway, such as the larynx (Fig. 12-2), (Figure Not Available) the jaw, and the diaphragm (Fig. 12-3 (Figure Not Available) , than in the more peripheral adductor of the thumb. Neuromuscular blockade develops faster, lasts a shorter time, and recovers more quickly in these muscles. Since several studies have been done (Table 12-2) that have measured the effects of neuromuscular blockers in the larynx, these data can be very useful clinically in precisely determining dosage for intubation, timing of intubation, and recovery time to levels of function compatible with airway protection.

Because neuromuscular blockade develops more rapidly in the airway than in the thumb, tracheal intubation can be performed before onset of complete block at the adductor

Figure 12-2 (Figure Not Available) Evolution of neuromuscular blockade in the larynx and thumb (adductor pollicis) following vecuronium (0.07 mg/kg). Onset and recovery from block occur more rapidly in the larynx. *(From Donati et al [23])*

pollicis. Onset of block in the larynx occurs 1 to 2 minutes earlier than at the adductor pollicis following administration of nondepolarizing neuromuscular blocking agents. The pattern of blockade (onset, depth, speed of recovery) in the orbicularis oculi is similar to that in the larynx. [33] By monitoring the onset of neuromuscular blockade at the orbicularis oculi, the quality of intubating conditions can be predicted. The onset of maximal block in the larynx also corresponds with the point where the adductor pollicis is beginning to show palpable evidence of weakening. Furthermore, because recovery in the airway musculature is faster than in the thumb, one can be sure that, once monitored responses in the thumb have been correctly diagnosed as having returned to normal, the identical responses in the airway musculature have already reached that point. In other words, return of thumb responses to normal suggests that the efferent muscular arc of protective airway reflexes is intact.

Clinical Conclusion: Choice of Relaxant and Testing of Recovery

It is not known what proportion of receptors must be available or how sensitive a test must be to ensure adequate

Figure 12-3 (Figure Not Available) Evolution of atracurium-induced blockade in the adductor pollicis and diaphragm following a dose of 0.6 mg/kg. Block develops and recovers more quickly in the diaphragm. *(From Pansard et al [24])*

muscle strength to overcome airway obstruction and permit effective coughing. The anesthesiologist should not rely on one test but should use as many tests as is practically possible (see Table 12-1) . For example, when the operative procedure is nearly finished and the patient is still under anesthesia, a tetanic stimulus of 50 Hz, TOF, twitch height, and inspiratory force may be used to determine whether a neuromuscular blockade has been antagonized completely. Then, with the patient awake, other tests, such as a 5-second head lift, can be employed. It is important to use several tests that stress the neuromuscular junction to detect subtle degrees of neuromuscular blockade. The results of Pavlin et al [31] and the frequent return to the recovery room of patients with partial paralysis [34] (i.e., not recognized by the anesthesiologist) emphasize the difficulty in clinically ensuring that no residual neuromuscular blockade exists after surgery and anesthesia. [35]

Several studies have found a much higher incidence of residual weakness in the postanesthesia care unit (PACU) following the administration of the long-acting drug pancuronium than following the use of the intermediateduration drugs vecuronium and atracurium. [36] [37] The findings of these studies document the much longer time required for adequate antagonism of deep levels of block induced

TABLE 12-2 -- Approximate Dose-Response of Some Neuromuscular Blocking Drugs in the Larynx[a]

by long-acting muscle relaxants than by those of intermediate duration. These observations suggest that the administration of long-acting relaxants to patients whose tracheas are to be extubated at the end of a procedure should be avoided. In such cases, even in rather long procedures (4 hours), it may be wiser to provide relaxation by infusion of intermediate or short-acting agents. The use of long-acting nondepolarizing neuromuscular blocking agents should be reserved for patients scheduled to remain intubated following lengthy and complicated procedures in order to facilitate continued mechanical ventilation in an intensive care unit or in the PACU.

Conversely, patients who are scheduled to undergo ambulatory surgical procedures and who are to be expected to function normally within minutes following the completion of the procedure should receive short- or intermediateacting relaxants for reasons of both safety and economy (see below).

CHEMISTRY

Molecular Features and Physiochemical Properties

Neuromuscular blocking drugs are quaternary ammonium compounds. Positive charges at these sites in the molecules mimic the quaternary nitrogen atom of the transmitter ACh and are the principal reason for the attraction of these drugs to cholinergic nicotinic receptors at the neuromuscular junction. These receptors are also located at other physiologic sites of action of ACh in the body, such as at nicotinic receptors in autonomic ganglia and at as many as three different muscarinic receptors on both the parasympathetic and sympathetic sides of the autonomic nervous system.

All relaxants are structurally related to ACh because of the quaternary groups. In some cases, such as pancuronium and vecuronium, entire ACh-like structures are intentionally incorporated into the molecule. The depolarizing relaxant succinylcholine is actually two molecules of ACh linked back-to-back through the acetate methyl groups (Fig. 12-4) ; hence, the older name "diacetylcholine."

Nearly all muscle relaxants contain two positive charges. In most of the drugs, the positive charges are permanent quaternary ammonium cations. In a few drugs, such as vecuronium, rocuronium, and dTc, there is one permanent quaternary cation and one tertiary amine that is protonated and therefore positively charged at physiologic pH. The two positive charges are separated by a bridging structure that is lipophilic and that varies in size. The bridging structure is different for various series of muscle relaxants and is also a major determinant of potency (see *Structure-Activity Relationships*).

Muscle relaxants are generally quite water-soluble, especially because of the quaternary groups. The water solubility of relaxants inhibits uptake into hepatocytes, so metabolism and/or excretion in the liver is usually not a major pathway of elimination. Furthermore, the cytochrome P-450 oxidative enzyme system in liver microsomes requires lipophilic substrates, generally excluding the relatively hydrophilic muscle relaxants. There are a few minor exceptions to this general

Figure 12-4 Structural relationship of succinylcholine, a depolarizing agent, and pancuronium, a nondepolarizing agent, to acetylcholine, the neuromuscular transmitter. Succinylcholine, originally called diacetylcholine, is simply two molecules of acetylcholine linked through the acetate methyl groups. Like acetylcholine, succinylcholine stimulates cholinergic receptors at the neuromuscular junction and at nicotinic (ganglionic) and muscarinic autonomic sites. Pancuronium may be viewed as two acetylcholine-like fragments properly oriented on a steroid nucleus. Pancuronium and other nondepolarizers inhibit the actions of acetylcholine at neuromuscular and autonomic cholinergic receptors.

lack of liver elimination, such as vecuronium, rocuronium, and ORG 9487 (rapacuronium) among the steroid-based relaxants.

The muscle relaxants display the hydrophilic physicochemical properties of cations in watery media such as the plasma and urine. Other chemical features of relaxants that promote either water solubility or hydrophilic properties or both are various oxygen-bearing groups. Some of these are the ester linkages of succinylcholine, mivacurium, cisatracurium, and atracurium; the acetate groups of pancuronium, vecuronium, rocuronium, and ORG 9487; the ether linkages of metocurine and dTc; the hydroxyl groups of dTc and alcuronium; and the methoxy groups of dTC, metocurine, doxacurium, mivacurium, cisatracurium, and atracurium (see *Individual Nondepolarizing Relaxants* for chemical formulas).

Because of their water solubility, the muscle relaxants are easily excreted by glomerular filtration in the urine. Urinary excretion is the principal route of elimination for the entire class of drugs as a whole. Similarly, their high water solubility generally prevents the passage of relaxants across lipoid membranous barriers, such as the blood-brain and placental barriers, and the lipid membranes of most cells, such as renal tubular cells, hepatocytes, nerve and muscle cells, and red blood cells.

Sources and Synthesis

Several relaxants are still purified from naturally occurring sources. For example, although dTc can be synthesized,

it is still the least expensive to obtain from the amazonian vine *Chondodendron tomentosum.* Similarly, the intermediates for the production of metocurine and alcuronium, which are semisynthetic, are obtained from *Chondodendron* and *Strychnos toxifera.* In fact, although pancuronium and vecuronium are entirely synthesized, their ancestor, Malouetine, the first steroidal neuromuscular blocking drug, was originally isolated from *Malouetia bequaertiana,* which grows in the jungles of Zaire in central Africa.

Atracurium, succinylcholine, pipecuronium, doxacurium, vecuronium, ORG 9487, mivacurium, rocuronium, cisatracurium, and gallamine are entirely synthetic. In any case, the final step in the synthesis of muscle relaxants is quaternization, which converts lipophilic tertiary amines into neuromuscular blocking drugs. In two cases, those of atracurium and cisatracurium, this final synthetic step has been taken advantage of as a source of potential drug degradation and inactivation, namely the Hofmann elimination reaction (see the section titled *Metabolism*).

Structure-Activity Relationships

There are many classic structure-activity relationships among neuromuscular blocking drugs. Bovet [38] originally noted structural differences between depolarizing muscle relaxants (leptocurares), which are long, thin, flexible molecules, and nondepolarizing muscle relaxants (pachycurares), which are large, heavy, rigid ring systems into which the quaternary groups are incorporated.

An optimum interonium distance (between two quaternary nitrogen atoms) of 12 to 14 angstrom (A) units (1.2-1.4 nm) was thought to be required for high neuromuscular blocking activity. Since the early 1960s, however, this concept has gradually lost importance. Although succinylcholine and decamethonium in their "extended" conformations may show interonium distances of 12 to 14 A, dTc, the toxiferines (alcuronium), and the steroids (pancuronium, vecuronium, and others) show internitrogen distances of only 10 to 11 A (1.0-1.1 nm). In addition, the second nitrogen of dTc, vecuronium, and rocuronium is a tertiary amine that is protonated at physiologic pH. These drugs are therefore really monoquaternaries, and gallamine is a trisquaternary structure. Thus, neuromuscular blocking potency need not be associated with a bisquaternary structure. Nevertheless, mivacurium, cisatracurium, and atracurium are bisquaternaries, but their internitrogen distances are between 21 A and 18 A. Thus, many of the old rules obviously no longer apply as to what structures are required to impose neuromuscular blocking properties on a compound.

Some other structure-activity correlations are:

Steroids/Ganglion Blockade.

A fixed interonium distance of 8 A seems to promote ganglion-blocking activity in steroidal bisquaternaries. [39] On the other hand, this type of side effect is minimized at 10, 18, and 21 A (pancuronium, rocuronium, vecuronium, atracurium, cisatracurium, mivacurium).

Gallamine/Muscarinic Blockade.

Muscarinic blocking properties (vagolytic effect) appear prominent in trisquaternary substances (gallamine).

Steroids/Muscarinic Blockade.

In steroidal-based neuromuscular blocking drugs, muscarinic blockade has always been a notable side effect (pancuronium) until recently, when this side effect was found to be largely due to the ACh-like substitution at positions 2 and 3 of the A-ring. This was corrected by Savage and colleagues simply by removing the quaternizing methyl group in the 2-position. This eliminates the positive charge, reducing the ACh-like character, and markedly reduces the antimuscarinic (vagolytic) property (vecuronium). [9] [10] [40] [41]

Potency/Onset.

Removal of both acetoxy groups from vecuronium results in an experimental relaxant of low potency but high affinity for cardiac muscarinic receptors. Although such a compound is clinically not useful because of its cardiovascular effects, Bowman et al [42] noted that lowpotency compounds have a rapid onset of action (see Fig. 12-6) . This original hypothesis is being proven clinically, where steroidal relaxants of low potency such as rocuronium and ORG 9487 (rapacuronium) do promote faster onset of blockade than the more potent drugs pancuronium and vecuronium.

Benzylisoquinolines/Histamine Release.

Benzylisoquinoline substances (dTc, metocurine, atracurium, and mivacurium) tend to cause release of histamine. In metocurine, mivacurium, and atracurium, this tendency is reduced by the methoxy group substitutions. It is further reduced in atracurium by the electron-withdrawing effect of the carboxyl groups in the chain and by specific stereochemistry (*cis* orientation) at the 1- to 2-positions in the benzylisoquinoline structure. [43] [44] For example, cisatracurium, the R- *cis,* R - *cis* isomer of atracurium, does not cause histamine release in the clinical dose-range and is the second benzylisoquinolinium (after doxacurium) to be largely free of this side effect. [45] [46]

Stereochemistry.

Studies of atracurium's isomers have shown that the phenomenon of histamine release may be stereospecific. The original observations of Wastila and colleagues [45] [46A] may lead to reduction of this side effect in other compounds related to cisatracurium and mivacurium.

PHARMACOLOGY OF SUCCINYLCHOLINE

Pharmacokinetics and Pharmacodynamics

The extremely brief duration of action of succinylcholine is primarily due to its rapid hydrolysis by pseudocholinesterase (plasma cholinesterase, butyrylcholinesterase), an enzyme of the liver and plasma. The initial metabolite (succinylmonocholine) is a much weaker neuromuscular blocker that is metabolized much more slowly to succinic acid and choline. Pseudocholinesterase has an enormous capacity to hydrolyze succinylcholine at a very rapid rate such that only a small fraction of the original intravenous dose actually reaches the neuromuscular junction. Because there is little or no pseudocholinesterase at the neuromuscular junction, the neuromuscular block of succinylcholine is terminated

by its diffusion away from the neuromuscular junction back into the circulation. Pseudocholinesterase, therefore, influences the onset and duration of action of succinylcholine by controlling the rate at which the drug is hydrolyzed before and after it reaches the neuromuscular junction.

Neuromuscular block induced by succinylcholine can be prolonged by a decreased concentration of normal enzyme or by the presence of an atypical form of the enzyme. Factors that have been described as lowering pseudocholinesterase concentration are liver disease, [47] pregnancy, burns, oral contraceptives, monoamine oxidase inhibitors, echothiophate, cytotoxic drugs, neoplastic disease, [37] anticholinesterase drugs, [48] [49] tetrahydroaminacrine, [50] hexafluorenium, [51] [52] and metoclopramide. [53] The histamine type 2 receptor antagonists have no effect on pseudocholinesterase activity or duration of succinylcholine effect. [54] Bambuterol, a pro-drug of terbutaline, produces marked inhibition of pseudocholinesterase activity and causes prolongation of succinylcholine-induced block. [55] [55A] The beta blocker esmolol inhibits pseudocholinesterase but causes only an insignificant prolongation of succinylcholine block. [55B] [55C]

Although not yet demonstrated in all cases, those drugs that influence the duration of action of succinylcholine by inhibiting pseudocholinesterase probably have a broadly similar effect on the nondepolarizing drug mivacurium, which is also hydrolyzed by pseudocholinesterase (see section on mivacurium).

Despite all the publications and efforts identifying those situations in which the normal pseudocholinesterase enzyme concentration may be low, this is not a major concern in clinical practice. In a study conducted by Foldes et al, [47] it was found that when pseudocholinesterase activity was reduced to 20 percent of normal by severe liver disease, the duration of apnea after the administration of succinylcholine was increased from a normal duration of 3 minutes to almost 9 minutes. Even when glaucoma treatment with echothiophate decreased pseudocholinesterase activity from 49 percent of control to no activity, the increase in duration of neuromuscular blockade varied from 2 to 14 minutes. In no patient did the total duration of neuromuscular blockade exceed 23 minutes. [55D] In an extensive clinical study, VibyMogensen [56] confirmed these observations that duration of blockade from the usual clinical dose of succinylcholine is only moderately increased by low cholinesterase levels (Fig. 12-5) (Figure Not Available) . Thus, if repeated doses are given only when recovery from the previous dose of succinylcholine is evident, low pseudocholinesterase levels should only slightly prolong a succinylcholine or mivacurium-induced blockade.

Figure 12-5 (Figure Not Available) Correlation between duration of succinylcholine neuromuscular blockade and pseudocholinesterase activity. Normal range of activity lies between arrows. *(From Viby-Mogensen [56])*

Dibucaine Number and Pseudocholinesterase Activity

A succinylcholine neuromuscular blockade can be prolonged if the patient has an abnormal genetic variant of pseudocholinesterase. The variant was found by Kalow and Genest [57] to respond to dibucaine differently than does normal pseudocholinesterase. Dibucaine inhibits normal pseudocholinesterase to a far greater extent than the abnormal enzyme. This observation led to the development of the test for dibucaine number. Under standardized test conditions, dibucaine inhibits the normal enzyme about 80 percent and the abnormal enzyme about 20 percent (Table 12-3) . Subsequently, many other genetic variants of pseudocholin- esterase have been identified, although the dibucaineresistant variants are the most important. Reviews by Pantuck [58] and Jensen and Viby-Mogensen [58A] can be consulted for more detailed information on this topic.

Although the dibucaine number indicates the genetic makeup of an individual with respect to pseudocholinesterase, it does not measure the concentration of the enzyme in the plasma, nor does it indicate the *efficiency* of the enzyme in hydrolyzing a substrate such as succinylcholine or mivacurium. Both the latter factors are accounted for in measurements of pseudocholinesterase *activity.* The activity of the enzyme refers to the number of substrate molecules (mumol) hydrolyzed per unit of time, often expressed in international units (IU). Pseudocholinesterase

TABLE 12-3 -- Relationship Between Dibucaine Number and Duration of Succinylcholine or Mivacurium Neuromuscular Block

TYPE OF PSEUDOCHOLINESTERASE	GENOTYPE	INCIDENCE	DIBUCAINE NUMBER[a]	RESPONSE TO SUCCINYLCHOLINE OR MIVACURIUM
Homozygous typical	$E_1^{u} E_1^{u}$	Normal	70-80	Normal
Heterozygous atypical	$E_1^{u} E_1^{a}$	1/480	50-60	Lengthened by about 50-100%
Homozygous atypical	$E_1^{a} E_1^{a}$	1/3,200	20-30	Prolonged to 4-8 hours

[a] The dibucaine number indicates the percentage of enzyme inhibited.

activity is certainly markedly influenced by the genotype but is also dependent on the concentration of enzyme in plasma. The latter may vary due to nutritional factors as well as to genetic background. A number of well-known drug interactions with pseudocholinesterase may lower its activity in plasma. Among those are the standard anticholinesterases neostigmine and pyridostigmine (but not edrophonium), pancuronium, alkylating agents, and echothiophate as well as other organophosphates used as active ingredients in insecticides.

The molecular biology of pseudocholinesterase is now well understood. The amino acid sequence of the enzyme is well known, and the coding errors responsible for most genetic variations have been identified. [58] [58A] Most variants are due to a single amino acid substitution error or sequencing error at or near the active site of the

enzyme. For example, in the case of the "atypical" dibucaine-resistant (A) gene, a mutation occurs at nucleotide 209, where guanine is substituted for adenine. The resultant change in this codon causes substitution of glycine for aspartic acid at position 70 in the enzyme. In the case of the fluoride-resistant (F) gene, two amino acid substitutions are possible, namely, methionine for threonine at position 243 and valine for glycine at position 390. Table 12-4 (Table Not Available) summarizes many of the known genetic variants of plasma cholinesterase: the amino acid substitution at position 70 is written as Asp
Gly. New variants of pseudocholinesterase genotypes continue to be discovered. [58B] [58C]

Cardiovascular Effects

Succinylcholine-induced cardiac arrhythmias are many and varied. The drug stimulates all cholinergic autonomic receptors: nicotinic receptors on both sympathetic and parasympathetic ganglia [59] and muscarinic receptors in the sinus node of the heart. In low doses, both negative inotropic and chronotropic responses may occur. These can be attenuated by prior administration of atropine. With large doses of succinylcholine, these effects may become positive. [60] One prominent clinical manifestation of this generalized autonomic stimulation is the development of cardiac arrhythmias. These are principally manifested as sinus bradycardia, junctional rhythms, and ventricular arrhythmias, ranging from unifocal premature ventricular contractions to ventricular fibrillation in certain special circumstances such as burns. Reports of clinical studies have noted these arrhythmias under various conditions in the presence of the intense autonomic stimulus of tracheal intubation; it is not entirely clear whether the cardiac irregularities are due to the action of succinylcholine alone or to the added presence of extraneous autonomic stimulation.

Sinus Bradycardia

The autonomic mechanism involved in sinus bradycardia is stimulation of cardiac muscarinic receptors in the sinus node, particularly in individuals with high sympathetic tone, such as children who have not received atropine. [61] [62] Sinus bradycardia has also been noted in adults and appears more commonly after a second dose of the drug is given approximately 5 minutes after the first. [63] The bradycardia may be prevented by thiopental, [64] [64A] atropine, [64] ganglion-blocking drugs, and nondepolarizing muscle relaxants, [64] [65] the implication being that direct myocardial effects, increased muscarinic stimulation, and ganglionic stimulation may all be involved in the bradycardiac response. The higher incidence of bradycardia after a second dose of succinylcholine [65] suggests that the hydrolysis products of succinylcholine (succinylmonocholine and choline) may sensitize the heart to a subsequent dose.

Nodal (Junctional) Rhythms

Nodal rhythms commonly occur as bradycardias that are slower than the sinus rate measured before the administration of succinylcholine and intubation of the trachea. The mechanism probably involves relatively greater stimulation of muscarinic receptors in the sinus node, suppressing the sinus mechanism and allowing the emergence of the atrioventricular node as the pacemaker. The incidence of junctional rhythm is greater after a second dose of succinylcholine but is prevented by prior administration of dTc. [64] [65]

TABLE 12-4 -- Human Plasma Cholinesterase Variants[a]

(Not Available)

Modified from Pantnel [58]

[a] Shown are variants whose structures were published before 1993

Ventricular Arrhythmias

Under stable anesthetic conditions, succinylcholine lowers the threshold of the ventricle to catecholamine-induced arrhythmias in the monkey and the dog. Circulating catecholamine concentrations increase 4-fold and potassium increases by one-third after succinylcholine administration in dogs. [66] Similar increases in catecholamines in response to succinylcholine are also observed in humans. [66A] [66B] Other autonomic stimuli, such as endotracheal intubation, [66C] hypoxia, hypercarbia, and surgery, are probably additive to the effect of succinylcholine. To these stimuli must be added the possible influence of drugs such as digitalis, tricyclic antidepressants, monoamine oxidase inhibitors, exogenous catecholamines, and anesthetic drugs such as halothane and cyclopropane, all of which may lower the ventricular threshold for ectopic activity or increase the arrhythmogenic effect of the catecholamines. Ventricular escape beats may also occur as a result of severe sinus and atrioventricular nodal slowing secondary to succinylcholine administration. The incidence of ventricular arrhythmias is further encouraged by the release of potassium from skeletal muscle as a consequence of the depolarizing action of the drug.

Complications

Pediatric

In recent years, attention has been called to the development of intractable cardiac arrest in hitherto apparently healthy children and adolescents who were given succinylcholine. [66D] In many of these cases, hyperkalemia, rhabdomyolysis, and acidosis have been documented. From muscle biopsy samples obtained after the event, subclinical Duchenne muscular dystrophy is a frequently associated pathologic feature.

Because these catastrophic events have occurred in previously asymptomatic children and have led to death in as many as 60 percent of such cases, the Malignant Hyperthermia Associations of the United States and Germany have strongly advised the discontinuation of succinylcholine administration to children. In the United States, the U.S. Food and Drug Administration has responded by including the following wording in the Glaxo-Wellcome package insert for succinylcholine: "it is recommended that the use of succinylcholine in children should be reserved for emergency intubation or instances where immediate securing of the airway is necessary...." It is still not clearly defined what age group is defined by "children," but in practice the group at highest risk is males 8 years old and younger (see package insert; also see sections on hyperkalemia and neuromuscular disease and Ch. 31). In view of the currently, available supply of nondepolarizing relaxants that may readily be substituted for succinylcholine, this seems a prudent and timely change in policy. In particular, the place of succinylcholine as the sole relaxant for intramuscular use has now been occupied as well by rocuronium. [66E] The administration into the deltoid of rocuronium 1.0 mg/kg (infants) and 1.8 mg/kg (children) permitted tracheal intubation in 2.5 to 3.0 minutes, albeit with a duration of action of approximately 2 hours. [66E] The new drug ORG 9487 (rapacuronium) has a shorter duration of action than rocuronium and may be more suitable as an alternative to succinylcholine for intramuscular administration. This possibility has yet to be investigated.

Hyperkalemia

Clinical reports and experimental studies have clearly shown that, in patients with certain diseases or conditions, an exaggerated release of potassium in response to succinylcholine may occur, occasionally of such magnitude that cardiac arrest ensues. [66D] [66G] Conditions that render the patient especially susceptible to the hyperkalemic response from succinylcholine are burns, trauma, nerve damage, neuromuscular disease, closed head injury, intra-abdominal infections, and renal failure. [66G]

Burns

See the section on burns for a full discussion.

Trauma

In studying soldiers who had undergone trauma associated with the Vietnam War, Birch et al [67] found that a significant increase in serum potassium did not occur in 59 patients until about 1 week after the injury, at which time a progressive increase in the serum potassium level occurred after the infusion of succinylcholine. Three

weeks after injury, three of these patients with especially severe injuries showed a marked hyperkalemia with increase in serum potassium of > 3.6 mEq/L, sufficient to cause cardiac arrest. Birch and coworkers [67] found that administration of dTc (6 mg IV) prevented the hyperkalemic response to succinylcholine. As with burns, in the absence of infection or persistent degeneration of tissue, a patient is susceptible to the hyperkalemic response probably for at least 60 days following massive trauma or until adequate healing of damaged muscle has occurred.

Nerve Damage or Neuromuscular Disease

Cooperman [68] described 40 patients with neuromuscular disease, 15 of whom had an increase in serum potassium of from 1 to 6 mEq/L after intravenous administration of succinylcholine (1 mg/kg). In another instance, Cooperman et al [69] reported a hyperkalemic response, one of which was 9.05 mEq/L, in three patients with hemiplegia or paraplegia secondary to upper motor neuron lesions. These investigators concluded that the vulnerable period appears to be within the first 6 months after the onset of hemiplegia or paraplegia and within a longer period of time in patients with progressive disease such as muscular dystrophy. Cooperman and colleagues speculated that in the latter instance, progressive muscle-wasting or other structural change accounted for the prolonged susceptibility. [69] They also found the degree of hyperkalemia to correlate with the degree and

extent of muscle affected. The greatest extent of hyperkalemia was found in those patients with greater neurologic deficit and involvement of more muscle mass. For an in-depth discussion of the clinical and pathophysiologic aspects of succinylcholine-induced hyperkalemia, the reader is referred to the review by Gronert and Theye. [70]

Closed Head Injury

Stevenson and Birch [71] described a single, well-documented case of a marked hyperkalemic response to succinylcholine in a patient with a closed head injury without peripheral paralysis.

Intra-Abdominal Infections

Kohlschutter et al [72] found that four of nine patients with severe abdominal infections had an increase in serum potassium (2.5 to 3.1 mEq/L) from succinylcholine. These researchers concluded that in the case of intra-abdominal infection that persisted longer than 1 week, the possibility of hyperkalemic response to succinylcholine should be considered.

Renal Failure

Several early case reports have suggested that patients with renal failure may be susceptible to a hyperkalemic response to succinylcholine. [73] [74] Nevertheless, more controlled studies have shown that renal failure patients are no more susceptible to an exaggerated response to succinylcholine than are those with normal renal function. [75] [76] [77] [78] [79] [80] In one author's (RDM) experience, in anesthetizing hundreds of patients with renal failure, succinylcholine may be a suitable alternative because of its lack of dependence on renal excretion for its elimination. One might postulate that patients who have uremic neuropathy may be susceptible to succinylcholine-induced hyperkalemia, although the evidence supporting this view is scanty. [79] [80] [80A] Because a number of nondepolarizing relaxants are now available that depend little or only partially on the kidney for elimination (e.g. atracurium, mivacurium, cisatracurium, vecuronium, and rocuronium), there are many alternatives to succinylcholine for muscle relaxation in patients with renal disease.

Metabolic Acidosis

It is less well appreciated that severe hyperkalemia may also follow the administration of succinylcholine to patients with severe metabolic acidosis and hypovolemia. [80B] In rabbits, the combination of metabolic acidosis and hypovolemia results in a high resting potassium and an exaggerated hyperkalemic response to succinylcholine. [80C] In this situation, the potassium originates from the gastrointestinal tract and not from muscle as in the classic hyperkalemic response. [80D] In patients with metabolic acidosis and hypovolemia, correction of the acidosis by hyperventilation and sodium bicarbonate administration should be attempted before succinylcholine administration. Should severe hyperkalemia occur, it can be treated with immediate hyperventilation, calcium chloride 1.0 to 2.0 mg intravenously, sodium bicarbonate 1 mEq/kg, and glucose (25-50 g) plus soluble insulin (10-20 U). [80E]

Increased Intraocular Pressure

Succinylcholine usually causes an increase in intraocular pressure (IOP). The increased IOP is manifested within 1 minute after injection, peaks at 2 to 4 minutes, and subsides by 6 minutes. [81] The mechanism by which succinylcholine increases IOP has not been clearly defined, but it is known to involve contraction of tonic myofibrils and/or transient dilatation of choroidal blood vessels. Apparently, sublingual administration of nifedipine will attenuate the increase in IOP from succinylcholine, suggesting a circulatory mechanism. [82] Despite this increase in IOP, the use of succinylcholine for eye operations is not contraindicated unless the anterior chamber is open. Although Meyers et al [83] were unable to confirm the efficacy of precurarization in attenuating increases in IOP following succinylcholine, numerous other investigators have found that prior administration of a subparalyzing dose of nondepolarizing relaxant (3 mg dTc, or 1 mg pancuronium) will prevent a succinylcholine-induced increase in IOP. [84] [85] Despite this discrepancy, one author (RDM) has successfully used this approach many times in providing anesthesia for patients undergoing eye surgery. Furthermore, Libonati et al [86] described the anesthetic management of 73 patients with penetrating eye injuries who received succinylcholine: no loss of global contents resulted. Thus, despite the theoretical objections expressed by Meyers and coworkers, [83] Libonati et al [86] and the authors of this chapter conclude that the use of succinylcholine in patients with penetrating eye injuries with a carefully controlled rapidsequence induction of anesthesia (including pretreatment with a nondepolarizing muscle relaxant) is an acceptable technique (Ch. 67) . As part of the total picture, succinylcholine is only one of many factors, which include endotracheal intubation and "bucking" on the tube, that may elevate IOP. [83] Of prime importance is ensuring that the patient is well anesthetized and is not straining. There are several approaches to accomplishing this goal, such as additional intravenous anesthetic drugs, deeper inhalation anesthesia, topical anesthesia to the trachea, or additional muscle relaxant, preferably a nondepolarizer.

There are probably three situations in which succinylcholine should either be avoided or the above measures taken to prevent its increasing IOP: if the patient is about to undergo repair of an ocular laceration, if the patient is about to have repair of a recent ocular surgical incision that is coming apart, or if the patient's anesthesia lightens during intraocular surgery. In the last case, succinylcholine should not be given to quiet the patient, but the surgeon should be asked to pause while anesthesia is deepened without the use of muscle relaxants or while the depth of nondepolarizing block is increased. [87]

Increased Intragastric Pressure

Unlike the rather consistent increase in IOP, the increase in intragastric pressure (IGP) from succinylcholine is quite

variable. In fact, Miller and Way [88] found that 11 of 30 patients essentially had no increase in IGP. Yet 5 of 30 patients had an increase in IGP greater than 30 cm H_2O. The increase in IGP from succinylcholine appeared to be related to the intensity of fasciculations. Accordingly, when fasciculations were prevented by prior administration of gallamine (20 mg) or dTc (3 mg), no increase in IGP was observed.

The increase in IGP from succinylcholine is presumed to be due to fasciculations of the abdominal skeletal muscle. This is not surprising because more coordinated abdominal skeletal muscle activity (e.g. straight leg-raising) may increase IGP to values as high as 120 cm H_2O. In addition to skeletal muscle fasciculations, the ACh-like effect of succinylcholine may be partly responsible for the observed increases in IGP. Greenan [89] observed consistent increases in IGP of 4 to 7 cm H_2O with direct vagal stimulation. Therefore, prior administration of vagolytic drugs may partly inhibit succinylcholine-based increases in IGP.

Are the increases in IGP following succinylcholine administration enough to cause incompetence of the gastroesophageal junction? Generally, IGP of greater than 28 cm H_2O is required to overcome the competence of the gastroesophageal junction. However, when the normal oblique angle of entry of the esophagus into the stomach is altered, as may occur with pregnancy, an abdomen distended by ascites, bowel obstruction, or a hiatus hernia, the IGP required to cause incompetence of the gastroesophageal junction is frequently less than 15 cm H_2O. [88] In these circumstances, regurgitation of stomach contents following succinylcholine is a distinct possibility, and precautionary measures should be taken to prevent fasciculation, or an appropriate nondepolarizing relaxant technique may be substituted (see the section *Dosage for Rapid Intubation of the Trachea*).

Apparently, succinylcholine does not increase IGP appreciably in infants and children. This may be related to the minimal or absent fasciculations from succinylcholine in these age groups. [90]

Muscle Pains

The incidence of muscle pain following administration of succinylcholine varies from 0.2 to 89 percent. [91] It occurs more frequently following minor surgery, especially in women and in ambulatory rather than bedridden patients. [92] Waters and Mapleson [92] postulated that pain is secondary to damage produced in muscle by the unsynchronized contractions of adjacent muscle fibers just before the onset of paralysis. That damage to muscle may occur has been substantiated by finding myoglobinemia and increases in serum creatine kinase following succinylcholine administration. [93] [93A] [93B] Prior administration of a subparalyzing dose of nondepolarizing muscle relaxant clearly prevents fasciculations from succinylcholine. [94] But the efficacy of this approach in preventing muscle pain is questionable. Although some investigators claim that pretreatment with a subparalyzing dose of nondepolarizing muscle relaxant has no effect, [91] most believe that the pain from succinylcholine is at least attenuated. [94A] [94B] [94C]

Miller [95] believes that the practice of preceding succinylcholine administration with a small dose of nondepolarizing muscle relaxant should be routine. The fasciculations certainly in no way are desirable. Furthermore, postoperative muscle pains and elevated IOP and IGP will be decreased or eliminated. Succinylcholine-induced increases in serum creatine phosphokinase and myoglobinuria may be attenuated as well. Although the succinylcholine dose should be increased by 50 percent, this appears to present no problems. [95] However, the use of a defasciculating dose of a nondepolarizing relaxant may slow the onset of succinylcholine and produce poorer conditions for tracheal intubation. [94B] [94C] The incidence of myalgia can reportedly be reduced without the use of a nondepolarizing relaxant by increasing the dose of succinylcholine to 3.0 mg/kg, which in addition produces excellent conditions for tracheal intubation. [93B] The incidence of myalgia can reportedly be reduced without affecting fasciculations or running the risk of the patient developing premature muscle weakness if succinylcholine 1.5 mg/kg is administered just 1 minute after dTc in a dose of 3 mg/70 kg. [95A]

Intracranial Pressure

Succinylcholine clearly has the potential to increase intracranial pressure (Ch. 56) . [95B] The mechanisms and clinical significance of this transient increase are unknown, but the rise in intracranial pressure does not occur following pretreatment with dTc. [95C] In patients in whom an increase in intracranial pressure may be harmful, an appropriate nondepolarizing relaxant should be substituted (see *Dosage for Rapid Intubation of the Trachea*).

Masseter Spasm

Succinylcholine causes masseter spasm, especially in children. [95D] [96] In all likelihood, this is an exaggerated contractile response at the neuromuscular junction and cannot be used to establish a diagnosis of malignant hyperthermia. There is currently no evidence that masseter spasm is a prodrome of malignant hyperthermia and no indication to change to a "nontriggering" anesthetic. [95D]

Interactions With Nondepolarizing Muscle Relaxants, Neostigmine, and Pyridostigmine

The interaction of succinylcholine with nondepolarizing muscle relaxants is complex, depending on whether succinylcholine is administered before or after the nondepolarizer. Both types of relaxants are administered concomitantly in three possible situations:

1. Succinylcholine is commonly given to facilitate intubation of the trachea, and then a nondepolarizing relaxant is administered. Succinylcholine given first may enhance the depth of block induced by a subsequent dose of nondepolarizing relaxant. [97] [98] [99] However, the effect on duration of action is variable; succinylcholine has no effect on pancuronium,

pipecuronium, or mivacurium [99] [100] but increases the duration of atracurium and rocuronium. [97] [98] The causes of these differences are not clear.
2. A small dose of nondepolarizing relaxant is commonly given before administration of succinylcholine to prevent some of the adverse affects of the latter. This approach is discussed in the section on myalgia.
3. A nondepolarizing relaxant can be injected for prolonged relaxation, and then the shorter-acting succinylcholine can be given to facilitate closure of the peritoneum. The amount of succinylcholine required for adequate relaxation in this case is directly dependent on the amount of residual effect of nondepolarizer present. [101] Despite the questionable pharmacologic reasoning, concomitant administration of an AChR-antagonist (the nondepolarizing relaxant) and an AChR-agonist (succinylcholine) appears to be clinically effective. [95] Whether it is the best way to solve the problem is the subject of considerable debate. Many prefer to give an additional dose of nondepolarizer that can be easily antagonized at the end of the operation or to deepen anesthesia. The latter two approaches seem more reasonable, certainly make better sense from a pharmacologic point of view, and are recommended by the authors.

In fact, current practice with intermediate- and shortacting nondepolarizing relaxants allows for greater control of the depth of neuromuscular blockade, such that block depth at the end of the procedure should have been adjusted to reach levels easily antagonized by anticholinesterases. Maintenance of relaxation by continuous infusion readily facilitates control of block depth. The latest studies of antagonism of residual blockade have clearly shown a more rapid and complete antagonism of blockade produced by intermediate- and short-acting relaxants than by longacting drugs. [36] [37] [102] The speed of antagonism of blockade is probably related to the rate of clearance of the relaxant and is inversely related to the half-life (see *Antagonism of Residual Neuromuscular Blockade*). Taken together, these factors suggest that (1) the practice of deepening block at the end of a case (e.g. for peritoneal closure) by injecting succinylcholine following long-acting nondepolarizers is not only pharmacologically incorrect, it is probably obsolete; and (2) maintenance of blockade for long cases (3-4 hours) with long-acting drugs may no longer be the preferred technique if the trachea is to be extubated early and rapid recovery of normal neuromuscular function is to be produced. It may be wiser and safer to maintain the blockade by administration of intermediate- or short-acting drugs in such cases, either by repetitive bolus dosing or by infusion.

Another interaction with succinylcholine involves neostigmine or pyridostigmine. For example, after dTc has been used for an intra-abdominal surgery of long-duration and the neuromuscular blockade has been reversed by neostigmine, the surgeon announces another 15 minutes is needed to retrieve a missing sponge. Should succinylcholine be given? The authors' experience is that succinylcholine (100 mg/70 kg IV) produces a neuromuscular blockade that normally lasts 5 to 10 minutes but may last up to 60 minutes when given soon after administration of neostigmine (5 mg). Sunew and Hicks [49] found that the effect of succinylcholine (1 mg/kg) was prolonged from 11 to 35 minutes when given 5 minutes after administration of neostigmine (5 mg). This can partly be explained by inhibition of pseudocholinesterase by neostigmine and, to a lesser extent, by pyridostigmine.

Clinical Management

The changing characteristics of succinylcholine neuromuscular blockade from a clinical point of view have been nicely reviewed by Lee and Katz [103] (Table 12-5) (Table Not Available) .

TOF stimulation has proven to be a very safe and useful guide in detecting the transition from a phase 1 to a phase 2 block (see Table 12-5) (Table Not Available) . Clearly, both the dose and the duration of administration of succinylcholine are important variables, although the relative contribution of each has not been established. Practically, if the administration of the drug is terminated shortly after TOF fade is clearly evident, rapid return of normal neuromuscular function should ensue. Also, the decision whether to attempt antagonism of a phase 2 block has always been controversial. However, it is now clear that if the TOF ratio is less than 0.4, administration of edrophonium or neostigmine should result in prompt antagonism. Ramsey et al [104] recommended that antagonism of a succinylcholine-induced

phase 2 block with edrophonium or neostigmine be attempted after spontaneous recovery

TABLE 12-5 -- Clinical Characteristics of Phase 1 and Phase 2 Neuromuscular Blockade During Succinylcholine Infusion

(Not Available)

Adapted from Lee and Katz [103]

of the twitch has been observed for 20 to 30 minutes and has reached a plateau phase with further recovery proceeding slowly. These researchers state that, in this situation, edrophonium and neostigmine invariably produce "dramatic" acceleration of the return of the TOF ratio toward normal. According to Ramsey et al, the dosage guideline in Table 12-5 (Table Not Available) applies only to halothane or to enflurane anesthesia. With nitrous oxide anesthesia supplemented by intravenous drugs, the dosage guidelines are more variable. In any event, monitoring neuromuscular function via peripheral nerve stimulation, such as with the TOF response, will help avoid succinylcholine overdose, detect development of phase 2 block, observe its rate of recovery, and assess the effect of edrophonium or neostigmine on recovery. The authors no longer see good reason for administration of succinylcholine for maintenance of neuromuscular blockade because of the availability of intermediate- and shortacting nondepolarizing relaxants such as atracurium, cisatracurium, vecuronium, rocuronium, and mivacurium. These drugs may be conveniently administered by repeated bolus or by infusion for periods of hours, with little concern for tachyphylaxis. After either infusion or repeated bolus administration of these intermediate- or short-acting drugs, spontaneous recovery occurs rapidly and/or residual blockade is readily antagonized.

PHARMACOLOGY OF NONDEPOLARIZING MUSCLE RELAXANTS

Introduction

Available nondepolarizing relaxants include a variety of agents that can be classified according to chemical class (the steroidal compounds and the benzylisoquinolinium substances) or according to duration of action (long-, intermediate-, and short-acting drugs). All the nondepolarizers block the neuromuscular junction by competitive inhibition of ACh at nicotinic receptors. The block is antagonized by conventional doses of anticholinesterases. In addition, the clinical effects of all the nondepolarizers may be monitored in the same way, using twitch, tetanus, TOF, and double-burst modes of stimulation. Recommended dosing is summarized in Tables 12-2 , 12-6 , and 12-7 .

The clinical pharmacology of each individual nondepolarizing relaxant is summarized in a later section. A general discussion of these drugs follows. For comparative reviews of the clinical and basic pharmacology of this group of relaxants, see later sections on pharmacokinetics and pharmacodynamics, metabolism, autonomic and cardiovascular effects, and renal and hepatobiliary disease.

TABLE 12-6 -- Guide to Nondepolarizing Relaxant Dosage (mg/kg) Under Different Anesthetic Techniques [a]

DRUG	ED_{95} UNDER N_2O/O_2	DOSE FOR INTUBATION	SUPPLEMENTAL DOSE AFTER INTUBATION	DOSAGE FOR RELAXATION	
				N_2O	ANESTHETIC VAPORS[b]
Long-acting					
Pancuronium	0.07	0.08-0.12	0.02	0.05	0.03
Metocurine	0.28	0.3-0.4	0.05	0.2	0.1
d-Tubocurarine	0.5	0.5-0.6	0.1	0.3	0.15
Gallamine	3.0	4.0-6.0	0.5	2.0	1.0
Alcuronium	0.25	0.3	0.05	0.2	0.08
Doxacurium	0.025	0.05-0.08	0.005-0.01	0.025	0.02
Pipecuronium	0.05	0.08-0.1	0.01-0.015	0.04	0.03
Intermediate-acting					
Vecuronium	0.05	0.1-0.2	0.02	0.05	0.03
Atracurium	0.23	0.5-0.6	0.1	0.3	0.15
Cisatracurium	0.05	0.15-0.2	0.02	0.05	0.04
Rocuronium	0.3	0.6-1.0	0.1	0.3	0.15
Short-acting					
Mivacurium	0.08	0.2-0.25	0.05	0.1	0.08
Rapacuronium (ORG 9487)	1.15	1.5-2.0	0.3-0.5 [c]	1.0	0.6
Continuous infusions	Dosage (mug/kg/min) required to maintain 90-95% twitch inhibi-tion under N_2O/O_2 with intrave-nous agents				
Mivacurium	3-15				
Atracurium	4-12				
Cisatracurium	1-2				
Vecuronium	0.8-2				
Rocuronium	9-12				
Rapacuronium	40-60				

[a] Suggested dosages provide good intubating conditions under light anesthesia. Satisfactory abdominal relaxation may be achieved at dosages listed after intubation without a relaxant or with succinylcholine. This table is intended as a general guide to dosage. Individual relaxant requirement should be confirmed with a peripheral nerve stimulator.
[b] The potentiation of nondepolarizing relaxants by different anesthetic vapors has been reported to vary 20-50 percent. Recent data suggest, however, that this variation may be much less, particularly in the case of the intermediate- and short-acting relaxants. Therefore, for the sake of simplicity, this table assumes a potentiation of 40 percent in the case of all volatile anesthetics.
[c] Cumulation may occur on repeat dosage as early as after first "topping-up" dose.

TABLE 12-7 -- Rapid Tracheal Intubation [a] With Succinylcholine or Nondepolarizing Relaxants [b]

DRUG	PRIMING DOSE[c] (mg/kg)	INTUBATING DOSE[d] (mg/kg)	CLINICAL DURATION[e]	FULL RECOVERY[f]
Succinylcholine	None	1.0	5-10	12-15
Succinylcholine	Nondepolarizer pretreatment	1.5	5-10	12-15
Rapacuronium (ORG 9487)	None	1.5-2.0	15-30	35-55
Rocuronium	None	0.6-1.0	30-60	60-120

Mivacurium	0.02	0.25-0.3	15-20	25-35
Vecuronium	0.01	0.2	60-75	90-120
Vecuronium	None	0.3-0.4	90-150	120-180
Cisatracurium	0.01	0.25	55-75	75-100
Cisatracurium	None	0.4	75-100	100-120

[a] Intubation within 60 to 90 seconds following injection of the intubating dose of the relaxant
[b] The administration of adequate dosage of intravenous anesthetic is assumed.
[c] This dose is given as preoxygenation is begun.
[d] This dose is given 2 to 4 minutes following the priming dose. For atracurium and mivacurium, slower injection (30 seconds) is recommended to minimize circulatory effects.
[e] Minutes from injection of the intubating dose to recovery of twitch to 25 percent of control
[f] Minutes from injection of the intubating dose to recovery of twitch to 95 percent of control and train-of-four of .70

Classification by Chemical Structure

Steroidal Compounds: Pancuronium, Pipecuronium, Vecuronium, Rocuronium and ORG 9487 (Rapacuronium)

The advantages of this class of compounds include high potency and lack of histamine release. This class generally exhibits a vagolytic property. This side effect is moderate in pancuronium and ORG 9487, slight to moderate in rocuronium, and absent within the clinical dose range in pipecuronium and vecuronium. All steroidal relaxants are excreted by the kidney. The duration of action may be altered by modification of the lipophilic/hydrophilic balance in the molecule, with the more lipophilic substances such as vecuronium, rocuronium, and ORG 9487 showing intermediate or short-to-intermediate durations of effect because of greater uptake by the liver. The onset of action of steroidal substances is shortened in less potent molecules such as rocuronium and ORG 9487 (Fig. 12-6) . [42]

The steroidal relaxants are generally not extensively metabolized: about 30 to 40 percent of an injected dose of vecuronium undergoes deacetylation in the liver at the 3- position to an active metabolite, 3-OH vecuronium. Similarly, about 15 to 20 percent of pancuronium undergoes 3-deacetylation to 3-OH pancuronium. Both metabolites are active, having neuromuscular blocking potencies of 50 to 80 percent those of the parent compounds. Pipecuronium and rocuronium are not metabolized to any known significant extent. ORG 9487 undergoes a moderate amount of deacetylation at the 3-position to a metabolite (ORG 9488), which is longer lasting than, and two to three times as potent as, the parent compound (see sections on kinetics and dynamics, metabolism, and hepatic and renal disease).

Benzylisoquinolinium Compounds: d-Tubocurarine, Metocurine, Doxacurium, Atracurium, Cisatracurium, and Mivacurium

Advantages of this class include high potency and lack of vagolytic effect. This class generally exhibits a tendency to cause release of histamine. [44] This side effect is promi-nent in dTc, moderate in metocurine, slight in atracurium and mivacurium, and absent (beyond the clinical dose range) in doxacurium and cisatracurium. [14] [17] [44] [105] [106] The benzylisoquinolinium compounds are excreted by the kidney. There is a relatively unimportant biliary excretory pathway for dTc and doxacurium. In the benzylisoquinolinium esters, degradation by Hofmann elimination (atracurium and cisatracurium) or metabolism by cholinesterasecatalyzed hydrolysis (mivacurium) occurs in the plasma. [15] [106A] (see sections on kinetics and dynamics, metabolism, and hepatic and renal disease.)

Phenolic Ether: Gallamine

Gallamine, a phenolic ether introduced in 1948, was the first synthetic relaxant used in clinical practice. This compound is a long-acting drug excreted entirely by the kidney and is strongly vagolytic. Consequently, it is no longer popular.

Strychnos Alkaloid: Alcuronium

Introduced in 1964, alcuronium is a long-acting agent that is the semisynthetic diallyl derivative of toxiferine. The latter is purified from *Strychnos toxifera.* Its advantage at the time of its introduction was a relative lack of side effects. It is mildly vagolytic and is excreted unchanged by the kidney with a minor secondary biliary pathway. Alcuronium is

Figure 12-6 Linear regression of onset of neuromuscular blockade (ordinate) versus potency of a series of steroidal relaxants studied in the cat model by Bowman and associates. [42] The data show that onset may be increased in compounds of low potency and encouraged the eventual development of rocuronium and rapacuronium (ORG 9487).

moderately popular in Europe, the Far East, and Australia. It is not available in the United States.

Classification by Duration of Action

The duration of action of the nondepolarizing relaxants is governed mainly by the pattern(s) of metabolism and elimination of each drug. See the sections on pharmacokinetics and pharmacodynamics, metabolism, and renal and hepatobiliary disease.

Long-Acting Relaxants

Long-acting relaxants include dTc, metocurine, doxacurium, pancuronium, pipecuronium, gallamine, and alcuronium. They generally show relatively slow onsets to maximum blockade of 3 to 6 minutes following doses given for tracheal intubation (1.5 to 2 times the ED_{95} for twitch inhibition). The clinical duration of action (to recovery of twitch to 25% of baseline) ranges from 80 to 120 minutes following intubating doses. All the long-acting relaxants require careful antagonism of residual blockade at the end of nearly every case. Selection of a long-acting relaxant is based primarily on the prominence or absence of the cardiovascular side effect. All the long-acting agents are primarily excreted unchanged by glomerular filtration in the urine, having undergone little or no metabolism.

Relaxants of Intermediate Duration

Intermediate-acting relaxants include vecuronium, rocuronium, atracurium, and cisatracurium. Onset of block following doses typically given for tracheal intubation is about 2 to 2½ minutes. Clinical duration is 30 to 60 minutes, and 95 percent twitch recovery occurs in 45 to 90 minutes. Vecuronium and rocuronium owe their intermediate duration to their dual excretory pathways (kidney and liver). Atracurium and cisatracurium are intermediate-acting because they undergo the chemical breakdown process of the Hofmann elimination in the plasma.

Short-Acting Relaxants

Mivacurium and rapacuronium (ORG 9487) are relatively short-acting. Mivacurium shows medium onset of about 2 minutes for intubation. The onset of ORG 9487 is fast, enabling intubation in 1 minute. The clinical duration of mivacurium is about 12 to 20 minutes, and 95 percent twitch recovery occurs in 25 to 35 minutes; corresponding times for rapacuronium are about 15 to 20 minutes and 25 to 50 minutes. The lower range of times for ORG 9487 is achieved after doses of 1.5 mg/kg, with the higher durations occurring following 2.0 to 2.5 mg/kg. Mivacurium is nearly completely destroyed by plasma cholinesterase at about 70 to 88 percent the rate of succinylcholine. [15] Less than 5 percent is excreted in the urine. ORG 9487 is partially deacetylated

at the 3-position and excreted in the bile and urine as the parent compound or the more active metabolite, ORG 9488. The metabolite is longer-acting than the parent compound and is most likely the cause of cumulation of the effect of ORG 9487, resulting in longer duration of action and slower recovery following repetitive dosage or periods of infusion of 30 minutes or more.

Pharmacokinetics and Pharmacodynamics

The principal action of nondepolarizing neuromuscular blocking drugs is competitive antagonism of acetylcholine at nicotinic receptors on the postjunctional membrane of the neuromuscular junction. [107] The potency of the drugs as antagonists is commonly expressed by the dose-response relationship. The drugs have different potencies as illustrated in Table 12-6 and Figure 12-7 . The dose-response relationship is sigmoidal in shape (see Fig. 12-7) and has been derived in a variety of ways. The simplest method is to perform simple linear regression over the approximately linear portion of a semilogarithmic plot between 25 and 75 percent effect. Alternatively, the curve can be subjected to probit or logic transform to linearize it over its whole length or be subjected to nonlinear regression using the sigmoid E_{max} model of the form:

This can be applied to the raw data. [109] [108] More complex models relating the concentration of muscle relaxant at the neuromuscular junction to their pharmacologic effect have been developed, and they will be discussed later. [110] [111]

Several factors can alter the potency of muscle relaxants, but in clinical practice the greatest effect is mediated by the halogenated anesthetics that increase the potency of the muscle relaxants. The magnitude of this effect may allow up to a 50 percent decrease in the required dose of muscle relaxant, halothane having the least effect and isoflurane and

Figure 12-7 Schematic representation of a semilogarithmic plot of muscle relaxant dose versus neuromuscular block. A drug of high potency would be represented by doxacurium, one of medium potency by atracurium, and one of low potency by gallamine. The graph illustrates that the relative potencies of the muscle relaxants span a range of approximately two orders of magnitude.

Figure 12-8 (Figure Not Available) Rates at which the plasma concentration of *d*-tubocurarine (dTc) and pancuronium decrease in patients with and without renal failure. Distribution of drug from plasma to the tissues is primarily responsible for the rapid decline in plasma concentrations in the first 30 minutes after administration. Thereafter, further decrease in plasma concentration is due to elimination, a slower process. *(Data for pancuronium from McLeod et al [119] and those for dTc are from Miller et al [120])*

enflurane having greater, approximately equal effects. [111A] Traditionally, doses used to facilitate tracheal intubation are two times the ED_{95} (this also approximates to four times the ED_{50}). Doses for maintenance are usually in the order of one-tenth to one-fourth of the intubating dose.

Following its injection into the circulation, the concentration of a muscle relaxant in the plasma decreases rapidly at first, then more slowly (Fig. 12-8) (Figure Not Available) . The shape of this curve is determined by the processes of distribution and elimination. Classically, this curve is divided into an initial (distribution) phase and a terminal (elimination) phase. In Figure 12-8 (Figure Not Available) the log-linear terminal phase is obvious from 60 minutes on. This curve can be represented mathematically by bi- or triexponential equations in the form

These multiexponential equations express the concept of drug distributing between two or three theoretical compartments.

Figure 12-9 illustrates the classic model whereby drug is administered intravenously into a central compartment with volume V1 and is distributed and eliminated only from this compartment. Drug distributes very rapidly throughout this central compartment, which includes the plasma volume and the organs of elimination, e.g., in the case of muscle relaxants, the kidneys and liver. The terms "k" are the rate constants for drug movement between compartments, in the direction of the arrows. The peripheral compartments (usually one or two in number, here represented by V2 and V3) can be thought of as the "tissues." The effect compartment, which will be discussed later, is the neuromuscular junction; for computational purposes, it has infinitesimal volume; therefore, it does not influence overall drug distribution. Drug administration and elimination are unidirectional; distribution is bidirectional.

Figure 12-9 Schematic representation of drug disposition into different compartments. These compartments are mathematical concepts only and do not represent real physiologic spaces. The effect compartment in this case would be the neuromuscular junction; for computational purposes, it has infinitesimal volume. The terms k_{nm} are the rate constants for drug movement, in the direction of the arrow, between these theoretical compartments. See text for further discussion.

Initially, drug concentration in the central compartment (plasma concentration) will exceed that in the peripheral compartment (tissue concentration), and drug will move from the plasma to the tissues. Later, as plasma concentration decreases, it becomes less than tissue concentration, and the net direction of drug movement is now from tissues to plasma. In general, this conceptual model is appropriate for all the muscle relaxants, with the exception of atracurium and cisatracurium, which also undergo elimination (by degradation) from the tissues. [113] For simplicity, the following discussion will assume only one peripheral compartment.

Volume of distribution is the volume to which the drug has distributed when the processes of distribution and elimination are in equilibrium. Elimination is represented by the variable, plasma clearance, i.e., the volume of plasma from which drug is irreversibly and completely eliminated per unit time. For most nondepolarizing muscle relaxants, the process of distribution is more rapid than that of elimination, and the initial rapid decline in plasma concentration is due primarily to distribution of the drug to the tissues. An exception to this rule is mivacurium, which has such a rapid clearance, due to metabolism by plasma cholinesterase, that elimination is the principal determinant of the initial decline in plasma concentration. [114]

Following the initial process of drug distribution to the tissues, the plasma concentration falls more slowly (terminal phase). The rate of decrease in plasma concentration during this terminal phase is often expressed in terms of elimination half-life, which equals the natural logarithm of 2 divided by the rate constant of decline (i.e., the slope of the terminal phase). During this terminal phase, the tissue drug concentration exceeds that of the plasma, and the rate of decrease of the plasma concentration is determined by two factors, the rate at which drug can move from the tissues back to the plasma and the clearance of drug from the plasma. In classic theory for muscle relaxants, drug can move rapidly from the tissues to the plasma, and elimination from the plasma (clearance) is the rate-limiting step. For this reason, the terminal portion of the curve is often termed the elimination phase, even though distribution of drug from tissues to the plasma is occurring continually throughout. Volume of distribution can also influence the terminal portion of the curve; the greater the volume of distribution, the slower the decline in plasma concentration.

The muscle relaxants are polar drugs, and their volume of distribution is classically thought to be limited to a volume roughly equivalent to a portion of the extracellular fluid space, i.e., 150 to 450 $mL \cdot kg^{-1}$ (see tables in renal and hepatobiliary sections). [112] With this model of drug distribution, the potential rate of drug movement from the tissues to the plasma exceeds the rate of elimination, and plasma clearance is the process that limits the rate of decline of plasma drug concentration. However, there is evidence that muscle relaxants distribute more widely, into tissues with low blood flows, e.g., connective tissue, [115] and the true volume of distribution of

tubocurarine has been estimated as high as 3.4 $L \cdot kg^{-1}$ and the elimination half-life as long as 40 hours (compare with values in Tables 12-13 and 12-14) . [116] Because the rate of drug movement from such tissues is slow, less than that of plasma clearance, this becomes the rate-limiting step in the rate of decline in plasma drug concentration.

This phase only becomes obvious when drug is administered for many days or when sampling is continued for 24 to 96 hours after drug administration. In normal operating room use of muscle relaxants, the amount of drug distributing to this compartment does not affect the clinical response to the drug. In conditions where clearance of the muscle relaxant is reduced, e.g., renal or hepatic disease, it is the terminal portion of the plasma concentration versus time curve that is most affected (see Figs. 12-8 (Figure Not Available) and 12-39 (Figure Not Available)). [117] The rate of decline of plasma concentration is slowed, and recovery from paralysis is potentially delayed. [117] In conditions associated with an increased distribution volume, e.g., renal or hepatic disease, early plasma concentrations of drug may be less than those observed when organ function is normal (see Fig. 12-38) (Figure Not Available) . However, during the terminal phase, the increased volume of distribution will result in a higher plasma concentration, which decreases more slowly (see Fig. 12-38) (Figure Not Available) Decreased protein binding of a drug results in a larger distribution volume, but as the degree of protein binding of muscle relaxants is small, changes in protein binding will have minimal effect on their distribution. [118]

Recovery of neuromuscular function takes place as plasma concentration declines, and Figure 12-8 (Figure Not Available) shows that the greater part of this decrease occurs primarily because of distribution, and early recovery of neuromuscular function, e.g., to 10 or 25 percent of control, often occurs during this phase. Thus, processes that primarily affect elimination of the drug, e.g., renal failure, may not be associated with prolonged duration of block. Observe that at 30 minutes, plasma concentrations are little different for patients with and without renal failure. [119] [120] However, as recovery comes to rely more on drug elimination than distribution, i.e., recovery from 25 to 75 percent or more or after administration of larger or repeated doses, the duration of action may be prolonged. [113] [121]

Following injection of a muscle relaxant, plasma drug concentration immediately starts to decrease. The effect (neuromuscular blockade) takes approximately 1 minute to begin, increases initially, and does not begin to recover for many more minutes despite continually decreasing plasma concentration of drug. This discrepancy between plasma concentration and drug effect occurs because the action of muscle relaxants is not in the plasma but at the neuromuscular junction. To produce paralysis, the drug must diffuse from the plasma to the neuromuscular junction, and the effect is terminated later by drug diffusion back into the plasma (see Fig. 12-9) . Thus, concentrations at the neuromuscular junction lag behind those in the plasma, and they are less during onset of block and greater during recovery. The plasma concentration-effect relationship exhibits hysteresis, i.e., for a given level of block, plasma concentrations are greater during onset than during recovery. For this reason, a concentration-effect relationship cannot be obtained simply by directly relating plasma concentration to level of neuromuscular blockade.

To overcome this problem, pharmacodynamic models have been developed to incorporate a factor for the delay caused by drug diffusion to and from the neuromuscular junction. [110] This factor, k_{e0} , is the rate-constant for drug equilibration between plasma and the neuromuscular junction. By measuring plasma drug concentrations and neuromuscular blockade, during both onset and recovery phases, and using the technique of simultaneous pharmacokinetic/ pharmacodynamic modeling, it is possible to collapse the hysteresis in the plasma concentration-effect curve, to estimate actual neuromuscular junction drug concentrations, and to derive true concentration-effect relationships ($Cpss_{50}$ and k_{e0}) for the neuromuscular relaxants (Table 12-8) . [110]

Results from studies using these techniques indicate that the potency of the muscle relaxants is increased by the volatile anesthetics in a dose-dependent manner (isoflurane > halothane) and is increased by prior administration of succinylcholine. The potency is less in neonates and infants than in older children and adults and in burned patients (see Table 12-6 and Fig. 12-40) (Figure Not Available) .

The long-acting muscle relaxants undergo minimal or no metabolism, and they are eliminated, largely unchanged, mostly by renal excretion. Hepatic pathways are less important. Vecuronium undergoes deacetylation at the 3-position of the steroid nucleus to 3-desacetylvecuronium. This compound has approximately 80 percent of the neuromuscular blocking potency of vecuronium, and it can accumulate and cause prolonged paralysis during long-term administration of vecuronium to patients with renal failure in the intensive care unit. [122] Atracurium and cisatracurium are extensively degraded by Hofmann elimination, principally to laudanosine. Degradation comprises at least 50 percent of the total clearance for atracurium. [113] Both vecuronium and atracurium have greater clearance than do the long-acting muscle relaxants (see Tables 12-13 and 12-14) . Mivacurium is cleared rapidly and almost exclusively by metabolism by plasma cholinesterase, resulting in a plasma clearance much greater than of any other nondepolarizing muscle relaxant (see Tables 12-13 and 12-14) . [15] In addition, because of its rapid metabolism in the plasma, there is limited opportunity for distribution, and its volume of distribution is small.

Clinical Management

There are two important safety issues in practice with muscle relaxants: cardiovascular side effects and adequacy of recovery to normal neuromuscular function. Of the two, the latter is by far the more important. It has been difficult to demonstrate that one muscle relaxant is truly "safer" than another. [123] [124] [125] To avoid prolonged residual paralysis or inadequate antagonism of residual blockade or both, the main goal should be to use the lowest possible dose that will provide adequate relaxation for surgery. The rational use of muscle relaxants depends on administration by an anesthesiologist who is familiar with the operative procedure, who knows when to use muscle relaxants, who correctly applies monitoring techniques to assess the magnitude and duration of action of the specific muscle relaxant, and who understands the clinical pharmacology of the drug, including its side effects and complications. The key factor again is to avoid overdosage. For example, in an adequately anesthetized and monitored patient, there is little reason to completely obliterate twitch or TOF responses to peripheral nerve stimulation during maintenance of relaxation. Supplemental doses of relaxants should be about one-fourth to one-tenth the initial dose and should not be given until there is clear evidence of beginning recovery from the previous

dose. This practice will help to avoid an excessive neuromuscular blockade that cannot be readily antagonized by anticholinesterases (see Tables 12-2 , 12-6 , and 12-9 for dosage guidelines). *The management of individual patients should always be guided by monitoring with a peripheral nerve stimulator.*

Several clinical alternatives to muscle relaxants are available to provide adequate surgical relaxation. It is important to keep them all in mind to avoid relying only on neuromuscular blockade to achieve a desired degree of relaxation. These options include adjustment of the depth of general anesthesia, regional anesthesia, proper positioning of the patient on the operating table, and proper adjustment of the depth of neuromuscular blockade. The choice of one or several of these options is determined by the estimated remaining duration of surgery, the anesthetic technique, and the surgical maneuver required.

Control of Depth of Anesthesia

Inhaled anesthetics are known to produce relaxation of skeletal muscle by multiple inhibitory influences on reflex pathways in the CNS that are responsible for maintenance of muscle tone. This action of anesthetics is dose-related but usually does not cause measurable neuromuscular blockade. Very deep anesthesia with isoflurane, desflurane, enflurane, and diethyl ether may cause a slight reduction of neuromuscular transmission, as measured by depression of sensitive indicators of clinical neuromuscular function, such as tetanus and TOF. [126] [127] There is a relationship between relaxation and anesthetic depth during all types of anesthesia. Thus, relaxation may be increased by deepening anesthesia using either inhaled or intravenous anesthetics for various surgical maneuvers such as peritoneal closure, fracture or dislocation reduction, and tracheal intubation. The effectiveness of neuromuscular blocking drugs increases proportionally with depth of inhalational anesthesia. [128] [129]

Control of Depth of Neuromuscular Blockade

The level of clinical neuromuscular blockade is demonstrable by appropriate use of a nerve stimulator (Ch. 39) . Relaxation is generally inadequate for most situations if all four responses are clearly visible or palpable during TOF monitoring. If one or two responses are visible or palpable, relaxation should be sufficient for abdominal surgery under adequate depth of anesthesia. If only one twitch is faintly visible or palpable, relaxation should be deep enough to permit intubation of the trachea under already-established general

Data are the median and range of reported values.

ED_{50} , ED_{90} , and ED_{95} are the doses of each drug that produce, respectively, 50%, 90%, and 95% decrease in the force of contraction or amplitude of the electromyogram of the adductor pollicis muscle following ulnar nerve stimulation.

anesthesia. *If anesthesia is too light, on the other hand, relaxation may prove inadequate, even if the indicators of monitoring seem appropriate.*

Regional Anesthesia

Regional anesthesia (Chs. 46 and 47) should always be considered alone or in combination with light general anesthesia as a means of achieving relaxation localized to the area of surgery. For example, continuous epidural or spinal anesthesia will provide good relaxation for lower abdominal surgery or for surgery on the hip. The patient may be spared the discomforts of abdominal exploration during epidural or spinal anesthesia by the supplemental administration of 0.5 to 1.0 MAC

levels of inhaled anesthetics or intravenous supplements such as propofol and/or opioids such as remifentanil.

Patient Positioning

Adequate relaxation for peritoneal closure, laryngoscopy, and other maneuvers depends considerably on suitable positioning (Ch. 30). The operating table may be flexed slightly to make it easier to close an abdominal wound. Placement of the head in the sniffing position for laryngoscopy and placement of the height of the operating table at a level slightly above the waist of the anesthesiologist can very much improve conditions for intubation of the trachea.

Dosage

General Dosage Guidelines

It is important to select the proper dose of a nondepolarizing relaxant in order to ensure that the desired effect is achieved without excessive overdosage. A general dosage guideline for administration of nondepolarizing relaxants is presented in Table 12-6 . In addition to a general knowledge of the guidelines, precise practice requires the use of a peripheral nerve stimulator to adjust relaxant dosage to the individual patient. Overdosage must be avoided for two reasons: (1) to limit the duration of drug effect to match the anticipated length of surgery and (2) to avoid unwanted cardiovascular side effects. The development of new relaxants with different lengths of action and lack of effect on the circulation

has made overdosage both easier to avoid and more safely tolerated.

Initial and Maintenance Dosage

The initial dosage is determined by the purpose of administration. If the trachea has already been intubated without a relaxant or with succinylcholine and the purpose is simply to produce surgical relaxation, a dose slightly less than the ED_{95} (Table 12-6) should be given, with adjustment upward as indicated by responses evoked by peripheral nerve stimulation. Downward adjustment of the initial dose is necessary in the presence of any of the potent inhaled anesthetics, which probably potentiate all the nondepolarizers to a similar extent (by 30-50%) (see Fig. 12-40) (Figure Not Available) when given in concentrations of about 1 MAC.

Supplemental (maintenance) doses of nondepolarizers range from 20 to 30 percent of the initial dose in the case of long-acting drugs to 35 to 50 percent of the initial dose in the case of intermediate- and short-acting relaxants.

Maintenance of relaxation by continuous infusion of intermediate and short-acting drugs can be performed and is useful to keep relaxation smooth and to rapidly adjust the depth of relaxation to surgical needs. By contrast, the depth of block in each patient is kept moderate, if possible, to ensure prompt spontaneous recovery or easy reversal at the end of the procedure. Table 12-6 lists approximate dose ranges that are usually required during infusion to maintain 90 to 95 percent block of the twitch (one twitch visible on TOF stimulation) under nitrous oxide-oxygen anesthesia supplemented with intravenous anesthetics. Infusion dosage is usually decreased by about 30 to 50 percent in the presence of potent inhaled anesthetics.

Dosage for Tracheal Intubation

If the purpose of the initial dose is to provide the very deep paralysis needed for tracheal intubation, bronchoscopy, or other manipulations of the airway, dosage in the range of two to three times the ED_{95} is usually given to facilitate the maneuver within 1 to 3 minutes, depending on the choice and dose of muscle relaxant (see Tables 12-2 , 12-6 , and 12-7) .

Dosage for Priming

Several groups of investigators have recommended that a small subparalyzing dose of the nondepolarizer (about 20% of the ED_{95} or about 10% of the intubating dose) be given 2 to 4 minutes before giving a second large dose for tracheal intubation. [130] [131] [132] [133] [134] This procedure, termed priming, has been shown to accelerate the onset of block of most nondepolarizing relaxants by about 30 to 60 seconds, with the result that intubation can be performed within approximately 90 seconds following the second dose (see Table 12-7) . Doses in Table 12-7 , which are recommended for rapid intubation following priming, are 50 to 100 percent higher than conventional doses recommended for intubation. This increase in dosage will ensure that conditions will be satisfactory within 90 seconds or less. Although priming in conjunction with such large doses clearly does shorten the onset time of nondepolarizers, the shortest onset is still produced by succinylcholine > rapacuronium (ORG 9487) > rocuronium.

With priming, intubating conditions at 60 to 90 seconds will be satisfactory following two to three times ED_{95} , provided that the patient has also received adequate dosage of intravenous anesthetic agents to produce hypnosis, amnesia, and analgesia, or a state of light general anesthesia. Considerably larger doses of intravenous anesthetics and neuromuscular blocking drugs may be required in healthy young adults and in children.

A caution in the use of the priming technique is the potential development of weakness or loss of airway control by the patient before induction of anesthesia. [134A] To prevent this, the following is suggested: the patient should be instructed, before receiving the priming dose, to report the development of diplopia after the dose is given. Once the patient reports diplopia, the priming effect may be considered to be in place, and induction of anesthesia with cricoid pressure should immediately follow. If diplopia is not reported within 2 to 4 minutes, induction should proceed at that time in any case. Needless to say, oxygen administration should be begun before administration of the priming dose of relaxant.

Dosage for Rapid Intubation of the Trachea

Succinylcholine is still preferred for this critical maneuver (Chs. 29 and 42). Now, however, there are suitable alternatives among the nondepolarizing relaxants (Tables 12-2 and 12-7) but as yet no replacement. There are five caveats in any case, whichever technique of rapid intubation is elected: (1) preoxygenation must be performed; (2) adequate dosage of intravenous drugs must be administered to ensure that the patient is adequately anesthetized; (3) intubation within 60 to 90 seconds is considered acceptable; (4) priming should be considered to shorten the onset of action of nondepolarizers; and (5) cricoid pressure should be applied subsequent to the injection of the induction agent.

When rapid tracheal intubation is performed with nondepolarizing relaxants, priming is recommended, with doses listed in Table 12-7 given 2 to 4 minutes before injection of the intubating dose in order to speed the onset of action. [130] [131] [132] [133] [134] (In the case of rocuronium and ORG 9487, onset is probably fast enough to make priming unnecessary. [135] [136] [137]) Large doses in the range of two to four times ED_{95} are advised for rapid intubation following priming. Following doses greater than five times ED_{95} , priming is probably not necessary with any of the short- or intermediateacting drugs. [138] Rapid intubation using long-acting drugs is no longer advised because of the unacceptably long period of block that results. Once again, the practitioner must remember that the price to be paid for giving large doses of muscle relaxants is longer duration of action and/or potentially increased circulatory effect. Lengthening of the duration of effect is more noticeable in drugs with longer half-lives, such as vecuronium (t½beta 50-60 minutes). Potentially increased circulatory effect in the case of the weak histamine-releasing property of atracurium (t½beta 20 minutes) and mivacurium (t½beta 2-3 minutes) should be dealt with by injecting three

times ED_{95} doses more slowly (e.g., over a 20- to 30-second period). [139] [140]

Table 12-7 also gives the approximate clinical duration following dosage for rapid intubation for each muscle relaxant. At this point the evoked twitch response has

recovered to about 25 percent of its baseline strength. Residual block by nondepolarizers can then be easily antagonized with neostigmine or edrophonium. The clinical duration is therefore a useful guideline for practice. The approximate time to full recovery is also a useful guideline. If spontaneous recovery from the particular muscle relaxant has appeared to have occurred within this period, then administration of an anticholinesterase may not be necessary. The decision not to give an anticholinesterase drug dictates that complete recovery from neuromuscular blockade must be verified by confirmatory monitoring data via a nerve stimulator; by adequate clinical evaluation, such as sustained head lift for 5 seconds; and by proper documentation on the anesthetic record and on the patient's chart.

Metabolism and Elimination

The specific pathways of metabolism (biotransformation) and elimination of neuromuscular blocking drugs are summarized in Table 12-10 . The following description is intended to give a general understanding of the various processes of clearance that affect the duration of neuromuscular block and contribute toward recovery from paralysis. Metabolism and elimination of specific drugs is also discussed in the sections on individual agents and in the sections on renal and hepatobiliary disease.

TABLE 12-10 -- Metabolism and Elimination of Neuromuscular Blocking Drugs

DRUG	DURATION	METABOLISM (%)	ELIMINATION		METABOLITES
			KIDNEY (%)	LIVER (%)	
Succinylcholine	Ultrashort	Plasma cholinesterase (98-99%)	< 2%	None	Monoester (succinyl monocholine) and choline. The monoester is metabolized much more slowly than succinylcholine.
Mivacurium	Short	Plasma cholinesterase (95-99%)	< 5%	None	Monoester and quaternary alcohol. The metabolites are inactive. They are most likely not themselves metab-olized any further.
			(Metabolites eliminated in urine and bile)		
Rapacuronium (ORG 9487)	Short-intermediate	to 3-desacetyl metabolite	20%	Unknown	The 3-OH derivative, ORG 9488, is two to three times more potent than the parent compound and has a longer half-life (see section on kinetics and section on rapacuronium).
Atracurium	Intermediate	Hofmann elimination and nonspecific ester hydrolysis (60-90%)	10-40%	None	Laudanosine, acrylates, alcohols, and acids (see Fig. 12-11) (Figure Not Available) . Although laudanosine has CNS-stimulating properties, the clinical relevance of this effect is negligible.
			(Metabolites eliminated in urine and bile)		
Cisatracurium	Intermediate	Hofmann elimination (77%?)	Renal clearance is 16% of total		Laudanosine and acrylates. Ester hydrolysis of the quaternary monoacrylate occurs secondarily (see Fig. 12-11 (Figure Not Available)). Because of the greater potency of cisatracurium, laudanosine quantities produced by Hofmann elimination are five to ten times lower than in the case of atracurium, making this a non-issue in practice.
Vecuronium	Intermediate	Liver (30-40%)	40-50%	50-60%	The 3-OH metabolite accumulates, particularly in renal failure. It has about 80% the potency of vecuro-nium and may be responsible for delayed recovery in ICU patients.
			(Metabolites excreted in urine and bile)		
			~40%	~60%	
Rocuronium	Intermediate	None	< 10%	> 70%	None
Pancuronium	Long	Liver (10-20%)	85%	15%	The 3-OH metabolite may accu-mulate, particularly in renal failure. It is about two-thirds as potent as the parent compound.
d-Tubocurarine	Long	None	80% (?)	20%	None
Pipecuronium	Long	Approximately 10%	> 90% (?)	< 10%	The 3-OH metabolite is produced in small quantities (~5%).
Metocurine	Long	None	> 98%	< 2%	None
Doxacurium	Long	None	> 90% (?)	< 10%	None
Alcuronium	Long	None	80-90% (?)	10-20%	None
Gallamine	Long	None	100%	0%	None

All relaxants are positively charged cations because they contain quaternary nitrogen atoms. [107] Nearly all relaxant molecules also contain ester linkages, acetoxy groups, and hydroxyl or methoxy groups. These substitutions, especially the quaternary nitrogen groups, confer a high degree of water solubility with only a slight lipid solubility. The hydrophilic nature of relaxant molecules enables easy elimination in the urine via glomerular filtration with no tubular resorption or secretion. Therefore, all muscle relaxants show elimination of the parent molecule in the urine as a basic route of elimination. Muscle relaxants with a long duration of action are eliminated predominantly in the urine and thus have a clearance rate limited by glomerular filtration (1-2 mL/kg/min).

Other processes of clearance may be added to renal elimination. Pancuronium and pipecuronium undergo a small amount of metabolism by deacetylation at the 3-position, [140A] [140B] [140C] [140D] but this makes a minimal contribution to their total clearance.

Vecuronium, the 2-desmethyl derivative of pancuronium, is more lipid-soluble than pancuronium because of the absence of the quaternizing methyl group at the 2-position. As a result, it undergoes a greater amount of metabolism (3-deacetylation). About 12 percent of vecuronium clearance is by conversion to 3-desacetylvecuronium, [141] and about 30 to 40 percent is cleared in the bile as parent compound. [142] [143] Vecuronium is also eliminated in the urine, and this combined organ elimination gives it a clearance of 3 to 6 mL/kg/min, [141] [143] [144] i.e., about twice that of pancuronium (Fig. 12-10) (Figure Not Available) .

In undergoing Hofmann elimination in the plasma (Fig. 12-11) (Figure Not Available) and interstitial fluid, atracurium is cleared two to three times more rapidly than the longacting drugs. [113] [145] [146] [147] [148] [149] Similar clearance values have been obtained for rocuronium [150] [151] [152] [152A] [152B] [152C] and cisatracurium. [153] [153A] [153B] [153C] [153D] In summary, relaxants such as vecuronium, rocuronium, atracurium, and cisatracurium, have clearances in the range 3 to 6 mL/kg/min because of multiple pathways of degradation, metabolism, and/or elimination, and these drugs have an intermediate duration of action.

Mivacurium is hydrolyzed in the plasma by plasma cholinesterase (Fig. 12-12) (Figure Not Available) . [15] [154] Mivacurium consists of three stereoisomers, and the clearances of the two most pharmacologically active isomers, the *cis-trans* and *trans-trans,* are approximately 100 and 50 to 70 mL/kg/min, respectively. [154A] [154B] [154C] This rapid enzymatic clearance of mivacurium accounts for its short duration. [15] [154B] The clearance of these two isomers is decreased by approximately 50 percent in patients with cirrhosis, [154C] and by approximately 20 percent in those with renal failure. [154D] The third stereoisomer, the *cis-cis* isomer, is present as only 4 to 8 percent of the mivacurium mixture and has less than 10 percent of the neuromuscular blocking potency of the other two isomers. [154B] Consequently, even though it has a much lower clearance (~4 mL/kg/min) than the two other isomers, it does not contribute significantly to the duration of action of mivacurium.

It is clear from the above discussion that renal elimination is basic to all muscle relaxants. Additional processes of clearance (e.g., biliary clearance) shorten the duration of effect. Very active metabolism and/or degradation shortens the action still further. All processes of clearance are additive.

Figure 12-10 (Figure Not Available) Metabolism of vecuronium as it occurs in the liver. About 30 to 40 percent of an injected dose is deacetylated at the 3- and 17-positions. The major metabolite is 3-OH vecuronium (heavy arrow). The metabolites are excreted in the urine and bile. The 3-OH metabolite is nearly as potent as the parent compound and is probably cleared from blood at a rate slightly slower than that of vecuronium. *(From Agoston et al [144A])*

Figure 12-11 (Figure Not Available) Degradation pathways of atracurium. The major metabolite, laudanosine, is excreted in urine and bile. Laudanosine is a tertiary amine that may enter the CNS. Less than 10 percent of atracurium is excreted as the parent compound. *(From Basta et al [293C])*

Of the nondepolarizing muscle relaxants listed in Table 12-10 , pancuronium, pipecuronium, vecuronium, atracurium, cisatracurium, mivacurium, and rapacuronium (ORG 9487) are the only ones that are metabolized or degraded. About 15 to 20 percent of an injected dose of pancuronium is deacetylated, almost entirely at the 3-position. It is a theoretical possibility that deacetylation occurs also at the 17-position, but this occurs to such a small extent as to be clinically irrelevant. The metabolites have been individually studied in anesthetized humans. [154D] The 3-desacetyl metabolite is the most potent of the three (approximately two-thirds the potency of pancuronium) and the only one present in detectable concentrations in the plasma. This metabolite has pharmacokinetics and duration of action similar to those of pancuronium. [154D]

Vecuronium is metabolized in a manner similar to that of pancuronium, with 3-desacetylvecuronium being the primary metabolite (see Fig 12-10) (Figure Not Available) . Other putative metabolites are 17-desacetylvecuronium and 3,17- *bis*desacetylvecuronium, neither of which occurs in clinically significant amounts. [140A] The 3-desacetylvecuronium is 80 percent as potent as the parent compound and has a total clearance of 3.5 mL/kg/min. Renal clearance accounts for approximately one-sixth of its elimination. [141] In the isolated perfused rat liver, about 40 percent of an injected dose of vecuronium appears unchanged in the bile. About 15 percent is recovered in the urine in the intact animal. [155] An additional 30 to 40 percent appears in the bile as 3-desacetylvecuronium. [155] In patients with renal failure in the intensive care unit (ICU) who receive vecuronium for more than 2 days, high concentrations of 3-desacetylvecuronium can be achieved. These concentrations may persist for several days after vecuronium administration is stopped and vecuronium concentrations have declined to almost zero. [122] Thus, the excretory pathways of vecuronium and its 3-desactyl metabolite may be different.

Theoretically, atracurium is metabolized via two pathways (see Fig 12-11) (Figure Not Available) . The drug undergoes Hofmann elimination, a purely chemical process that results in loss of the positive charges by molecular fragmentation to laudanosine (a tertiary amine) and a monoquaternary acrylate. [156] [157] Under the proper chemical conditions, these breakdown products may actually be used to synthesize the parent compound. They were thought to have no neuromuscular and little or no cardiovascular activity of clinical relevance. [156] [157] The Hofmann elimination process is nonbiologic and does not require renal, hepatic, or enzymatic function. It occurs at physiologic pH and temperature and is slowed by a decrease in pH and especially by a decrease in temperature. [158] [159] In fact, atracurium's duration of action is markedly prolonged by hypothermia. [159A] (Alterations in pH within the physiologic range do not cause a significant increase in the duration

Figure 12-12 (Figure Not Available) Metabolism of mivacurium by plasma cholinesterase. The reaction occurs at about 70 to 88 percent the rate of succinylcholine *in vitro.* The metabolites are inactive and carry positive charges, suggesting minimal CNS entry. *(From Savarese et al [15])*

of action.) Thus, atracurium is relatively stable at pH 3.0 and 4°C and becomes unstable when injected into the blood stream. Early observations of the breakdown of the drug in buffer and plasma showed a faster degradation in plasma, suggesting a possible enzymatic hydrolysis of the ester groups. [160] Further evidence suggests that this second pathway, ester hydrolysis, may be of more importance than was originally realized in the breakdown of atracurium. [161] By using a pharmacokinetic analysis, Fisher et al [162] concluded that a significant amount of clearance of atracurium may be by routes other than ester hydrolysis and Hofmann elimination. Atracurium's metabolism is complicated and may not be completely resolved. [162] [163]

Because of its central nervous system (CNS)-stimulating properties, laudanosine, the main metabolite of atracurium, has received much attention and has been the subject of multiple studies, some of which are cited here. Clearly, the ability of laudanosine to cause CNS stimulation depends on the total dose of atracurium given. Unlike atracurium, laudanosine is dependent on the liver and kidney for its elimination and has a longer elimination half-life. [164] [165] Laudanosine concentrations are elevated in patients with liver disease [166] and those who have received atracurium for many hours in an ICU. [167] Laudanosine freely crosses the blood-brain barrier. [164] Beemer et al [168] found that patients awakened at a 20 percent higher arterial concentration of thiopental when atracurium had been given; this was attributed to the CNS stimulatory effect of laudanosine. These relatively low concentrations of laudanosine, however, did not influence an animal model of epilepsy [169] or lidocaineinduced seizures. [170] In the ICU, blood levels of laudanosine can be as high as 5 to 6 mug/mL. [167] Although not known in humans, the seizure threshold in animals ranges from 5.0 mug/mL in rabbits [171] to 17 mug/mL in dogs. [172] Thus, no adverse effects are likely to occur with atracurium use in the operating room, but the issue may still be unresolved following prolonged use in the ICU. Laudanosine also has cardiovascular effects. In dogs, hypotension occurs at a blood concentration of about 6 mug/mL, [164] [172] a level higher than usually found in patients in the ICU. However, there is one case report of a patient who had severe hypotension and bradycardia while receiving atracurium, which resolved only when vecuronium was substituted. [173] Laudanosine enhances stimulation-evoked release of norepinephrine, [174] [175] which also may partly account for its CNS-stimulating effect.

Atracurium is a mixture of 10 optical isomers. Cisatracurium, on the other hand, is the single 1R- *cis* 1R - *cis* isomer. [175A] Like atracurium, it is metabolized by Hofmann elimination. There is no ester hydrolysis of the parent molecule. [175B] Hofmann elimination accounts for 77 percent of the total clearance of 5 to 6 mL/kg/min. [153B] Clearance of cisatracurium and laudanosine formation is little affected by liver dysfunction. [153A] Because cisatracurium is about four to five times as potent as atracurium, about five times less laudanosine is produced, and accumulation of this metabolite is not thought to be of any consequence in clinical practice.

Mivacurium, a benzylisoquinolinium ester, is rapidly hydrolyzed by plasma cholinesterase (see Fig. 12-12) (Figure Not Available) at a rate slower than that of succinylcholine. [15] Specifically, the hydrolysis rate of mivacurium is 70 to 88 percent that of succinylcholine. [15] [154] This mechanism of metabolism allows mivacurium to have a duration of action much shorter than that of vecuronium and atracurium but about twice that of succinylcholine. [175D] However, when plasma cholinesterase activity is severely deficient, e.g., in rare patients (1/3,000) who are homozygotes with genetically atypical enzyme, the duration of action of mivacurium can be prolonged by several hours. [175E] [175F] [175G] [175H] The metabolites of mivacurium have no neuromuscular blocking potency and do not cause CNS simulation.

ORG 9487 (rapacuronium) is a new muscle relaxant with a fast onset and short-to-intermediate duration of action. [175I] It has a clearance of between 8 and 11 mL/kg/min. [176] [177] It likely undergoes metabolism to its 3-desacetyl derivative (ORG 9488), which contributes significantly to its neuromuscular blocking effect. [176] The metabolite (ORG 9488) is more potent and shows considerably longer kinetics than the parent compound. Accumulation of the metabolite may be a reason for cumulation of ORG 9487 during clinical use. [178] The pharmacokinetic and pharmacodynamic interaction of the parent drug and its metabolite is complex and requires further elucidation.

Autonomic Effects

Cholinoceptive Interactions (Nicotinic and Muscarinic Effects)

Neuromuscular blocking drugs interact with the transmitter acetylcholine at nicotinic and muscarinic cholinergic receptors within the sympathetic and parasympathetic nervous systems and at the nicotinic receptors of the neuromuscular junction. Important interactions also occur at esteratic receptors: the active sites of both

acetylcholinesterase and pseudocholinesterase (plasma cholinesterase). These are collectively termed cholinoceptive sites (listed in Table 12-11) .

Interactions with cholinergic receptors form the basis for some of the classic cardiovascular side effects of the relaxants. For example, the depolarizing agent succinylcholine stimulates both nicotinic and muscarinic receptors. All the nondepolarizing drugs can potentially block all autonomic receptors. However, the likelihood of autonomic blockade by nondepolarizing relaxants, especially by the newer agents, is remote because the dose-response curves for autonomic inhibition lie far to the right of the curve for neuromuscular blockade.

Dose ratios comparing the neuromuscular blocking potency of relaxants (ED_{95}) with their potencies in blocking vagal (parasympathetic) or sympathetic ganglionic transmission (ED_{50}) can be constructed (Table 12-12) . These ratios are termed the autonomic margin of safety of the relaxant in question. The higher the dose ratio, the lower the likelihood of or the greater the safety ratio for the occurrence of the particular autonomic effect. For example, in the case of pancuronium, vagal inhibition (ED_{50}) becomes prominent in the cat at about three times the ED_{95} for neuromuscular blockade (twitch inhibition). [179] The vagal margin of safety is therefore 3.0. Similarly, blockade of vagal transmission by doxacurium is not measurable in the cat unless at least 100 times the ED_{95} for neuromuscular blockade is given. The autonomic effects of the neuromuscular blocking drugs when used in clinical practice are summarized in Table 12-12 A. Interpretation of this table is as follows and should be correlated with safety ratios listed in Table 12-12 . The side effect is absent (none) in clinical practice if the safety ratio is greater than 5. The side effect is weak or slight if the safety ratio is 3 or 4, moderate if 2 or 3, and strong or prominent if the ratio is 1 or less.

These autonomic responses are not reduced by slower injection of the relaxant. They are dose-related and are additive over time if divided doses are given. If identical to the original dose, subsequent doses will produce a similar response, that is, no tachyphylaxis will occur. This is not the case when the side effect of histamine release is in question. Cardiovascular responses secondary to histamine release are decreased by slowing the injection rate, and the response undergoes rapid tachyphylaxis. That side effect is discussed below.

TABLE 12-11 -- Cholinoceptive Sites That Interact With Neuromuscular Blocking Drugs

TYPE RECEPTOR	LOCATION	FUNCTION	RELAXANT INTERACTIONS
Nicotinic	Neuromuscular junction: postsynaptic	Initiates depolarization in muscle end plate	Succinylcholine stimulates: nondepolarizers block
Nicotinic	Neuromuscular junction: presynaptic	Maintains ACh release during high-frequency stimulation	Succinylcholine stimulates, nondepolarizers block
Nicotinic	Autonomic ganglion: ganglion cell bodies	Initiates depolarization of ganglion cell	Succinylcholine stimulates: *d*-tubocurarine blocks
Nicotinic	Postganglionic neuron terminal of autonomic nerves	Positive feedback for transmitter release	Succinylcholine stimulates: *d*-tubocurarine and other nondepolarizers may block
Muscarinic	Sinus node of heart	Slows cardiac rate	Succinylcholine stimulates: gallamine, pancuronium, alcuronium, rocuronium block, and rapacuronium (ORG 9487)
Muscarinic (M1)	Autonomic ganglia: interneuron cell bodies	Inhibits depolarization by hyper-polarization	Pancuronium and gallamine block
Muscarinic (M2)	Autonomic ganglia: ganglion cell bodies	Augments depolarization: slow, delayed depolarization	Atropine blocks: not affected by nondepolarizing muscle relaxants
Muscarinic	Postganglionic neuron terminal of autonomic nerves	Negative feedback for transmitter release	Pancuronium and gallamine block
Esteratic	AChE	Hydrolysis of ACh	Not significantly affected by relaxants
Esteratic	Pseudocholinesterase	Hydrolysis of ACh, succinylcholine, and mivacurium	Succinylcholine and mivacurium are substrates Inhibited by pancuronium Weakly inhibited by vecuronium and atracurium

ACh, acetylcholine; AChE, acetylcholinesterase

TABLE 12-12 -- Approximate Autonomic Margins of Safety of Nondepolarizing Relaxants[a]

Specific Autonomic Mechanisms

Ganglionic Stimulation

The depolarizing relaxant succinylcholine may produce an elevation in heart rate and in arterial pressure secondary to the mechanism of ganglionic stimulation, [59] [60] which is probably mediated by activation of nicotinic receptors on ganglion cells on both sides of the autonomic nervous system. In patients who have received an anticholinergic drug, e.g., atropine, the chief cardiovascular response is elevated heart rate and arterial pressure. In subjects not given an anticholinergic drug beforehand, the result of ganglionic stimulation by succinylcholine may be either bradycardia and a decrease in blood pressure or increased heart rate and blood pressure, depending on the activity of the patient's autonomic nervous system at the time of administration of succinylcholine. For example, the cardiovascular response to succinylcholine in a patient who is very anxious before induction of anesthesia or who is receiving a catecholamine infusion may include ventricular arrhythmias. In patients receiving beta-adrenergic blockers, on the other hand, bradycardia after succinylcholine should be expected.

Succinylcholine produces a dose-related positive chronotropic effect through stimulation of the sinoatrial node by the release of catecholamines from adrenergic nerve endings. By contrast, succinylmonocholine causes a decrease in heart rate. [180]

TABLE 12-12A -- Clinical Autonomic Effects of Neuromuscular Blocking Drugs

DRUG TYPE	AUTONOMIC GANGLIA	CARDIAC MUSCARINIC RECEPTORS	HISTAMINE RELEASE
Depolarizing substance			
Succinylcholine	Stimulates	Stimulates	Slight
Benzylisoquinoline class

Gallamine	None	Blocks strongly	None

[a] Has not been extensively studied; may also block calcium channels

Ganglionic Blockade

The ganglion-blocking effect of dTc occurs closer to the neuromuscular blocking effects than in the case of any other muscle relaxant. [177] [181] Nevertheless, the principal reason for the hypotensive property of dTc in humans is its histamine-releasing action. [182] Tables 12-12 and 12-12A show that the dose ratio of dTc for histamine release is about 0.6, well within the neuromuscular blocking dose range.

Muscarinic Blockade

Vagal block, resulting in tachycardia, is produced by muscarinic receptor blockade at the sinus node of the heart in response to pancuronium and gallamine. Gallamine is a potent vagolytic substance in which this side effect occurs within a lower dose range than that for neuromuscular blockade. [179] The dose-response curve for the vagolytic property of pancuronium lies slightly to the right of its neuromuscular blocking effects, [179] so that in clinical practice pancuronium is probably only partially vagolytic. The result is usually only a moderate rise in heart rate (10 to 25 beats/min) when high doses of pancuronium are administered. [183] [184] The new steroidal relaxant rocuronium shows a dose ratio of vagal block to neuromuscular block of about 5.0. Some clinical studies have shown dose-related increases in heart rate, suggesting that rocuronium may be slightly vagolytic at high dosage in human subjects. [185] The new short-to-intermediate-acting steroidal agent ORG 9487 (rapacuronium) is also moderately vagolytic within the clinical dose range. The vagolytic effect of relaxants is limited to receptors in the sinus node of the heart. Other classic muscarinic sites in the parasympathetic nervous system, such as bowel, bladder, bronchi, and pupils, are not affected.

Muscarinic Blockade Within the Sympathetic Nervous System

There are at least three sets of muscarinic receptors in the sympathetic nervous system (Fig. 12-13) (Figure Not Available) . Two of these are blocked by neuromuscular blocking agents, such as pancuronium and gallamine, that have a vagolytic property. That is, these relaxants can block muscarinic receptors in the sinus node of the heart, on the parasympathetic side of the autonomic nervous system. One mechanism, muscarinic receptor blockade on a dopaminergic interneuron within a pathway responsible for inhibitory input to sympathetic ganglion cells, [186] results in less modulation of augmented ganglionic traffic during periods of relatively intense stimulation; and another mechanism, muscarinic receptor blockade at adrenergic neuron terminals, results in reduction of a negative feedback mechanism regulating catecholamine output. [187] Both mechanisms may not only contribute to increases in heart rate normally seen with pancuronium but may also represent supportive mechanisms facilitating exaggerated cardiovascular responses sometimes seen in the presence of pancuronium block under light anesthesia during intense surgical stimulation (including laryngoscopy and tracheal intubation).

Inhibition of Catecholamine Reuptake

Pancuronium inhibits reuptake of norepinephrine by adrenergic nerves. [188] [189] [190] [191] This mechanism may also contribute

Figure 12-13 (Figure Not Available) Muscarinic receptors within the autonomic nervous system. These are labeled M1, M2, and M3. Vagolytic neuromuscular blocking drugs classically block M2 receptors at the sinus node of the heart. They may also block at M2 receptors at postganglionic neuroeffector junctions, where blockade of receptors located on postganglionic nerve terminals facilitates release of transmitter. Blockade of M2 receptors on a dopaminergic interneuron in the sympathetic nervous system augments ganglionic transmission by inhibiting a "braking" mechanism. N, nicotinic receptor; dTC, *d*-tubocurarine; F, fazadinium; P, pancuronium; G, gallamine. *(From Birdsall et al [185A])*

to exaggerated cardiovascular responses during pancuronium block.

Histamine Release

Quaternary ammonium compounds, such as muscle relaxants, are generally weak histamine-releasing substances relative to tertiary amines, such as morphine. Nevertheless, when large doses of certain muscle relaxants are injected rapidly by the intravenous route, some degree of erythema of the face, neck, and upper torso may develop, possibly together with a brief fall in arterial pressure and a slight-to-moderate rise in heart rate. Bronchospasm is very rare. The side effect of histamine release is most often noted following administration of the benzylisoquinolinium class of muscle relaxants, although it has been noted in steroidal relaxants of low potency. The effect is usually of short duration (1-5 minutes), is dose-related, and is clinically insignificant in healthy patients. The side effect may be reduced considerably by a slower injection rate. It is also prevented by prophylaxis with combinations of histamine $_1$ - and histamine$_2$ - blockers. If a minor degree of histamine release such as described above occurs after an initial dose of muscle relaxant, subsequent doses will generally cause no response at all, as long as they do not exceed the original dose. This is clinical evidence of tachyphylaxis, an important characteristic of histamine release.

A much more significant degree of histamine release occurs during anaphylactic or anaphylactoid reactions; these reactions are very rare. Anaphylactic reactions are mediated through immune responses involving IgE antibodies fixed to mast cells. Anaphylactoid reactions probably are not immune-mediated and represent exaggerated pharmacologic responses in very rare and very sensitive individuals.

For an excellent review of the topic of histamine release by muscle relaxants, see the paper by Basta. [192] The side effect of histamine release by the benzylisoquinolinium class of muscle relaxants may be viewed as a pharmacologic response wherein, as dosage is increased, the percentage of individuals responding with some manifestation of the side effect increases. This type of response involves chemical displacement of the contents of mast cell granules containing histamine, prostaglandin, and possibly other vasoactive substances. [192] The serosal mast cell, located in the skin and connective tissue and near blood vessels and nerves, is principally involved in the degranulation process. [192]

Hatano et al [193] showed that the hypotensive cardiovascular response to dTc (0.6 mg/kg) in humans is prevented (Fig. 12-14) (Figure Not Available) not only by antihistamines but also by NSAIDs (e.g., aspirin). These investigators concluded that the final step in dTc-induced hypotension is modulated by prostaglandins that are vasodilators. [193]

When an increase of histamine levels in plasma to 200 to 300 percent of baseline levels occurs, a brief decrease in arterial blood pressure (1-5 minutes), an increase in heart rate, and skin erythema about the face and neck may occur. The benzylisoquinolinium substances dTc, metocurine, mivacurium, and atracurium release these amounts of histamine in a dose range of 0.5 to 3 times the ED_{95} for each compound. Thus, the safety margin for this side effect is about three times greater for atracurium and mivacurium

Figure 12-14 (Figure Not Available) Inhibition by aspirin or diphenhydramine of the blood pressure decrease in anesthetized patients following *d*-tubocurarine (dTc) (0.6 mg/kg). The corresponding rise in $PGF_{1\ alpha}$ was also prevented by aspirin or diphenhydramine, suggesting that prostaglandin-induced vasodilation is the final step in dTc-induced hypotension. AP, aspirin-treated; DH, diphenhydramine-treated. *(From Hatano et al [193])*

and two times greater for metocurine than for dTc. [192] [193] [194] [195] The side effect occurs well within the clinical dose range for dTc and is therefore common during its use. It is less prominent with metocurine, atracurium, and mivacurium, unless doses in the range of three times the ED_{95} are injected rapidly (5-10 seconds). As in the case of dTc, [182] any decrease in blood pressure that may develop during the use of these drugs is probably directly related to elevation of serum histamine levels. The amount of histamine released by any of these drugs is both dose-related and related to the speed of injection. [182] [192] [193] [194] [195] Thus, cardiovascular responses to a very large dose of atracurium (0.6 mg/kg) may be prevented by slow injection or by prophylaxis with antihistamines (both histamine $_1$ - and histamine$_2$ -blockers are necessary). [196] Although multiple cardiovascular studies have been performed with atracurium, the most aggressive was that conducted by Hosking et al. [197] They gave atracurium (1.5 mg/kg) (six times the ED_{95}) as an intravenous bolus. Not surprisingly, they observed an average decrease in mean arterial blood pressure of 30 percent and a large (10- to 20-fold) increase in plasma histamine concentrations. Scott et

al [196] and Hosking et al [197] found that combined histamine$_1$ - and histamine$_2$ -receptor blockade attenuated these histamine-induced changes. Mivacurium releases histamine in about the same multiples of the ED_{95} as does atracurium. When 0.15 mg/kg (two times the ED_{95}) is given over 60 seconds to patients with coronary artery disease, only minimal cardiovascular changes occur. [198] When mivacurium is given more rapidly or in larger doses to these patients, hypotension is more likely to occur. In healthy patients, a brief decrease in arterial pressure may develop at a dosage greater than two times ED_{95} when these larger doses are injected rapidly [140] [195] (Fig. 12-15) (Figure Not Available) .

Clinical Cardiovascular Manifestations of Autonomic Mechanisms

Hypotension

d-Tubocurarine causes hypotension, probably as a result of the liberation of histamine; in larger doses, it produces ganglionic blockade. [199] [200] [201] [202] Dowdy et al [202] proposed that hypotension is not caused by the dTc itself but by the preservative in its formulation. However, in anesthetized patients, Stoelting [203] [204] disproved this theory. Premedication with promethazine, an antihistamine drug, will attenuate dTcinduced hypotension. [204] Hypotension is directly related to dose of dTc and to anesthetic depth, [201] especially if the anesthetic is itself a sympathetic nervous system depressant such as halothane or isoflurane. With a light level of surgical anesthesia and the use of smaller doses of dTc (15 mg/70 kg), the incidence of significant hypotension is markedly attenuated. Although hypotension can occur after administration of metocurine, the incidence and magnitude are much less than those associated with dTc. Atracurium in doses greater than 0.4 mg/kg and mivacurium in doses greater than 0.15 mg/kg occasionally cause transient hypotension due to histamine release. Histamine release can be minimized by slower administration (20-30 seconds at three times ED_{95}) of these muscle relaxants [195] [196] [198] (see Fig. 12-15) (Figure Not Available) .

Tachycardia

Pancuronium causes a moderate increase in heart rate and, to a lesser extent, in cardiac output, with little or no change in systemic vascular resistance. [183] [184] Although pancuronium-induced tachycardia has been attributed to a vagolytic action, [179] [183] numerous investigators have implicated the sympathetic nervous system as well. Both indirect (release of norepinephrine from adrenergic nerve endings) [188] [205] and direct (blockade of neuronal uptake of norepinephrine) mechanisms have been suggested. [188] [189] [190] Vercruysse et al [191] suggested that both gallamine and pancuronium augment the release of norepinephrine in vascular tissues under vagal control. In studies in humans, Roizen et al [206] surprisingly found a decrease in plasma norepinephrine levels after administration of either pancuronium or atropine. These researchers postulated that the increase in heart rate or rate-pressure product occurs because

Figure 12-15 (Figure Not Available) Dose response to mivacurium in patients under nitrous oxide-oxygen-opioid anesthesia. Maximum changes at each dose are shown; *n* = 9 subjects per group. (A), With fast injection a 15 to 20 percent decrease in arterial pressure occurred at 2.5 to 3 times ED_{95} (0.20 to 0.25 mg/kg). (B) The changes were less than 10 percent when slower injection (30 seconds) was done. *(From Savarese et al [140])*

pancuronium (or atropine) acts through baroreceptors to reduce sympathetic outflow. More specifically, the vagolytic effect of pancuronium increases heart rate and, hence, blood pressure and cardiac output (Fig. 12-16) (Figure Not Available) , in turn influencing the baroreceptors to decrease sympathetic tone. Support for this concept is provided by the fact that prior administration of atropine will attenuate or eliminate the cardiovascular effects of pancuronium. [183] Gallamine increases heart rate by both a vagolytic effect [179] [207] and sympathetic stimulation. [208] Specifically, gallamine releases norepinephrine from adrenergic nerve endings in the heart by an unknown mechanism. [208] However, a positive chronotropic effect that places emphasis on the vagolytic mechanism has not been found in humans. [209] It would not be surprising to find out ultimately that gallamine and pancuronium act by similar mechanisms.

Figure 12-16 (Figure Not Available) Hemodynamic responses to pancuronium (0.1 mg/kg) and to pipecuronium (0.05, 0.1, or 0.15 mg/kg) in patients under opioid anesthesia. Injection was done at time = 0. Expected increases in heart rate and cardiac index were noted after pancuronium (open circles). These changes were not seen after any of the three doses of pipecuronium (squares, closed

circles). *(From Tassonyi et al [235])*

Arrhythmias

Gallamine, dTc, and succinylcholine actually reduce the incidence of epinephrine-induced arrhythmias. [210] Possibly because of enhanced atrioventricular conduction, [211] the incidence of arrhythmias from pancuronium appears to increase during halothane anesthesia. [183] Edwards et al [212] observed a rapid tachycardia (more than 150 beats/min) that progressed to atrioventricular dissociation in two patients anesthetized with halothane. The only factor common to these two patients was that both were receiving tricyclic antidepressants. In further studies, Edwards et al found the incidence of severe ventricular arrhythmia to be common in response to administration of pancuronium to dogs receiving halothane (but not enflurane) and chronically administered tricyclic antidepressants. In conclusion, the drug interaction among tricyclic antidepressants, halothane, and pancuronium must be avoided. Use of another nonvagolytic muscle relaxant, such as vecuronium or cisatracurium, is probably the most convenient approach in a patient receiving tricyclic antidepressants who must have halothane anesthesia.

Bradycardia

Several case reports [213] [214] have described severe bradycardia and even asystole following vecuronium or atracurium administration. All of these cases were associated with opioid administration. Subsequent studies indicate that vecuronium or atracurium alone does not cause bradycardia, [215] but when combined with other drugs (e.g., fentanyl) that do cause bradycardia, the nonvagolytic relaxants such as vecuronium, cisatracurium, and atracurium simply allow this mechanism to occur unopposed. The moderate vagolytic effect of pancuronium is often used to counteract opioid-induced bradycardia.

Individual Nondepolarizing Relaxants

d-Tubocurarine

d-Tubocurarine (curare, dTc) was the first relaxant introduced into clinical practice (1942). It was introduced by Griffith and Johnson [1] in Montreal, where it was first administered during an appendectomy. The corrected formula is shown in Figure 12-17 , where dTc is depicted as a monoquaternary compound. Curare remained popular until the early 1970s, when pancuronium became the most commonly prescribed nondepolarizer. The drug is indicated for longer operations (3-4 hours) in which early extubation is not important and in which a decrease in blood pressure is acceptable or desired.

	DOSAGE (mg/kg)	CLINICAL DURATION (min)
ED_{95}	0.5	
Intubation (at t = +3 min)	0.5-0.6	60-100
Relaxation (N_2O/O_2)	0.3-0.5	30-60
Relaxation (Vapor)	0.2-0.3	30-60
Maintenance	0.1-0.15	30-45

Cardiovascular Side Effect

The most common side effect of dTc is release of histamine, [182] [192] [193] [199] which occurs when a dosage of more

Figure 12-17 The chemical formula of *d*-tubocurarine shows that it is a monoquaternary compound. The tertiary nitrogen at the lower right is shown in the protonated form.

Figure 12-18 (Figure Not Available) Relationship of decrease in blood pressure to increase in plasma histamine concentration following *d*-tubocurarine administration to patients under nitrous oxide-oxygen-barbiturate-opioid anesthesia. There is a highly significant correlation, which is dose-related. *(From Moss et al [182])*

than 0.3 mg/kg is given rapidly as a bolus (10-15 seconds). Plasma histamine levels may increase as much as 10-fold (Fig. 12-18) (Figure Not Available) , causing a transient decrease in blood pressure of 30 to 50 percent. [182] Although a ganglion-blocking effect is easily demonstrable in animals, [179] [199] this side effect is probably beyond the clinical dose range. *d*-Tubocurarine is nonvagolytic; as such, increases in heart rate are uncom-mon, except as part of the syndrome of histamine release. [179] [182] [199] Histamine release is prevented by slow administration of the drug (e.g., at a rate of 0.3 mg/kg/min) or by administration of smaller doses of the drug.

Metabolism and Elimination

There is no active metabolism of dTc. The kidney is the major pathway of elimination, with approximately 50 percent of a dose being eliminated through renal pathways. The liver is probably a secondary route of elimination. The drug is not indicated for use in patients with either renal [120] or hepatic [216] failure, as more suitable agents are available.

PHARMACOLOGY OF NONDEPOLARIZING MUSCLE RELAXANTS - continued

Individual Nondepolarizing Relaxants

Metocurine

Metocurine (Fig. 12-19) is a semisynthetic derivative of dTc, first synthesized by King [217] in 1935 as part of the work that first suggested a chemical structure for dTc. It is the N,O,O-trimethylated compound. Unlike dTc, it is a bisquaternary molecule. It was introduced into clinical practice in 1948 by V.K. Stoelting et al, [218] who recognized its lesser cardiovascular effect in comparison with dTc. Metocurine is about twice as potent as curare in human subjects, with a similarly long duration of action. [219] Its principal advantage over curare is its weaker histamine-releasing property--less than one-half that of dTc. [194] [199] Metocurine is indicated for longer operations (3-4 hours) in which early extubation is unnecessary and in which no change in heart rate is desirable.

Figure 12-19 Chemical formula of metocurine. Metocurine is a bisquaternary compound. With respect to *d*-tubocurarine (dTc), it is additionally methylated at both phenolic hydroxyl groups and at the tertiary nitrogen. It is therefore the trimethylated derivative of dTc.

	DOSAGE (mg/kg)	CLINICAL DURATION (min)
ED_{95}	0.28	
Intubation (at t = +3 min)	0.3-0.4	60-120
Relaxation (N_2O/O_2)	0.15-0.2	40-60
Relaxation (Vapor)	0.1-0.15	40-60
Maintenance	0.05-0.1	30-45

Cardiovascular Side Effects

The only effect pertinent to clinical practice is histamine release, which may occur at a dosage in the range of 0.3 to 0.4 mg/kg or more. [194] [199] A brief decrease in blood pressure may result from rapid administration of these doses. [219] Metocurine has no ganglion-blocking or vagolytic effect. [179] [199]

Metabolism and Elimination

Metocurine is excreted only by the kidney. It has no alternate biliary pathway, and no metabolism occurs in the liver. [220]

Gallamine

Gallamine is a long-acting drug (Fig. 12-20) . It was the first synthetic neuromuscular blocking drug to be introduced into clinical practice. Gallamine was synthesized originally by Bovet [38] and colleagues as part of an extensive

Figure 12-20 Chemical formula of gallamine, a trisquaternary ether of gallic acid. Gallamine is the only trisquaternary compound zavailable. Its strong vagolytic property is likely due to the trisquaternary structure.

structure-activity study that helped evolve the concepts of "pachycurares" and "leptocurares." Succinylcholine also evolved from this work, for which Bovet received the Nobel Prize.

The trisquaternary structure of gallamine confers a strong vagolytic property. [179] Although gallamine might be indicated for longer operations (3-4 hours), its obligatory renal excretion [221] and vagolysis may render it less suitable than other agents, particularly when a distinct increase in heart rate is not desirable.

	DOSAGE (mg/kg)	CLINICAL DURATION (min)
ED_{95}	3.0	
Intubation (at t = +2 min)	4.0-6.0	90-120
Relaxation (N_2O/O_2)	2.0-3.0	40-60
Relaxation (Vapor)	1.0-2.0	40-60
Maintenance	0.3-0.5	30-40

Cardiovascular Side Effects

The strong vagolytic effect of gallamine [179] and the increased release of myocardial catecholamines that is associated with its use [208] result in an increased heart rate. The tachycardia may be marked and is very evident, even at low doses that do not produce any neuromuscular blockade (0.2-0.3 mg/kg), because the dose-response curve for the vagolytic property actually lies considerably to the left of that for neuromuscular blockade. [179] Blood pressure, as well as heart rate, is

often elevated. [209] Gallamine does not release histamine or block autonomic ganglia [179] and therefore does not cause a decrease in blood pressure.

Metabolism and Elimination

Gallamine is not metabolized and is excreted unchanged in the urine only. There is no alternative biliary excretory pathway. [221]

Alcuronium

Alcuronium (Fig. 12-21) is the semisynthetic diallyl derivative of toxiferine I. It is a long-acting drug with few cardiovascular side effects and, therefore, is indicated for longer operations (3-4 hours) in which cardiovascular stability is desired and early extubation is not needed.

	DOSAGE (mg/kg)	CLINICAL DURATION (min)
ED_{95}	0.2	
Intubation (at t = +3 min)	0.25-0.3	60-120
Relaxation (N_2O/O_2)	0.15-0.2	40-60
Relaxation (Vapor)	0.1-0.15	40-60
Maintenance	0.05-0.1	30-45

Figure 12-21 Chemical formula of alcuronium, the semisynthetic diallyl derivative of toxiferine. The quaternizing allyl groups actually reduce the potency by a factor of 3 to 5.

Cardiovascular Side Effects

Alcuronium is a very weak ganglion blocker and is very weakly vagolytic. [179] A slight increase in heart rate is occasionally observed following its administration. Decreases in blood pressure are rare. [222] The drug does not cause release of histamine.

Metabolism and Elimination

There is little or no metabolism. The urine is the major excretory pathway. There is a small amount of biliary clearance of unchanged drug. [223]

Pancuronium

Pancuronium (Fig. 12-22) is a long-acting drug. The drug was originally designed by Hewett and Savage. [224] In a brilliant medicinal-chemical maneuver, they appended two acetylcholine-like moieties to the rigid steroidal androstane framework. [225] [226] The drug was an instant success [6] because its high potency, lack of hypotensive effect, and mild-to-moderate vagolytic property contrasted markedly with the cardiovascular side effects of dTc and gallamine, the only two commonly used nondepolarizers in the United States at that time (1970-1971). Its administration is ideally suited to longer operations (3-4 hours) in which prompt extubation is not necessarily important and in which a slight-to-moderate increase in heart rate and blood pressure might be desirable.

Figure 12-22 Chemical formula of pancuronium. The introduction of acetylcholine-like fragments into the A and D rings of pancuronium is a unique feature that is retained in all other clinically available steroidal relaxants. The vagolytic property is largely due to the A-ring substitutions.

	DOSAGE (mg/kg)	CLINICAL DURATION (min)
ED_{95}	0.06-0.07	
Intubation (at t = +2-3 min)	0.08-0.12	60-120
Relaxation (N_2O/O_2)	0.05-0.06	30-60
Relaxation (Vapor)	0.03	30-60
Maintenance	0.01-0.015	30-40

Cardiovascular Side Effects

A moderate vagolytic effect [179] and stimulation of the sympathetic nervous system [186] [187] [188] [189] [190] [191] [205] usually cause an increase in heart rate, blood pressure, [183] [184] and cardiac output (see Fig. 12-15) (Figure Not Available) . The mechanisms that contribute to sympathetic nervous system stimulation include facilitation of ganglionic transmission, increased catecholamine release, and decreased reuptake of catecholamines [186] [187] [188] [189] [191] [205] (see Fig. 12-16) (Figure Not Available) .

Metabolism and Elimination

Pancuronium is cleared largely by the kidney. [227] A small amount (10-20%) is deacetylated at the 3-position in the liver. [143] [228] The parent compound and the 3-OH metabolite are cleared in small [143] [228] amounts via the minor liver pathway. The total clearance is delayed, and the duration of action is significantly lengthened by severe disorders of renal or hepatic function. [119] [229] [230] [231] [232] The 3-OH metabolite is about half as potent a neuromuscular blocking agent as the parent compound. [233] It has a duration of action and kinetic pattern similar to that of pancuronium. The 3-OH metabolite is also most likely excreted largely by the kidney. [233]

Pipecuronium

Pipecuronium (Fig. 12-23) is a pancuronium derivative in which the 2,16-substitutions are piperazinium groups. It was introduced in eastern Europe during the early 1980s and in the United States nearly 10 years later. [234] Pipecuronium is about 20 to 30 percent more potent than pancuronium. Like pancuronium, it is a long-acting drug. Therefore, it is suited to longer operations (3-4 hours) in which early extubation is not mandatory.

Figure 12-23 Chemical formula of pipecuronium. The positive charge on the quaternary nitrogens is further separated by two carbon atoms from the carboxyl groups than in the case of pancuronium. This chemical change reduces the vagolytic effect by a factor of about 10.

	DOSAGE (mg/kg)	CLINICAL DURATION (min)

ED_{95}	0.04-0.05	
Intubation (at t = +2-3 min)	0.08-0.12	80-120
Relaxation (N_2 O/O_2)	0.04-0.06	40-60
Relaxation (Vapor)	0.2-0.3	40-60
Maintenance	0.005-0.01	30-45

Cardiovascular Side Effects

Because in pipecuronium the 2,16-substitutions are piperazinium groups, the quaternary nitrogens are moved farther away from the 3,17-acetoxy substitutions. This lessens the vagolytic property of the relaxant by a factor of about 10 when compared with pancuronium. Additionally, pipecuronium does not block autonomic ganglia, nor does it release histamine. As such, it does not affect cardiovascular responses in the clinical dose range. Tassonyi et al [235] compared the hemodynamic responses following administration of pipecuronium or pancuronium in anesthetized patients (see Fig. 12-16) (Figure Not Available) . As expected, a significant increase in heart rate (30%) and cardiac index (12%) was observed after somewhat less than two times ED_{95} of pancuronium (0.10 mg/kg), whereas hemodynamic changes were minimal following pipecuronium doses of up to 0.15 mg/kg (three times ED_{95}).

Metabolism and Elimination

There is very little metabolism of pipecuronium. Only a very small amount of the drug (5%) may be deacetylated at the 3-position. The major excretory pathway is the kidney. The liver is possibly a minor secondary pathway. Excretion is delayed, clearance is decreased, and the elimination half-life is lengthened in the presence of major disorders of renal or hepatic function. [236] [237] [238]

Doxacurium

Doxacurium (Fig. 12-24) is a very potent, very longacting benzylisoquinolinium ester. Interestingly, although it is an ester of succinic acid, it undergoes no hydrolysis by pseudocholinesterase. [14] This may be due to its very high neuromuscular blocking potency and the relatively small

Figure 12-24 Chemical formula of doxacurium. Although an ester of succinic acid, this very potent benzylisoquinolinium compound is not metabolized in human subjects. Consequently, it is a long-lasting substance.

amount of drug administered with each dose. It was introduced in 1991 as the first benzylisoquinolinium relaxant free of side effects. [14] [239] It is about 20 times as potent as dTc and is indicated for longer operations (3-4 hours) in which cardiovascular stability is important and in which early extubation is not necessary.

	DOSAGE (mg/kg)	CLINICAL DURATION (min)
ED_{95}	0.025	
Intubation (at t = +3-4 min)	0.05-0.08	90-150
Relaxation (N_2 O/O_2)	0.02-0.03	45-60
Relaxation (Vapor)	0.015-0.02	45-60
Maintenance	0.005-0.01	30-60

Cardiovascular Side Effects

There is no vagolytic or ganglion-blocking effect associated with the administration of doxacurium. Doses of up to four times ED_{95} do not cause histamine release. [14] Consequently, there are no cardiovascular side effects of note in clinical practice. [14] [239] [240] Stoops et al [240] demonstrated minimal changes in hemodynamic variables (cardiac output, right- and left-sided filling pressure, heart rate, mean arterial pressure) following doxacurium doses up to and including three times ED_{95} (0.075 mg/kg).

Metabolism and Elimination

There is no metabolism of doxacurium in humans. The drug is excreted in the urine and bile as the unchanged parent molecule. The urine is the major route of elimination, with the bile a minor secondary pathway. [241] [242]

Vecuronium

Vecuronium (Fig. 12-25) , the 2-desmethyl analogue of pancuronium, was recognized in the mid-1970s by Savage, Durant, Bowman, and Marshall [9] [40] [243] as having much less vagolytic effect and a shorter duration of action than pancuronium in the cat. These pharmacologic properties were subsequently confirmed in surgical patients. [244] [245] The identification of vecuronium represents a noteworthy collaborative

Figure 12-25 Chemical formula of vecuronium. Vecuronium is the monoquaternary analogue of pancuronium. The lack of a quaternizing methyl group in the 2-position removes the vagolytic effect and enables greater liver uptake with regard to pancuronium.

effort between industrial chemists and academic pharmacologists working at the University of Strathclyde in Glasgow, Scotland, and at Organon's chemical laboratories at nearby Newhouse. Remarkably, in a similar collaborative effort at Strathclyde, atracurium was discovered during the same period by Stenlake and coworkers (see below). The two groups of investigators were working on separate floors in the same building of the university.

	DOSAGE (mg/kg)	CLINICAL DURATION (min)
ED_{95}	0.5	
Intubation (at t = +1.5-3 min)	0.1-0.2	45-90
Relaxation (N_2 O/O_2)	0.05	25-40
Relaxation (Vapor)	0.03-0.04	25-40
Maintenance	0.01-0.02	15-30
Infusion	0.8-2.0 mug/kg/min	

Vecuronium and atracurium, together, revolutionized clinical practice as the first nondepolarizers of intermediate duration. [246] The major contributions of the

intermediate-acting drugs are (1) more facile tracheal intubation with nondepolarizers; (2) easier administration by infusion for maintenance of blockade during surgery; and (3) faster and more complete antagonism of residual blockade at the end of the case. In addition, vecuronium's remarkable lack of cardiovascular effect established a benchmark for future relaxants.

Cardiovascular Side Effects

Vecuronium is about 20 times weaker as a vagolytic substance than pancuronium. The structural feature responsible for this difference is the absence of the 2-methyl quaternizing group. This markedly reduces the ACh-like character of the A-ring substitutions, resulting in less attraction to cardiac muscarinic receptors. The markedly reduced vagolytic property, together with absent ganglionic blocking and histamine-releasing effects, results in a noteworthy lack of cardiovascular responses throughout a wide clinical dose range from one to eight times the ED_{95} (0.05 to 0.40 mg/kg). [247] [248]

Metabolism and Elimination

The metabolic pathways of vecuronium are shown in Figure 12-10 (Figure Not Available) . Vecuronium is taken up into the liver by a carrier-mediated transport system. [249] Vecuronium is deacetylated at the 3-position by liver microsomes. Vecuronium undergoes two to three times as much metabolism as pancuronium, such that 12 to 30 percent of vecuronium is eventually excreted as the metabolite 3-desacetylvecuronium (3-OH vecuronium). [250] [251] [252] Although the liver is the principal organ of elimination for vecuronium, the drug also undergoes significant (up to 25%) renal excretion. [250] [252]

The principal metabolite, 3-desacetylvecuronium, is a potent (
80% of vecuronium) neuromuscular blocking drug

in its own right. The metabolite, however, has a lower plasma clearance and longer duration of action than vecuronium. [252] In patients in the ICU who have renal failure, 3desacetylvecuronium can accumulate and produce prolonged neuromuscular blockade. [253]

The excretion of vecuronium is diminished in the presence of decreased renal or hepatic function in the elderly and in children younger than 1 year of age. [254] The duration of action of vecuronium is longer in these groups of patients, and recovery is slower than in young healthy individuals. Despite its lengthening of action in patients with hepatic or renal dysfunction, vecuronium can be given to these patients provided its administration is guided by neuromuscular monitoring (Ch. 39).

Rocuronium

Rocuronium (ORG 9426) (Fig. 12-26) is a steroidal relaxant of intermediate duration, with an onset of action that is faster than that of vecuronium. [255] [256] [257] [258] It has become popular because of its faster onset. It is seven to eight times less potent than vecuronium [255] [256] [257] [258] [259] but has about the same molecular weight; thus, a greater number of drug molecules are able to reach junctional receptors within a few circulation times, enabling faster development of neuromuscular blockade. Weaker binding to receptors (lower potency), however, prevents *buffered diffusion,* a process that occurs with potent drugs, which causes repetitive binding and unbinding to receptors, keeping potent drugs in the neighborhood of effector sites and potentially lengthening the duration of effect. Diffusion of less potent drugs away from receptors very likely occurs much more readily, thereby helping to limit the duration of blocking effect. This is most likely the reason why the duration of action of rocuronium remains intermediate. [260] [261] The duration of action of rocuronium is also limited by avid liver uptake and elimination into the bile, [262] due to an increase in the lipophilic nature of the molecule with respect to vecuronium. The relationship of lower potency to faster onset of block in steroidal molecules has been described by Bowman et al [42] (see Fig. 12-6) and in the use of drugs in the clinic by Kopman. [138A] At appropriate dosage, 0.9 to 1.2 mg/kg, rocuronium enables tracheal intubation within 60 to 90 seconds, [263] [264] [265] and may be used as a substitute for succinylcholine in rapid intubation of the trachea. [266] [267] Other aspects of the clinical neuromuscular pharmacology of rocuronium seem similar to the properties of vecuronium.

Figure 12-26 Chemical formula of rocuronium, a vecuronium derivative of faster onset and intermediate duration. The faster onset is conferred by lowered potency induced by the D- and A-ring modifications (see Figs. 12-6 and 12-25).

	DOSAGE (mg/kg)	CLINICAL DURATION (min)
ED_{95}	0.3-0.4	
Intubation (at t = +60-90 s)	0.6-1.0	35-75
Relaxation (N_2 O/O_2)	0.3-0.4	30-40
Relaxation (Vapor)	0.2-0.3	30-40
Maintenance	0.1-0.15	15-25
Infusion	8-12 mug/kg/min	

Cardiovascular Side Effects

The autonomic safety ratio for vagal block (3.0-5.0) is about 10 times less than that of vecuronium. [268] [269] In doses up to 1.2 mg/kg, rocuronium has minimal cardiovascular effects both in healthy patients [270] [271] [272] [273] and in those with cardiovascular disease. [275] There is no detectable histamine release following rocuronium in doses up to 1.2 mg/kg. [270] Reports of slight to moderate increases in heart rate may be due either to the fact that rocuronium produces pain on injection [276] [277] or to its weak vagolytic effect. The heart rate increase may be controlled by the prior administration of fentanyl. [276] [277] In summary, rocuronium in doses up to 0.6 mg/kg has cardiovascular effects that are negligible. At higher dosage (0.9-1.2 mg/kg), increases in heart rate of 10 to 25 percent may occasionally be observed due to the weak vagolytic effect.

Metabolism and Elimination

Rocuronium is eliminated primarily by the liver, with a small fraction (
10%) eliminated in the urine. [262] It is taken up into the liver by a carrier-mediated active transport system. [278] [279] The putative metabolite, 17-desacetylrocuronium, has not been detected in significant quantities. In patients with hepatic disease (most commonly cirrhosis), the distribution volume of rocuronium is increased, [265] [280] [281] [282] and its clearance may be decreased. [282] The duration of action of rocuronium is prolonged in hepatic disease, [280] [281] [282] and its onset may be prolonged. [280] Consequently, dosing in patients with hepatic disease should be conservative and guided by careful monitoring of neuromuscular function. In patients with renal failure, the plasma clearance of rocuronium may be decreased, [283] and its distribution volume increased, [284] but the duration of action of single and repeated doses is not significantly affected. [285] In the elderly, the clearance of rocuronium is decreased and its distribution volume increased, and as a consequence, its duration of action is prolonged. [286]

Rapacuronium (ORG 9487)

Rapacuronium (ORG 9487) (Fig. 12-27) is a steroidal muscle relaxant, the 16N-allyl, 17beta propionate analogue of vecuronium. [287] It has low potency (ED_{90} 1.15 mg/kg), a fast onset, and short-to-intermediate duration of action depending on dosage. [287] [288] [289] Compared with vecuronium, rapacuronium has an onset of action that it twice as fast and a duration of action about one-half as long. [289] The peak effect of a

Figure 12-27 Chemical formula of rapacuronium (ORG 9487). The lower potency of this compound enables a speed of onset that approaches that of succinylcholine. The duration is short-to-intermediate, depending on dosage.

dose of 1.5 mg/kg occurs in 62 seconds at the laryngeal muscles and 96 seconds at the adductor pollicis during TOF stimulation. [290] Rapacuronium in doses of 1.5 to 2.0 mg/kg produces good intubating conditions at 60 seconds, [280] [291] which are similar to those of succinylcholine 1 mg/kg [288] and which have a clinical duration of action (recovery to 25% twitch height) of about 20 minutes, depending on dosage. [291] Intubating conditions at 60 and 90 seconds are comparable in young and elderly adults, respectively. There is an increased duration of action with increasing age. [291] With continued infusion for an hour, the time of recovery increases to that of an intermediate-duration relaxant. [292] This observation may be due to the accumulation of the 3-desacetyl metabolite (ORG 9488), which is more potent and longer-acting than the parent compound. [292] There is little clinical experience with this drug as yet, but it seems suitable for tracheal intubation and procedures lasting less than 60 minutes and may serve as an acceptable alternative to succinylcholine for emergent intubation of the trachea.

	DOSAGE (mg/kg)	CLINICAL DURATION (min)

Maintenance	0.2-0.5	15-20
Infusion [a]	12 9 mug/kg/min	

[a] Cumulation and slowed recovery tend to develop.

Cardiovascular and Other Side Effects

Despite its low potency and the consequent need to administer large amounts of the drug, some animal data suggest that rapacuronium may have little cardiovascular effect. [293] On the other hand, in early studies in anesthetized patients, doses in the range of 2-3 mg/kg were shown by Pitts et al [293A] to cause 20 to 22 percent decreases in blood pressure lasting more than 5 minutes. The dose of 3 mg/kg in this study was associated with an increase of plasma histamine of approximately 1 mug/mL. No cutaneous flushing or bronchospasm was noted in this study. Yamaguchi et al [293B] have shown that ORG 9487 can produce vasodilation in isolated human mammary arteries as a result of blockade of both receptor- and voltage-activated calcium channels. The effect on voltage-activated calcium channels is greater than that of vecuronium. [293B] In another study involving intubation of almost 200 patients after doses of up to 2.5 mg/kg, adverse cardiovascular effects were not common [291] ; bronchospasm was reported, however, at an incidence of about 5 percent during that study.

In any event, these early impressions of the effects of rapacuronium on vessels and bronchi in humans require further study, and greater experience with the drug in the clinic is needed.

Metabolism and Elimination

Rapacuronium has a plasma clearance of 8.5 to 11.1 mL/kg/min, which is consistent with its short-to-intermediate duration of action. [292] It has a steady-state volume of distribution of 457 mL/kg and an elimination half-life of 72 to 88 minutes. [287] Renal excretion amounts to 22 percent of an administered dose, [292] so it is possible that its principal route of elimination may be via the liver. The principal metabolite is 3-desacetylrapacuronium (ORG 9488), which is approximately twice as potent as the parent drug. With continued administration of rapacuronium, the metabolite may make a proportionately greater contribution to the neuromuscular blockade and more than likely cause delayed recovery. [287] [292]

Atracurium

Atracurium (Fig. 12-28) , a benzylisoquinolinium diester relaxant of intermediate duration of action, emerged from a series of studies by Stenlake and colleagues [43] in the mid-1970s that were designed to produce a nondepolarizing relaxant that might undergo Hofmann elimination. In this chemical reaction, a cyclic quaternary nitrogen grouping, under the influence of high pH and temperature, opens to a tertiary amine. In atracurium, Stenlake et al adapted the reaction to a molecule that not only has good neuromuscular blocking potency but also undergoes the reaction at physiologic pH and temperature. [106A] The drug was introduced into

Figure 12-28 Chemical formula of atracurium, a benzylisoquinolinium diester that undergoes Hofmann degradation (see Fig. 12-11) (Figure Not Available) . The reaction is facilitated at physiologic pH by the orientation of the ether oxygens toward the center of the chain, enabling the rupture of the linkage of the chain with the terminal ring system (laudanosine).

clinical practice in Britain by Payne and Hughes [293C] in 1981 and in the United States by Basta et al in 1982. [293D]

Atracurium is the first nondepolarizing muscle relaxant to be largely broken down in the blood stream; perhaps the most significant advance made with atracurium is its degradation by a chemical reaction (Hofmann elimination) that is not affected by biologic disorders (see Fig. 12-11) (Figure Not Available) .

	DOSAGE (mg/kg)	CLINICAL DURATION (min)
ED_{95}	0.23	
Intubation (at t = +2-3 min)	0.5-0.6	30-45
Relaxation (N_2O/O_2)	0.3-0.4	30-45
Relaxation (Vapor)	0.2-0.3	30-45
Maintenance	0.1-0.15	15-20
Infusion	4-12 mug/kg/min	

Cardiovascular Side Effect

Atracurium, being a benzylisoquinolinium, may cause the release of histamine at high dosage. This may occur when doses of more than 0.5 mg/kg (more than two times ED_{95}) are injected rapidly [139] [192] [194] [196] [293D] (Fig. 12-29). (Figure Not Available) When plasma histamine levels increase to over 1,000 pg/mL, facial erythema

and a transient decrease in blood pressure may be noted. Histamine release may be decreased by slower injection of the relaxant (30-60 seconds) [139] [192] [196] (see the section titled *Mivacurium*[140] [195] or by administration of smaller or divided doses of the relaxant. Combined histamine$_1$ - and histamine$_2$ -receptor blockade effectively prevents the cardiovascular manifestations of histamine release, which may be associated with the rapid administration of high doses of atracurium. [192] [196] [197] For example, Hosking et al [197] treated patients with intravenous diphenhydramine (1 mg/kg) and cimetidine (4 mg/kg) 30 minutes before giving a very large dose of atracurium (1.5 mg/kg or six times the ED_{95}). Atracurium-induced decreases in mean arterial pressure were reduced from 30 mm Hg (37% below baseline) in control subjects to 8 mm Hg (10% below baseline) in treated patients, despite a 10- to 20-fold increase in plasma

Figure 12-29 (Figure Not Available) Dose response to atracurium in patients under nitrous oxide-oxygen-barbiturate-opioid anesthesia. Curves represent maximum responses in at least nine patients per group. At two times ED_{95} for twitch inhibition (0.5 mg/kg), a decrease in arterial pressure and a slight increase in heart rate was noted. The divergence of arterial pressure and heart rate responses is characteristic of histamine release. *(From Basta et al [293C])*

histamine levels. Scott et al [196] obtained similar results in patients pretreated with chlorpheniramine and cimetidine 15 minutes before an atracurium dose of 0.6 mg/kg. Atracurium is nonvagolytic and does not block autonomic ganglia. [106A]

Metabolism and Elimination

Atracurium is degraded by the Hofmann elimination (see Fig. 12-11) (Figure Not Available) . The reaction is a purely chemical process that is accelerated by alkaline pH and increase in temperature. In fact, pH changes during clinical practice probably have very little effect on the speed of the reaction, whereas a decrease in the temperature of the patient below 34°C will slow the reaction and lengthen the blocking effect considerably. Some degree of enzymatic ester hydrolysis, not related to plasma cholinesterase, probably also occurs. [157] [160] [161] Although the actual amounts remain debated, [162] the majority of atracurium is destroyed in the plasma, and a much smaller amount is eliminated through renal pathways. There is no biliary excretion of atracurium.

A major metabolite of atracurium, laudanosine is a tertiary amine that can enter the central nervous system (CNS). Very high doses of laudanosine itself (5-15 mg/kg) may cause CNS excitation in laboratory animals, [164] [169] [170] [171] [172] but no clear-cut cases have been noted in humans, even when renal and hepatic failure are present. [167] [168] The potential effects of this metabolite of atracurium in the CNS in human subjects are likely subclinical, although difficult to determine in the ICU in patients who are partially paralyzed and/or sedated. Laudanosine is excreted in the urine and bile and is cleared more slowly than atracurium itself. [165]

Cisatracurium

Cisatracurium, the 1R- *cis,* 1R
- *cis* configuration of atracurium (Fig. 12-30) , is one of the ten stereoisomers that comprise atracurium. The atracurium mixture of isomers consists of approximately 15 percent cisatracurium. Cisatracurium is about four times more potent than atracurium and has minimal cardiovascular side effects. [46A] [294] [294E] Like atracurium, it has an intermediate duration of action. [294A] [294B]

A comparison of the speed of onset of blockade versus the potency of the various isomers of atracurium yields a very cogent proof that onset is accelerated in less potent compounds and decreased in compounds of higher potency in the benzylisoquinolinium series of relaxants (Fig. 12-31) (Figure Not Available) . The proof is so compelling because all stereoisomers of atracurium, of course, have the same molecular weight. [46A]

	DOSAGE (mg/kg)	CLINICAL DURATION (min)
ED_{95}	0.05	
Intubation (at t = +1.5-3 min)	0.15-0.2	40-75
Relaxation (N_2O/O_2)	0.05	30-45
Relaxation (Vapor)	0.03-0.04	30-45
Maintenance	0.01-0.02	15-20
Infusion	1-2 mug/kg/min	

Figure 12-30 Chemical formula of cisatracurium (51W89). This compound is one of the stereoisomers of atracurium. The R- *cis,*R
- *cis* conformation confers greater potency and significantly reduces the side effect of histamine release in comparison with atracurium.

Cardiovascular Side Effects

The autonomic safety ratios for cisatracurium, atracurium, and vecuronium were compared in the cat. [45] [469] Cisatracurium had higher autonomic safety ratios than atracurium. Furthermore, it had less propensity to cause histamine release. Atracurium was shown to cause marked elevations of plasma histamine at doses of 25 to 50 times ED_{95} in the cat, whereas cisatracurium did not affect plasma histamine concentrations in doses as high as 80 times ED_{95} . [45] [469]

In humans as well as animals, cisatracurium does not cause histamine release. [294C] [294D] [295] Doses of eight times ED_{95} do not cause cardiovascular changes suggestive of histamine release or increases in plasma histamine concentration even when administered as a rapid (5-second) intravenous bolus. Doses of two times ED_{95} have been given to patients with coronary artery disease, and hemodynamic

Figure 12-31 (Figure Not Available) Regression of onset (ordinate) versus potency in atracurium and its individual isomers. As in the case of steroidal relaxants (see Fig. 12-6) , onset is faster in substances of low potency. The relationship is very compelling in this series of benzylisoquinolinium molecules because their molecular weights are identical. *(From Wastila et al [175A])*

Figure 12-32 Slopes of spontaneous recovery of twitch following 0.1, 0.2, and 0.4 mg/kg of cisatracurium. These doses represent 2x, 4x, and 8x ED_{95} . All the slopes are parallel, including the slope of recovery from infusions, and average 30 to 35 minutes. The data indicate constant speed of recovery unrelated to dose or to duration of administration, suggesting lack of cumulative effect.

changes were indistinguishable from those seen in a similar group of patients receiving vecuronium. [295A]

Like atracurium, cisatracurium undergoes Hofmann elimination to yield laudanosine and a monoquaternary alcohol metabolite. [295B] [295C] [296] As a result of this degradation, which occurs in the plasma and extracellular fluid, the slope of recovery from blockade is unaffected by dosage or by duration of administration (Fig. 12-32) . Cisatracurium does not undergo hydrolysis by nonspecific plasma esterases. Twenty-three percent of the drug is cleared through organ-dependent means, with renal elimination accounting for 16 percent of this. [296] In patients with chronic renal failure, the duration of action of cisatracurium is not prolonged. [296A] The clearance of the drug is slightly decreased (by 13%) in this patient population. [296B] In patients in hepatic failure, there is an increased volume of distribution that is offset by greater clearance of cisatracurium. The result is minimal net change in pharmacodynamics. [296C] Recovery from cisatracuriuminduced block is not prolonged in patients in the intensive care unit. [297]

Mivacurium

Mivacurium (Fig. 12-33) is a benzylisoquinolinium diester. This nondepolarizing relaxant is hydrolyzed by plasma cholinesterase at 70 to 88 percent the rate of succinylcholine. [15] [154] Enzymatic hydrolysis gives the drug its short duration of action. [15] The duration of relaxation is one-half to one-third that of the

intermediate-acting nondepolarizers and about two to three times that of succinylcholine. [15] [297] [297B]

The short duration of action of mivacurium enables maintenance of relaxation by continuous infusion for short- to intermediate-length surgical procedures of 30 to 90 minutes

Figure 12-33 Chemical formula of mivacurium, a benzylisoquinolinium diester that is hydrolyzed by pseudocholinesterase at about 70 to 88 percent the rate of succinylcholine. Cholinesterase-catalyzed hydrolysis is facilitated by orientation of the ether oxygen of the carboxyl group toward the quaternary nitrogen atom.

or more. [297D] [297e] Longer infusions may be given with minimal increase in recovery time. [15] [297D] The slope of recovery is not affected by dose or by duration of administration by infusion (Fig. 12-34) (Figure Not Available) . The block is antagonized by anticholinesterases [15] [298] or by administration of pseudocholinesterase [298A] [298B] (see *Antagonism of Residual Neuromuscular Blockade*).

	DOSAGE (mg/kg)	CLINICAL DURATION (min)
ED_{95}	0.07-0.08	
Intubation (at t = +2.0-3.0 min)	0.2-0.25	15-20
Relaxation (N_2 O/O_2)	0.1	10-15
Relaxation (Vapor)	0.08	10-15
Maintenance	0.05-0.1	5-10
Infusion	3-15 (average 6) mug/kg/min	

Cardiovascular Side Effects

Mivacurium can cause histamine release. Following rapid injection of doses of 0.2 to 0.25 mg/kg, transient facial erythema and a brief decrease in blood pressure may occur [198] [298C] (see Fig. 12-15 (Figure Not Available) A). Because these doses are used to facilitate tracheal intubation within about 120 seconds, [299] [299A] [299B] a slower rate of administration of the drug (30 seconds) should be used if histamine release is to be minimized [298C]

Figure 12-34 (Figure Not Available) Slopes of spontaneous recovery of twitch following mivacurium. Four different bolus doses from 1.5 to 4 times ED_{95} are shown, together with recovery following infusion (average duration of infusion is 92 minutes); *n* = at least 9 per bolus group and 38 for the infusion group. Recovery times from 5 to 95 percent twitch height do not differ significantly and average 13 to 14 minutes. *(From Savarese et al [15])*

(Fig. 12-15 (Figure Not Available) B). There is no blockade of autonomic ganglia, nor is there any vagolytic effect. [299C]

Isomers of Mivacurium

Mivacurium consists of three stereoisomers. The more potent *cis-trans* and *trans-trans* isomers make up about 95 percent of the preparation. These isomers are rapidly hydrolyzed by plasma cholinesterase and show elimination half-lives of 2 to 3 minutes. [299D] The *cis-cis* isomer is more slowly hydrolyzed, and its elimination half-life is 55 minutes. As this isomer constitutes only 5 percent of the preparation of mivacurium and is 10 to 15 times less potent than the more active *cis-trans* and *trans-trans* isomers, [299C] it is not likely to contribute significantly to the blocking activity of mivacurium in human subjects. [297D]

Metabolism and Elimination

Mivacurium is nearly completely metabolized in the plasma (see Fig. 12-12) (Figure Not Available) by hydrolysis by pseudocholinesterase. Less than 5 percent is excreted as the parent compound in the urine. The metabolites of hydrolysis are the mivacurium monoester and the amino alcohol Fig. 12-12) (Figure Not Available) . These are excreted in urine and bile. [300] The metabolites are positively charged, making CNS entry unlikely. They show less than 1/100 the neuromuscular blocking activity of the parent compound. They do not affect the autonomic nervous system. [300]

Although not directly dependent on the kidney or the liver for elimination from the body, the dynamics of the relaxant are altered in patients with hepatic or renal failure. The duration of action of mivacurium is lengthened (by 10-15 minutes) in renal failure. [114] In anhepatic subjects undergoing liver transplantation, its duration of action is lengthened by a factor of 3. These alterations are likely due to decreased pseudocholinesterase activity. [114] Plasma cholinesterase is synthesized in the normal liver and is decreased in the presence of uremia.

Atypical Pseudocholinesterase Case

In the case of persons who carry atypical forms of pseudocholinesterase, the action of mivacurium is lengthened. In patients heterozygous for the atypical enzyme, mivacurium's duration of action is lengthened by 30 to 100 percent (10-30 minutes). In patients homozygous for the atypical enzyme (incidence 1 in 3,000), the duration of action of mivacurium is markedly prolonged. In these patients, mivacurium is extremely potent and long-lasting. Full paralysis after an ordinary intubating dose of 0.2 mg/kg will last 3-4 hours. [300A] [300B] Once signs of the beginning of recovery are noted, antagonism of residual block should be attempted as if antagonizing a long-acting nondepolarizing agent. A large dose of neostigmine (60-70 mug/kg) together with atropine or glycopyrrolate should be administered once spontaneous recovery of neuromuscular function has begun. Alternatively, pseudocholinesterase may be given (see *Antagonism of*

Residual Neuromuscular Blockade) to induce metabolism of mivacurium in these patients. [298A]

GW 280430A

GW 280430A (Fig. 12-35) represents a new class of nondepolarizing relaxants, called asymmetric mixed-onium chlorofumarates that are rapidly degraded by chemical mechanisms in blood *in vitro*. The compound has an ultra-short duration of action in the monkey, the dog, and the cat. A study in anesthetized human volunteers evaluated the onset and recovery profiles of GW 280430 in the thumb and larynx. The pattern of blockade resembles that of succinylcholine, with fully paralyzing doses (2-3 times ED_{95} or 0.3-0.5 mg/kg) producing 100 percent block of TOF within 50 to 60 seconds in the larynx. Spontaneous recovery to TOF of 0.9 develops in the thumb within about 12 to 15 minutes following administration. The recovery is accelerated by edrophonium. The cardiovascular changes following rapid (5-second) bolus doses in these volunteers have averaged less than 10 percent from baseline.

Further careful evaluation of GW 280430 therefore seems needed in patients, with respect to its dosage requirements, pharmacodynamics and kinetics, and cardiovascular properties.

Figure 12-35 The chemical formula of GW 280430. This substance represents a new chemical class of relaxants called asymmetric mixed-onium chlorofumarates, which are degraded chemically *in*

vitro. The rapid breakdown may explain an ultra-short duration of action noted in animals and in human volunteers (see text).

EFFECTS IN THE CENTRAL NERVOUS SYSTEM

Despite being ionized, intravenously administered nondepolarizing muscle relaxants do pass into the cerebrospinal fluid (CSF). [301] Neuromuscular blocking doses of gallamine given intravenously have been found to increase the seizure threshold to lidocaine in dogs. [302] Forbes et al [303] found intravenously administered pancuronium to reduce halothane anesthetic requirement by 25 percent. However, more recent studies indicate that muscle relaxants do not alter anesthetic requirement. [304]

When neuromuscular blocking drugs have been administered accidentally into the CSF (i.e., wrong drug given for a spinal anesthetic), myotonia, autonomic changes, and even convulsions have occurred. [305] [306] Furthermore, prolonged administration of vecuronium, and probably of other muscle relaxants, will result in these drugs entering the CSF in critical care patients. [306A] On the basis of these limited data, the authors of this chapter conclude that small amounts of intravenously administered muscle relaxants do pass into the CSF, but the clinical significance is unclear. Also, laudanosine, a metabolite of atracurium, crosses the blood-brain barrier. [164] In large doses in animals, laudanosine may cause central nervous system stimulation.

During the clinical use of atracurium, however, the accumulation of quantities of this metabolite sufficient to cause CNS stimulation has not been documented even in the most arcane of circumstances. Furthermore, because the new isomer cisatracurium is four to five times as potent as the parent compound atracurium, quantities of laudanosine produced during breakdown of cisatracurium are theoretically four times less than during the use of atracurium. In fact, measured laudanosine quantities produced during cisatracurium administration are five to ten times lower than during atracurium use, making laudanosine accumulation a nonissue in clinical practice with cisatracurium.

Whether the CNS effects of muscle relaxants contribute to the morbidity and mortality of critical care patients is another matter. Further studies are very much needed in this area, since critical care patients may receive relaxants continuously for many weeks (see also *Muscle Relaxants in the Intensive Care Unit, Metabolism and Elimination,* and *Individual Nondepolarizing Relaxants: Atracurium* and *Cisatracurium*).

SPECIAL POPULATIONS

Pediatric Patients

The development of the neuromuscular junction is not complete at birth. [307] [307A] Goudsouzian [308] pointed out that maturation of neuromuscular transmission in humans occurs after the first 2 months of age. In spite of this, muscle relaxants can be used safely in term and preterm infants.

It is not apparent from older studies whether the newborn is more sensitive than adults to nondepolarizing muscle relaxants. [309] [310] [311] [312] [313] [314] [315] More recent studies by Fisher and colleagues [316] [316A] [316B] of the pharmacokinetics and pharmacodynamics of relaxants in infants, children, and adults, however, have made it possible to better understand the

clinical pharmacology of these drugs in pediatric patients (Ch. 63). Neonates and infants are more sensitive than adults to the neuromuscular blocking effects of dTc. [316] A lower plasma concentration of this muscle relaxant is required to achieve a desired level of neuromuscular blockade in these young patients. However, dosage should not be decreased because infants have a larger volume of distribution. The increased volume of distribution and slower clearance (Fig. 12-36) (Figure Not Available) contribute to a longer elimination half-life, [316] [317] which means that in infants dTc may require less frequent dosing (longer dosing intervals) than in older children.

Atracurium, vecuronium, cisatracurium, and rocuronium are commonly administered to children. The popularity of these drugs in children most likely stems from the following points: they are intermediate-acting muscle relaxants, minimal residual paralysis is seen in the postoperative period, [318] and a faster onset of action occurs in children than in adults.

Atracurium and vecuronium, in comparison, show very different kinetic and dynamic patterns in infants. As with the long-acting relaxants, the sensitivity of infants to vecuronium is greater than it is in children (ED_{95} 0.047 versus 0.081 mg/kg, respectively). [319] An increased duration of action in infants is most likely secondary to the increased volume of distribution of vecuronium because its clearance is unchanged. [316A] [317] Vecuronium therefore acts as a longacting muscle relaxant in the neonate. [316A] [317] [320]

In contrast, the duration of action of atracurium is not significantly different in the pediatric patient from that in the adult. [321] [322] [323] As with vecuronium and dTc, the volume of distribution is increased in infants. [316B] However, the clearance of atracurium is also more rapid. [316B] Therefore, the same dose (0.5-0.6 mg/kg) can be used in infants, children, and adults for tracheal intubation without any major difference in its duration of action in the three groups. Cisatracurium is a single isomer of atracurium. In children a dose of 0.1 mg/kg has an onset of just over 2 minutes and a clinical duration of approximately 30 minutes during balanced or halothane anesthesia. [324] Although further studies need to be done, the authors recommend an intubating dosage of 0.2 mg/kg of cisatracurium in children (as in adults) to facilitate good intubating conditions within 90 seconds. The clinical duration at this dosage should be in the neighborhood of 45 to 50 minutes.

The short-acting muscle relaxant mivacurium can be safely used in children. The ED_{95} of mivacurium is greater in children than in adults (0.10 mg/kg during narcotic anesthesia and 0.09 mg/kg during halothane anesthesia). [325] Children, therefore, require larger doses of mivacurium than adults to achieve a given depth of neuromuscular block. [325] [326] Onset time, as with atracurium [322] and vecuronium, [327] is faster in children than in adults, so maximal block is achieved in less than 2 minutes. A dose of 0.25 to 0.30 mg/kg facilitates tracheal intubation in about 90 seconds in children. A dose of twice the ED_{95} (0.2 mg/kg) results in only a 20 percent increase in the duration of block as compared with the ED_{95} . [326] And, in contrast to adults, with this dose there is less hemodynamic instability. At doses of 0.25 mg/kg, facial flushing and transient hypotension secondary to histamine release are observed less often (in about 10-15% of the pediatric population who receive this amount as a rapid 5-10 second injection). [325]

Mivacurium's clinical duration of action is shorter in children than in adults (12 versus 15-20 minutes). Although halothane potentiates mivacurium-induced neuromuscular block, it does not prolong its duration of action. [325] [326] Because of its short duration of action, mivacurium is best used as an infusion in children for maintenance of relaxation. Infusion rates required by children (10-20 mug/kg/min) are about twice those required by adults, probably because of a significantly higher plasma cholinesterase activity. [328] [329] [330]

Rocuronium in adults is an intermediate-acting relaxant with a fast onset of action, and this is also true in infants and children. [330A] [330B] Its potency is greater in infants than in children, but its onset is faster in the latter age group. [330B] In children, rocuronium 0.6 mg/kg produces better conditions for rapid tracheal intubation than does vecuronium 0.1 mg/kg or atracurium 0.5 mg/kg. [330A] If given by intramuscular injection into the deltoid (1.0 mg/kg in infants and 1.8 mg/kg in children), rocuronium allows for tracheal intubation in approximately 3 minutes. [330C] As with adults, for rapid-sequence intubation (60 seconds) in the presence of a full stomach, high doses of 1.2-1.5 mg/kg are suggested.

Antagonism of residual neuromuscular blockade in the

Figure 12-36 (Figure Not Available) Correlation between age, glomerular filtration, and clearance of curare. *(From Fisher et al [316])*

case of the various nondepolarizers is similar in children and adults. Fisher et al [331] [332] described some minor variations in neostigmine and edrophonium dosage for pediatric patients. For example, the ED_{50} of neostigmine for antagonism of a dTc-induced 90 percent block of the adductor pollicis twitch was 22.9 mug/kg in adults, compared with 15.5 mug/kg in infants. [331] In the case of edrophonium, the ED_{50} for antagonism of dTc-induced 90 percent block was 128 mug/kg in adults. In children, the ED_{50} was 233 mug/kg, and in infants the ED_{50} was 145 mug/kg. [332]

It seems that despite the above variations, neostigmine and edrophonium dosage in various age groups should be liberal enough to ensure return of monitoring variables such as TOF to clinical adequacy within a reasonable time, i.e., 10-15 min. The authors recommend neostigmine dosage of 50 to 60 mug/kg for reversal in children and edrophonium dosage of 500 to 1,000 mug/kg. In all cases, tests of clinical recovery, such as head lift, leg lift, and cry, should be performed and documented for pediatric patients and adults.

The routine administration of succinylcholine to healthy children should be discontinued. In apparently healthy children, intractable cardiac arrest with hyperkalemia, rhabdomyolysis, and acidosis may develop following succinylcholine administration, particularly in patients with unsuspected muscular dystrophy of the Duchenne type. [332A] In response to this, the U.S. Food and Drug Administration and Glaxo-Wellcome have modified the package insert for succinylcholine, warning against the use of succinylcholine in children except for emergent control of the airway (see the section on complications of succinylcholine; see also Ch. 31).

Elderly Patients

The pharmacodynamics of muscle relaxants are altered in elderly patients (Ch. 65). There are a number of physiologic changes that accompany the aging process, including decreases in total body water, increases in total body fat, decreases in hepatic and renal blood flow, and decreases in cardiac reserve, which account for the altered responses of the elderly to muscle relaxants. A number of physiologic and anatomic changes at the neuromuscular junction also occur with aging. These include an increase in the distance between the junctional axon and the motor endplate, a flattening of the folds of the motor endplate, a decreased concentration of ACh receptors at the motor endplate, a decrease of the amount of ACh in each vesicle in the prejunctional axon, and decreased release of ACh from the preterminal axon in response to a neural impulse. [333] As shown by Matteo et al, [334] despite all these changes, ACh receptor sensitivity to nondepolarizing muscle relaxants is not altered by advancing age (Fig. 12-37) (Figure Not Available) . That is, the elderly as well as young adults have similar degrees of neuromuscular blockade at the same plasma concentration of a muscle relaxant. Rather, it appears that, in the elderly, decreased splanchnic and renal blood flow, decreased glomerular filtration rate, and decreased hepatic function are responsible for the prolonged durations of action of most muscle relaxants. However, the impact of aging per se versus disease states often associated with the aging process may be difficult to distinguish in identifying mechanisms of altered muscle relaxant action in the elderly.

Figure 12-37 (Figure Not Available) Correlation of plasma metocurine concentration versus percentage paralysis (twitch depression) in young and elderly patients (open and closed squares). Differences are not significant. *(From Matteo et al [334])*

Pancuronium, [335] [336] metocurine, [334] dTC, [334] vecuronium, [336A] [337] and rocuronium [338] all show altered pharmacodynamics and pharmacokinetics in the elderly patient population. Decreased clearance of each of these drugs from the plasma explains their prolonged duration of action in these patients. These muscle relaxants depend on the kidney and/or the liver for their metabolism and elimination.

Surprisingly, the pharmacokinetics and pharmacodynamics of the newer long-acting muscle relaxants doxacurium [339] and pipecuronium, [340] which rely almost exclusively on the kidney for their elimination, do not seem to be significantly different in the elderly. The duration of neuromuscular blockade induced with doxacurium has been found to be more variable in the elderly than in younger patients and tends to be longer. However, clearance and elimination half-lives are the same in the two patient groups. Similarly, recovery from pipecuronium-induced neuromuscular blockade, volume of distribution, clearance, and elimination half-life of the drug are the same in young and old patients. Further studies in the elderly with doxacurium and pipecuronium may be needed to better define the issue.

In the case of drugs whose elimination is independent of hepatic or renal blood flow, pharmacokinetics and pharmacodynamics should be unaffected by age. This is true of atracurium, which depends on Hofmann degradation for its clearance. [341] [342] Cisatracurium, which also undergoes Hofmann elimination, has a delayed onset of effect in elderly patients. [342A] [342B] Duration of action of the relaxant appears not to be influenced by advanced age. The prolonged elimination half-life of the drug in the elderly is due to an increased volume of distribution. Clearance is not decreased with advanced age.

Plasma cholinesterase activity in the elderly, although in the normal range, is decreased by approximately 26 percent when compared with that in young adults. [343] Because mivacurium

is metabolized by plasma cholinesterase, its clearance is likely to be slightly reduced in the elderly, resulting in a 20 to 25 percent longer duration of action [343A] and a decreased infusion requirement to maintain a stable depth of block. [343B]

Obese Patients

There are conflicting reports concerning the effect of obesity on the pharmacodynamics of nondepolarizing neuromuscular blockade [344] [345] [346] Although the duration of action of pancuronium is unaffected by patient weight, [346] obese patients recover more slowly from metocurine- , [347] doxacurium- , [347A] or vecuronium-induced [348] neuromuscular blockade. The duration of action of rocuronium is prolonged in obese patients. [348A] These findings imply that the elimination of these drugs is decreased. The recovery from atracurium-induced neuromuscular blockade is not affected by obesity, [348] which is most likely secondary to its lack of dependence on end-organ function for its elimination.

Muscle relaxants should be dosed in the obese patient more precisely on the basis of about 20 percent more than lean body mass, rather than on actual body weight [349] to ensure that these patients are not receiving relative overdoses.

Severe Renal Disease

Renal failure influences the pharmacology of nondepolarizing muscle relaxants by producing either decreased elimination of the drug or its metabolites via the kidney, or decreased activity of enzymes that metabolize the drug, e.g., mivacurium (Table 12-13) . Consequently, the duration of action of muscle relaxants may be prolonged in patients with renal failure. An early example of prolonged neuromuscular blockade due to renal failure was a case of postoperative respiratory failure following gallamine, reported in 1950. [350]

Renal failure does not alter the *sensitivity* (doseresponse) of patients to the neuromuscular blocking action of gallamine, [351] dTc, [352] pancuronium, [352A] atracurium, [352B] vecuronium, [352C] or mivacurium, [352D] but it does cause resistance to metocurine. [352E]

Gallamine [351] and metocurine, [352E] which rely almost exclusively on the kidney for their elimination, have reduced plasma clearance and potentially a very long duration in patients with renal failure (see Table 12-13) . Pancuronium and dTc are eliminated predominantly via the kidney, and renal failure is associated with a reduced plasma clearance and increased elimination half-life for these drugs. [353] [353A] As a consequence of these pharmacokinetic changes, the duration of neuromuscular blockade produced by these drugs is longer and more variable than in patients with normal renal function. [353] For doxacurium, in renal failure its plasma clearance is decreased, its elimination half-life is increased, and its duration of action is prolonged. [354] [354A] Pipecuronium is eliminated predominantly by the kidney. In the 24 hours after its administration, approximately 40 percent is excreted in the urine and only 2 percent in the bile. [354B] Its plasma clearance is decreased by one-third, and its elimination half-life is increased 2-fold in patients with renal failure. [354C] Although the duration of action of a dose of 0.07 mg/kg was not prolonged by renal failure, the pharmacokinetic changes observed suggest that larger or repeat doses are quite likely to produce prolonged neuromuscular blockade. [354C] Because of the potential for prolonged block and the availability of intermediate- and short-acting relaxants, there is no longer any reason to recommend the use of the long-acting relaxants in patients with renal failure.

The pharmacokinetics and duration of action of atracurium are unaffected by renal failure. [355] [356] [357] This lack of effect is in part because atracurium undergoes spontaneous chemical degradation (Hofmann elimination) and ester hydrolysis, [357B] processes that account for 50 percent of its total clearance. [357C] The elimination half-life of laudanosine, the principal metabolite of atracurium, increases significantly in renal failure. [357] [358] Concern has been expressed about possible accumulation of laudanosine in patients with renal failure, [358A] but recent evidence suggests that significant concentrations of laudanosine are not achieved during the administration of atracurium in the operating room setting. [357] [358] However, the accumulation of laudanosine during atracurium administration in the ICU is not as clear (see the section on the ICU).

Vecuronium relies principally on hepatic, not renal, mechanisms for its elimination. [358B] [358C] However, its clearance is reduced and its elimination half-life is increased in patients with renal failure. [359] [359A] [360] In one study, the duration of action of vecuronium, 0.1 mg/kg, was both longer and more variable in patients with renal failure than in those with normal renal function. [360] In three other studies, the duration of action of vecuronium, 0.05-0.14 mg/kg, was not prolonged by renal failure, but this result was probably obtained because relatively small doses were administered or because the sample sizes were too small to detect a difference. [358C] [359] [359A] The principal metabolite of vecuronium, 3-desacetylvecuronium, has 80 percent of the neuromuscular blocking activity of vecuronium [361] ; it may cause prolonged paralysis in patients with renal failure in the intensive care unit. [362] [363] Although their pharmacokinetics differ, in clinical use for patients with renal failure, the duration

of action and rate of recovery from vecuronium or atracuriuminduced neuromuscular blockade are similar. [364] [365] [366]

Mivacurium is a short-acting nondepolarizing muscle relaxant metabolized by plasma cholinesterase at approximately 70 percent of the rate of succinylcholine. [367] [368] Mivacurium is a mixture of three stereoisomers; the pharmacokinetics of the two most pharmacologically active isomers (the *trans-trans* and *cis-trans*) are unaffected by renal failure; the clearance of the third isomer *(cis-cis),* which has little clinical effect, is decreased by renal failure. [369] The effect of renal failure on the duration of action and recovery from mivacurium-induced block is variable. In some studies renal failure had no effect, [369] [369A] whereas in another the duration of action and recovery were lengthened and the infusion dose requirements were decreased by renal failure. [370] The effect of renal failure on mivacurium's duration of action is most probably mediated through its effect on plasma cholinesterase. Renal failure can decrease plasma cholinesterase activity, [370A] and this decrease would be expected to lengthen the duration of mivacurium effect. [370B] In the studies where renal failure had no effect on mivacurium's duration, plasma cholinesterase activity in patients with and without renal failure was not different. [369] [369A] In contrast, where patients with renal failure had decreased

[b] Values expressed as mL/min, not weight-adjusted

cholinesterase activity, the duration of mivacurium was longer. [370] [370C] Because a patient's plasma cholinesterase activity is not known preoperatively, when mivacurium is used in patients with renal failure, doses should be conservative, and its effect should be carefully monitored.

When rocuronium is administered to patients with renal failure undergoing renal transplantation, compared with patients with normal renal function, plasma clearance is unchanged (2.89 mL/kg/min), volume of distribution is increased by 28 percent, and elimination half-life is lengthened by 37 percent (Fig. 12-38) (Figure Not

Available) . [370D] [370E] In patients with renal failure the duration of action of rocuronium is not prolonged, and it shows no evidence of cumulation. [370F]

Cisatracurium is the single R- *cis,* R
- *cis* isomer of atracurium. Organ-independent mechanisms (Hofmann elimination) account for 77 percent of the total clearance of cisatracurium. [371] Because renal excretion accounts for only 16 percent of cisatracurium elimination, renal failure should have little impact on its duration of action. [371]

Hepatobiliary Disease

Patients with hepatobiliary disease may exhibit prolonged block with *d*-tubocurarine, [372] pancuronium, [372A] doxacurium, [372B] vecuronium, [372C] rocuronium, [372D] [372E] and mivacurium.

Figure 12-38 (Figure Not Available) "Average" plasma concentration (Cp) versus time following rocuronium (0.6 mg/kg) in patients with normal renal function (solid line) or patients undergoing renal transplantation (dashed line). *(From Szenohradszky et al [15C])*

[372F] [372G] In the case of pancuronium, [372A] vecuronium, [372C] and mivacurium, [372F] [372G] this prolonged action is associated with a decreased plasma clearance of the drug. However, this is not a consistent relationship, and many studies have described a reduction in clearance without a prolonged duration. In the case of atracurium, one study even reports increased clearance in patients with cirrhosis, but the duration of action was normal. [372H]

A concern raised about administering atracurium to patients with hepatic disease was the possible cumulation of its principal metabolite, laudanosine. [373] However, although laudanosine relies principally on hepatic mechanisms for its elimination, the concentrations encountered during liver transplantation are unlikely to be associated with clinical sequelae. [373] [374]

The influence of hepatobiliary disease on the pharmacokinetics of muscle relaxants is complex (Table 12-14) . In most studies, hepatic disease is associated with an increased volume of distribution, and as a result, there is an apparent resistance to the effect of dTc, [372] [374A] pancuronium [375] [375A] atracurium, [376] and rocuronium. [376A] The effect of hepatic disease on the pharmacokinetics of the muscle relaxants (see Table 12-14) suggests that initial doses may need to be greater than for patients with normal hepatic function but that once the desired level of block has been achieved, subsequent recovery may be slower. This is illustrated in the case of vecuronium, in which doses up to 0.15 mg/kg have a normal duration of action, [377] [378] [378A] but a dose of 0.2 mg/kg has a prolonged action [378] [378B] (Fig. 12-39) (Figure Not Available) .

There are several mechanisms by which hepatic disease can alter the elimination of muscle relaxants. The principal route of metabolism of pancuronium and vecuronium is deacetylation at the 3-position. [379] [380] [380A] This metabolic process is presumed to occur in the liver because 10 to 20 percent of the total dose of pancuronium and 40 percent of that of vecuronium is found in the liver and bile as both parent drug and metabolite. [379] [380] [380A] [380B] In hepatic disease, increased plasma concentration of bile salts can reduce the hepatic uptake of pancuronium and vecuronium, [380C] [380D]

Figure 12-39 (Figure Not Available) Disappearance of vecuronium from the plasma following a single bolus dose of 0.2 mg/kg. Semilogarithmic plot of the mean concentration versus time for patients with normal hepatic function (filled circles) and cirrhotic patients (open circles). Error bars are the SD for that value. *(From Lebrault et al [142])*

and this may be an explanation for the decreased clearance of these drugs observed by some investigators. [372A] [378B] [380E]

In patients with severe liver disease, plasma cholinesterase activity is decreased probably due to decreased synthesis of the enzyme in the liver. [372F] [372G] Consequently, the plasma clearances of the isomers of mivacurium are decreased (see Table 12-14) , and its duration of action is prolonged and may be almost tripled. [372F] [372G]

Atracurium and cisatracurium share organ-independent modes of elimination, namely, Hofmann elimination and ester hydrolysis. [380F] [380G] As a consequence, their clearance should be little affected by hepatic disease. In fact, and in contrast to all other muscle relaxants, the plasma clearances of atracurium and cisatracurium are increased slightly (see Table 12-14) in patients with liver disease. [372H] [380H] Because elimination of atracurium and cisatracurium occurs outside of, as well as from within, the central compartment, it has been suggested that a larger distribution volume should be associated with a larger clearance. [380G] In two studies, [372H] [380H] volumes of distribution and clearances of the drugs increased with liver disease, lending support to the theory of Kisor et al. [380G] This increased clearance with liver disease is not reflected by a decrease in the drugs' durations of action. [372H] [380H]

IMPORTANT INTERACTIONS

Anesthetics

Inhaled anesthetics augment the neuromuscular blockade from nondepolarizing muscle relaxants in a dose-dependent fashion [381] [381A] (Fig. 12-40) (Figure Not Available) , which may also depend on the duration of anesthesia. [382] Not all types of anesthetics enhance neuromuscular block to the same extent. For example, isoflurane, and enflurane may have a greater effect than halothane, which in turn has a greater effect than nitrous oxide-barbiturate-opioid or propofol anesthesia [383] [384] (Fig. 12-41) (Figure Not Available) . Sevoflurane enhances blockade produced by vecuronium, pancuronium, or atracurium to a degree similar to that of isoflurane. [384A] [384B] Desflurane appears to have a slightly greater effect than isoflurane on vecuroniuminduced blockade. [384C]

Interestingly, not all muscle relaxants are affected to the same degree by the presence of volatile anesthetics. The reason may be partly due to differences in experimental design. However, atracurium and vecuronium do not seem to be as much affected by the choice of general anesthesia as are dTc and pancuronium. [385] There is an approximately 20 percent difference in the dose-response curves of these two intermediate-acting relaxants with nitrous oxide-barbiturateopioid anesthesia compared with isoflurane anesthesia. In contrast, with dTc and pancuronium, there may be as much as a 50 percent difference. Isoflurane and enflurane do, however, markedly reduce the infusion rate of vecuronium [385A] or rocuronium [385B] required to maintain a stable depth of neuromuscular blockade compared with opioidnitrous oxide anesthesia (Fig. 12-42) (Figure Not Available) . In addition, the presence of isoflurane will slow recovery from vecuronium [386] [386A] and apparently mivacurium-induced neuromuscular blockade as compared with opioid anesthesia, [386A] [387] such that,

Figure 12-40 (Figure Not Available) Effect of anesthetics on a *d*-tubocurarine dose-response curve. *(From Ali and Savarese [381B])*

Figure 12-41 (Figure Not Available) Shift of pancuronium dose response to the left as the end-tidal concentration of Forane (isoflurane) is increased from 0.5 to 1.5 percent. *(From Miller et al [128])*

pharmacodynamically, they behave more like long- and intermediate-acting relaxants, respectively, particularly at the end of lengthy procedures.

Gencarelli et al [388] demonstrated that a stepwise decrease in enflurane concentration from 2.2 to 0.5 percent during a constant infusion of dTc resulted in a reduction of neuromuscular blockade from 92 to 8 percent twitch inhibition. This suggests that when potent inhaled anesthetics are used, a significant fraction of the neuromuscular blockade can be removed by simply decreasing the anesthetic concentration.

Several mechanisms have been proposed by which inhaled anesthetics may affect the neuromuscular blockade from muscle relaxants. The mechanisms that are probably most important are those due to the following actions of inhaled anesthetics: (1) to increase muscle blood flow, so that a greater fraction of the injected relaxant may reach the neuromuscular junction, [389] probably a factor mainly with isoflurane; (2) to induce relaxation at sites proximal to the neuromuscular junction, obviously the CNS [390] ; (3) to maintain release of ACh from the motor nerve terminal [391] ; (4) to exert

Figure 12-42 (Figure Not Available) Infusion rates of vecuronium necessary to maintain constant 90 percent depression of control twitch tension during three different anesthetics. I, standard deviation;
, range of infusion rates. *(From Cannon et al [129])*

no demonstrable effect on the ACh receptor [392] [393] (5) to decrease the sensitivity of the postjunctional membrane to depolarization [394] ; and (6) possibly to act at a site distal to the cholinergic receptor and the postjunctional membrane, such as the muscle membrane. [390] [393] [394]

In generally healthy individuals, volatile anesthetics do not decrease twitch tension. Desflurane is an exception to this and at end-tidal concentrations of up to 2.0 MAC has been reported to cause as much as 30 percent depression of the TOF response in healthy humans. [381] [395] Although the majority of volatile anesthetics do not depress twitch tension, they reduce the margin of safety of neuromuscular transmission. Waud and Waud [391] [392] indicate that halothane acts at a site beyond the cholinergic receptor, perhaps on either calcium conductance or ACh release via depolarization. Other studies indicate that inhaled anesthetics have specific effects on the ACh receptor channels. Using a patch clamp technique, Brett et al [396] found that isoflurane reduces the average open duration of the ACh receptor channels during activation. The end-plate current is reduced in amplitude by the muscle relaxant and, because of isoflurane, has an accelerated decay. Both factors reduce the net charge transfer across the end plate, which impairs neuromuscular transmission.

Because of their action on the CNS, volatile anesthetics often produce adequate relaxation with minimal neuromuscular blockade. Therefore, when potent anesthetic vapors are used, good surgical conditions can exist in the absence of deep neuromuscular blockade.

Some potent anesthetics (e.g., isoflurane) increase muscle blood flow. Diversion of a larger fraction of the cardiac output to muscle may result in a proportionally greater quantity of relaxant being delivered to muscle. This mechanism has been proposed as a factor to explain why the potentiating effect of isoflurane is greater than that of halothane. [389] Clearly the most important mechanism is that anesthetics inhibit motor end-plate depolarization; the effect is directly related to anesthetic concentration. [397]

Despite changes in regional, renal, and hepatic blood flow, inhaled anesthetics have little or no effect on the pharmacokinetics of muscle relaxants in humans. [385A] [398] The ability of inhaled anesthetics to augment a nondepolarizing neuromuscular block is a pharmacodynamic one, that is, the blood concentration of muscle relaxants required to produce paralysis is decreased by inhaled anesthetics (see Fig. 12-42) (Figure Not Available) .

The ability of enflurane to enhance a dTc neuromuscular block is time-dependent. Stanski et al [399] found that, despite a constant blood level of dTc, paralysis increased at a rate of 9 ± 4 percent/h. They speculated that halothane achieves its maximum effect so rapidly because it acts on neural tissue (e.g., neuromuscular junction) where blood flow is high. Conversely, they speculated that, in addition to the neuromuscular junction, enflurane may also act on skeletal muscle, where blood flow is less. Thus, a longer time would be required for enflurane to achieve its maximal enhancement of nondepolarizing neuromuscular blockade. The specificity of enflurane in this time-dependent potentiating effect is now less certain because Kelly et al [381] have shown a similar time-dependent action of desflurane as well. A time- dependent effect of halothane and isoflurane on maintenance dosage of mivacurium given by infusion has also been demonstrated. [400] [400A]

There is still debate about the influence of volatile anesthetics on reversal of neuromuscular blockade. Some studies have suggested that maintenance of anesthesia with anesthetic vapors can impede reversal of nondepolarizing neuromuscular blockade by neostigmine or edrophonium. [400B] [400C] [400D] [401] It has even been suggested that the effect is different for different anesthetics and that sevoflurane may impede neostigmine-induced antagonism more than isoflurane. [400C] That so many factors may act to impede adequate reversal stresses the need for close clinical monitoring of neuromuscular function and the avoidance of attempting antagonism with no

evidence of at least the beginning of spontaneous recovery. However, it has also been suggested that withdrawal of the anesthetic vapor at the end of surgery (and consequently reduction of its enhancement of the neuromuscular blockade) will speed pharmacologic reversal. [386]

Temperature

The force of contraction of the adductor pollicis decreases by 10 to 16 percent per degree centigrade decrease in muscle temperature below 35.2°C, during both nitrous oxide/isoflurane and nitrous oxide/fentanyl anesthesia. [402] [403] To maintain the muscle temperature above 35.2°C, central temperature must be maintained at 36.0°C. [404] Mild hypothermia significantly prolongs the duration of action of both vecuronium and atracurium in humans. [404] [405] The duration of action (recovery to 10% twitch height) of vecuronium, 0.1 mg/kg, increases from 28 minutes at a mean central temperature of 36.4°C to 64 minutes at 34.4°C (see Fig. 12-39) (Figure Not Available) . [404] For atracurium, 0.5 mg/kg, the duration of action is 44 minutes at 37°C and 68 minutes at 34.0°C. [405] In contrast, in cats, the durations of both pancuronium and dTc are similar at 39 and 34°C. [406] [407] However, reduction of central temperature in the cat to 28 to 29°C is associated with increased duration of action of both drugs. [406] [407] The prolonged action at these lower temperatures is associated with diminished renal and hepatic excretion, and for pancuronium, serum clearance decreases with decreasing temperature. [406] [407] In humans, there are no differences in the pharmacokinetics or pharmacodynamics of dTc at 31.8°C versus 35.8°C. [408]

The influence of temperature on the sensitivity of a muscle to neuromuscular blockade is complex. In cats, the neuromuscular junction is more sensitive to pancuronium at 29°C than at 39°C, [407] in contrast to dTc, for which the opposite is true. [406] In humans, the sensitivity to dTc is similar at 31.8°C and 35.8°C, [408] and for vecuronium, sensitivity at 34.4° and 36.8°C is similar. [409] The dose of muscle relaxants producing 50 percent decrease in force of contraction of a rat hemidiaphragm preparation, the ED_{50} , was studied at a control temperature of 37°C and over the range 27° to 42°C. [410] Compared to control, the ED_{50} of pipecuronium did not change over the temperature range 27° to 42°C. [410] The ED_{50} of vecuronium and pancuronium decreased with both increasing and decreasing temperature. [410] Succinylcholine was potentiated at 17° and 27°C but not at higher temperatures. [410] *d*-Tubocurarine showed a biphasic response. [410] The ED_{50} decreased by half at 32°C, and increased back to normal at 27°C, and decreased again at

Figure 12-43 (Figure Not Available) Clinical duration of action of vecuronium in 10 normothermic and in 10 hypothermic patients. Duration of action was significantly prolonged during hypothermia (62 ± 8 minutes compared with 28 ± 4 minutes at normothermia; mean ± SD). *(From Heier et al [404])*

17°C. It did not change with hyperthermia. Thus, the effect of hypothermia on neuromuscular junction sensitivity to block will vary with species studied, with different muscle relaxants, and at different temperatures.

Changes in temperature will affect interpretation of the results of monitoring neuromuscular blockade. The duration of action of vecuronium measured in an arm cooled to a skin temperature of 27°C is prolonged, and monitoring by post-tetanic count in that arm is unreliable. [411] In the same patient, TOF responses are different if the arms are at different temperatures, and the correlation of responses in the two arms becomes progressively poorer as the temperature difference between the arms increases. [412]

In summary, the effects of altered temperature on the course of neuromuscular blockade in humans seem to vary widely from one relaxant to another. As hypothermia invariably lengthens the duration of block (Fig. 12-43) (Figure Not Available) , maintenance of normal temperature both centrally and in the limb being monitored will promote improved precision of practice.

Drug Interactions

So many drugs have been shown to interact with neuromuscular blockers and/or their antagonists in animals that it is beyond the scope of this chapter to review them all. The reader is referred to excellent reviews on drug interactions for more detailed information. [413] [414] Some of the more important drug interactions are discussed in the following sections.

Antibiotics

Antibiotics can cause neuromuscular blockade in the absence of neuromuscular blocking agents, [414A] and many reports concerning enhancement of neuromuscular blockade from muscle relaxants by antibiotics have appeared in the literature. Some of the antibiotics have been shown to cause a magnesium-like depression of the evoked release of ACh (a prejunctional effect). Yet these same antibiotics exhibit postjunctional activity. [415] [416] [417] [418] Many investigators have attempted to classify antibiotics according to whether the prejunctional or postjunctional activity is dominant. There may, however, be no common mechanism of antibiotic-induced neuromuscular blockade as different antibiotics have their effect on neuromuscular blockade through different mechanisms. This makes recommendation of a standard therapy for antibiotic-augmented neuromuscular blockade difficult, leading some to conclude that continued mechanical ventilation is the preferred treatment in this clinical setting. [417]

All aminoglycosides can potentiate neuromuscular blockade. Antagonism of rocuronium-induced neuromuscular blockade has been reported to be more difficult following oral neomycin. [418A] Dupuis et al [419] found that gentamicin and tobramycin prolong a vecuronium- but not an atracurium-induced neuromuscular blockade. It is difficult to imagine that antibiotics would affect nondepolarizing muscle relaxants differently; and a more recent study [419A] demonstrated potentiation of atracurium-induced neuromuscular blockade by gentamicin. One approach to a prolonged neuromuscular blockade involving antibiotics is straightforward. Administer neostigmine up to 5 mg/70 kg. If this is ineffective in facilitating full recovery, ventilation should be controlled until the neuromuscular blockade terminates spontaneously. Calcium should not be used to hasten recovery of neuromuscular function for two reasons: the antagonism it produces is not sustained, and it may prevent the antibacterial effect of the antibiotics.

Magnesium and Calcium

The effects of magnesium- and calcium-induced alterations of neuromuscular blockade have been studied in animals and in humans. Magnesium sulfate, given for treatment of preeclampsia and eclamptic toxemia, enhances the neuromuscular blocking properties of both dTC and succinylcholine. [420] [421] Magnesium decreases the amount of ACh released from the motor nerve terminal, the depolarizing action of ACh on the postjunctional membrane, the excitability of the muscle fiber itself, and the amplitude of the end-plate potential. [422] Thus, magnesium enhances dTCinduced blockade by reducing ACh output from the motor nerve terminal and by reducing sensitivity of the postjunctional membrane.

Enhancement of succinylcholine block probably involves the same mechanisms; reduced transmitter output and reduced postjunctional membrane sensitivity will delay the return of normal function. Magnesium may also inhibit plasma cholinesterase.

Although calcium enhances the release of ACh from the motor nerve terminal and enhances excitation-contraction coupling in muscle, [423] it also stabilizes the postjunctional membrane. This stabilization may explain why calcium only partially antagonizes combined magnesium- and dTCinduced blockade. [421] Calcium is less effective in antagonizing combined magnesium- and succinylcholine-induced blockade and will augment a desensitization block from succinylcholine. This is probably explained by membrane stabilization. [424] A prolonged block should be anticipated when a relaxant is administered to a patient receiving magnesium. In these patients, neostigmine and calcium are only partially effective antagonists.

Local Anesthetics and Antiarrhythmics

In large doses given intravenously, most local anesthetics block neuromuscular transmission; in smaller doses, they enhance the neuromuscular block from both nondepolarizing and depolarizing muscle relaxants. [425] [426] Telivuo and Katz [425] found an additional decrease in twitch height and tidal volume from lidocaine, mepivacaine, prilocaine, and bupivacaine in patients partially paralyzed with alcuronium. Local anesthetics, therefore, particularly when given intravenously as

antiarrhythmic agents intraoperatively or postoperatively, may augment a residual neuromuscular blockade. The ability of neostigmine to antagonize a combined local anesthetic-relaxant neuromuscular blockade has not been studied.

In small intravenous doses, local anesthetics depress post-tetanic potentiation, and this is thought to be a neural, prejunctional effect. [427] With higher doses, local anesthetics block ACh-induced muscular contractions, and this suggests that local anesthetics have a stabilizing effect on the postjunctional membrane. [428] Local anesthetics also have a direct effect on the muscle membrane. They decrease the strength of contraction of a curarized or denervated muscle in response to a single shock. [429] Procaine has been shown to displace calcium from the sarcolemma and thus inhibit caffeine-induced contracture of skeletal muscle. [430] Most of these mechanisms of action probably apply to all the local anesthetics. Local anesthetics have actions on the presynaptic, postjunctional, and muscle membranes. Additionally, procaine inhibits plasma cholinesterase and may augment the effects of succinylcholine and mivacurium by decreasing their hydrolysis by the enzyme.

Several drugs used for the treatment of arrhythmias augment the block from muscle relaxants, particularly that of dTC. [431] For example, patients have become "recurarized" after receiving quinidine in the recovery room. These cases may represent unrecognized residual curarization augmented by the administration of quinidine. Quinidine potentiates the neuromuscular block from both nondepolarizing and depolarizing muscle relaxants. [432] Edrophonium is ineffective in antagonizing a nondepolarizing blockade after quinidine. In clinical doses, quinidine appears to act at the prejunctional membrane as judged by its lack of effect on ACh-evoked twitch. However, large, nonclinical doses of quinidine given intra-arterially produce a neuromuscular blockade of the depolarizing type, augmented by edrophonium. [433]

Any drug that influences conduction and the electrical properties of the heart may also influence ion transport at the neuromuscular junction and, therefore, the action of muscle relaxants. Examples of such drugs include betaadrenergic blockers and calcium channel blockers. Although there can be no doubt that these cardiovascular drugs may influence the action of muscle relaxants, the clinical significance of these interactions is probably minor.

Antiepileptic Drugs

Chronic phenytoin or carbamazepine therapy ac- celerates recovery from long-acting and intermediateacting relaxants. It has been well documented by Ornstein and colleagues [434] [435] [436] that metocurine-, doxacurium-, and vecuronium-induced blockades recover as much as 50 percent faster in patients receiving chronic anticonvulsants. Patients receiving two anticonvulsants were very resistant to the blocking effects of atracurium and recovered remarkably quickly from blockade (25-75% recovery index 2 minutes versus 8 minutes in control patients), [435] and those receiving only carbamazepine were not resistant to atracurium-induced block. [436A]

The mechanism of the relative resistance to nondepolarizing neuromuscular blockade in patients receiving anticonvulsants remains unclear, and CNS effects as well as peripheral effects of antiepileptic drugs have been suggested. The clearance of vecuronium in patients receiving carbamazepine is twice as high as it is in patients not receiving carbamazepine. [436B] This, coupled with the lack of a relationship between drug-induced resistance and alpha $_1$ -acid glycoprotein levels [436C] suggests a kinetic rather than a pharmacodynamic reason for the effects of anticonvulsant agents.

Calcium Channel Blockers

A number of observations in experimental animals and in human subjects suggest that any effect of calcium channel blockers on the evolution of neuromuscular blockade in patients is likely subclinical. No interaction between nifedipine and atracurium or vecuronium was found by Bell et al, [437] who studied patients under anesthesia with fentanyl and nitrous oxide. Neither nicardipine nor verapamil affected the recovery index of vecuronium in patients under halothane. [438]

Dantrolene

Dantrolene (Ch. 31), a drug used for the treatment of malignant hyperthermia, depresses skeletal muscle directly and also blocks excitation-contraction coupling. Although it does not block neuromuscular transmission, the mechanical response will be depressed without demonstrating any effect on the electromyogram. [439] [440] The effects of nondepolarizing muscle relaxants are enhanced by dantrolene. [441]

Diuretics

In patients undergoing renal transplantation, the intensity and duration of dTC neuromuscular blockade was increased following a dose of furosemide (1 mg/kg intravenously). [442] This has been investigated further with the rat diaphragm and cat soleus preparations. In the rat diaphragm, the concentration of dTC required for neuromuscular blockade is markedly reduced at clinically relevant doses of furosemide. This diuretic has an effect on the nerve terminal (presynaptic), probably relating to the cyclic nucleotide system.

Furosemide appears to inhibit the production of cyclic adenosine monophosphate. The breakdown of ATP is inhibited, resulting in a reduced output of transmitter, causing enhanced dTC blockade. This effect has been documented as clinically significant. [442]

By contrast, mannitol appears to have no effect on a nondepolarizing neuromuscular blockade. Furthermore, increasing urine output by administration of mannitol or other osmotic or tubular diuretics has no effect on the rate at which dTC and presumably other muscle relaxants are eliminated in the urine. [443] However, this lack of effect on the excretion of dTC should not be surprising. Urinary excretion of all relaxants that are long-acting depends primarily on glomerular filtration. Mannitol is an osmotic diuretic that exerts its effects by altering the osmotic gradient within the proximal tubules so that water is retained within the tubules. An increase in urine volume in patients with adequate glomerular filtration, therefore, would not be expected to increase excretion of muscle relaxants.

Azathioprine

Azathioprine, an immunodepressant drug used in renal transplantation, has a minor antagonistic action on muscle relaxant-induced neuromuscular blockade. [444] [445]

Interactions Among Nondepolarizing Relaxants

The authors of this chapter believe there is little reason to combine nondepolarizing relaxants, particularly as few of the possible multiple combinations [446] [447] have been studied for the presence of either potentiation or a simple additive effect. The original clinical reason for combining pancuronium and metocurine was the resulting lack of cardiovascular side effect of the combination. [448] [449] Vecuronium, pipecuronium, and doxacurium, all with minimal cardiovascular side effects, are now available, making the original combination seem less appropriate.

Although little has yet been published on the subject, it is important to consider the sequential administration of long- and short-acting nondepolarizers.

The general rule is the following: the changeover from one drug to another, when the durations are dissimilar, is a matter of simple kinetics. Three half-lives will be required for a clinical changeover (so that 95% of the first drug has been cleared) and for the block duration to begin to take on the characteristics of the second drug. Consequently, the change in blocking characteristics (most noticeable as change in the speed of recovery) will occur within only 10 to 15 minutes following mivacurium but will require 4 to 6 hours if change from long- to short-acting drug is attempted. A few pertinent examples follow.

Change from Short- to Intermediate- or Long-Acting Drug

When the short-acting nondepolarizer mivacurium is given for tracheal intubation with the intention of continuing maintenance of relaxation with a longer-acting drug, the following approach is recommended. A maintenance dose of the long-acting muscle relaxant (e.g., 0.5 mg [0.01 mg/kg] of doxacurium) should be given when the TOF response has begun to recover (e.g., to two or three twitches visible). The clinician will note that the duration of effect of this first maintenance dose is much shorter than commonly observed. Only after the second maintenance dose of longer-acting muscle relaxant will the expected longer duration establish itself. This changeover, however, does make sense in clinical practice, more so if the change intended is from short- to intermediate-acting drug than if the change is from short-

to long-acting drug. Definitive studies are needed to support these considerations.

Change from Longto Short-Acting Drug

When relaxation has been maintained, for example, for 3 hours with dTC or any other long-acting relaxant, if the clinician wishes to administer a maintenance dose of mivacurium to obtain a shorter duration of block, a very small dose should be given (10-20 mug/kg). The clinician will note that this dose will have an unexpectedly long duration of action, nearly as though another small dose of dTC were given. This should not be surprising; the established kinetics are those of the long-acting drug, with its 1½ to 2-hour half-life. Addition of a small amount of mivacurium at this point will have very little effect on this kinetic pattern. Therefore, this change of drug sequence makes little clinical sense and is probably not worth attempting.

"Priming" with a Long-Acting Muscle Relaxant

If a priming dose of long-acting muscle relaxant (e.g., 10 mug/kg of pancuronium, 50 mug/kg of dTc, 5 mug/kg of doxacurium) is given prior to an intubating dose of mivacurium (0.25 mg/kg), then the clinician will note a much longer-than-usual duration of action of mivacurium. This should be expected, because the priming dose of the long-acting drug still has a half-life of 1½ to 2 hours. Therefore, the subclinical effect of the priming dose of the long-acting drug will be additive to the action of mivacurium throughout the normal course of action of the long-acting drug, in effect lengthening the duration of action of mivacurium considerably. Consequently, priming with a long-acting or intermediate-acting muscle relaxant prior to mivacurium (or even prior to an intermediate-acting drug) does not seem to make any clinical sense, unless the intent is to lengthen the action of the endotracheal intubating drug.

In summary, few actual measurements have been made of the consequences of changing from one nondepolarizer to another with a different duration of action. The switch from the short-acting mivacurium to the longer-acting drugs seems to make the most clinical sense, because here the kinetic changes are most appropriate to clinical practice patterns. Change from one of the relaxants of intermediate duration (atracurium, vecuronium, cisatracurium, or rocuronium) to one of the long-acting relaxants also seems reasonable, although the time differences will not be as noticeable. Certainly, whenever such changeover is undertaken, careful monitoring with a peripheral nerve stimulator is mandatory. Clinical studies are certainly needed to better define these scenarios.

ANTAGONISM OF RESIDUAL NEUROMUSCULAR BLOCKADE

The criteria for determining whether a block has been adequately antagonized have been described in the section *Monitoring Neuromuscular Function*. The drugs used to antagonize residual neuromuscular block, neostigmine, edrophonium, and pyridostigmine are anticholinesterases. They antagonize a nondepolarizing neuromuscular blockade primarily by increasing the concentration of ACh at the muscle end plate mainly by inhibition of acetylcholinesterase. In addition, they may also increase release of ACh from the motor nerve terminals, block neural potassium channels, and have a direct agonist effect. [449A] The reader should consult Chapter 22 and the following review articles for more details regarding the mechanisms of action of these antagonists. [450] [451]

Major Determinants of Speed and Completeness of Reversal

Antagonism of nondepolarizing block requires a certain amount of time. Reversal occurs at a rate that depends primarily on five factors: (1) depth of block at the time of administration of the antagonist, (2) the particular antagonist administered, (3) the dose of the antagonist, (4) the rate of spontaneous recovery from the muscle relaxant, and (5) the concentration of the inhaled anesthetic present during reversal.

Depth of Block

The deeper the block, the longer the time required for restoration of adequate neuromuscular function. [451A] [451B] [451C] Figure 12-44 (Figure Not Available) presents data for antagonism of pancuronium block by a standard dose of 2.5 mg (about 35 mug/kg) of neostigmine. The data shown in the figure are for antagonism of the *single twitch response* of the adductor pollicis, a peripheral muscle. Note that antagonism of TOF to 0.7 or more would take longer. Figure 12-44 (Figure Not Available) shows that the relationship of reversal time (speed of reversal) to depth of block is apparently hyperbolic, with a "knee" in the curve occurring at 80 to 90 percent twitch inhibition. At block depth of less than 80 percent, only 8 to 12 minutes are required for antagonism of pancuronium. Deeper blocks require much longer times (15-30 minutes) for adequate reversal. Therefore, it is recommended that one bear in mind the longer period (15-30 minutes), with the further understanding that even longer time may be required for restoration of TOF ratio to more than 0.7 when block by longacting drugs is being antagonized.

The maximum antagonistic effect of neostigmine occurs in about 10 minutes or less. [452] [452A] If adequate recovery does not occur within this time, then subsequent recovery is slow. For profound vecuronium-induced block in which no twitch recovery has occurred, the administration of neostigmine, 70 mug/kg, produces an initial reversal that falls far short of adequate recovery. [453] Subsequent recovery is at the same rate as spontaneous recovery and is due to the decrease

Figure 12-44 (Figure Not Available) Correlation between twitch height when a bolus of neostigmine (2.5 mg) was given intravenously and time it took for twitch height to return to its control height. *(From Katz [451A])*

in plasma concentration of vecuronium as the drug is eliminated. [453] Administration of a second dose of neostigmine has no further effect on recovery. [453]

If the block at the time of neostigmine administration is sufficiently deep that adequate recovery does not occur within 10 minutes, then the time until full recovery does occur will depend on the inherent duration of action of the relaxant. [451C] With long-acting drugs this period of inadequate neuromuscular function can be 30 to 60 minutes or longer, whereas with intermediate-duration drugs it will be much shorter (e.g., 15-30 minutes). [453A]

Antagonist Administered

Under conditions of moderate depth of block (e.g., two to three twitches palpable by TOF), the order of rapidity of antagonism of residual blockade by anticholinesterases is edrophonium > neostigmine > pyridostigmine. [452] [453B] For this reason, and because of its lesser atropine requirement, edrophonium regained popularity as an antagonist during the 1980s. [452] However, Rupp et al [454] found that edrophonium is not as effective as neostigmine in antagonizing profound blockade of greater than 90 percent twitch depression (only one twitch palpable by TOF). When the dose of edrophonium was increased from 0.5 to 1.0 mg/kg, edrophonium was more active but possibly still not as effective as neostigmine. [454] To be equivalent to neostigmine 40 mug/kg as an antagonist of deep vecuronium blockade, edrophonium has to be administered in a dose of 1.5 mg/kg. [454A]

Donati et al [455] showed that the relative potencies of edrophonium and neostigmine differ at various intensities of block (Fig. 12-45) (Figure Not Available) . In fact, edrophonium becomes less potent with respect to neostigmine as the depth of blockade becomes more intense. In other words, the dose-response curves are not parallel and become increasingly divergent (i.e., the dose ratio increases) as the depth of blockade intensifies. This difference does indicate that edrophonium may be less effective than neostigmine at very deep levels of blockade.

Figure 12-45 (Figure Not Available) First twitch height (logit scale) versus dose (log scale) 10 minutes after administration of neostigmine and edrophonium given at either 1 percent (99% block) or 10 percent (90% block) first twitch recovery. Thin dashed lines represent the standard error of estimate for the mean. *(From Donati [455])*

Dose of Antagonist

Larger doses of anticholinesterases should antagonize neuromuscular blockade more rapidly and more completely than smaller doses. This relationship is true up to the point of maximum effective dose, beyond which further amounts of anticholinesterase will not produce any greater antagonism. For neostigmine, this maximum dosage is in the range 60 to 80 mug/kg. [453] [455A] For edrophonium, this dose is in the range 1.0 to 1.5 mg/kg. [454] [454A] The maximum effect of the anticholinesterase occurs within 10 minutes; further recovery to normal function subsequently occurs at a rate that is largely dependent on the rate of spontaneous recovery. [453] [455B]

One of the better recent demonstrations of the relationship of dose of neostigmine to speed of reversal is the work of Donati et al [456] (Fig. 12-46) (Figure Not Available) , who studied reversal of 90 percent block induced by either dTC or pancuronium. They showed that increasingly greater amounts of antagonism of

Figure 12-46 (Figure Not Available) Rate of antagonism of 90 percent pancuronium block by increasing doses of neostigmine. Note that even after 0.05 mg/kg of neostigmine, only 80 percent twitch height had been reached within 10 minutes. *(From Donati [456])*

neuromuscular block occurred over the course of 10 minutes as neostigmine dosage was increased from 5 to 50 mug/kg. Note, however, that even after 50 mug/kg, the twitch had reached only 80 percent of normal strength 10 minutes after neostigmine administration.

Mixing or combining antagonists is not advisable. Neostigmine and edrophonium do not potentiate each other; in fact, their effects in combination may not even be

additive. [457] Therefore, when inadequate reversal occurs, one should not be tempted to add a different anticholinesterase but should ensure only that the maximum dose of the original drug has been administered. Ventilation should then be supported until adequate neuromuscular function is achieved, e.g., head lift. If function is not adequate 30 to 60 minutes following antagonist administration, then an additional dose of antagonist (about half the original dose) may be given. This time-frame is somewhat less than one half-life of any of the antagonists.

Rate of Spontaneous Recovery of the Relaxant

Following administration of an anticholinesterase, two processes contribute to recovery of neuromuscular function. The first is antagonism induced by the effect of the anticholinesterase at the neuromuscular junction; the second is the natural process of decrease in plasma (and hence neuromuscular junction) concentration of the relaxant consequent on its elimination (spontaneous recovery). [451C] [451B] As a result, the more rapid the elimination of the relaxant, in general, the faster the recovery of adequate neuromuscular function following administration of an antagonist (Fig. 12-47) (Figure Not Available) . A clear illustration of this principle is the difference in antagonizing the block induced by relaxants with an intermediate versus a long duration of action. The plasma concentrations of drugs with an intermediate duration of action

Figure 12-47 (Figure Not Available) Comparative mean speed of antagonism by neostigmine of neuromuscular blockade induced by long-acting agents (doxacurium, pancuronium, pipecuronium), intermediate-acting drugs (atracurium and others), and the short-acting agent mivacurium. Antagonism is more rapid as processes of clearance increase (see text). *(From Savarese [457A])*

decrease more rapidly than those with a long duration, [457B] and consequently recovery of neuromuscular function is more rapid. [452A] [458] [458A] The incidence of inadequate neuromuscular function in the postoperative period is less with intermediate-acting than with long-acting relaxants. [453A] [459] This difference in speed of reversal between intermediate- and long-acting drugs is due to the effect of different rates of spontaneous recovery and not due to a difference in response to neostigmine. [459A] The proof is that when neostigmine is administered to antagonize a stable level of block maintained by continuous infusion of either vecuronium or pancuronium, the rate and degree of recovery are similar in the case of each relaxant. [459A]

The interaction of spontaneous recovery and anticholinesterase-induced reversal of mivacurium is more complex. The inherent rate of spontaneous recovery of mivacurium is more rapid than that of any other nondepolarizing relaxant because of its rapid hydrolysis by plasma (butyryl) cholinesterase. [459B] Neostigmine-induced reversal of mivacurium is similar to or faster than that of atracurium. [459B] [459C] In the circumstance of profound (<3% twitch recovery) mivacurium-induced block, the administration of neostigmine may possibly prolong recovery. [460] [460A] This complexity exists in theory because neostigmine has two major effects relevant to mivacurium. First, it inhibits acetylcholinesterase at the neuromuscular junction and facilitates recovery. Second, it inhibits plasma cholinesterase, the enzyme responsible for the metabolism of mivacurium, and slows the normally rapid decrease in the plasma concentration of mivacurium. [460B] A similar effect is less likely with edrophonium because edrophonium has little inhibitory effect on plasma cholinesterase. [460C] Regardless of the complexity of the pharmacologic interactions, if there is already easily detectable recovery (twitch height 10% or greater), then administration of neostigmine 20 to 40 mug/kg, or edrophonium 0.3-0.5 mg/kg, will certainly accelerate recovery from mivacurium. [450] [461] [461A] [461B]

It has been suggested that routine administration of an anticholinesterase may often be omitted because spontaneous recovery from mivacurium is so rapid. [461C] However, this strategy may possibly lead to inadequate recovery and postoperative weakness *unless enough time is allowed (at least 20 minutes) for spontaneous recovery.* [461] [461A] The authors advise against attempting anticholinesterase-induced reversal of mivacurium when no twitch or TOF responses are present and suggest that small doses of neostigmine or edrophonium should be used if mivacurium administration has continued till near the end of the surgical procedure, and acceleration of already-present spontaneous recovery is desired.

Because mivacurium is extensively metabolized by plasma cholinesterase, its recovery might, in theory, be made more rapid by the administration of exogenous human butyryl-cholinesterase. The administration of purified human cholinesterase does produce some antagonism of mivacurium-induced block, [462] but it is ineffective in profound block [462A] and no better than edrophonium alone. [462B] It may be justified to administer purified butyrylcholinesterase to patients with genetic abnormality of the enzyme who have prolonged block, [463] but this therapy has yet to be adequately tested and is expensive.

Concentration of Inhaled Anesthetic

Several recent studies have documented that antagonism of residual block is actually retarded by anesthetizing concentrations of anesthetic vapors (this does make sense, because the nondepolarizers are potentiated by the potent vapors). Thus, for example, Delisle and Bevan [400B] showed that pancuronium reversal by neostigmine under enflurane occurred more slowly than under nitrous oxide and intravenous anesthetics. [463A] However, a study by Baurain [464] showed that the situation is complex. The presence of isoflurane during the reversal of vecuronium by neostigmine resulted in a lower TOF ratio but a similar degree of fade to 50 Hz tetanus and a lesser degree of fade at 100 Hz, compared with an anesthetic without vapor. [464] The current state of knowledge is incomplete, but there is evidence that isoflurane may impair some, but not all, parameters of neuromuscular recovery after neostigmine reversal of neuromuscular block. [464] [465] In any event, it is good clinical practice to reduce concentrations of potent anesthetic vapors as much as possible to facilitate reversal at the end of a case.

Other Factors That May Interfere With Antagonism

It is not advisable to administer further antagonist if maximal doses of edrophonium (1.5 mg/kg), neostigmine (70 mug/kg), or pyridostigmine (350 mug/kg) fail to antagonize residual block. [454A] [455A] These doses inhibit acetylcholinesterase completely, and if they fail to fully antagonize residual block, the most likely cause of the inadequate antagonism should be sought. Some of these additional potential causes follow.

Acid-Base State

Both metabolic and respiratory acidosis may augment a nondepolarizing neuromuscular blockade, but only respiratory acidosis prevents adequate antagonism. [453B] [467] [467A] In other words, the probability of achieving adequate antagonism of a nondepolarizing neuromuscular blockade in the presence of significant respiratory acidosis (Pa CO_2 greater than 50 mm Hg) is low. For example, if a patient hypoventilates in the recovery room, attempts to antagonize a residual block may fail. Administration of narcotics to relieve pain may, by producing hypoventilation, increase the likelihood of this adverse event. Such a sequence contains an element of potential undesirable and potentially dangerous positive feedback in which respiratory depression produces more acidosis and greater block--hence, more respiratory depression, etc.

Although metabolic acidosis might also be predicted to prevent antagonism by neostigmine, this theory has not been substantiated. [453B] [467] [467A] To the authors' surprise, metabolic alkalosis, but not metabolic acidosis, prevented neostigmine antagonism of dTC and pancuronium. [453B] [466] [467] These results suggest that extracellular hydrogen ion concentration (pH) per se may not be as important as changes in electrolytes and intracellular pH. Because so many factors are involved,

the simplest and most obvious objective of the clinician should be the maintenance of a normal acid-base state in the patient.

Electrolyte Imbalance

Although it has been the subject of several review articles, [468] few data are available on the effect of electrolyte imbalance on a nondepolarizing neuromuscular blockade and its antagonism by neostigmine. Low extracellular concentrations of potassium do enhance the blockade from nondepolarizing muscle relaxants and diminish the ability of neostigmine to antagonize the blockade. This effect is based on the increase in end-plate transmembrane potential that results from a higher ratio of intracellular to extracellular potassium. Thus, a decrease in extracellular potassium causes hyperpolarization and produces resistance to depolarization. Patients with an imbalance in potassium may have other diseases or injuries that alter their response to muscle relaxants (e.g., patients with burns). Cohen [469] and Feldman [468] speculated that, in chronic diseases, both intracellular and extracellular potassium is depleted with little net effect on transmembrane potential. Therefore, the response to muscle relaxants and their antagonists should be normal. However, the muscle transmembrane potentials are changed in patients who are

severely ill or bedridden for a few days. [470] Also, severe dehydration should concentrate the relaxant present in plasma, in effect decreasing the volume of distribution, thereby increasing muscle relaxant activity. In an animal model of chronic hypokalemia, cats were given a diuretic without potassium supplement for 15 days. Less pancuronium was required for neuromuscular blockade and more neostigmine for antagonism. [470A] Even though the differences were small, the blockade was always antagonized completely. Assuming that this animal model approximates the clinical situation, changes in potassium appear to be of relatively minor consequence with respect to the clinical question of adequacy of reversal.

Other Factors

The calcium channel blocker verapamil will potentiate nondepolarizing neuromuscular blocking drugs and may produce difficulty with obtaining adequate reversal. [470B] [470C] [471] When attempting reversal of neuromuscular blockade in patients receiving verapamil, edrophonium may be more effective than neostigmine. [470B] [470C] Other factors that may interfere with antagonism are hypothermia or the administration of antibiotics, particularly of the aminoglycoside or polypeptide classes. [453A] [455A] [471A] [471B] In the case of the antibiotics, the administration of an anticholinesterase may in fact deepen the blockade. [453A]

In general, any significant perturbation of homeostasis may be regarded as potentially interfering with antagonism of residual neuromuscular blockade and should raise a level of suspicion that reversal may prove to be inadequate. In the situation where reversal appears incomplete, and maximum doses of the chosen anticholinesterase have been administered, the following management will provide the best route to a safe and trauma-free outcome for the patient: (1) leave or reinsert the endotracheal tube in the patient's trachea; (2) if respiration is inadequate, support ventilation; (3) explain the situation to the patient, and administer a sedative/anxiolytic and, if indicated, an analgesic; (4) correct metabolic and acid-base disorders and return the patient's temperature to normal. Continue these supportive measures until there is good clinical evidence for adequate recovery of neuromuscular function, at which point the patient's trachea may be extubated. Clinical criteria should be used to assess adequacy of recovery; monitoring with a nerve stimulator may give misleading results, particularly if aminoglycosides have been administered. [472] This management strategy is simple, safe, and, if handled appropriately, with proper attention to sedation and personal attention to psychologic support, should prove to be minimally traumatic for the patient. Other approaches involving calculations of half-lives of the relaxants and antagonists to allow repeat doses of the latter to be given may present other potential problems. The administration of calcium is unlikely to result in a more rapid and safe resolution of the problem and is no longer recommended.

Cardiovascular Effects of Antagonism

Because only the nicotinic effects of edrophonium, neostigmine, and pyridostigmine are desired, the muscarinic effects must be blocked by atropine or glycopyrrolate. [449A] Atropine induces its vagolytic effect much more rapidly than does glycopyrrolate. To minimize cardiovascular changes, the authors believe atropine is better suited together with the rapid-acting edrophonium, [472A] and glycopyrrolate is better suited with the slower-acting neostigmine and pyridostigmine. [472B] In general, 7 to 10 mug/kg of atropine should be given with 0.5 to 1.0 mg/kg of edrophonium. [452] Glycopyrrolate (7-15 mug/kg) should be given with neostigmine (40-70 mug/kg). Administration of atropine with pyridostigmine will induce an initial tachycardia, [473] and giving glycopyrrolate with edrophonium may result in an initial bradycardia unless it is administered at least 1 minute earlier. [473A] Arrhythmias can occur, [473A] [473B] [474] [475] [476] and anticholinesterases should be used with caution in patients with autonomic neuropathy. [473B] When cardiac arrhythmias are a concern, glycopyrrolate may be preferable to atropine, [476] and the anticholinesterases and anticholinergics may be administered over a longer time (e.g., 2-5 minutes) in order to help reduce the incidence and severity of the disorders of rhythm.

Pharmacokinetics of Neostigmine, Pyridostigmine, and Edrophonium

The pharmacokinetics of edrophonium, neostigmine, and pyridostigmine are summarized in Table 12-15 . [477] [478] [479] [479A] Several important clinical conclusions can be derived from these data.

1. The longer duration of action of pyridostigmine probably has a pharmacokinetic basis in view of the longer elimination half-life. [477] [478]

2. By comparing elimination half-lives in patients with and without renal failure, the authors conclude that renal excretion accounts for about 50 percent of excretion of neostigmine and about 75 percent of that of pyridostigmine and edrophonium. Of prime importance clinically is that renal failure decreases plasma clearance of neostigmine, pyridostigmine, and edrophonium as much as, if not more than, that of the long-acting relaxants such as pancuronium and dTc. Therefore, if proper doses of anticholinesterase drugs are given and overdoses of muscle relaxants are avoided, renal failure should not be associated with "recurarization." [477] [478] This remote possibility is further diminished if the clinician restricts relaxant administration to intermediate- or short-acting drugs in patients with renal failure. There is no longer any justification for giving long-acting drugs, which are excreted almost exclusively by the kidneys, to patients with markedly decreased renal function.
3. Edrophonium was once believed to be an unsuitable antagonist in clinical practice because its duration of action might be too short. However, when larger doses (i.e., 0.5-1.0 mg/kg) are given, sustained antagonism of a nondepolarizing neuromuscular blockade results. [480] [481] In fact the elimination half-life of edrophonium is similar to that of neostigmine or pyridostigmine [479A] (see Table 12-15) . That edrophonium has a quicker onset of action and probably fewer side effects may justify more frequent use of this drug when antagonizing a nondepolarizing neuromuscular blockade.

TABLE 12-15 -- Pharmacokinetics of Neostigmine (N), Pyridostigmine (P), and Edrophonium (E) in Patients Without and With Renal Failure

MEASURE	WITHOUT RENAL FAILURE			WITH RENAL FAILURE		
	N	P	E	N	P	E
Distribution half-life (t½alpha, min)	3.4	6.7	7.2	2.5	3.9	7.0
Elimination half-life (t½beta, min)	77	113	110	181	379	304
Volume of central compartment (L/kg)	0.2	0.3	0.3	0.3	0.4	0.3
Total plasma clearance (mL/kg/min)	9.1	8.6	9.5	4.8	3.1	3.9

Data from Cronnelly et al [477] ; Cronnelly et al [478] ; Morris et al [479] ; Morris et al [479A]

Mild hypothermia (i.e., 34-35°C), as commonly occurs intraoperatively, has detrimental effects on the pharmacokinetics of neostigmine. The clearance is decreased from 16.2 mL/kg/min at 36.5°C to 13.5 mL/kg/min at 34.5°C. [481A] Also, the onset of peak effect is prolonged by mild hypothermia from 4.2 to 5.5 minutes. [481A] The peak effect and duration of effect were unchanged by hypothermia. Thus, if hypothermia has any influence on the effectiveness of neostigmine-induced reversal, it is more likely to be due to the effect of temperature on the muscle relaxant (e.g. prolonged duration of action [481B]) than to the pharmacology of neostigmine.

The pharmacokinetics of the anticholinesterases depend on several factors, including metabolism as well as distribution and elimination. In the case of neostigmine, a carbamylated complex with acetylcholinesterase is formed, [481C] [481D] and it is the rate of dissociation of neostigmine from this complex, i.e., its metabolism, that is probably the major determinant of its duration of action. The decay in its plasma concentration, i.e., its distribution and elimination, [481E] may not be as pertinent a determinant of the duration of action of the drug.

DISEASES THAT MAY ALTER MUSCLE RELAXANT ACTION

The following diseases show complex pathophysiology. Only that aspect directly relating to the use of muscle relaxants is discussed.

Myasthenia Gravis

Excellent reviews of this topic are presented in references [482] [483] [484] [485] . Because myasthenia is an autoimmune disease where there is decreased postjunctional receptor substance, myasthenic patients are often extremely sensitive to nondepolarizing relaxants and are usually somewhat resistant to succinylcholine. [486] [487] Not all the musculature is affected to the same degree. Careful monitoring with a peripheral nerve stimulator is mandatory when relaxants are to be given to these patients; more effective management must include (1) a preoperative consultation with the patient's neurologist to learn of the recent history and progress of management; (2) knowledge of current medications (usually an anticholinesterase such as pyridostigmine, also commonly referred to by the trade name Mestinon) and/or corticosteroids; (3) counseling and preparation of the patient for possible postoperative endotracheal intubation and mechanical ventilation; (4) monitoring at several sites with a nerve stimulator, such as at the ulnar nerve-adductor pollicis, the facial nerve and musculature, and the peroneal nerve-extensor hallucis-tibialis anterior (dorsiflexion of the toe and ankle); and (5) clinical judgment of adequacy of neuromuscular function when a decision to discontinue mechanical ventilation and to extubate the trachea is being considered postoperatively. Once again, at this point, consultation with the patient's neurologist is mandatory in order to ensure smooth transition and continuation of management.

Often, surgical relaxation can be provided for the myasthenic patient using only a potent inhaled anesthetic. However, many patients are very well compensated on medication and show surprisingly adequate neuromuscular function and a virtually normal response to nondepolarizing relaxants. It may be safer and more convenient to intubate the trachea and to provide abdominal relaxation with the aid of relaxants in these patients than to use deep anesthesia.

Short-acting or intermediate-acting drugs should be used in low dosage as guided by monitoring with a nerve stimulator. About one-tenth to one-fifth the ED_{95} should be given as a test dose to estimate the patient's requirement. Again, individual response will vary from extreme sensitivity, such that the test dose is all that is needed, to nearly normal relaxant requirements.

Because the myasthenic patient is usually receiving pyridostigmine therapy, the medication should be continued preoperatively. Pyridostigmine will modify the response to relaxants as follows: (1) the sensitivity to nondepolarizers will be diminished; (2) the response to succinylcholine or mivacurium may be lengthened somewhat, because therapeutic levels of pyridostigmine may partially inhibit pseudocholinesterase; and (3) reversal of residual block at the end of the case may be ineffective because much acetylcholinesterase inhibition already exists as a result of chronic pyridostigmine therapy. Consequently, it is probably safer to allow spontaneous recovery from relaxation postoperatively while continuing supportive mechanical ventilation. This recommendation is consistent with the authors' experience and is in agreement with the literature. [488] [489] Conservatism in postoperative management of the disease is mandatory because surgery and anesthesia may exacerbate the myasthenic state in an unpredictable manner. [488] [489]

Myasthenic Syndrome (Eaton-Lambert Syndrome)

Eaton-Lambert syndrome is an association between carcinomatous conditions (especially oat cell carcinoma of the bronchus) and motor neuropathy and clinically resembles myasthenia gravis. The disease is differentiated from myasthenia by electromyography, in which facilitation of the electromyogram (EMG) response, rather than fade, occurs during high-frequency (30-50 Hz) stimulation. These patients are unusually sensitive to both nondepolarizing and depolarizing muscle relaxants.

Myotonia

The myotonic syndromes include myotonia congenita, myotonia dystrophica, and paramyotonia congenita. With the latter condition, myotonia appears only on exposure to cold.

Myotonic dystrophy (atrophica), the most common of the three, is an inherited, autosomal-dominant disease. Clinical features include weakness and wasting of the facial, cervical, and proximal limb muscles; frontal baldness; cataracts; gonadal atrophy; thyroid nodules; endocrine failure; and voluntary and percussion myotonia. Continuous, low-voltage activity with high-voltage, fibrillation-like potential bursts will be evident on the EMG. A mechanical stimulus will evoke a burst of rhythmic EMG potentials at 90 to 100/s, which eventually slows to low-voltage activity. Cardiac conduction defects and myocardial failure are commonly present as the disease progresses. Respiratory involvement, secondary to skeletal muscle weakness, is also common. While the carbon dioxide response curves are normal, mechanical ability to ventilate is impaired, as reflected by a diminished vital capacity and forced vital capacity in 1 second, as well as reduced maximum expiratory force. Some patients have weakness of pharyngeal muscles with recurrent aspiration pneumonitis. The onset of the disease is most common in the 2nd to 4th decade and progresses to muscular atrophy in later years.

Anesthetic and operative mortality is increased for several reasons. The most common complication is postoperative respiratory failure due to decreased mechanical ability, which interferes with deep breathing and coughing. Intraoperatively, cardiac conduction abnormalities may cause hemodynamic instability. Generalized myotonia may follow administration of succinylcholine in some patients. Occasionally, the severity of the myotonic response has precluded attempts to control ventilation. Although it is difficult to collect a large clinical experience, [490] Mitchell et al [491] thoroughly evaluated three patients with myotonia dystrophica and their response to muscle relaxants and concluded that (1) the response to nondepolarizing muscle relaxants is normal, (2) patients with myotonia are more likely than normal patients to develop apnea after administration of sedative or anesthetic drugs, and (3) the use of depolarizing muscle relaxants is hazardous because marked generalized contracture of skeletal muscle may develop, preventing adequate airway maintenance and ventilation. The use of anticholinesterases may exacerbate myotonia. This last point, though, is not well documented and was not confirmed by Mitchell et al. Should myotonia develop intraoperatively, nondepolarizing neuromuscular blocking drugs will not attenuate it, as the disease is primarily a disorder of the muscle membrane. Myotonia may also develop in response to percussion or to shivering postoperatively. Local infiltration of the involved muscles with local anesthetics may help to attenuate percussion myotonia. Quinine and procainamide have been used for generalized myotonia.

Familial Periodic Paralysis

Familial periodic paralysis is associated with hyperkalemia, hypokalemia, or normokalemia and is characterized by intermittent attacks of skeletal muscle weakness and flaccid paralysis, usually sparing the bulbar musculature. With the hypokalemic type, intravenous fluids should be chosen to avoid a large carbohydrate or salt load and should treat hypokalemia. Postoperatively, if such a patient is weak, the weakness is usually secondary to hypokalemia. Muscle relaxants should generally be avoided, although Siler and Discavage [492] noted a normal response to succinylcholine. By contrast, in hyperkalemic patients, carbohydrate stores should be

maintained with dextrose-rich, potassium-free intravenous solutions. Muscle relaxants, especially succinylcholine, should be avoided. Succinylcholine can cause myotonia in these patients. [493]

Upper and Lower Motor Neuron Disease

The potential hazards of giving succinylcholine to patients with upper or lower motor neuron disease is described earlier in this chapter. These patients' response to nondepolarizing

muscle relaxants is exaggerated. This was well documented by Rosenbaum et al, [494] who found that dTC (1.5 mg) given over 30-minutes to a man with amyotrophic lateral sclerosis caused difficulty with speech and swallowing.

Lower motor neuron denervation results in a resistance to nondepolarizing muscle relaxants because of a proliferation of ACh receptors. [495] By administering small doses of nondepolarizing muscle relaxants plus monitoring with a peripheral nerve stimulator, the anesthesiologist should be able to avoid significant problems in these patients. However, monitoring with a peripheral nerve stimulator may not be reliable in patients with an upper motor neuron lesion because a paretic limb is relatively resistant to nondepolarizing block. [496] [497] Monitoring of the unaffected limb and other confirmatory clinical measures of depth of neuromuscular blockade and adequacy of recovery should be undertaken in these patients.

Burns

Patients with burn injuries have abnormal responses to both depolarizing and nondepolarizing muscle relaxants.

The rise in serum potassium that normally follows succinylcholine administration is markedly exaggerated in burned victims. [498] Potassium levels as high as 13 mEq/L, resulting in ventricular tachycardia, fibrillation, and cardiac arrest, have been reported. [499] [500] [501] The mechanism of this exaggerated response to depolarizing relaxants seems to be similar to that in victims of denervation injuries. Apparent proliferation of extrajunctional acetylcholine receptors occurs. [502] [503] Stimulation of these receptors by succinylcholine causes massive potassium release sufficient to cause cardiac arrhythmias and death.

When in the course of the burn injury this hyperkalemic response appears and later subsides remains unclear. Succinylcholine has been safely administered within 24 hours of a burn injury. Following this initial 24 hours, however, sufficient alteration in muscle response may have occurred such that the use of succinylcholine is best avoided. The magnitude of the hyperkalemic response does not appear to closely correlate with the magnitude of the burn injury. A marked hyperkalemic response has been noted following only an 8 percent total body surface area burn. [502] The length of time during which a burn patient may be at risk for the hyperkalemic response is also not well defined. Whereas susceptibility to hyperkalemia may persist only several weeks to months, an altered response to nondepolarizing relaxants has been reported in one patient as long as 463 days after the thermal injury. [504]

The time course of abnormal muscle membrane function corresponds with that of the healing process. Once normal skin has regrown, and any infection subsides, return of normal ACh receptor populations appears to occur. [502] Normal responses to succinylcholine have been demonstrated in burn patients studied 3 years postinjury. [502] A conservative guideline therefore would be to avoid the use of succinylcholine in patients 24 to 48 hours following a thermal injury and for at least 1 to 2 years after the burned skin has healed.

TABLE 12-16 -- Reported Indications for Use of Muscle Relaxants in the ICU

Facilitate mechanical ventilation
Facilitation of endotracheal intubation
Enable patient to tolerate mechanical ventilation
High pulmonary inflation pressures, e.g., acute respiratory distress syndrome
Hyperventilation for elevated intracranial pressure
Facilitate therapeutic or diagnostic procedures
Tetanus
Status epilepticus
Reduce oxygen consumption
Abolish shivering
Reduce work of breathing

MUSCLE RELAXANTS IN THE INTENSIVE CARE UNIT

Currently, neuromuscular blocking drugs are used in many intensive care units (ICU). [505] [506] [507] Pancuronium and vecuronium were the most commonly used nondepolarizing drugs, but atracurium, cisatracurium, rocuronium, and doxacurium are now are being used commonly. [505] [508] [509] [510] The indications for use of muscle relaxants in the ICU are outlined in Table 12-16 . There are few data to support their use, and evidence for a beneficial effect on pulmonary function or patient oxygenation is inconclusive. [511] [511A] [511B]

Complications associated with both short- and long-term use of muscle relaxants for ICU patients are outlined in Table 12-17 . The specific, short-term side effects of muscle relaxants are covered elsewhere in this chapter. Of particular concern in the ICU setting is the risk of paralyzed patients receiving inadequate analgesia and sedation. [512] [513] [514] Inadequate analgesia and sedation occur in part because in

TABLE 12-17 -- Complications of Muscle Paralysis in the ICU

Short-term use
Specific, known drug side effects
Inadequate ventilation
Circuit disconnection
Ventilator failure
Inadequate analgesia and/or sedation
Long-Term Use
Complications of immobility
Deep venous thrombosis and pulmonary embolus
Peripheral nerve injuries
Decubitus ulcers
Inability to cough
Retention of secretions and atelectasis
Pulmonary infection
Prolonged paralysis after stopping relaxant
Persistent neuromuscular blockade
Steroid-associated myopathy
Motor neuropathy
Neuromuscular dysfunction
Combination of the above
Unrecognized effects of drug or metabolites
Succinylcholine and metabolic acidosis/hypovolemia
3-desacetylvecuronium and neuromuscular blockade
Laudanosine and cerebral excitation
CNS effects of muscle relaxants

up to 15 percent of ICUs, sedative drugs are not normally administered to paralyzed patients, and also because ICU nurses and physicians may be unfamiliar with the pharmacology of the drugs they are using. [506] [513] Pancuronium was thought to be an anxiolytic by 50 to 70 percent of ICU nurses and house staff, and 5 to 10 percent thought it was an analgesic. [513] In addition, diazepam was considered to be an analgesic by 40 to 80 percent. [513] Such misconceptions explain why patients sometimes report frightening experiences while paralyzed in the ICU. [512]

The complications of long-term administration of muscle relaxants in the ICU are outlined in Table 12-17 . The first two categories are consequences of immobilization and loss of the ability to cough. Preventing these complications relies on skilled nursing care and intensive physical therapy and is not in the realm of the physician; consequently, they will not be discussed. The complications of long-term use of muscle relaxants of relevance to this section are prolonged paralysis after the relaxant is stopped and effects, either unrecognized or not fully investigated, of the drugs or their metabolites.

When long-term relaxant administration is stopped, most patients recover full muscle strength within a few hours. [515] [516] However, a subgroup of patients who receive muscle relaxants for periods of several days or weeks have persistent weakness after relaxant administration is stopped. [516A] [516B] Because muscle strength may not return, weaning from mechanical ventilation can be delayed, full recovery of muscle strength may not occur for months, and the impact on the patients can be devastating. [516A] [516B] The additional health-care cost of one case of persistent weakness was estimated as almost $67,000. [516C] Personnel caring for ICU patients must attempt to minimize the risk of this serious complication.

Muscle relaxant-associated persistent weakness is a distinct pathologic entity and is not simply a manifestation of critical illness polyneuropathy. [517] The prospective study by Kupfer et al [517A] showed a 70 percent incidence of persistent weakness in ICU patients who received muscle relaxants for more than 2 days, compared with 0 incidence in similar ICU patients who got no muscle relaxant. This is compelling evidence for the role of relaxants in this complication. Persistent weakness has several pathologic forms.

Weakness may be due to persistent pharmacologic neuromuscular blockade. After muscle relaxant administration is stopped, the persistence of the drug itself, or a metabolite with muscle relaxant properties, results in persistent paralysis. [517B] [517C] The principal metabolite of vecuronium is 3-desacetylvecuronium, which has 80

percent of the muscle relaxant potency of vecuronium. [517D] This metabolite has been identified as a likely cause of persistent paralysis in patients who received vecuronium for more than 2 days. [517B] Additional risk factors for persistent paralysis were renal failure and female gender. [517B] Pancuronium and pipecuronium also have 3-desacetyl metabolites, and despite an absence of specific data, it would seem wise to avoid long-term administration of these drugs to patients with renal failure.

There is a striking clinical picture of flaccid quadriplegia following administration of muscle relaxants to patients with severe asthma who are receiving high doses of corticosteroid. [518] [519] [520] [521] [522] [523] [524] The syndrome is characterized by severe flaccid paralysis, increased creatine kinase (CK) concentrations, myonecrosis, and slow recovery that can take several months to complete. The incidence of myopathy in asthmatics who require mechanical ventilation is 15 to 40 percent. [518] [522] The syndrome is more likely to occur the greater the dose of muscle relaxant and the greater the dose of steroid administered. [518] [522] Initial reports of this myopathy involved pancuronium or vecuronium, leading to a belief that the complication was due to their steroidal structure, and thus the belief that it might not occur with atracurium. More recently, myopathy has also been reported in patients who received atracurium, [521] [523] so the complication therefore appears unrelated to the structural class of the muscle relaxant. Plasma CK concentrations usually increase with the development of myopathy. [525] The authors recommend daily monitoring of CK concentrations in ICU patients who receive muscle relaxants and high-dose steroids. Doses of steroid and muscle relaxant should be kept to a minimum, and if CK concentrations increase, muscle relaxant administration should be stopped.

Another syndrome, motor neuropathy without myopathy, can follow the long-term use of vecuronium or pancuronium. [517A] [526] The neuropathy affects the upper and lower limbs and may be accompanied by absent tendon reflexes and muscle wasting. Weaning from mechanical ventilation may be delayed, and full recovery may take several months. The motor neuropathy is more likely to occur as the dose and duration of relaxant administration increase. [517A] [526]

Yet another clinical syndrome consisting of persistent motor weakness without sensory involvement has followed long-term use of pancuronium, vecuronium, or metocurine. [527] Electrodiagnostic studies were consistent with failed neuromuscular transmission, and the weakness took several months to resolve.

The incidence of prolonged paralysis following long-term use of muscle relaxants will vary among institutions, depending on their patient populations, but it is of the order of 5 percent overall, 20 percent for patients who receive muscle relaxants for more than 6 days, [516A] 15 to 40 percent for asthmatic patients who also receive high-dose steroids, [518] [522] and almost 50 percent in female patients with renal failure who receive vecuronium. [517B] Risk factors for prolonged weakness are: (1) use of vecuronium by female patients with renal failure; (2) concomitant high-dose steroid administration; and (3) large doses and long duration of relaxant administration. The phenomenon affects the motor system only and probably reflects pathologic effects due to chronic pharmacologic denervation of the muscle. It is not yet resolved whether the syndromes described (with the exception of persistent pharmacologic neuromuscular blockade) represent distinct pathologic processes or are simply different manifestations of a common underlying cause. Regardless of the cause, the impact for the patient is severe. Weaning from mechanical ventilation will be delayed, and their ICU stay will be prolonged. This will result in increased costs, increased risk of the complications of mechanical ventilation, and the need to remain in an ICU. Because recovery of muscle strength often takes several months, the impact on the patient's career and finances may be significant.

For most patients, the initial doses of relaxant that patients

require are similar to the doses used in the operating room (e.g., vecuronium, 0.1 mg/kg / h, or atracurium, 0.5 mg/kg/h. [528] [529] [530] [531] These initial doses will often need to be increased within 1 to 3 days because of the development of tolerance. [528] [529] [530] [531] Tolerance develops in the first 24 to 72 hours of administration, occurs in children as well as adults, and is such that vecuronium doses as high as 32 mg/h have been required. [530] The likely cause of tolerance is upregulation of acetylcholine receptors consequent to chronic pharmacologic denervation. [532] The clinical problem is that patients who seem to require large doses for clinical relaxation may subsequently go on to develop prolonged paralysis when relaxant administration is stopped. [533]

The effect of muscle relaxant administration is most commonly monitored clinically in the ICU by the use of a nerve stimulator with assessment of TOF responses. [533A] [533B] There is evidence that monitoring versus no monitoring results in decreased amounts of muscle relaxant used, decreased costs, and decreased incidence of prolonged weakness. [533C] It is not clear whether monitoring by clinical criteria or by use of a nerve stimulator is superior. In one study comparing monitoring by clinical criteria with the use of a nerve stimulator, the amounts of drug used and comparative patient recovery times were similar. [533D] A different study concluded that the use of a nerve stimulator with TOF monitoring resulted in less drug use and lower costs than monitoring using clinical criteria. [533E] Whatever form of monitoring is used, the principle should be to administer the minimum amount of drug needed to achieve the desired therapeutic effect.

In most, but not all, of the reports of prolonged weakness, no monitoring was used. In one study in which neuromuscular function was monitored with a peripheral nerve stimulator and at least one twitch in the TOF response was maintained, all patients recovered rapidly from vecuronium-induced block. [534] However, in that study the average length of administration of vecuronium was only 40 hours, and prolonged weakness would not be expected after such a relatively short period of administration. In addition, none of the patients had organ dysfunction. Therefore, prolonged weakness would not have been expected to occur in that group of patients, and the effectiveness of monitoring to reduce the incidence of prolonged weakness cannot be judged from that study. It is possible for patients to have TOF responses throughout the whole period of relaxant administration and still to have persistent weakness occur. [521]

Succinylcholine is often used to facilitate emergent tracheal intubation in the ICU. Several well-recognized conditions predispose to severe acute hyperkalemia and are contraindications to the use of succinylcholine (see the section on succinylcholine). The risk of hyperkalemia in patients who have hypovolemia and metabolic acidosis is not well recognized. [535] [535A] Schwartz et al [535] reported a case of hyperkalemic cardiac arrest in a postpartum patient who had severe blood loss and metabolic acidosis. The risk of hyperkalemia following succinylcholine in the setting of severe blood loss and metabolic acidosis was confirmed in a study in rabbits. [536] It appears that in this situation the source of potassium is the splanchnic circulation. [536A] Before administration of succinylcholine to a hypovolemic, acidotic patient in the ICU, consideration should be given to hyperventilation of the patient and to the administration of sodium bicarbonate. Alternatively, if it is considered appropriate, rocuronium may replace succinylcholine to facilitate rapid-sequence intubation. [510] [536B] [536C]

Because of the reports of complications involving vecuronium and pancuronium, atracurium became popular for long-term use in the ICU, and this raised concerns regarding its principal metabolite, laudanosine. This metabolite has no muscle relaxant effects, but it is an analeptic. The toxic dose in humans is not known, but there are case reports of patients having seizures while receiving atracurium, and laudanosine has not been ruled out as a cause of these seizures. [537] [537A] [538] The infusion of atracurium in the ICU has been associated with recurrent episodes of bradycardia and hypotension, effects that may be due to the CNS effects of laudanosine and that resolved when vecuronium was substituted for atracurium. [539] [540] Cisatracurium is a single isomer of atracurium, and because it is four to five times more potent than atracurium, it is given in smaller doses. Consequently, the risk of laudanosine-related adverse effects, even with long-term administration of cisatracurium, should be minimal. [508] [540A] [540B]

The muscle relaxants are polar molecules and do not readily cross the blood-brain barrier, but vecuronium and 3-desacetylvecuronium have been detected in the CSF of patients in the ICU, and laudanosine is found in the CSF of ICU patients who receive atracurium. [540C] The CNS effects of muscle relaxants and their metabolites in humans have not been well studied, but in rats atracurium, pancuronium, and vecuronium injected into the CSF will cause dose-related cerebral excitation culminating in seizures. [541] Cerebral excitation with consequent increased cerebral oxygen demand is undesirable in ICU patients at risk of cerebral ischemia.

Currently there are insufficient data to conclude that the long-term administration of muscle relaxants to patients in the ICU is safe or even efficacious. Indeed, the problems so far identified--principally, persistent weakness--have such grave consequences for the patient that they may be considered as a contraindication to the long-term use of muscle relaxants in certain "at risk" patients. Until the cause of the complications is better understood and more is known about the safe use of muscle relaxants in the ICU, the authors believe that relaxant administration should be minimized whenever possible. When relaxants are used, then the guidelines in Table 12-18 may help to minimize the incidence of complications.

TABLE 12-18 -- Recommendations for the Use of Muscle Relaxants in the ICU

Avoid the use of muscle relaxants by
Maximal use of analgesics and sedatives
Manipulation of ventilatory parameters and modes

Minimize the dose of relaxant

Do not administer for more than 2 days continuously

Administer by bolus rather than infusion

Administer only when required and to achieve a well-defined goal

Continually allow recovery from paralysis

Consider alternative therapies

Avoid vecuronium in female patients with renal failure

Isoflurane in place of muscle relaxants in severe asthmatics

Minimize the dose of steroid in asthmatics

ECONOMICS AND OUTCOME IN PRACTICE WITH NEUROMUSCULAR BLOCKING DRUGS

The introduction of vecuronium and atracurium heralded a new age in the use of neuromuscular blocking drugs. These were the first drugs with an intermediate duration of action and rapidly became the first-line drugs for most clinical situations. [542] However, the acquisition costs of the intermediate-acting relaxants is considerably greater than that of long-acting drugs like pancuronium, and in recent years there has been pressure to reduce health-care costs by reverting to more widespread use of long-acting relaxants. [543] [544] However, merely comparing acqusition cost of drugs is simplistic and potentially misleading, and a more complete pharmacoeconomic analysis must take into consideration the impact of different drugs on patient outcome and thus the overall cost to the health-care institution. [545]

The most significant outcome difference between long-acting and intermediate-acting drugs is the relative incidence of residual neuromuscular block in the postoperative period. In 1979, a study by Viby-Mogensen and colleagues [546] showed that the incidence of residual weakness in the recovery room was more than 40 percent. At that time only long-acting drugs were available. With the introduction of vecuronium and atracurium, the incidence of residual weakness declined significantly to less than 10 percent. [547]

The greater incidence of residual blockade with longacting relaxants is because reversal of their neuromuscular blocking effect takes longer than with intermediate-acting drugs. [548] [549] This difference in ease of reversal is crucial as even minor degrees of residual neuromuscular blockade have significant adverse effects. [550] [551] [552] [553] The muscles of airway protection are very sensitive to residual block, [550] and this predisposes patients to pulmonary aspiration. [552] In addition, residual neuromuscular blockade may compromise a patient's "street readiness" in the postoperative recovery period. [553] There is mounting evidence that the standard for acceptable recovery of neuromuscular function is no longer a TOF ratio of 0.7, but in fact greater safety might be achieved at 0.9. [552] [553] As the level of neuromuscular recovery considered adequate increases, so will the differential between relaxants with long versus intermediate durations of action become greater.

As a result of these adverse effects of residual neuromuscular blockade, the use of long-acting versus intermediateacting relaxants can predispose patients to a greater risk of postoperative pulmonary complications. [554] These complications constitute the greatest potential added expenses, which accrue as a result of the choice of long-acting relaxants over shorter-acting drugs. Delayed discharge from the PACU [555] also has a significant cost impact. The increased length of stay in the PACU with long-acting relaxants has an estimated cost penalty to the institution of $40 per patient. [555]

There is an argument that the use of long-acting relaxants is without adverse effect if strict practice guidelines regarding their use and dosing are implemented and continuously enforced. [556] However, even with strict regulation, the use of pancuronium in place of an intermediate-acting relaxant is associated with a delay (a mean of 3 minutes) in the time from the end of the surgical procedure until the patient reaches the PACU. Much debate has been generated about the importance of this 3-minute delay.

The risks of residual weakness associated with use of long-acting relaxants apply to the situation where the patient's trachea will be extubated at the end of the surgical procedure. Following cardiac surgery, for instance, where the endotracheal tube will remain in place and the patient's ventilation will be supported for hours or days postoperatively, there is no cost penalty in the use of long-acting relaxants. [557]

With the current state of knowledge, the use of intermediate- and short- versus long-acting relaxants comes down to a philosophic debate. On one side, there is a body of evidence that strongly suggests but does not absolutely prove that a greater risk to patients is incurred with the use of long-acting relaxants. This potential added risk may translate to greatly increased expense of anesthetic care as a result of a higher incidence of complications. [554] On the other side is the rather simple economic argument whereby it is easy to demonstrate a reduction in drug acquisition costs by using long-acting relaxants, even though the full pharmacoeconomic impact of this is not established because all the risk and safety issues and all the added efficiencies are not carefully cost-accounted. Perhaps we can be guided by this excerpt from the Hippocratic oath--"I will prescribe regimen for the good of my patients according to my ability and my judgment and never do harm to anyone." Where evidence for one position over another is conclusive, the authors believe that one should always take the option that involves the least risk of harm to the patient.

Chapter 13 - Local Anesthetics

Charles B. Berde
Gary R. Strichartz

INTRODUCTION

Local anesthesia may be produced by many tertiary amine bases, certain alcohols, and a variety of other drugs and toxins. However, all currently available clinically useful agents are either aminoesters or aminoamides. These drugs, when applied in sufficient concentration at the site of action, prevent conduction of electrical impulses by the membranes of nerve and muscle. When local anesthetics are given systemically, the functions of cardiac, skeletal, and smooth muscle, as well as the transmission of impulses in the peripheral nervous system and the central nervous system (CNS) and within the specialized conducting system of the heart, may all be altered. Local anesthetics may provide analgesia in various parts of the body by topical application, injection in the vicinity of peripheral nerve endings and major nerve trunks, or instillation within the epidural or subarachnoid spaces. Toxicity may be local or systemic. The CNS and cardiovascular system are most commonly involved in acute clinical toxicity.

BASIC PHARMACOLOGY

Chemistry

Local Anesthetic Molecule

The typical local anesthetic molecule, exemplified by lidocaine and procaine (Fig. 13-1) , is a tertiary amine attached to a substituted aromatic ring by an intermediate chain. The tertiary amine is a base (proton acceptor). The chain always contains either an ester

or amide

linkage; local anesthetics may therefore be classified as aminoester or aminoamide compounds. The aromatic ring system gives a lipophilic character to its portion of the molecule, whereas the tertiary amine end is relatively hydrophilic, particularly because it is partially protonated and thus bears some positive charge in the physiologic pH range. Lidocaine, for example, is 65 percent protonated at pH 7.4. The structures of commonly administered local anesthetic drugs are given in

TABLE 13-1 -- Representative Local Anesthetic Agents in Common Clinical Use

(Not Available)

Modified from Covino and Vassallo [1,2,3]

Figure 13-1 Structures of two local anesthetics, the aminoamide lidocaine and the aminoester procaine. In both drugs, a hydrophobic aromatic group is joined to a more hydrophilic base, the tertiary amine, by an intermediate bond.

Table 13-1 (Table Not Available) , and their physicochemical properties are listed in Table 13-2 (Table Not Available) .

Structure-Activity Relations and Physicochemical Properties

The intrinsic potency and duration of action of local anesthetics are clearly dependent on certain features of the molecule.

Lipophilic-Hydrophilic Balance

The lipophilic versus hydrophilic character of the local anesthetic depends on the size of alkyl substituents on or near the tertiary amine and on the aromatic ring. Lipophilicity expresses the tendency of a compound to associate with membrane lipids, usually approximated by the equilibrium partitioning into a hydrophobic solvent such as octanol. [1] Such octanol/buffer partition coefficients are comparable with membrane/buffer partition coefficients for the uncharged species of local anesthetics, but they greatly underestimate the membrane partitioning for the charged, protonated species, octanol being a poor model for the polar regions near the membrane surface. [2] In this chapter, we use the term hydrophobicity, expressed by octanol/buffer partitioning, to describe a physicochemical property of local anesthetics.

Compounds with a more hydrophobic nature are obtained by increasing the size of the alkyl substituents. These agents are more potent and produce longer-lasting blocks than their less hydrophobic congeners. [3] [4] [5] For example, etidocaine, which has three more carbon atoms than lidocaine in the amine end of the molecule, is four times as potent and five times as long-lasting when these compounds are compared in the isolated frog sciatic nerve.

Hydrogen Ion Concentration

Local anesthetics in solution exist in a chemical equilibrium between the basic uncharged form (B) and the charged cationic form (BH^+). At a certain hydrogen ion concentration ($\log_{10}{}^{-1}$ [-pH]) specific for each drug, the concentration of local anesthetic base is equal to the concentration of charged cation. This hydrogen ion concentration is called the pK_a . The relationship is defined by

The pK_a values for standard local anesthetic agents are listed in Table 13-2 (Table Not Available) . The tendency to be protonated also depends on environmental factors, such as temperature and ionic strength, and on the medium surrounding the drug. [1] In the relatively apolar milieu of a membrane, the average pK_a of local anesthetics is lower than in solution. [6] This is chemically equivalent to saying that the membrane concentrates the base form of the local anesthetic more than it

concentrates the protonated cations.

TABLE 13-2 -- Relative In Vitro Conduction Blocking Potency and Physiochemical Properties of Local Anesthetic Drugs

(Not Available)

From Strichartz, et al [131]

Figure 13-2 (Figure Not Available) The fraction of local anesthetic in the protonated, cationic form of aqueous solution at physiologic pH (7.4) as a function of the pK_a of the drug. *(From Covino and Vassallo* [123] *)*

The pH of the medium into which the local anesthetic is injected influences drug activity by altering the relative percentage of agent present in the basic or protonated forms. The relationship between pK_a and the percentage of local anesthetic present in the cationic form is shown in Figure 13-2 (Figure Not Available) . As described later, there are dual effects of pH, depending on where the local anesthetic is injected and on the importance of the base form for tissue penetration.

ANATOMY OF THE PERIPHERAL NERVE

Each peripheral nerve axon possesses its own cell membrane, the axolemma. Nonmyelinated nerves, such as autonomic postganglionic and nociceptive afferent C fibers, are encased in a single Schwann cell sheath. Most large motor and sensory fibers are enclosed in many layers of myelin, which consists of plasma membranes of specialized Schwann cells that wrap themselves around the axon during axonal outgrowth. Myelin greatly increases the speed of nerve conduction by insulating the axolemma from the surrounding conducting salt medium and forcing the action current to flow through the axoplasm to the nodes of Ranvier, which are periodic interruptions in the myelin sheath where the action currents are regenerated (Fig. 13-3) . The Na^+ channels that serve impulse generation and propagation are highly concentrated at the nodes of Ranvier of myelinated fibers, [7] but they are distributed all along the axon of nonmyelinated fibers (see Fig. 13-3) . A classification of peripheral nerves according to fiber size and physiologic properties is presented in Table 13-3 (Table Not Available) .

A typical peripheral nerve consists of several axon bundles, or fascicles. Each axon has its own connective tissue covering, the endoneurium. Each fascicle of axons is encased by a second connective tissue layer, the perineurium, and the entire nerve is wrapped in a loose outer sheath called the epineurium (Fig. 13-4) . To reach its site of action (the nerve axon), a local anesthetic molecule must traverse four or five layers of connective tissue and/or lipid membranous barriers.

Structure of the Axonal Membrane

Biologic membranes consist of a molecular lipid bilayer containing proteins adsorbed on the surfaces as well as embedded in or spanning the hydrocarbon core (Fig. 13-5) . The bilayer character is imposed by the amphiphilic phospholipids, which have long hydrophobic fatty acyl tails that lie in the center of the membrane and polar hydrophilic head groups composed of zwitterionic (containing positive and negative charges) components that project into the cytoplasm or the interstitial fluid. Within the membrane there is some lateral and rotational diffusion, which allows lipids and certain proteins to migrate in a fluid mosaic, but most membrane proteins are fixed within specific regions of a membrane. [7]

A dynamic interaction exists between the cell's membrane and cytoplasm. Although we focus here on the channel-blocking actions of local anesthetics, it is noteworthy that many other cellular activities are inhibited by these drugs.

Physiology of Nerve Conduction

The neural membrane is able to maintain a voltage difference of 60 to 90 mV between its inner and outer aspects because at rest it is relatively impermeable to sodium ions but is selectively permeable to potassium ions. An active, energy-dependent

Figure 13-3 The direction of action currents flowing in a large nonmyelinated axon (e.g., of the squid) **(A)** and in a myelinated axon **(B).** During propagation of impulses from left to right, current entering the axon at the initial rising phase of the impulse (open arrows) passes down the axoplasm (local circuit current) and depolarizes the adjacent membrane. This ionic current passes uniformly along the nonmyelinated axon but is funneled from one node of Ranvier to another in the myelinated axon.

TABLE 13-3 -- Classification of Peripheral Nerves According to Fiber Size and Physiologic Properties

(Not Available)

Modified from Bonica [234]

mechanism, the Na^+ -K^+ pump, sustains the ion gradients that drive this potential difference by constant extrusion of sodium from within the cell in exchange for a net uptake of potassium, using adenosine triphosphate as an energy source. Although the membrane is relatively permeable to potassium ions, an intracellular-to-extracellular potassium ratio of 150 mmol/L to 5 mmol/L, or 30:1, is maintained because of the membrane's impermeability to other, potentially cotransported ions and the active removal of potassium.

The nerve at rest behaves largely as a potassium electrode, according to the Nernst equation:

where E_m is the membrane potential; E_k is the potassium equilibrium potential; R is the gas constant; T is temperature (Kelvin); F is Faraday's constant; and $[K^+]$ is the potassium ion concentration inside (i) and outside (o) the cell. For potassium, therefore,

An opposite situation exists for Na^+ , which is at higher concentration outside the cell and has a Nernst potential, E_{Na} , of about +60 mV. During an action potential, the nerve membrane transiently switches its permeability from K^+ selective to Na^+ selective, thus changing the membrane potential from negative to positive, and back again. [8] The progress of this potential change and the underlying events are graphed in Figure 13-6 . They provide a basis for understanding local anesthetic conduction block.

Ion permeation through membranes occurs via special proteins called ion channels. [9] The conformation of these channels is often sensitive to the membrane potential; both Na^+ and K^+ channels in nerve membranes are activated to an open conformation by membrane depolarization. Sodium channels, in addition, close to an inactivated conformation following their initial activation. A small membrane depolarization, extending along an axon from a region of excited membrane for example, begins to open both Na^+ and K^+

Figure 13-4 Transverse sections of a peripheral nerve **(A)** showing the outermost epineurium, the inner perineurium that collects nerve axons in fascicles, and the endoneurium that surrounds each myeli-nated fiber. Each myelinated axon **(B)** is encased in the multiple membranous wrappings of myelin formed by one Schwann cell, each of which stretches longitudinally over approximately 100 times the diameter of the axon. The narrow span of axon between these myelinated segments, the node of Ranvier, contains the ion channels that support action potentials. Nonmyelinated fibers (C) are enclosed in bundles of 5 to 10 axons by a chain of Schwann cells that tightly embrace each axon with but one layer of membrane.

Figure 13-5 Drawing of a typical plasma membrane showing the lipid bilayer composed of phospholipids and cholesterol molecules (in a 10:1 ratio), embedding the membrane integral proteins, and the relationship of the cytoplasmic peripheral proteins and the carbohydrate moieties facing the extracellular medium. Probable sites for local anesthetics are also shown.

channels. The Na^+ channels open faster, however, and because the membrane potential is initially much further from the Nernst potential for Na^+ than from that for K^+, the inwardly directed Na^+ current is larger (see Fig. 13-6) . Sodium ions thus entering the nerve depolarize it further, leading to the opening of more Na^+ channels and increasing the current even further (Fig. 13-7) . This sequence of events continues in the *positive feedback of the depolarizing phase* until some of the Na^+ channels have become inactivated and enough of the potassium channels have opened to change the balance of current, resulting in a net outward current that produces membrane repolarization (see Fig. 13-7) . After one action potential, the concentrations of Na^+ and K^+ have changed very little. The small amount of Na^+ entering and K^+ leaving the cell as a result of this process is restored by the Na^+-K^+ pump. [10]

Depolarizations too weak to activate enough Na^+ channels to produce a net inward current are below the membrane's excitability threshold. The precise value of the threshold varies among different regions of the cell and also changes with time. Directly after an impulse, when some Na^+ channels are still inactivated and some K^+ channels still activated, the threshold is higher than the resting value, and the membrane is refractory to stimulation. In the immediately repolarized membrane, as Na^+ inactivation decays and as K^+ channels return to their closed conformation, the original threshold value is progressively restored.

The impulse is a wave of depolarization that is propagated along the axon by a continuous coupling between excited and nonexcited regions of membrane. Ionic current (the action current) entering the axon in the excited, depolarized region flows down the axoplasm and exits through the surrounding membrane, thus passively depolarizing the adjacent region (see Fig. 13-3) . Although this *local circuit current* spreads away from the excited zone in both directions, the region behind the impulse, having just been depolarized, is absolutely refractory, and impulse propagation is thus unidirectional.

The local circuit current spreads rapidly along a length of insulated internode in a myelinated axon (see Fig. 13-3) , and many nodes of Ranvier in sequence are depolarized to threshold with little intervening delay. Single impulses do not jump from node to node as separate, discrete events, but instead the active depolarization occurs simultaneously along several centimeters of the largest axons [11] (see Fig. 13-10) (Figure Not Available) . Indeed, the local circuit current is so robust that it can skip past two completely nonexcitable nodes and may successfully stimulate a third. [12] If nodal excitability is partially reduced, by inhibition of some of the Na^+ channels for example, the amplitude of impulses in successive nodes falls decrementally, a process that can continue for many centimeters. [13] This situation probably occurs during certain phases of local anesthesia, as discussed later. However, when the inhibition of Na^+ channels is sufficient, so that local circuit current fails to bring the adjacent resting region to threshold, then the impulse is extinguished.

Figure 13-6 Membrane potential (E_m), conductances of sodium (g_{Na}) and potassium (g_K), and the corresponding membrane currents (I_{Na} and I_K) that occur during a propagated action potential. Modeled from the original studies of Hodgkin and Huxley on the squid giant axon (see Hodgkin [9]), these relationships hold for almost all invertebrate and vertebrate nerve fibers. The direction of the total ionic current (I_t), which is the sum of I_{Na} and I_K, is inward (negative values) for the depolarizing phase of the action potential and outward (positive values) for the repolarizing phase.

MECHANISM OF ACTION OF LOCAL ANESTHETICS (PHARMACODYNAMICS)

Active Form

Local anesthetic bases are poorly to sparingly soluble in water, but they are soluble in relatively hydrophobic organic solvents. Therefore, as a matter of convenience, most of these drugs are marketed as the hydrochloride salts. The pK_a of the drug and the tissue pH determine the amount of drug that exists in solution as free base or as positively charged cation when injected into living tissue (see earlier). Furthermore, the uptake of the drug by the tissue, largely resulting from lipophilic adsorption, also alters its activity, both by shifting the effective pK_a downward, and thereby favoring the neutral base form, and by limiting the diffusion of the anesthetic away from the site of injection. Moderately hydrophobic local anesthetics act more rapidly than either hydrophilic or highly hydrophobic agents, delivered at the same concentration, for the following reasons. Moderately hydrophilic local anesthetics, such as lidocaine, are less bound to tissues than are very hydrophobic drugs (i.e., tetracaine), but they still are more membrane permeant than very hydrophilic ones (e.g., chlorprocaine). The highly hydrophobic local anesthetics also have higher intrinsic potency [4] (see Table 13-2) (Table Not Available) , they are used in lower concentrations, and their rate of onset is correspondingly reduced.

A lengthy debate has taken place over the issue of which form of the local anesthetic, charged cation or neutral base, is actually responsible for impulse blockade. Early observations showed that alkaline solutions of local anesthetics more effectively blocked nerve conduction. [14] In the desheathed nerve and in the isolated single axon, the rate of inhibition by tertiary amine anesthetics also was greater at alkaline than at neutral external pH. [15] [16] From these observations, it was concluded that either the neutral base in the external solution is the active species or membrane penetration and transport, highly favored by base over cation species, are essential for the channel-blocking action. The second possibility is, in fact, the explanation for the acceleration of rate in alkaline media. [15] [16] [17] Direct control of axoplasmic pH [18] or internal perfusion with permanently charged quaternary amine homologues shows the dominant potency of the cationic species acting from the cytoplasmic surface. [19] [20] The uncharged base also has intrinsic pharmacologic activity, however, and in addition to those molecules with tertiary amine moieties, those having hydroxyl (alcohols) or alkyl groups (e.g., benzocaine) can also inhibit Na^+ channels and may block impulses. [16] [17] [21] [22]

To obtain a clear picture of the mechanism, the channel-inhibitory kinetics are necessary, but it is almost impossible to measure the rate of binding of local anesthetics to the receptor after their addition to a bathing solution. Drug diffusion through the unstirred layer of solution next to the membrane and the membrane itself present steps that limit the

Figure 13-7 Factors contributing to the regenerative, depolarizing phase of the action potential. Positive factors (solid arrows) increase the rate of depolarization, each element in the cycle favoring the subsequent one. Negative factors (open arrows) decrease the depolarization rate by reducing or opposing the related positive factor.

rate of receptor binding. [16] [23] However, once the drug has equilibrated with membranes and solutions, it is possible to perturb the channels by depolarizing the membrane and to follow the phasic inhibition by local anesthetics in order to clarify the details of the binding reaction, as described later.

Electrophysiologic Effect of Local Anesthetics

The resting membrane potential of nerve is little affected by local anesthetics. [24] As the concentration of local anesthetic applied to the nerve is increased, a decrease in the rate and degree of impulse depolarization is produced. Until the impulse is abolished, however, it is not possible to derive direct data on the binding of local anesthetics to Na^+ channels from measurement of nerve impulses.

By using a voltage-clamp procedure instead, Na^+ currents and their inhibition by local anesthetics can be directly assayed (Fig. 13-8) (Figure Not Available) . When the membrane is rapidly depolarized to a constant value by voltage-clamp, the time course of ionic currents is observed. Sodium currents are reduced during one initial depolarization by subclinical doses of local anesthetic (e.g., 0.2 mmol/L lidocaine) and are totally abolished by clinical doses (e.g., 1% lidocaine, which equals about 40 mmol/L). If the test depolarization is repeatedly applied, for example, at frequencies higher than 5 Hz (5 pulses/s), the partially depressed (tonically inhibited) Na^+ current is further reduced, incrementally for each pulse, until a new steady-state level of inhibition is reached. [20] [25] This frequency-dependent inhibition, also called *phasic inhibition*, is reversed when stimulation is slowed or stopped, and currents return to the level of tonic inhibition observed in the resting nerve. The potency for local anesthetics to produce both tonic and phasic inhibition is similarly dependent on their structure, hydrophobicity, and pK_a . [25] [26] At its simplest, there appears to be a single binding site for local anesthetics on the Na^+ channel, with a tonic affinity at rest and increased phasic affinity occurring as a result of depolarization. The phasic blocking mode can thus be used to reveal the true kinetics of local anesthetic binding to the functional receptor, the Na^+ channel itself.

There are two fundamental mechanisms of inhibition. Na^+ currents are reduced by local anesthetics primarily because the drug-bound channels fail to open. Investigations with neutral and cationic compounds show that the channel-activation process is disrupted by local anesthetics. [27] [28] A sodium channel inhibited by a local anesthetic is functionally similar to an inactivated channel; both inactivation and anesthetic binding prevent the complete conformational changes of the activation process by partially immobilizing the channel. [29] Blockade of the ion-conducting pore, the second mechanism, plays a part in channel inhibition, but the contribution from this action seems minor.

Figure 13-8 (Figure Not Available) Inhibition of Na^+ currents in myelinated nerves exposed to lidocaine or to bupivacaine. Traces show the inward ionic currents during a 16-ms-long depolarization to -20 mV, before drug addition (control), for the first depolarization imposed 5 minutes after beginning drug exposure (0, tonic inhibition), and for the subsequent pulses in a train of depolarizations applied to 10 Hz (identified numerically by their order in the sequence; use-dependent inhibition). T = 13°C. Toad node of Ranvier. *(From Chernoff [38])*

Figure 13-9 Schematic drawing of drug access routes to a putative local anesthetic binding site on the Na^+ channel. The hydrophilic route, from the cytoplasmic phase, mediates binding of aqueous drug (L_a) directly to the receptor site. The hydrophobic route mediates binding to membrane-associated drug (L_m) to the site. The activated channel (induced by membrane depolarization) binds drug more tightly than the resting channel, but both states of the protein appear to favor the hydrophobic route.

Are inactivated channels essential for local anesthetic binding and action? No, because when inactivation is prevented by various chemical reagents or toxins, there

is only a small change in the tonic and phasic actions of local anesthetics. [30] Phasic channel inhibition occurs during depolarizations that are as short as neuronal impulses (1-5 ms) because local anesthetics bind more rapidly and with higher affinity to activated channels (some open, some in intermediate activated conformations preceding the open state) than to resting channels. During longer depolarizations, additional binding to drug-free inactivated channels also can occur [17] [25] ; this mode of binding probably accounts for much of the cardiotherapeutic action of local anesthetic-like class I antiarrhythmics. [31] [32]

Regardless of the channel state that binds the drug, by its very binding the local anesthetic stabilizes that state. During phasic block, therefore, more channels become drug-bound during activation, and reciprocally, less activation can occur. Thus, overall binding of anesthetic is increased by channel activation for two reasons: more binding sites become accessible during activation (the guarded receptor model), [33] and drug dissociation from activated channels is slower than from resting channels (the modulated receptor model). [17]

The specific binding rates and affinities for the different conformations of the sodium channel depend on the particular local anesthetic drug. When the details of this dependence are correlated with the physicochemical properties of the drug and with the experimental conditions, they provide insight into the nature of the local anesthetic binding site. [4] [5]

Nature of the Local Anesthetic Binding Site

Kinetic and equilibrium measurements of inhibition by diverse local anesthetics reveal much about the binding site. Like the rate of onset of tonic block, the rate of binding for phasic block is greater at more alkaline external pH. [26] Curiously, cytoplasmic pH has almost no effect on phasic inhibition. [34] Drugs of greater hydrophobicity are proportionately more potent for both tonic and phasic block than less hydrophobic congeners. [4] [35] [36] However, at equipotent doses for channel blockade of two local anesthetics that differ 100-fold in hydrophobicity and in intrinsic potency (but have very similar pK_a), the rate of phasic binding is almost the same despite the 100-fold difference in their concentrations in solution. The apparent discrepancy between rates and concentrations can be reconciled by postulating that the primary blocking reaction occurs from drugs that are in the membrane phase, in which the more potent drug is concentrated (even 100-fold) by hydrophobic uptake [17] [26] (Fig. 13-9) .

Dissociation of local anesthetic from the open channel depends little on hydrophobicity, pK_a, or external pH, but it is faster for smaller molecules. In contrast, drug dissociation from the closed channels depends strongly on all these factors. Dissociation is slightly faster for more hydrophobic compounds, [4] [37] [38] markedly faster at more alkaline than at neutral external pH, [38] [39] and faster for drugs of lower pK_a. The latter observation suggests that extracellular H^+ can bind to the amine portion of the bound local anesthetic molecule and trap it in the Na^+ channel. [26] [37] [40] One interpretation of these findings is that anesthetics can leave their blocking site by either a hydrophobic or a hydrophilic pathway. [17] The former accommodates the uncharged base primarily and is 20 to 50 times as fast as the latter, which accommodates the cationic species and is the preferred exit route from open channels.

Integrating these physicochemical findings resolves a dynamic picture of local anesthetic action (see Fig. 13-9) . The binding of tertiary amine compounds occurs primarily from the membrane phase and favors the neutral base species. Dissociation of drug involves primarily the closed conformations of the channel (excitation occurring only briefly) and is slowed by extracellular protons. In brief, hydrophobicity delivers the drug to the receptor and charge keeps it there. Studies with intentionally mutated Na^+ channels show that decreasing the hydrophobicity of certain amino acid residues near the putative pore decreases local anesthetic affinity, indicating a locus for drug binding at the molecular level. [41] [42]

Neurophysiologic Aspects of Phasic Inhibition

Impulse blockade is also increased by repetitive stimulation. As the frequency of impulse traffic in an axon is increased, the probability of impulse blockade by local anesthetic also rises. This phenomenon develops along the length of axon exposed to drug, as shown by the simulation in Figure 13-10 (Figure Not Available) . The first impulse to traverse the fiber, where 16 consecutive nodes have been exposed to lidocaine at a concentration that blocks 50 percent of the Na^+ channels

Figure 13-10 (Figure Not Available) Decremental inhibition of conducted impulses modeled in a myelinated axon shows use-dependent block. In this computer simulation, the membrane potential at each of 26 sequential nodes of Ranvier is plotted as the impulse, stimulated at the leftmost node, propagating to the right. Fifteen nodes in the middle of this fiber are exposed to local anesthetics, which reduces both Na^+ and K^+ conductances to tonically inhibited levels (see Fig. 13-8) (Figure Not Available) for the first impulse in a train (top frame). Although this impulse's amplitude decrements continuously over the exposed length, local current at the last exposed node is still sufficient to stimulate the next, unexposed node, and conduction continues. Use-dependent drug binding during this spike lowers the Na^+ conductance available for subsequent impulses in the train, which therefore decreases further (compare spike 2 and spike 10) and fails to sustain conduction within the exposed region. *(From Raymond et al. [44] Reproduced with permission of S. Karger AG, Basel.)*

at rest, suffers decreasing conduction along the drug-exposed region [43] ; yet the reduced impulse still provides enough current at the last anesthetized node to raise the adjacent drug-free region to threshold. Impulse propagation is thus slowed, but it does not fail. However, the second impulse in the train encounters an exposed region of axon rendered less excitable by the residual phasic inhibition of the first impulse. Action currents at the end of the exposed region are now lower than the margin of safety, and propagation fails. [44] The third impulse propagates along a path of an even more sharply decreasing excitability. Each subsequent impulse in the train similarly fails to traverse the drugged axon; impulse activity entering the anesthetized region thus maintains its own failure.

An identical phenomenon occurs *in vivo.* In this situation, the pattern of impulses encodes neuronal information (e.g., in sensory fibers, the intensity of the physiologic stimulation is encoded in the frequency of the discharge). Local anesthetics significantly disrupt this pattern, as shown by the example in Figure 13-11 (Figure Not Available) of an afferent A fiber coupled to a slowly adapting mechanoreceptor in the rat's footpad. [44] Application of a subclinical dose of lidocaine to the ensheathed sciatic nerve *in vivo* leads to a progressive reduction in the average frequency of impulses propagated by one axon, even though the mechanical stimulus intensity is increased beyond the original control level.

Different fiber types in the nerve are affected differently during local anesthesia. At least part of this difference arises from pharmacokinetic factors. At the onset of and during recovery from clinical block, in particular, the longitudinal and radial diffusion of drug produces concentration variations within and along the nerve. [45] This variation is superimposed on the dynamic use-dependent inhibition to provide variable propagation, which depends on a fiber's geometry, position within the nerve, and functional as well as electrophysiologic properties. Different fiber types are also differentially

Figure 13-11 (Figure Not Available) The pattern of impulses *in vivo* in a cutaneous afferent fiber of the rat is strongly modified by local anesthetic. Discharge frequency (upper traces, shown on a logarithmic scale) in response to increasing pressure on the rat's footpad (lower traces) maintains a relatively constant value (50/s, average) in this slowly adapting mechanoreceptor before drug. Bathing the ensheathed sciatic nerve with lidocaine (0.01% over a 2- to 3-cm length) inhibits impulse conduction through the exposed region, so that after 24 minutes of drug exposure, the average frequency has fallen by 90 percent, despite the faster and larger mechanical stimulation. *(From Raymond et al. [44] Reproduced with permission of S. Karger AG, Basel.)*

sensitive to local anesthetic blockade. No clear relationship has been established between an axon's diameter and its absolute susceptibility to block by local anesthetics. [46] Despite many claims to the contrary, the smallest sensory afferents, nociceptive C fibers, are actually less susceptible to local anesthetic blockade than are the larger-diameter mechanosensitive A beta or nociceptive A delta fibers. [47] Nevertheless, the temporal sequence of loss of various sensory and sympathetic functions during regional block is well documented. [48] [49] For an explanation of the clinical observation, we must look beyond the strictly geometric aspects of an axon. A consideration of fiber functions and physiologic properties, as well as the relationship between relative impulse blockade among different types of fiber and functional deficits, may provide a basis for developing functionally selective nerve blocks.

Summary of Local Anesthetic Mechanisms

Impulse blockade by local anesthetics may be summarized by the following chronology: [4]

1. Solutions of local anesthetic are deposited near the nerve. Diffusion of drug molecules away from this locus is a function of tissue binding, removal by the circulation, and local hydrolysis of aminoester anesthetics. The net result is penetration of the nerve sheath by the remaining drug molecules.

2. Local anesthetic molecules then permeate the nerve's axon membranes and equilibrate there and in the axoplasm. The speed and extent of these processes depend on a particular drug's pK_a and on the lipophilicity of its base and cation species.
3. Binding of local anesthetic to sites on voltage-gated Na^+ channels prevents opening of the channels by inhibiting conformational changes that underlie channel activation.
4. During onset of and recovery from local anesthesia, impulse blockade is incomplete, and partially blocked fibers are further inhibited by repetitive stimulation, which produces an additional, use-dependent binding to Na^+ channels.
5. One local anesthetic binding site on the Na^+ channel may be sufficient to account for the drug's resting (tonic) and use-dependent (phasic) actions. The access to this site may potentially involve multiple pathways, but for clinical local anesthetics, the primary route is the hydrophobic approach from within the axon membrane.
6. The clinically observed rates of onset and recovery from blockade are governed by the relatively slow diffusion of local anesthetic molecules into and out of the whole nerve, not by their much faster binding and dissociation to ion channels.

CLINICAL PHARMACOLOGY

The successful use of regional anesthesia requires knowledge of the pharmacologic properties of the various local anesthetic drugs, as well as technical skill in the performance of the nerve block. Local anesthetic requirements vary considerably, depending on factors such as type of block, surgical procedure, and physiologic status of the patient.

The clinically useful aminoester local anesthetics are procaine, chloroprocaine, tetracaine, and cocaine. The aminoamides consist of lidocaine, mepivacaine, prilocaine, bupivacaine, and etidocaine. The ester and amide local anesthetics differ in their chemical stability, locus of biotransformation, and allergic potential. Amides are extremely stable, whereas esters are relatively unstable in solution. The aminoesters are hydrolyzed in plasma by the cholinesterase enzymes, whereas the amide compounds undergo enzymatic degradation in the liver. The exception to this trend is cocaine, an ester

that is metabolized predominantly by hepatic carboxylesterase. [50] [51]

p-Aminobenzoic acid is one of the metabolites of ester-type compounds that can induce allergic-type reactions in a small percentage of patients. The aminoamides are not metabolized to *p*-aminobenzoic acid, and reports of allergic reactions to these agents are extremely rare.

General Considerations

The clinically important properties of the various local anesthetics include potency, speed of onset, duration of anesthetic action, and differential sensory/motor blockade. As previously indicated, the profile of the individual drugs is determined by their physicochemical characteristics (see Table 13-2) (Table Not Available) .

Anesthetic Potency

Hydrophobicity appears to be a primary determinant of intrinsic anesthetic potency, [5] [35] [51] [52] because the anesthetic molecule must penetrate the nerve membrane and must bind at a partially hydrophobic site on the Na^+ channel. Clinically, however, the correlation between hydrophobicity and anesthetic potency is not as precise as in an isolated nerve. For example, etidocaine is more potent than bupivacaine in an isolated nerve whereas, clinically, etidocaine is actually less active than bupivacaine. [53] [54] [55] The difference between *in vitro* and *in vivo* results is related to a number of factors such as the vasodilator or tissue redistribution properties of the various local anesthetics. For example, lidocaine causes a greater degree of vasodilation than prilocaine, resulting in its more rapid vascular uptake, so that fewer lidocaine molecules are available for neural blockade. [56] The extremely high lipid solubility of etidocaine may result in a greater uptake of this agent by adipose tissue, such as in the epidural space, which again causes fewer molecules to be available for neural blockade as compared with bupivacaine.

Onset of Action

The onset of conduction block in isolated nerves is related to the physicochemical properties of the individual agents. *In vivo* latency is also dependent on the dose or concentration of local anesthetic. For example, 0.25 percent bupivacaine possesses a slow onset of action, but increasing the concentration to 0.75 percent results in a significant acceleration of anesthetic effect. [55] Chloroprocaine demonstrates a rapid onset of action in humans even though its pK_a is approximately 9, its proportion of charged molecules is high (97%), and thus its onset of action in isolated nerves is relatively slow. [57] However, the low systemic toxicity of this agent allows its use in high concentrations (e.g., 3%). Therefore, the rapid onset *in vivo* of chloroprocaine may be related simply to the large number of molecules placed in the vicinity of peripheral nerves. In humans, 1.5 percent lidocaine produced a more rapid onset of epidural anesthesia than 1.5 percent chloroprocaine [58] ; however, 3 percent chloroprocaine resulted in a more rapid onset than 2 percent lidocaine.

Duration of Action

The duration of action of the various local anesthetics differs markedly. Procaine and chloroprocaine demonstrate a short duration of action. Lidocaine, mepivacaine, and prilocaine produce a moderate duration of anesthesia, whereas tetracaine, bupivacaine, and etidocaine have the longest durations. For example, with procaine, the duration of brachial plexus blockade is 30 to 60 minutes, whereas up to approximately 10 hours of anesthesia has been reported following the use of bupivacaine or etidocaine for brachial plexus blockade. [59]

In humans, the duration of anesthesia is markedly influenced by the peripheral vascular effects of the local anesthetic drugs. Many local anesthetics have a biphasic effect on vascular smooth muscle; at low concentrations, these agents tend to cause vasoconstriction, whereas at clinically employed concentrations, they cause vasodilation. [60] [61] However, differences exist in the degree of vasodilator activity produced by the various drugs. For example, lidocaine is a more potent vasodilator than mepivacaine or prilocaine. Although little difference in the duration of conduction block is apparent among these agents in an isolated nerve, *in vivo* the anesthesia produced by lidocaine is of shorter duration than that produced by mepivacaine or prilocaine. In spinal cord, the pial vessels are dilated by bupivacaine, but they are constricted by ropivacaine, a finding suggesting a stereoselective effect on vascular tone independent of nerve block per se. [62]

Differential Sensory/Motor Blockade

Another important clinical consideration is the ability of local anesthetic agents to cause a differential inhibition of sensory and motor activity. Bupivacaine became popular in the 1980s for epidural blocks because it was better than previously available agents in producing adequate antinociception without profound inhibition of motor activity, particularly when dilute solutions are employed. Bupivacaine and etidocaine provide an interesting contrast in their differential sensory and motor blocking activity, although they are both potent, long-acting anesthetics [63] (Fig. 13-12) . Bupivacaine is widely used epidurally for obstetric analgesia and postoperative pain management because it can provide acceptable analgesia with only mild muscle weakness, particularly when it is used in concentrations of 0.125 percent or less (Ch. 57) . Ropivacaine appears to provide greater sensory selectivity than bupivacaine in some studies, but not in others (see later).

Traditional texts often state that small-diameter axons, such as C fibers, are more susceptible to local anesthetic block than are larger-diameter fibers. However, when careful measurements are made of single-impulse annihilation in individual nerve fibers, exactly the opposite differential susceptibility is seen. [64] [65] Repetitive stimulation, such as occurs during propagation of trains of impulses--the normal mode of operation for neuronal information coding (see Fig. 13-11) (Figure Not Available) --produces a further, phasic inhibition of excitability, but it is unclear how this will effect a functionally selective failure of impulses. The length of drug-exposed nerve in the intrathecal space, imposed by anatomic restrictions,

Figure 13-12 Comparative inhibition of sensory and motor activity following the epidural administration of varying concentrations of bupivacaine and etidocaine.

can explain clinically documented differential spinal or epidural blockade, [45] because longer drug-exposed regions yield block by lower concentrations of local anesthetic. [66] However, this reasoning does not explain the functionally differential loss from peripheral nerve block. Other factors may include the actual spread of the drug along the nerve, [67] or its selective ability to inhibit Na^+ channels over K^+ channels, [68] which in itself can produce a differential block because these channels are present in very different proportions in different types of nerves. [69] Because of these confounding factors, clinicians should be discouraged from making conclusions about fiber type involvement in chronic pain syndromes based on the dose or concentration requirement for pain relief in diagnostic nerve blockade. [70]

Factors Influencing Anesthetic Activity in Humans

Dosage of Local Anesthetic

As the dosage of local anesthetic is increased, the probability and duration of satisfactory anesthesia increase, and the time to onset of block is shortened. The dosage of local anesthetic can be increased by administering either a larger volume or a more concentrated solution. For example, increasing the concentration of epidurally administered bupivacaine from 0.125 to 0.5 percent while maintaining the same volume of injectate (10 mL) resulted in shorter latency, improved incidence of satisfactory analgesia, and produced a longer duration of sensory analgesia. [71] Similarly, an increase in the concentration of epidural bupivacaine in surgical patients from 0.5 to 0.75 percent with a concomitant increase in dosage from approximately 100 to 150 mg produced a more rapid onset and prolonged sensory anesthesia, a greater frequency of satisfactory sensory anesthesia, and more profound motor blockade [55] (see Fig. 13-12) . The volume per se of anesthetic solution probably influences the spread of anesthesia. For example, 30 mL of 1 percent lidocaine administered into the epidural space produced a level of anesthesia that was 4.3 dermatomes higher than that achieved when 10 mL of 3 percent lidocaine was given. [48]

Addition of Vasoconstrictors

Vasoconstrictors, usually epinephrine (5 mug/mL or 1:200,000), are frequently included in local anesthetic solutions to decrease the rate of vascular absorption, thereby allowing more anesthetic molecules to reach the nerve membrane and so improve the depth and duration of anesthesia, as well as to provide a marker for inadvertent intravascular injection. [72] Epinephrine in a concentration of 1:200,000 has been reported to provide the optimal degree of vasoconstriction when it is employed with lidocaine for epidural or intercostal use. [67] Other vasoconstrictor agents, such as norepinephrine and phenylephrine, have been used, but they do not appear to be superior to epinephrine. For example, equipotent concentrations, for vasoconstriction, of epinephrine and phenylephrine prolong to a similar extent the duration of spinal anesthesia produced by tetracaine. [73]

The extent to which epinephrine prolongs the duration of anesthesia depends on the specific local anesthetic employed and on the site of injection. Epinephrine significantly extends the duration of both infiltration anesthesia and peripheral nerve blocks with many agents, such as lidocaine. [74] [75] Epinephrine does not markedly prolong the duration of motor blockade by epidural bupivacaine or etidocaine; however, it does extend sensory blockade by these epidural agents. [63] The depth and duration of epidural analgesia in obstetric patients were improved slightly when epinephrine 1:300,000 was added to 0.25 percent bupivacaine. [76] alpha-Adrenergic receptors in the spinal cord are known to activate endogenous analgesic mechanisms, [77] and the increased depth of analgesic action produced by epinephrine with both epidural and intrathecal local anesthetics may arise both from this pharmacodynamic mechanism and from the pharmacokinetic (vasoconstrictive) action.

Site of Injection

The most rapid onset but the shortest duration of action occurs following intrathecal or subcutaneous administration of local anesthetics. The longest latencies and durations are observed following brachial plexus blocks. For example, intrathecal bupivacaine usually produces anesthesia within 5 minutes that persists for 3 to 4 hours. However, when bupivacaine is administered for brachial plexus blockade, the onset time is approximately 20 to 30 minutes, whereas the duration of anesthesia averages 10 hours. These differences

---

in the onset and duration of anesthesia are due in part to the particular anatomy of the area of injection, which influences the rates of diffusion and vascular absorption and, in turn, affects the amount of drug employed for various types of regional anesthesia. In the subarachnoid space, for example, the lack of a nerve sheath around the spinal cord and the deposition of the local anesthetic solution in the immediate vicinity of the spinal cord are responsible for the rapid onset of action, whereas the relatively small amount of drug employed for spinal anesthesia probably accounts for the short duration of conduction block.

On the other hand, the onset of brachial plexus blockade is slow, because the anesthetic agent is usually deposited at some distance from the nerve and must diffuse through various tissue barriers before reaching the nerve membrane. The prolonged blockade is probably related to the decreased rate of vascular absorption from that site and to the much larger doses of drug required for this regional anesthetic technique.

Carbonation and pH Adjustment of Local Anesthetics

The presence of bicarbonate carbon dioxide in a solution of local anesthetic applied to an isolated nerve results in a more rapid onset and a decrease in the minimum concentration required for conduction blockade. [78] [79] [80] Although the effect of carbon dioxide on local anesthetic activity is easily demonstrable in isolated nerve, [78] [79] controversy exists concerning the clinical utility of carbonated local anesthetic solutions. For example, some studies have failed to demonstrate a significantly more rapid onset of action for lidocaine carbonate as compared with lidocaine hydrochloride for epidural blockade, [81] whereas others have reported a significant reduction in onset time of epidural blockade with lidocaine carbonate. [82] Similar discrepancies existed when bupivacaine hydrochloride and bupivacaine carbonate were evaluated clinically. [83] [84] Although the general effect of carbon dioxide on the latency of conduction blockade may be controversial, carbonated solutions appear to improve the depth of sensory and motor blockade when they are administered into the epidural space. [81] [82] In addition, these solutions may produce a more complete blockade of the radial, median, and ulnar nerves when they are employed for brachial plexus blockade. [85]

Addition of sodium bicarbonate to local anesthetic solutions has also been reported to decrease the onset time of conduction blockade. [85] [86] An increase in the pH of the local anesthetic solution increases the amount of drug in the uncharged base form and thus should enhance the rate of diffusion across the nerve sheath and nerve membrane, resulting in a more rapid onset of anesthesia. Alkalinization of solutions of bupivacaine or lidocaine reportedly does significantly decrease the latency of onset of brachial plexus and epidural blockade. [85] [86] On the other hand, at least one study failed to demonstrate an improved onset of brachial plexus blockade when the pH of bupivacaine solution was increased by addition of sodium bicarbonate. [87]

Studies on isolated, desheathed nerves using a variety of impulse blocking agents at constant extracellular pH have shown that un-ionized anesthetics (e.g., benzocaine) and ionizable tertiary amines are potentiated by bicarbonate carbon dioxide buffers. [80] In contrast, the potency of permanently cationic (quaternary) local anesthetics is unaffected by bicarbonate carbon dioxide. Therefore, the mechanism of ion trapping, whereby the ionized form of the drug is concentrated in the axoplasm by the internal acidification wrought by membrane-permeant carbon dioxide molecules, does not fully account for potentiation by bicarbonate carbon dioxide. Furthermore, this potentiation in isolated, desheathed nerve is strongly dependent on bicarbonate concentration but is almost independent of carbon dioxide tension (P_{CO_2}). At present, there is no easy explanation for the potentiation of local anesthetics by bicarbonate buffers, nor has a clear connection been established between *in vitro* results and clinical phenomena.

Mixtures of Local Anesthetics

The use of mixtures of local anesthetics for regional anesthesia has become relatively popular in recent years. The basis for this practice is to compensate for the short duration of action of certain rapidly acting agents such as chloroprocaine and lidocaine and the long latency of other agents such as tetracaine and bupivacaine.

Mixtures of chloroprocaine and bupivacaine theoretically should offer significant clinical advantages, owing to the rapid onset and low systemic toxicity of chloroprocaine and the long duration of action of bupivacaine. A mixture of 3 percent chloroprocaine and 0.5 percent bupivacaine was reported to produce a short latency and prolonged duration of brachial plexus blockade. [88] However, subsequent studies indicated that the duration of epidural anesthesia produced by a mixture of chloroprocaine and bupivacaine was significantly shorter than that obtained with bupivacaine alone, whereas time to onset of anesthesia was longer than that of chloroprocaine alone. [89] Isolated nerve studies suggest that a metabolite of chloroprocaine may inhibit the binding of bupivacaine to membrane sites. [90] At present, there do not appear to be any clinically significant advantages to the use of mixtures of local anesthetic agents. Etidocaine and bupivacaine provide clinically acceptable onsets of action and prolonged durations of anesthesia. In addition, the use of catheter techniques for many forms of regional anesthesia makes it possible to extend the duration of action of rapidly acting agents such as chloroprocaine or lidocaine indefinitely. Conversely, clinicians should be cautioned not to use maximum doses of two local anesthetics in combination in the mistaken belief that toxicities of these agents are independent. [91] In the absence of additional data, the toxicities should be presumed to be additive.

Pregnancy

The spread and depth of epidural and spinal anesthesia are reported to be greater in pregnant than in nonpregnant women [92] (Ch. 57) . This finding was originally attributed to mechanical factors associated with pregnancy; that is, dilated epidural veins decrease the diameter of the epidural and subarachnoid space. Hormonal alterations may also play a role in the apparent increase in local anesthetic sensitivity

during pregnancy, because a greater spread of epidural anesthesia occurs during the first trimester of pregnancy, preceding any gross change in vascular dimensions within the epidural or subarachnoid spaces. [93] A correlation appears to exist between progesterone concentrations in cerebrospinal fluid and the milligrams per segment requirement of lidocaine for spinal anesthesia in pregnant and nonpregnant patients. [94] Lidocaine's block of sciatic nerve functions in pregnant rats significantly outlasts that in age-matched nonpregnant female or male rats. [95] Isolated nerve studies have shown a more rapid onset and an increased sensitivity to local anesthetic-induced conduction blockade in vagus nerves obtained from pregnant rabbits as compared with nonpregnant control subjects. [96] [97] However, direct measures of lidocaine uptake kinetics in isolated rat nerve show no effect of pregnancy, [95] a finding suggesting that any pharmacokinetic differences are not due to the nerve per se. These results suggest that hormonal changes associated with pregnancy enhance the apparent potency of local anesthetics; thus, the dosage probably should be reduced in patients in all stages of pregnancy.

CHOICE OF LOCAL ANESTHETIC FOR VARIOUS REGIONAL ANESTHETIC PROCEDURES

On the basis of anatomic considerations, regional anesthesia may be divided into infiltration anesthesia, intravenous regional anesthesia, peripheral nerve blockade, central neural blockade, and topical anesthesia (Chs. 42 to 44 , 69 , and 70) . An additional method of local anesthetic injection, tumescent anesthesia, is included, because it is widely used in office plastic surgery practice.

Infiltration Anesthesia

Any local anesthetic may be employed for infiltration anesthesia. Onset of action is almost immediate for all agents following intradermal or subcutaneous administration; however, duration of anesthesia varies (Table 13-4) . Epinephrine markedly prolongs the duration of infiltration anesthesia by all local anesthetic drugs, although this effect is most pronounced when epinephrine is added to lidocaine. Choice of a specific drug for infiltration anesthesia basically depends on the desired duration of action.

The dosage of local anesthetic required for adequate infiltration anesthesia depends on the extent of the area to be anesthetized and on the expected duration of the surgical procedure. When large surface areas have to be anesthetized, large volumes of dilute anesthetic solutions should be used. These considerations are particularly important when performing infiltration anesthesia in infants and smaller children. As an example, consider a 4-kg infant receiving infiltration anesthesia using the maximum safe dose of lidocaine, 5 mg/kg. Dosing to 5 mg/kg × 4 kg permits 20 mg, which is 1 mL of 2 percent solution, or 4 mL of 0.5 percent solution. Lidocaine is effective for infiltration in concentrations as dilute as 0.3 to 0.5 percent, so the more dilute solution can be used to anesthetize a larger area.

Patients frequently experience pain immediately after subcutaneous injection of local anesthetic solutions. [98] This response is due in part to the acidic nature of these solutions. [95] [100] For example, neutralization of lidocaine solutions by addition of sodium bicarbonate reduces pain on skin infiltration and may improve onset (see earlier). In addition, certain agents such as etidocaine are associated with a greater frequency and intensity of pain, whereas lidocaine is perceived as less painful. [6] [99]

Intravenous Regional Anesthesia

Intravenous regional anesthesia involves intravenous administration of a local anesthetic into a tourniquet-occluded limb (i.e., Bier block). The local anesthetic diffuses from the peripheral vascular bed to nonvascular tissue such as axons and nerve endings. Both the safety and efficacy of this regional anesthetic procedure depend on the interruption of blood flow to the involved limb and on the gradual release of the occluding tourniquet. Intravenous regional anesthesia has been used primarily for surgical procedures on the upper limbs. Shorter procedures on the foot can also be successfully performed with the patient under intravenous regional anesthesia. If a lower leg tourniquet is used, it should be applied just below the fibular neck to avoid pressure over the superficial peroneal nerve.

TABLE 13-4 -- Infiltration Anesthesia

DRUG	CONCENTRATION (%)	PLAIN SOLUTION		EPINEPHRINE-CONTAINING SOLUTION	
		MAXIMUM DOSE (mg)	*DURATION (min)*	*MAXIMUM DOSE (mg)*	*DURATION (min)*
Short duration					
Procaine					
Chloroprocaine	1.0-2.0	800	15-30	1,000	30
Moderate duration					
Lidocaine	0.5-1.0	300	30-60	500	120
Mepivacaine	0.5-1.0	300	45-90	500	120
Prilocaine	0.5-1.0	500	30-90	600	120
Long duration					
Bupivacaine	0.25-0.5	175	120-240	225	180
Etidocaine	0.5-1.0	300	120-180	400	180

Lidocaine has been the drug most frequently used for intravenous regional anesthesia and is the only drug officially approved by the U.S. Food and Drug Administration for intravenous regional anesthesia in the United States. Prilocaine, mepivacaine, chloroprocaine, procaine, bupivacaine, and etidocaine have also been used successfully. One could suppose a safety advantage with the amino-ester linked compounds, because of their hydrolysis in blood; however, thrombophlebitis has been reported in several patients in whom chloroprocaine was used. [101] Cardiovascular collapse has been reported following the use of bupivacaine for intravenous regional anesthesia, and this use of bupivacaine is discouraged. [102]

In general, approximately 3 mg/kg (40 mL of 0.5% solution) of preservative-free lidocaine without epinephrine is used for upper extremity procedures. For surgical procedures on the lower limbs, 50 to 100 mL of 0.25 percent lidocaine has been used.

Peripheral Nerve Blockade

Regional anesthetic procedures that inhibit conduction in fibers of the peripheral nervous system can be classified together under the general category of peripheral nerve blockade (Chs. 43 and 44) . This form of regional anesthesia has been subdivided arbitrarily into minor and major nerve blocks. Minor nerve blocks are defined as procedures involving single nerve entities such as the ulnar or radial nerve, whereas major nerve blocks involve the blocking of two or more distinct nerves or a nerve plexus.

Most local anesthetic drugs can be used for minor nerve blocks. The onset of block is rapid with most drugs, and the choice of drug is determined primarily by the required duration of anesthesia. A classification of the various drugs according to their duration of action is shown in Table 13-5 (Ch. 43) . The duration of both

sensory analgesia and motor blockade is prolonged significantly when epinephrine is added to the various local anesthetic solutions.

In 1986, a technique of intrapleural regional analgesia was described as an alternative to multiple intercostal nerve blocks. [103] This procedure involves administration of local anesthetic solution into the pleural space. An epidural needle is inserted into the pleural space, usually by way of the fourth to the ninth intercostal space. An epidural catheter is then passed into the pleural space approximately 5 cm beyond the tip of the needle. The needle is removed, and the local anesthetic is administered through the catheter. Intrapleural analgesia can also be positioned by the surgeon through the open chest during thoracotomy. Although this technique appeared useful for unilateral postoperative analgesia following cholecystectomy, mastectomy, and nephrectomy, [104] [105] its efficacy for post-thoracotomy pain is doubtful. [106] Most frequently, 22 to 30 mL of 0.5 percent bupivacaine with epinephrine is employed in this technique; the duration of analgesia averages approximately 8 hours with a range of 4 to 24 hours. The advantage of the technique is the ability to administer subsequent injections of local anesthetics via catheter to provide long-lasting analgesia without subjecting patients to repeated multiple intercostal nerve blocks. Caution is advised, however, because this technique has been associated with extremely high plasma concentrations of anesthetic, with an associated risk of convulsions. [103]

Brachial plexus blockade for upper limb surgery is the most common major peripheral nerve block technique. A significant difference exists among the onset times of various agents when these blocks are used (Table 13-6) (Ch. 43) . In general, the agents of intermediate potency exhibit a more rapid onset than the more potent compounds. Onset times of approximately 14 minutes for lidocaine and mepivacaine have been reported, compared with approximately 23 minutes for bupivacaine. [107] Etidocaine may be an exception, because it produces a relatively rapid onset and a long duration of block.

Epinephrine prolongs the duration of most local anesthetics employed for brachial plexus blockade, but it is less effective with drugs having intrinsically longer durations of action. The variation in duration of anesthesia after brachial plexus blockade is also considerably greater than that observed with other types of conduction block. For example, durations of anesthesia varying from 4 to 30 hours have been reported for bupivacaine. It would be prudent to forewarn patients who are about to be given a major nerve block about the possibility of prolonged sensory and motor block in the involved region, particularly when agents such as bupivacaine and etidocaine are employed. Knowledge shapes expectation and can often relieve anxiety over unusual sensations and may thus increase comfort and reduce pain.

TABLE 13-5 -- Minor Nerve Blocks

DRUG	USUAL CONCENTRATION (%)	PLAIN SOLUTIONS			EPINEPHRINE-CONTAINING SOLUTIONS
		USUAL VOLUME (mL)	*DOSAGE (mg)*	*AVERAGE DURATION (min)*	*AVERAGE DURATION (min)*

Tetracaine	0.25-0.5	30-50	200	20-30	300-600

Central Neural Blockade

Any of the local anesthetic drugs may be used for epidural anesthesia (Table 13-7) , although procaine and tetracaine are rarely used, owing to their long onset times (Ch. 42) . The drugs of intermediate potency produce surgical anesthesia of 1 to 2 hours' duration, whereas the long-acting drugs usually produce 3 to 5 hours of anesthesia. The duration of short- and intermediate-acting drugs is significantly prolonged by the addition of epinephrine (1:200,000), whereas the long-acting drugs benefit little from its addition. Onset of lumbar epidural anesthesia occurs within 5 to 15 minutes following administration of chloroprocaine, lidocaine, mepivacaine, and prilocaine. Bupivacaine has a slower onset of action.

Bupivacaine at 0.125 and 0.25 percent produces adequate analgesia with minimal motor deficit. These solutions of bupivacaine are useful for obstetric epidural analgesia and postoperative analgesia. Bupivacaine at 0.5 to 0.75 percent is associated with a more profound degree of motor block, which makes these solutions most suitable for major surgical procedures. Etidocaine produces adequate sensory analgesia and profound, long-lasting motor block and is primarily useful for surgical procedures in which muscle relaxation is required.

Drugs available for subarachnoid administration are shown in Table 13-8 (Ch. 42) . Tetracaine is available both as crystals and as a 1 percent solution, which may be diluted with 10 percent glucose to obtain a 0.5 percent hyperbaric solution.

Hypobaric solutions of tetracaine (tetracaine in sterile water) may be used for specific operative situations; for example, anorectal or hip surgery. Isobaric tetracaine obtained by mixing 1 percent tetracaine with cerebrospinal fluid or normal saline is occasionally used. Bupivacaine is widely used as a spinal anesthetic, either as a hyperbaric solution at a concentration of 0.75 percent with 8.25 percent dextrose or by using the nearly isobaric 0.5 percent solution.

Intrathecal bupivacaine possesses an anesthetic profile similar to that of tetracaine. [108] [109] However, differences do exist between the two drugs. Although two-segment regression of anesthesia is similar for bupivacaine and tetracaine, the total duration of sensory anesthesia is significantly longer following the subarachnoid administration of tetracaine. The depth and duration of motor blockade are also greater with tetracaine than with bupivacaine. On the other hand, bupivacaine has been reported in some studies to be associated with less hypotension than tetracaine. In addition, the frequency of tourniquet pain in the lower limbs during certain orthopedic surgical procedures has been reported to be significantly reduced when bupivacaine instead of tetracaine is employed for spinal anesthesia. [110] [111]

Whereas tetracaine and bupivacaine are considered to be agents of long duration, lidocaine provides a short duration of spinal anesthesia. Onset of spinal anesthesia is extremely rapid with a drug such as lidocaine. The addition of vasoconstrictors may prolong the duration of spinal anesthesia: for example, addition of 0.2 mg of epinephrine to tetracaine solutions produces a 50 percent or greater increase in duration. The duration of spinal anesthesia produced by tetracaine can also be increased to a similar extent by adding 1 mg of phenylephrine. The addition of epinephrine to bupivacaine or lidocaine may not significantly prolong the duration of

surgical anesthesia (e.g., in thoracic segments [112] [113]) although the total duration of anesthesia (e.g., lower extremity motor block) is significantly increased.

Topical Anesthesia

Several local anesthetic formulations are available for topical anesthesia (Table 13-9) (Table Not Available) , most commonly lidocaine,

TABLE 13-7 -- Epidural Anesthesia

dibucaine, tetracaine, and benzocaine. In general, these preparations provide effective but relatively short durations of analgesia when they are applied to mucous membranes or abraded skin. In addition, lidocaine and tetracaine sprays have been employed for endotracheal anesthesia prior to intubation. A topical anesthetic formulation, Emla, which is a eutectic mixture of 2.5 percent lidocaine base and 2.5 percent prilocaine base, is widely used for cutaneous analgesia. [114] Clinical studies have demonstrated that this preparation can decrease the pain associated with the percutaneous insertion of intravenous needles and cannulas. [115] In addition, Emla has been successfully employed for cutaneous anesthesia in skin grafting procedures. [116] This preparation must be applied under an occlusive bandage for 45 to 60 minutes to obtain effective cutaneous anesthesia. Emla appears quite safe in neonates, and methemoglobinemia from prilocaine is exceedingly uncommon. Emla is more effective for newborn circumcision than placebo, but it is less effective than dorsal penile nerve block. Several alternative topical local anesthetic formulations also are in use, including tetracaine. Physical methods to accelerate local anesthetic transit across skin are also under study, including iontophoresis and electrophoration.

Topical anesthesia through cut skin may be provided by a mixture of tetracaine, epinephrine (adrenaline), and cocaine, known as TAC. TAC is widely used in pediatric emergency rooms in the United States for liquid application into lacerations that require suturing. TAC is usually supplied as tetracaine 0.5 percent, epinephrine 1:2,000, and cocaine 10 to 11.8 percent, although studies suggest that more dilute concentrations may be almost equally effective and are less likely to cause toxicity. The generally recommended safe

TABLE 13-9 -- Various Preparations Intended for Topical Anesthesia

(Not Available)

Modified from Covino and Vassallo [123]

maximum dose is 3 to 4 mL for adults or 0.05 mL/kg for children. TAC is ineffective through intact skin; in contrast, it can be absorbed rapidly from mucosal surfaces, thus leading to toxic reactions. There is a report of a fatal reaction following application to a nasal laceration, with presumed dripping into the mouth and rapid mucosal absorption. [117] [118]

Because of concerns regarding cocaine toxicity and the potential for diversion and abuse, several groups have investigated alternative cocaine-free topical preparations. Tetracaine-phenylephrine preparations were found to be as effective as TAC. [119]

Tumescent Anesthesia

A technique of local anesthesia most commonly employed by plastic surgeons during liposuction procedures involves subcutaneous injection of large volumes of dilute local anesthetic in combination with epinephrine and other agents. Total doses of lidocaine ranging from 35 to 55 mg/kg have been reported to produce safe plasma concentrations, which may peak more than 8 to 12 hours after infusion. [120] Despite these seemingly huge doses, very good outcomes have been reported in large series. [121] The factors governing uptake and clearance from this method of local anesthetic delivery deserve further study. Clinicians should use great caution in administering additional local anesthetics by infiltration or other routes for at least 12 to 18 hours following use of this technique.

/das/book/view/29494766/875/159.html

PHARMACOKINETICS

The concentration of local anesthetics in blood is determined by the amount injected, the rate of absorption from the site of injection, the rate of tissue distribution, and the rate of biotransformation and excretion of the specific drug. Patient-related factors such as age, cardiovascular status, and hepatic function influence the physiologic disposition and the resultant blood concentrations of local anesthetics.

Absorption

The systemic absorption of local anesthetics is determined by the site of injection, dosage and volume, addition of a vasoconstrictor agent, and pharmacologic profile of the agent itself. A comparison of the blood concentration of local anesthetics following various routes of administration reveals that the anesthetic drug level is highest after intercostal nerve blockade, followed, in order of decreasing concentration, by injection into the caudal epidural space, lumbar epidural space, brachial plexus, and subcutaneous tissue [122] (Fig. 13-13) (Figure Not Available) . When a local anesthetic solution is exposed to an area of greater vascularity, a greater rate and degree of absorption occur. This relationship is of clinical significance because use of a fixed dose of a local anesthetic agent may be potentially toxic in one area of administration but not in others. For example, the use of 400 mg of lidocaine without epinephrine for intercostal nerve block results in an average peak venous plasma level of approximately 7 mug/mL, which is sufficiently high to cause symptoms of

Figure 13-13 (Figure Not Available) Peak venous blood concentrations of various local anesthetics following injection into different sites. *(From Covino and Vassallo [123])*

CNS toxicity in some patients. [122] By comparison, this same dose of lidocaine employed for brachial plexus block yields a mean maximum blood level of approximately 3 mug/mL, which is rarely associated with signs of toxicity.

The maximum blood level of local anesthetic drugs is related to the total dose of drug administered for any particular site of administration. For most drugs, there is a linear relationship between the amount of drug administered and the resultant peak anesthetic blood levels. [123] Higher blood levels also follow from administration of larger volumes of a correspondingly dilute solution than from the same dose in a smaller volume.

Local anesthetic solutions frequently contain a vasoconstrictor agent, usually epinephrine, in concentrations varying from 5 to 20 mug/mL. Epinephrine decreases the rate of absorption of certain agents from various sites of administration and thus lowers their potential systemic toxicity. A 5 mug/mL dose of epinephrine (1:200,000) significantly reduces the peak blood levels of lidocaine and mepivacaine irrespective of the site of administration. The peak blood levels of bupivacaine and etidocaine are minimally influenced by addition of a vasoconstrictor following injection into the lumbar epidural space. [124] However, epinephrine significantly reduces the rate of vascular absorption of these drugs when they are used for peripheral nerve blocks such as brachial plexus blockade. [125]

Differences also exist in the rate of absorption of various local anesthetic drugs. For example, a comparison of drugs of similar anesthetic profiles reveals that lidocaine is absorbed more rapidly following brachial plexus blockade than

TABLE 13-10 -- Pharmacokinetic Properties of Various Amide Local Anesthetics

AGENT	$t_{1/2alpha}$ (min)	$t_{1/2beta}$ (min)	V_{DSS} (L)	$t_{1/2gamma}$ (h)	CLEARANCE (L/min)

Lidocaine	1.0	9.6	91	1.6	0.95
Mepivacaine	0.7	7.2	84	1.9	0.78
Bupivacaine	2.7	28.0	72	3.5	0.47
Etidocaine	2.2	19.0	133	2.6	1.22

$t_{1/2\ alpha}$, $t_{1/2\ beta}$, elimination half-life; $t_{1/2\ gamma}$, V_{dss} , volume of distribution at steady state

is prilocaine, whereas bupivacaine is absorbed more rapidly than etidocaine. [123]

Distribution

The systemic distribution of local anesthetics can be described sufficiently by a two-compartment model. [126] The rapid disappearance phase is believed to be related to uptake by rapidly equilibrating tissues (i.e., tissues that have a high vascular perfusion). The slower phase of disappearance from blood is mainly a function of the particular compound [127] (Table 13-10) . The half-lives of lidocaine and mepivacaine are similar, but a comparison of bupivacaine and etidocaine reveals that etidocaine has a more rapid rate of tissue redistribution and biotransformation than does bupivacaine. [128]

Local anesthetic drugs are distributed throughout all body tissues, but the relative concentration in different tissues varies. In general, the more highly perfused organs show higher concentrations of local anesthetic drug than the less well perfused organs. Local anesthetics are rapidly extracted by lung tissue, so that the whole blood concentration of local anesthetics decreases markedly as these agents pass through the pulmonary vasculature. [129] [130] The highest percentage of an injected dose of a local anesthetic is found in skeletal muscle. Although this tissue does not show any particular affinity for this class of drugs, the mass of skeletal muscle makes it the largest reservoir for local anesthetic drugs.

Biotransformation and Excretion

The pattern of metabolism of local anesthetic agents varies according to chemical classification. The ester, or procaine-like, drugs undergo hydrolysis in plasma by the pseudocholinesterase enzymes. Chloroprocaine shows the fastest rate (4.7 mol/mL/h), compared with a rate of 1.1 mol/mL/h for procaine and 0.3 mol/mL/h for tetracaine. [131] [132]

The aminoamide drugs undergo enzymatic degradation primarily in the liver. Lidocaine is metabolized more rapidly than mepivacaine, [132] and bupivacaine is

metabolized more slowly than either lidocaine or mepivacaine. [133] Some degradation of the amide-type compounds may take place in tissues other than liver; in particular, the metabolism of lidocaine is discussed in detail elsewhere. [132]

The excretion of the metabolites of amide-type local anesthetics occurs via the kidney. Less than 5 percent of the unchanged drug is excreted via the kidney into the urine.

Pharmacokinetic Alterations by Patient Status

A patient's age may influence the physiologic disposition of local anesthetics. The half-life of lidocaine following intravenous administration averaged 80 minutes in human volunteers whose ages varied from 22 to 26 years. On the other hand, volunteers 61 to 71 years of age demonstrated a significantly prolonged lidocaine half-life of 138 minutes [134] (Ch. 61) .

Newborn infants have immature hepatic enzyme systems and prolonged elimination of lidocaine and bupivacaine [135] [136] (Chs. 58 and 59) . Prolonged elimination is particularly an issue for continuous infusions of local anesthetics in infants, and seizures have been associated with high bupivacaine infusion rates. [137] [138] Based on analysis of these cases, a maximum infusion rate of 0.4 mg/kg/h for prolonged bupivacaine infusions has been proposed for children and adults, whereas prolonged infusion rates for neonates and young infants should not exceed 0.2 mg/kg/h. Even at 0.2 mg/kg/h, plasma bupivacaine concentrations were found to be rising toward a toxic range in some younger infants after 48 hours. Similarly, prolonged lidocaine infusions in neonates should not exceed 0.8 mg/kg/h.

The rate of degradation of the amide type of local anesthetic drugs is influenced by the hepatic status of the individual patient. In those patients in whom liver blood flow is abnormally low or liver function is poor, significantly higher blood levels of the amide drugs occur. An average lidocaine half-life of 1.5 hours was reported in volunteers with normal hepatic function, whereas patients with liver disease demonstrated an average half-life of 5.0 hours. [139] The rate of lidocaine disappearance from blood has also been shown to be markedly prolonged in patients with congestive heart failure. [140]

TOXICITY

Local anesthetic drugs are relatively free of side effects if these agents are administered in an appropriate dosage and in the correct anatomic location. However, systemic and localized toxic reactions can occur, usually owing to accidental

intravascular or intrathecal injection or to administration of an excessive dose. In addition, specific adverse effects are associated with the use of certain drugs, such as allergic reactions to the aminoester drugs and methemoglobinemia following the use of prilocaine.

Systemic Toxicity

Systemic reactions to local anesthetics primarily involve the CNS and the cardiovascular system (Chs. 42 to 44 and 70) In general, the CNS is more susceptible to the actions of systemic local anesthetics than the cardiovascular system, and thus the dose and blood level of local anesthetic required to produce CNS toxicity are usually lower than those resulting in circulatory collapse (Fig. 13-14) (Figure Not Available) .

Central Nervous System Toxicity

The initial symptoms of local anesthetic-induced CNS toxicity are feelings of lightheadedness and dizziness, followed frequently by visual and auditory disturbances such as difficulty in focusing and tinnitus. Other subjective CNS symptoms include disorientation and occasional feelings of drowsiness. Objective signs of CNS toxicity are usually excitatory and include shivering, muscle twitching, and tremors initially involving muscles of the face and distal parts of the extremities. Ultimately, generalized convulsions of a tonic-clonic nature occur. If a sufficiently large dose or a rapid intravenous injection of a local anesthetic is administered, the initial signs of CNS excitation are rapidly followed by a state of generalized CNS depression. Seizure activity ceases, and respiratory depression and, ultimately, respiratory arrest may occur. In some patients, CNS depression without a preceding

Figure 13-14 (Figure Not Available) Relationship between plasma concentration of lidocaine and various signs and symptoms of toxicity. (*Modified from Mather and Cousins* [235])

excitatory phase is seen, particularly if other CNS depressant drugs have been administered.

CNS excitation is thought to be the result of an initial blockade of inhibitory pathways in the cerebral cortex by local anesthetic drugs. [141] The blockade of inhibitory pathways allows facilitatory neurons to function in an unopposed fashion, which results in an increase in excitatory activity leading to convulsions. An increase in the dose of local anesthetic leads to an inhibition of activity of both inhibitory and facilitatory circuits, resulting in a generalized state of CNS depression.

In general, a correlation exists between anesthetic potency and intravenous CNS toxicity of various drugs (Fig. 13-15) . For example, in cats, the dose of intravenous procaine required to cause convulsions is approximately seven times greater than the convulsive dose of bupivacaine. [142] However, bupivacaine is also approximately eight times more potent than procaine as a local anesthetic. [143] Intravenous infusion studies in human volunteers have also demonstrated an inverse relationship between the intrinsic anesthetic potency of various drugs and the dosage required to induce CNS toxicity. [143] [144]

The rate of injection and the rapidity with which a particular blood level is achieved alter the toxicity of local anesthetic drugs. For example, in human volunteers, an average dose of 236 mg of etidocaine and a venous blood level of 3.0 mug/mL resulted in CNS symptoms when an infusion rate of 10 mg/min was employed. [143] When the infusion rate was increased to 20 mg/min, an average of 161 mg of etidocaine, which produced a venous plasma level of approximately 2 mug/mL, caused symptoms of CNS toxicity.

Respiratory or metabolic acidosis increases the risks of CNS toxicity from local anesthetics in animals and patients. In cats, the convulsive threshold of various local anesthetics was inversely related to the arterial P_{CO_2} level [142] (see Fig. 13-15) . An increase in Pa $_{CO_2}$ from 25 to 40 mm Hg to 65 to 81 mm Hg decreases the convulsive threshold of procaine, mepivacaine, prilocaine, lidocaine, and bupivacaine by approximately 50 percent.

An elevation of Pa $_{CO_2}$ enhances cerebral blood flow, so that more anesthetic is delivered more rapidly to the brain. In addition, diffusion of carbon dioxide into neuronal cells decreases intracellular pH and thus facilitates the conversion of the base form of the drugs to the cationic form. The cationic form does not diffuse well across the nerve membrane, so that ion trapping occurs and increases the apparent CNS toxicity of local anesthetics.

Hypercarbia and/or acidosis also decreases the plasma protein binding of local anesthetic agents. [145] [146] Accordingly, an elevation in Pa $_{CO_2}$ or a decrease in pH increases the proportion of free drug available for diffusion into the brain. On the other hand, acidosis increases the cationic form of the local anesthetic, a change that should decrease the rate of diffusion through lipoid barriers. The clinical implication of this effect of hypercapnia and acidosis on toxicity deserves emphasis. Seizures and CNS depression produce hypoventilation and respiratory acidosis, which further exacerbates the CNS toxicity. In the setting of local anesthetic toxic reactions, it is essential to provide prompt assisted ventilation and circulatory support as needed to prevent or correct hypercapnia and acidosis.

Figure 13-15 Relationship between convulsive dose of procaine, lidocaine, and bupivacaine in cats and their relative *in vivo* anesthetic potency. The open bar represents convulsive dose during normocarbia, and the hatched bar is the convulsive dose under hypercarbic conditions.

Cardiovascular System Toxicity

Local anesthetic agents can exert a direct action on both the heart and the peripheral blood vessels.

Direct Cardiac Effects

The primary cardiac electrophysiologic effect of local anesthetics is a decrease in the rate of depolarization in the fast conducting tissues of Purkinje fibers and

ventricular muscle. [141] [142] This reduction in rate is believed to be due to a decrease in the availability of fast Na^+ channels in cardiac membranes. Action potential duration and the effective refractory period are also decreased by local anesthetics. [147] However, the ratio of effective refractory period to action potential duration is increased both in Purkinje fibers and in ventricular muscle.

Qualitative differences may exist among the electrophysiologic effects of various agents. Bupivacaine depresses the rapid phase of depolarization (V_{max}) in Purkinje fibers and ventricular muscle to a greater extent than does lidocaine. [147] In addition, the rate of recovery from a use-dependent block is slower in bupivacaine-treated papillary muscles than in lidocaine-treated muscles. [148] This slow rate of recovery results in an incomplete restoration of Na^+ channel availability between action potentials, particularly at high heart rates. In contrast, recovery from lidocaine is complete, even at rapid heart rates. These differential effects of lidocaine and bupivacaine have been advanced as explanations of the antiarrhythmic properties of lidocaine and the arrhythmogenic potential of bupivacaine.

Electrophysiologic studies in intact dogs and in humans have shown that high blood levels of local anesthetics prolong conduction time through various parts of the heart, as indicated in the electrocardiogram by an increase in the PR interval and QRS complex duration. Extremely high concentrations of local anesthetics depress spontaneous pacemaker activity in the sinus node, resulting in sinus bradycardia and sinus arrest.

Local anesthetic drugs also exert profound effects on the mechanical activity of cardiac muscle. All local anesthetics exert a dose-dependent negative inotropic action on isolated cardiac tissue. [149] [150] This depression of cardiac contractility is proportional to the conduction blocking potency of the various agents in isolated nerves [150] and in dogs [151] [152] [153] (Table 13-11) . Thus, bupivacaine and tetracaine are more potent cardiodepressants than lidocaine, which, in turn, is a more potent cardiodepressant than chloroprocaine.

Local anesthetics may depress myocardial contractility by affecting calcium influx and triggered release. For example, procaine blocks the intracellular release of calcium in isolated sarcoplasmic reticular preparations. [154] However, in the isolated guinea pig heart, an increase in the extracellular concentration of calcium failed to reverse the negative inotropic action of bupivacaine or lidocaine. [155]

Voltage-clamp studies show that lidocaine inhibits cardiac sarcolemmal Ca^{2+} currents as well as Na^+ currents. [156] This action alone should be antagonized by an increase in extracellular Ca^{2+}, so it is likely that the negative inotropy of local anesthetics involves several mechanisms, not just the blockade of inward currents.

Direct Peripheral Vascular Effects

Local anesthetic drugs exert a biphasic effect on peripheral vascular smooth muscle. Low concentrations of lidocaine and bupivacaine produced vasoconstriction in the cremaster muscle of rats, whereas high concentrations increased arteriolar diameter, indicative of vasodilation. [60] [61]

In vivo studies have also demonstrated that small doses of

TABLE 13-11 -- Comparative Effect of Various Local Anesthetic Drugs on Cardiac Contractility and Cardiac Output

DRUG	RELATIVE ANESTHETIC POTENCY	ISOLATED GUINEA PIG ATRIA (50%) (mu g/mL)	CARDIAC OUTPUT IN DOGS (50%) (mg/kg)
Procaine	1	277	100
Chloroprocaine	1	102	30
Cocaine	2	56	--
Lidocaine	2	67	30
Prilocaine	2	42	40
Mepivacaine	2	55	40
Etidocaine	6	--	20
Bupivacaine	8	6	10
Tetracaine	8	6	20

local anesthetics decrease peripheral arterial flow without any change in arterial blood pressure, whereas larger doses increased blood flow. [56] Cocaine is the only local anesthetic that consistently causes vasoconstriction at all concentrations, owing to its ability to inhibit the uptake of norepinephrine by storage granules and thus to potentiate neurogenic vasoconstriction. [157] [158]

Some studies in anesthetized animals and in isolated heart-lung preparations have found increases in pulmonary vascular resistance from local anesthetic infusions. [152] [153] [159] Addition of lidocaine to cultured smooth muscle cells acutely elevates intracellular Ca^{2+} and could be a mechanism for local vasoconstriction. How many of these pulmonary vascular effects are direct actions and how much they reflect responses to circulatory or respiratory depression from drug acting on the CNS are not determined.

Comparative Cardiovascular Toxicity

In recent years, the more potent drugs (i.e., bupivacaine and etidocaine) have been reported to cause rapid and profound cardiovascular depression (Ch. 57) . The cardiotoxicity of the more potent drugs such as bupivacaine appears to differ from that of lidocaine in the following manner: [49]

1. The ratio of the dosage required for irreversible cardiovascular collapse (CC) and the dosage that produces CNS toxicity (convulsions)--that is, the CC/CNS ratio--is lower for bupivacaine and etidocaine than for lidocaine.
2. Ventricular arrhythmias and fatal ventricular fibrillation may occur often following rapid intravenous administration of a large dose of bupivacaine, but they occur far less frequently with lidocaine.
3. The pregnant animal or patient may be more sensitive to the cardiotoxic effects of bupivacaine than the nonpregnant animal or patient.
4. Cardiac resuscitation is more difficult following bupivacaine-induced cardiovascular collapse.
5. Acidosis and hypoxia markedly potentiate the cardiotoxicity of bupivacaine.

Cardiovascular Collapse/CNS Ratio

In sheep, the CC/CNS dose and blood level ratios for bupivacaine and etidocaine were found to be lower than those for lidocaine. [160] A CC/CNS dose ratio of 7.1 ± 1.1 was found for lidocaine, a finding indicating that seven times as much drug was required to induce irreversible cardiovascular collapse as was needed to produce convulsions (Fig. 13-16) . The CC/CNS dose ratio for bupivacaine was 3.7 ± 0.5, whereas that for etidocaine was 4.4 ± 0.9, and the CC/CNS blood level ratio for lidocaine was 3.6 ± 0.3, compared with 1.6 to 1.7 for bupivacaine and etidocaine. At the time of cardiovascular collapse, higher concentrations of bupivacaine and etidocaine than of lidocaine were present in the myocardium, a finding that suggests that some of the enhanced cardiac toxicity of these more potent agents is due to greater myocardial uptake.

Ventricular Arrhythmias

Bupivacaine and, to a lesser degree, etidocaine may produce severe cardiac arrhythmias, including ventricular fibrillation, in various animal species [155] [161] [162] [163] [164] [165] (Table 13-12) . Ventricular arrhythmias were rarely seen with lidocaine, mepivacaine, or tetracaine. [166] These electrophysiologic effects of bupivacaine may result

in conduction abnormalities, leading to a reentrant type of arrhythmia similar to torsades de pointes arrhythmias. [162] Although the cardiac arrhythmias observed in bupivacaine-treated animals are due in part to a direct cardiac effect, injection of bupivacaine directly into certain regions of the brain resulted in the development of cardiac arrhythmias, a finding that may indicate a relationship between the CNS and cardiotoxic effects of bupivacaine. [167] [168]

Enhanced Cardiotoxicity in Pregnancy

A number of the cardiotoxic reactions reported following the use of bupivacaine occurred in pregnant patients (Ch. 57) . As a result, the 0.75 percent solution is no longer recommended for use in obstetric anesthesia in the United States. In studies in pregnant and nonpregnant sheep, the CC/CNS dose ratio of bupivacaine decreased from 3.7 ± 0.5 in nonpregnant to 2.7 ± 0.4 in pregnant animals. [160] However, little difference was observed in the CC/CNS blood level ratio, which varied from 1.6 ± 1.0 in nonpregnant animals to 1.4 ± 0.1 in pregnant ewes. The blood level of bupivacaine

Figure 13-16 Dose of lidocaine, bupivacaine, and etidocaine that produces convulsive activity (CD) and cardiovascular collapse (CC) in sheep.

at which circulatory collapse occurred was lower in pregnant animals, but no difference in the myocardial uptake of bupivacaine in pregnant and nonpregnant sheep was observed at the time of cardiovascular collapse. Thus, if the pregnant patient is more susceptible to the cardiotoxic effects of bupivacaine, this effect apparently is not related to a greater myocardial uptake of drug.

Subsequent electrophysiologic studies in rabbits *in vivo* have shown that both pregnancy and prolonged (4-day) progesterone treatment of previously ovariectomized females

TABLE 13-12 -- Ventricular Arrhythmias Following the Use of Lidocaine and Bupivacaine in Various Animal Preparations

ANIMAL MODEL	VENTRICULAR ARRHYTHMIAS	
	LIDOCAINE	***BUPIVACAINE***
Unanesthetized paralyzed cat	6% PVC	100% PVC
Anesthetized dog	0	0
Unanesthetized dog	0	40%--VT, VF
Unanesthetized sheep	0	80-100%--PVC, VT
Hypoxic, acidotic sheep	0	17-50%--VT, VF
Isolated guinea pig heart	0	33-50%--PVC bigeminy, trigeminy
Intracoronary injection in anesthetized pigs	VF at 64 mg	VF at 4 mg
Intracranial injections in cats	17% VT	100% VT
Intracranial injections in rats	55% VT No deaths	55% VT 50% deaths

PVC: premature ventricular contractions; VF: ventricular fibrillation; VT: ventricular tachycardia

lead to increased myocardial [169] [170] and peripheral nerve [165] [166] conduction block by local anesthetics. In the myocardium of these animals, there are a reduction of excitability and the occasional appearance of secondary slow waves in response to a single stimulus that could develop into a circus rhythm and could support ventricular tachycardia, leading to fibrillation and cardiac collapse.

Cardiac Resuscitation

Studies in acidotic and hypoxic sheep have demonstrated that cardiac resuscitation following bupivacaine-induced toxicity is difficult. [171] Studies in cats and hypoxic dogs rendered toxic with bupivacaine indicate that resuscitation is possible [172] [173] if massive doses of epinephrine and atropine are employed. In addition, bretylium, but not lidocaine, could raise the ventricular tachycardia threshold that was lowered by bupivacaine. [174] Other agents have been tested for their effects in resuscitation from bupivacaine cardiotoxicity. Amrinone was found to be effective in two studies in dogs, but it was ineffective in a study in rats. Case reports have suggested that either bretylium or phenytoin may be effective.

Ropivacaine

In response to reports of cardiovascular toxicity from accidental intravenous injections of bupivacaine, [102] a long-lasting amide local anesthetic was developed. Ropivacaine (Naropin) differs from bupivacaine both in the substitution of a propyl for the butyl group on the piperidine ring's tertiary nitrogen atom and in that it consists of a single enantiomer, the *S*-stereoisomer. Commercial bupivacaine is a

racemic mixture of both isomers, whereas lidocaine, lacking a chiral center, has no stereosymmetry. With these designed changes in molecular structure, it was hoped that ropivacaine would be less intrinsically cardiotoxic. The hope that it would be cleared more rapidly from the circulation if the drug were injected intravenously has, however, been confounded by the evidence that the *S*-enantiomers of mepivacaine and bupivacaine are metabolized by the liver more slowly than the corresponding *R*-enantiomers, as well as having a slower rate of total body clearance. [175] [176]

The cardiovascular toxicity of local anesthetics is complex, involving direct effects on the myocardium, [150] on vascular tissue [156] (both smooth muscle and its neuronal supply), and on the central innervation of the heart. [167] [177] In both neuronal and cardiac Na^+ channels, the S-isomers of these piperidine-containing local anesthetics are less potent than the *R*-isomers, [178] [179] but the stereopotency of the cardiovascular effects mediated through vascular tissue and CNS is not known. Because of the smaller propyl substituent, (S-)ropivacaine is slightly less potent than S-bupivacaine in its effect on single sodium channels [180] and on isolated nerve action potentials. [181] More germane to the direct cardiotoxic actions is that the very slow reversal of Na^+ channel blockade after a cardiac action potential, a hallmark of bupivacaine, is considerably faster with ropivacaine. [182] Such slow drug reversal has been related to persistent conduction slowing, reentry circuits, and the development of ventricular tachycardias leading to fibrillation. [148] In addition to these electrical differences, the negative inotropic potency of ropivacaine on isolated cardiac tissue appears to be considerably less than that of bupivacaine. [182] [183] Both electrical and mechanical differences in the toxic profiles may arise from the selective inhibition of Ca^{2+} currents by bupivacaine. [149] [166] [184]

Do the data so far support the claim of a greater therapeutic index for ropivacaine than bupivacaine, particularly with regard to cardiotoxicity? In clinical studies comparing potencies of ropivacaine and bupivacaine administered for brachial plexus [185] or lumbar epidural block, [186] [187] the anesthetic profiles of the drugs were almost identical. A third study comparing lumbar epidural 0.5 percent bupivacaine with 0.75 percent ropivacaine also found no significant differences in motor or sensory effects between the drugs at these different concentrations. [188] Overall, it appears that ropivacaine is slightly less potent than (11.3 to 11.5) or as potent as bupivacaine for regional anesthesia. In laboratory animals and in humans, ropivacaine also produces blocks of shorter duration than those due to bupivacaine. [187] [189] [190]

At the projected equipotent doses for nerve block, are the drugs equally toxic? The overall impression is that ropivacaine is less cardiotoxic than bupivacaine. In contrast to the studies on isolated tissues, ropivacaine and bupivacaine injected intravenously *in vivo* were cardiodepressant in the order of their nerve blocking potency. [191] [192] Electrical signs of conduction slowing *in vivo* are less with intravenous ropivacaine than with bupivacaine, [191] and cardiac collapse and ventricular

fibrillation in dogs were far more frequent with bupivacaine than with ropivacaine delivered at the same doses. [193] Chirality rather than the difference between propyl and butyl *N*-piperidine substituent may account for the greater safety of ropivacaine, for many fewer cardiotoxic events also occur when *S*-bupivacaine (levobupivacaine) rather than racemic bupivacaine is administered to sheep. In contrast, death from ventricular arrhythmias is comparable between ropivacaine and bupivacaine at equipotent doses in sheep. Convulsant doses of ropivacaine are larger than those of bupivacaine, but they are smaller than those of lidocaine. [194] [195]

Perhaps the most notable difference between these two drugs is that aggressive cardiac resuscitation after an intentional intravenous bolus in dogs led to effective reversal of the toxic effects far more frequently with ropivacaine than with bupivacaine. [193] Furthermore, intravenous ropivacaine is cleared from the circulation more rapidly than intravenous bupivacaine. [196] This feature enhances the safety of ropivacaine relative to bupivacaine when the drugs are used for repeated dosing or by infusion. Finally, the major problem with intravenous bupivacaine that prompted the search for a new long-lasting local anesthetic, namely, increased cardiovascular toxicity during pregnancy, [197] [198] appears to have been overcome with ropivacaine. The cardiotoxic profile of ropivacaine in pregnant ewes is the same as the corresponding profile in nonpregnant ewes. [198] For these several reasons, it appears that ropivacaine may be a significantly safer drug than bupivacaine for local and regional anesthesia.

Acidosis and Hypoxia

Hypercarbia, acidosis, and hypoxia potentiate the negative chronotropic and inotropic actions of lidocaine and bupivacaine in isolated cardiac tissue, and the combination of hypoxia and acidosis markedly potentiates the cardiodepressant effects of bupivacaine. Hypoxia and acidosis also increased the frequency of cardiac arrhythmias and the mortality rate in sheep following intravenous administration of bupivacaine. [171] [199] Hypercarbia, acidosis, and hypoxia occur very rapidly in some patients following seizure activity owing to the rapid accidental intravascular injection of local anesthetic agents. [200] Thus, the cardiovascular depression observed in some patients following accidental intravenous injection of bupivacaine may be related in part to the severe acid-base changes that occur during toxic reactions to this agent.

Methemoglobinemia

A unique systemic side effect associated with a specific local anesthetic is the development of methemoglobinemia following administration of large doses of prilocaine. [201] A dose-response relationship exists between the amount of prilocaine administered epidurally and the degree of methemoglobinemia; in general, 600-mg doses are required for development of clinically significant levels of methemoglobinemia. The metabolism of prilocaine in the liver results in the formation of *o*-toluidine, which is responsible for the oxidation of hemoglobin to methemoglobin. [202] The methemoglobinemia associated with the use of prilocaine is spontaneously reversible or may be treated by intravenous administration of methylene blue. With increased use of Emla (which contains prilocaine) for neonates and young infants, there has been a concern regarding the risk of methemoglobinemia. [203]

Standard dosing of Emla in term newborns produced minimal amounts of methemoglobin, and Emla should be regarded as very safe in the great majority of newborns. Risks may be increased in rare newborns made more susceptible by metabolic disorders and concomitant administration of other drugs that impair reduction of methemoglobin. [203]

Allergies

The aminoester drugs such as procaine may produce allergic-type reactions. These drugs are derivatives of *p*-aminobenzoic acid, which is known to be allergenic. The aminoamide local anesthetics are not derivatives of *p*-aminobenzoic acid, and allergic reactions to the amino- amides are extremely rare. Intradermal injections of aminoester anesthetics in patients without a presumptive history of local anesthetic allergy resulted in positive skin reactions in 30 percent of the patients, [204] but no cutaneous reactions occurred following the use of the aminoamide drugs. Similarly, the majority of patients with a history of alleged local anesthetic allergy showed a positive skin reaction to procaine, tetracaine, or chloroprocaine, but no positive cutaneous response was seen following administration of lidocaine, mepivacaine, or prilocaine. No signs of systemic anaphylaxis occurred in any of the patients. Although the aminoamide anesthetics appear to be relatively free of allergic-type reactions, solutions of these drugs may contain a preservative, methylparaben, whose chemical structure is similar to that of *p*-aminobenzoic acid.

Local Tissue Toxicity

Local anesthetic drugs employed clinically rarely produce localized nerve damage. Concentrations of lidocaine required to produce irreversible conduction blockade in isolated desheathed peripheral nerves overlap the concentrations used clinically, such as 2 percent, but these are applied clinically to ensheathed nerve *in situ,* embedded in drugabsorbing tissue. Irreversible block in desheathed nerve by lidocaine has a threshold of 20 mmol/L and a 50 percent effective concentration (EC_{50}) of 45 mmol/L (1.1%) as compared with the EC_{50} of 1 mmol/L for reversible impulse blockade *in vivo.*[205] The intrathecal administration of tetracaine or etidocaine in rabbits resulted in histopathologic spinal cord changes following the use of 2 percent tetracaine, which exceeds the maximum concentration of 1 percent employed for spinal anesthesia in humans. [206]

Although local anesthetics are usually packaged and injected at concentrations much higher than their physiologically effective range, in the process of delivery they are usually diluted sufficiently that no harm is done. If this dilution does not occur, however, long-term or permanent neural deficits do result. Thus, the application of 5 percent (200 mmol/L) lidocaine in viscous, dense solutions through narrow intrathecal catheters has been associated with a high frequency of cauda equina syndrome. [207] Laboratory investigations showed that such high concentrations of local anesthetics alone applied directly to bare nerve fibers produced irreversible conduction block in less than 5 minutes. [208] Indeed, previous studies on ensheathed peripheral nerves *in vivo* had shown neurologic and histologic changes following infiltration of the space surrounding the nerve with local anesthetics at concentrations as low as 1 to 2 percent. [209] Clinicians should be aware that the concentrations of formulated local anesthetic solutions are neurotoxic per se, and that their dilution, *in situ* or in the tissue, is essential for safe use.

In the late 1970s and early 1980s, prolonged sensory and motor deficits were reported in some patients following the epidural or subarachnoid injection of large doses of chloroprocaine. [210] [211] Studies in animals have proved contradictory regarding the potential neurotoxicity of chloroprocaine [212] [213] [214] [215] [216] [217] (Table 13-13) . The results of these studies suggest that the combination of low pH, sodium bisulfite, and inadvertent intrathecal dosing is responsible in part for the neurotoxic reactions observed following use of large amounts of chloroprocaine solution. Chloroprocaine itself at high concentrations may also be neurotoxic, but these concentrations are not achieved during properly positioned epidural anesthesia. The currently available commercial solutions of chloroprocaine do not contain sodium bisulfite. This was initially replaced by EGTA, a preservative and a high-affinity calcium chelator, which was occasionally reported to cause local muscle spasms after epidural administration. More recently, chloroprocaine has become available in an entirely preservative-free preparation. Chloroprocaine has unique utility when rapid plasma clearance is required to prevent excessive systemic accumulation of local anesthetic. Chloroprocaine has been used by epidural infusion in young infants when lidocaine and bupivacaine could not provide an effective therapeutic index. [218]

Concerns regarding local anesthetic-associated neurotoxicity were increased following studies of continuous spinal anesthesia using microcatheters. [207] A number of patients in these initial studies developed transient or longer-term radicular irritation or, in some cases, cauda equina syndrome. Investigations suggested that microcatheters may facilitate localized injection of high concentrations of drug, which are inadequately dispersed and diluted in cerebrospinal fluid, leading to high intraneural drug concentrations around sacral roots and consequent toxicity.

TABLE 13-13 -- Animal Studies Concerning Potential Neurotoxicity of 2-Chloroprocaine and Other Local Anesthetics

TYPE OF STUDY	RESULTS
In vitro rabbit vagus nerve	Local irritation with 2-CP but not lido and bup
In vivo rat sciatic nerve	No irritation with 2-CP and lido
In vitro rabbit vagus nerve	Irreversible block with commercial 2-CP and Na bisulfite but not with pure 2-CP
Spinal dog	Paralysis with 2-CP, but not with bup or low pH saline
Spinal rabbit	Paralysis with commercial 2-CP and Na bisulfite but not with pure 2-CP
Spinal sheep	Minimal toxicity with 2-CP, lido, bup, and control solution

Spinal monkey	Minimal toxicity with 2-CP and bup

bup, bupivacaine; 2-CP, 2-chloroprocaine; lido, lidocaine

Related investigations showed that single-shot spinal anesthesia with commonly recommended doses and concentrations of local anesthetics can produce more limited and transient neurologic symptoms (back pain, paresthesias, radicular pain, or hypesthesia). [219] Transient neurologic symptoms have since been observed with many different local anesthetics. Some studies have found that mepivacaine and lidocaine, at a range of dilutions, cause more frequent symptoms than bupivacaine. [220] The risk of transient neurologic symptoms following spinal anesthesia was not diminished by dilution of lidocaine from 5 to 1 to 2 percent. Differences in study design, method of questioning, and criteria for inclusion may be partially responsible for differences in prevalence of radicular sequelae in different studies. Intraoperative positioning also appears to be a risk factor. Patients having surgery in the lithotomy position appear at increased risk of neurologic symptoms following either spinal or epidural anesthesia. It is unknown at present why this association produces increased risk. Lithotomy position per se can produce neurologic sequelae and lower extremity compartment syndromes, particularly with prolonged surgery and use of the Trendelenburg position. Neurotoxicity appears to be unrelated to conduction block per se, because tetrodotoxin, a highly potent blocker of sodium channels, can produce intense conduction blockade without histologic or behavioral signs of nerve injury. [221]

Skeletal muscle changes have been observed following the intramuscular injection of local anesthetic agents such as lidocaine, mepivacaine, prilocaine, bupivacaine, and etidocaine. [222] [223] [224] In general, the more potent, longer-acting agents bupivacaine and etidocaine appear to cause more localized skeletal muscle damage than the less potent, shorter-acting agents lidocaine and prilocaine. This effect on skeletal muscle is reversible, and muscle regeneration occurs rapidly and is complete within 2 weeks following injection of local anesthetic agents. Furthermore, such skeletal muscle processes have not been associated with overt signs of local irritation and probably cannot account for transient neurological syndromes.

Prolonged Infusions of Local Anesthetics, Tachyphylaxis, and Development of Long-Duration Local Anesthetics

Local anesthetics are used increasingly by continuous infusion for several days following surgery or for weeks to months in the treatment of chronic malignant and nonmalignant pain. With prolonged infusions, there is the potential for delayed systemic accumulation and toxicity. Continuous infusions of bupivacaine up to 30 mg/h in adults for up to 2 weeks produced no overt CNS or cardiac toxicity, despite total plasma bupivacaine concentrations in the range from 2 to 5 mug/mL in several patients.

Apparent reductions in effectiveness of local anesthetic infusions may be due to a number of causes unrelated to tolerance per se, including dislodgement of epidural catheters and changes in the dermatomal origin or intensity of nociceptive inputs. In obstetric patients receiving epidural bolus injections, recurrence of pain prior to the next injection resulted in a reduction in the intensity and duration of block, whereas repeat injection prior to return of pain prevented this rapidly occurring form of tolerance, or tachyphylaxis. In postoperative patients, coadministration of systemic opioids prevented regression of segmental block in patients receiving thoracic epidural bupivacaine infusions. [225] Studies in rats suggest that both pharmacokinetic and pharmacodynamic mechanisms are involved. In a rat model, tachyphylaxis was linked to development of hyperalgesia, [226] and drugs that inhibit hyperalgesia, including *n*-methyl- D-aspartate receptor antagonists [227] and nitric oxide synthase inhibitors, [228] also prevented tachyphylaxis. Conversely, repeated sciatic injections of lidocaine produced reduced intraneural lidocaine content along with reduced duration of block. [229] In addition, compound action potential recordings from rat sciatic nerve following repeated blocks *in vivo* show diminished suppression of the compound action potential with repeated blocks (C. Wang, C. Berde, R. Wilder, unpublished observations, 1998).

Several methods are under investigation to produce long-duration nerve blockade. Liposomal encapsulation can prolong block, depending on the dose and the physical properties of the liposome (surface charge, size, lamellar structure). [230] [231] Local anesthetics can be incorporated into biodegradable polymer microspheres for sustained release. These preparations produce peripheral nerve block in animal models ranging from 2 to 8 days, depending on the dose, site, and species. [232] Prolonged duration local anesthesia also appears feasible by use of site 1 sodium channel toxins, e.g., tetrodotoxin, in combination with either local anesthetics or adrenergics. [233]

It remains to be determined whether prolonged-duration local anesthetics will receive widespread use in clinical practice. If they prove safe and effective, they may have potential utility in peripheral nerve blockade and wound infiltration, particularly for surgery of the thorax and abdomen, in which protective sensation is comparatively less important than for limb surgery.

Chapter 14 - The Autonomic Nervous System

Jonathan Moss
Cheryl L. Renz

INTRODUCTION

Much of the action of the body in maintaining cardiovascular, gastrointestinal, and thermal homeostasis occurs through the autonomic nervous system (ANS). The ANS is also our primary defense against challenges to that homeostasis. It provides involuntary (outside of consciousness) control and organization of both maintenance and stress responses. In the words of Claude Bernard, "... nature thought it provident to remove these important phenomena from the capriciousness of an ignorant will." Activation of the sympathetic nervous system elicits what is traditionally called the "fight or flight" response, including redistribu-tion of blood flow from the viscera to skeletal muscle, increased cardiac function, sweating, salivation, and pupillary dilatation. The parasympathetic system governs activities of the body more closely associated with maintenance of function, such as digestive and genitourinary functions. A major goal of anesthetic administration is maintaining optimum homeostasis in the patient, in spite of powerful challenges to a sometimes tenuous physiologic balance. The intelligent administration of anesthetic care to patients requires a knowledge of ANS pharmacology in order to achieve desirable interactions of anesthetics with the involuntary control system and to avoid responses or interactions with deleterious effects. In addition, disease states may impair ANS function to a significant extent and may thereby alter the expected responses to surgery and anesthesia. Last, pos-sible negative effects of the human stress response have long been appreciated, and considerable effort has been expended in examining the possibility that modification or ablation of the stress response may improve perioperative outcome.

History and Definitions

Initially, nerves were thought to be connected in a giant syncytium. Claude Bernard, a student of Magendie, postulated the theory of chemical synapse transmission. Later, Sherrington initiated a systemic study of reflexes describing some characteristics of reflex function. A chemist, J.J. Abel, first synthesized epinephrine (EPI) in 1899, and his student Langley demonstrated that EPI caused the same effect as stimulating postganglionic sympathetic neurons. Langley found that when the nerve was cut and EPI was injected there was a more profound effect, thus demonstrating de-nervation supersensitivity. From these observations, the concept of chemical transmission in the ANS developed. Sir Henry Dale isolated choline and studied an ester, acetylcholine (ACh), in animals. He demonstrated that it caused a marked decrease in blood pressure and vasodilatation, mimicking parasympathetic activity.

Nerves are traditionally classified by the chemical transmitters they contain. Nerves containing ACh are called cholinergic, whereas those containing norepinephrine (NE) or EPI are called adrenergic. In addition to classifying nerves, the term "cholinergic" refers to other structures or functions that relate in some way to ACh. For instance, *cholinergic receptors (*or *cholinoceptors*) are proteins in cell membranes that react with ACh and cause the cell to respond in a characteristic way (e.g., muscles contract, glands secrete). *Cholinergic agonists* are drugs that act like ACh on cholinoceptors to cause the cell to react in its characteristic way. They are sometimes referred to as *cholinomimetic* drugs. *Cholinergic antagonists* are drugs that react with cholinoceptors to block the access by ACh and so prevent its action. These drugs may also be referred

to as *cholinolytic, cholinergic-blocking,* or *anticholinergic drugs.*

Because muscarine, a chemical isolated from a mushroom, causes effects similar to those produced by activation of the parasympathetic nervous system, it was thought to be the endogenous parasympathetic transmitter. Since then, drugs that mimic the effects of muscarine on the parasympathetically innervated structures, including the heart, smooth muscles, and glands, have been called *muscarinic* drugs. Because muscarinic drugs act mainly in the parasympathetic system, agonists sometimes are called *parasympathomimetic* drugs, whereas antagonists are called *parasympatholytic* drugs. As yet, there are no drugs marketed that are selective for one muscarinic effect or another.

In the early years of this century, nicotine was found to act on ganglionic and skeletal muscle synapses and on nerve membranes and sensory endings. Accordingly, drugs that act on these parts of the cholinergic system are called *nicotinic* drugs. Nicotinic drugs that are more specific in their action have been discovered and are referred to by the name of the system they affect, such as ganglionic drugs or neuromuscular drugs. Both agonists and antagonists exist in each category, with little crossover of effect between drugs acting at the ganglia and those acting at the neuromuscular junction.

For purposes of this chapter, cholinergic nerves include the following (Fig. 14-1) :

1. All the motor nerves that innervate skeletal muscle.
2. All postganglionic parasympathetic neurons.
3. All preganglionic parasympathetic and sympathetic neurons.
4. Some postganglionic sympathetic neurons, such as those that innervate sweat glands and certain blood vessels.
5. Preganglionic sympathetic neurons that arise from the greater splanchnic nerve and innervate the adrenal medulla.
6. Central cholinergic neurons.

Drugs mimicking the action of NE are referred to as *sympathomimetic,* whereas drugs inhibiting these effects of NE are called *sympatholytic.* NE is the transmitter acting at adrenergic nerves, whereas both EPI and NE are released by the adrenal medulla. Adrenergic receptors have been identified and subdivided into alpha- and beta-receptors and further subdivided into $alpha_1$, $alpha_2$, $beta_1$, $beta_2$, and so forth. $alpha_2$ -Receptors are primarily located on the presynaptic membrane, whereas $alpha_1$ -receptors mediate smooth muscle vasoconstriction. $beta_1$ -Receptors are found primarily on cardiac tissue, and $beta_2$ - receptors mediate smooth muscle relaxation in some organs. We define adrenergic neurons as follows:

1. Postganglionic sympathetic neurons.
2. Some interneurons.
3. Certain central neurons.

New Concepts of Transmitter Action

Until recently, nervous control of the vasculature was considered predominantly in terms of classic transmitters: NE and ACh. For many years, these were the only transmitters recognized in perivascular nerves. Beginning in the early 1960s, various other compounds, including monoamines, purines, amino acids, and polypeptides, were identified that fulfilled the criteria of functional neurotransmitters. [1] [2] Furthermore, as reviewed by Burnstock, [3] nonadrenergic, noncholinergic components are part of the ANS. Other transmitter candidates demonstrated in perivascular nerves using histochemical and immunohistochemical techniques include adenosine 5
-triphosphate (ATP), vasoactive intestinal polypeptide (VIP), substance P (SP), 5-hydroxytryptamine (5-HT), neuropeptide Y (NPY), and calcitonin gene-related peptide (CGRP). Immunocytochemical studies show that more than one transmitter or putative transmitter may be *colocalized* in the same nerve. *The most common*

combinations of transmitters in perivascular nerves are NE, ATP, and NPY in sympathetic nerves; ACh and VIP in parasympathetic nerves; and SP, CGRP, and ATP in sensory-motor nerves. Many of these putative transmitters act through *cotransmission,* which is the synthesis, storage, and release of more than one transmitter by a nerve. [4] Initially, the multiplicity

Figure 14-1 Autonomic nervous sys-tem neurotransmission. ACh, acetylcholine; NE, norepinephrine; Epi, epinephrine.

of transmitters released in various combinations appears random and bewildering, but a pattern is now emerging that clarifies the situation. Autonomic nerves exhibit "chemical coding": individual neurons subserving a specific physiologic function contain distinct combinations of transmitter substances. [5]

The concepts of cotransmission and neuromodulation have become accepted mechanisms in autonomic nervous control. In order to establish that transmitters coexisting in the same nerves act as cotransmitters, it is necessary to demonstrate that, on release, each substance acts postjunctionally on its own specific receptor to produce a response.

In the case of many, but not all, perivascular sympathetic nerves, there is evidence that NE and ATP act as cotransmitters, being released from the same nerves but acting on alpha$_1$ -adrenoceptors and P_2 -purinoceptors, respectively, to produce vasoconstriction [6] [7] (Fig. 14-2) (Figure Not Available) . ATP, once thought to act only as an electrical buffer for the charged NE, now is believed to mediate contraction through P $_{2X}$ -receptors by voltage-dependent calcium channels. The fast component of contraction appears to be mediated by these purinoceptors, whereas NE itself sustains contraction of muscle by acting on the alpha $_1$ -adrenoreceptor via receptor-operated calcium channels. Specific drugs have been designed to interact with this purinergic component. [8]

Neuromodulators modify the process of neurotransmission. Such neuromodulators may be circulating neurohormones, local agents, or neurotransmitter substances released from the same nerves or from others nearby. Neuromodulation can occur either prejunctionally, by decreasing or increasing the amount of transmitter released during transmission, or postjunctionally, by altering the extent or time course of neurotransmitter effect. In all known examples in which both prejunctional and postjunctional neuromodulation occur, these substances act in concert either to attenuate or to augment effective transmission. The rationale for such may reflect the variable geometry of the autonomic neuroeffector junction. [9] [10] Unlike the neuromuscular junction, the autonomic neuroeffector junction exists in a dynamic state and manifests only modest postjunctional specialization. Biogenic amines often must traverse wide distances. Given their short half-lives, neuromodulation provides a biologic mechanism for augmentation and prolongation of their action. [11]

NPY is also colocalized with NE and ATP. However, in some vessels, NPY has little, if any, direct action; instead, NPY acts as a neuromodulator, prejunctionally to inhibit the release of NE from the nerve and/or postjunctionally to enhance the action of NE [12] [13] (Fig. 14-3 (Figure Not Available) A). In other vessels, notably those of the spleen, skeletal muscle, and cerebral and coronary vasculature, NPY has direct vasoconstrictor actions. In the heart and brain, local intrinsic (nonsympathetic) neurons use NPY as the principal transmitter (Fig. 14-3 (Figure Not Available) B). In the spleen, NPY appears to act as a genuine cotransmitter with NE in perivascular sympathetic nerves [14] (Fig. 14-3 (Figure Not Available) C). The frequency of stimulation determines which vesicles are mobilized to release their transmitters.

Figure 14-2 (Figure Not Available) Diagram showing that adenosine triphosphate (ATP) and norepinephrine (NE) are released as cotransmitters from the sympathetic nerves supplying the vas deferens and some blood vessels. ATP acts on P_2 -purinoceptors on the smooth muscles to initiate excitatory junction potentials, action potentials, and a fast initial contraction involving electromechanical coupling via voltage-dependent calcium channels. In contrast, NE acts on alpha $_1$ -adrenoceptors to produce the second, slower phase of the contraction by pharmacomechanical (or at least spike-independent) coupling via receptor-operated calcium channels. Prejunctional alpha$_2$ -adrenoceptors and P_1 -purinoceptors can reduce transmitter release when activated by NE and adenosine (AD), respectively (prejunctional neuromodulation), whereas NE and ATP enhance each other's actions (postjunctional neuromodulation). *(Modified from Burnstock [7])*

Figure 14-3 (Figure Not Available) Schematic representation of different interactions that occur between neuropeptide Y (NPY) and adenosine triphosphate (ATP), and norepinephrine (NE) released from single sympathetic nerve varicosities. (A) Diagram showing what occurs in the vas deferens and many blood vessels, where NE and ATP, probably released from small granular vesicles, act synergistically to contract (+) the smooth muscle via alpha $_1$ -adrenoceptors and P_2 -purinoceptors, respectively. (B and C) Sympathetic neurotransmission in the heart and brain (B) and the spleen (C). *(Modified from Lincoln and Burnstock [15])*

A classic transmitter such as ACh coexists with VIP in the parasympathetic nerves of many organs, but in this instance the two transmitters are stored in separate vesicles. They can be released differentially at different stimulation frequencies, depending on where they are located. [15] [16] For example, in the salivary gland, they can act independently on acinar cells and glandular blood vessels [7] (Fig. 14-4) (Figure Not Available) . Cooperation is achieved by the selective release of ACh at low frequencies and of VIP at high frequencies of stimulation. Elements of pre- and postjunctional modulation have also been described. It is becoming increasingly apparent that in many biologic states, including pregnancy, [17] hypertension, and aging, the relationships among cotransmitters may be an important determinant of a compensatory response, allowing finer control of important physiologic function.

FUNCTIONAL ANATOMY

Sympathetic Nervous System

The sympathetic nervous system originates from the spinal cord in the thoracolumbar region, from the first thoracic through the second or third lumbar segment. The preganglionic sympathetic neurons have cell bodies within the horns of the spinal gray matter (the intermediolateral columns). Nerve fibers from these cell bodies extend to three types of ganglia, grouped as paired sympathetic chains, various unpaired distal plexus, or terminal or collateral ganglia near the target organ.

The 22 paired ganglia lie along either side of the vertebral column. Nerve trunks connect these ganglia to each other, and gray rami communicantes connect the ganglia to the spinal nerves. The preganglionic fibers leave the cord in the anterior nerve roots, join the spinal nerve trunks, and enter the ganglion at that level via the white (myelinated) ramus. Leaving the ganglion, postsynaptic fibers reenter the spinal nerve via the gray (unmyelinated) ramus, then go on to innervate pilomotor and sudomotor (sweat gland) effectors and blood vessels of the skeletal muscle and skin (Fig. 14-5) (Figure Not Available) . Sympathetic innervation of the trunk and limbs is thus carried by the spinal nerves.

The sympathetic distribution to the head and neck, enabling and mediating vasomotor, pupillodilator, secretory, and pilomotor functions, comes from the three ganglia of the cervical sympathetic chain. Preganglionic fibers of these cervical structures originate in the upper thoracic segments. In 80 percent of people, the stellate ganglion is formed by

Figure 14-4 (Figure Not Available) A classic transmitter, acetylcholine (ACh), coexists with vasoactive intestinal polypeptide (VIP) in parasympathetic nerves supplying the cat salivary gland. ACh and VIP are stored in separate vesicles; they can be released differentially at different stimulation frequencies to act on acinar cells and glandular blood vessels. Cooperation is achieved by the selected release of ACh at low-impulse frequencies and of VIP at high frequencies. Pre- and postjunctional modulation is indicated. *(Modified from Burnstock [7])*

the fusion of the inferior cervical ganglion with the first thoracic ganglion on each side (Chs. 43 and 70).

The unpaired prevertebral ganglia reside in the abdomen and pelvis anterior to the vertebral column and are primarily the celiac, superior mesenteric, aorticorenal, and inferior mesenteric ganglia. The celiac ganglion is innervated by T5-T12 and innervates the liver, spleen, kidney, pancreas, small bowel, and proximal colon. Many preganglionic fibers from T5 to T12 may pass through the paired paravertebral ganglia to form the splanchnic nerves; most do not synapse until in the celiac ganglion, whereas others innervate the adrenal medulla. The superior mesenteric ganglion innervates the distal colon, whereas the inferior mesenteric ganglion subserves the rectum, bladder, and genitals (Fig. 14-6) (Figure Not Available) . Postganglionic fibers arising from the synaptic links of upper thoracic sympathetic fibers in vertebral ganglia form terminal cardiac, esophageal, and pulmonary plexus. These fibers also innervate the viscera of the abdomen and pelvis. Ganglia of the third type, the terminal or collateral ganglia, are small, few in number, and near their target organs. The adrenal medulla and other chromaffin tissue are homologous to sympathetic ganglia and all are derived embryonically from neural crest cells; unlike sympathetic ganglia, the adrenal medulla releases both EPI and NE.

Sympathetic preganglionic fibers are relatively short, because sympathetic ganglia are generally close to the central nervous system (CNS), but they are distant from the effector organs; therefore, postganglionic fibers run a long course before innervating effector organs (see Fig. 14-1) . The distribution is also diffuse and is capable of amplification: preganglionic

Figure 14-6 (Figure Not Available) Schematic representation of the autonomic nervous system depicting the functional innervation of peripheral effector organs and the anatomic origin of peripheral autonomic nerves from the spinal cord. Although both paravertebral sympathetic ganglia chains are presented, the sympathetic innervation to the peripheral effector organs is shown only on the right part of the figure, whereas the parasympathetic innervation of peripheral effector organs is depicted on the left. The roman numerals on nerves originating in the tectal region of the brain stem refer to the cranial nerves that provide parasympathetic outflow to the effector organs of the head, neck, and trunk. *(From Ruffolo [21])*

sympathetic fibers may pass through multiple ganglia before actually synapsing, so terminal fibers may contact large numbers of postganglionic neurons. Terminal fibers of preganglionic axons may synapse with more than 20 ganglia; in addition, one cell may be supplied by several preganglionic fibers. *Sympathetic nerves need not synapse solely in the ganglion of their origin, but they can course up and down the paired ganglia of the spinal cord.* Thus, sympathetic response is not confined to segments from which the stimulus originates. This allows for a more dramatic response, with diffuse discharge of the sympathetic system.

Autonomic reflexes remain after transection of the spinal cord. The autonomic reflexes are normally inhibited by supraspinal feedback, but this supraspinal inhibition is lost with the division of the spinal tracts. Thus, after transection, trivial stimuli may elicit an exaggerated sympathetic discharge. (See the discussion of spinal cord transection in the section *Autonomic Dysfunction.*)

Parasympathetic Nervous System

The parasympathetic nervous system arises from cranial nerves III, VII, IX, and X, as well as from sacral segments. *Unlike in the sympathetic nervous system, the ganglia of the parasympathetic nervous system occur proximal to or within the innervated organ.* This location of ganglia makes the parasympathetic nervous system more targeted and less robust than the sympathetic nervous system.

Preganglionic fibers of the parasympathetic nervous system originate in three areas of the CNS: the midbrain, medulla oblongata, and the sacral part of the spinal cord. Fibers arising in the Edinger-Westphal nucleus of the oculomotor nerve course in the midbrain to synapse in the ciliary ganglion. This pathway innervates the smooth muscle of the iris and the ciliary muscle. In the medulla oblongata lie parasympathetic components of the facial (lacrimatory nucleus), glossopharyngeal, and vagus (dorsal nucleus) nerves. The facial nerve gives off parasympathetic fibers to the chorda tympani and greater superficial petrosal nerve, which subsequently synapse in the ganglia of the submaxillary or sublingual glands and the sphenopalatine ganglion, respectively. The glossopharyngeal nerve synapses in the otic

ganglion. These postganglionic fibers innervate the mucous, salivary, and lacrimal glands; they also carry vasodilator fibers.

The vagus is unquestionably the most important of the parasympathetic nerves. The vagus transmits fully three-fourths of the traffic of the parasympathetic nervous system. It supplies the heart, tracheobronchial tree, liver, spleen, kidney, and all the gastrointestinal tract except the distal colon. The preganglionic fibers of the vagus are long, whereas the postganglionic fibers are short. Most vagal fibers do not synapse until they arrive at small ganglia on and about the thoracic and abdominal viscera. Although the parasympathetic nerves may synapse with a 1:1 ratio of nerve to effector cells, the vagal innervation of the Auerbach plexus may connect 1 nerve fiber to 8,000 cells.

Finally, the second through fourth sacral segments contribute the nervi erigentes, or pelvic splanchnic nerves. They synapse in terminal ganglia associated with the rectum and genitourinary organs.

Enteric Nervous System

Given the importance of clinical phenomena such as nausea, vomiting, and alterations in bowel and bladder function associated with anesthesia, it is surprising how little is understood about the third branch of the ANS. The enteric nervous system is the system of neurons and their supporting cells found within the walls of the gastrointestinal tract, including the neurons within the pancreas and gallbladder. [18] The history of this system is as rich as its innervation: Meissner (1829-1903) and Auerbach (1828-1897) first described the ganglionated plexus of the system; Dogiel (1852-1922) recognized and classified the unique morphologies of enteric neurons and correctly predicted that differences in shape would indicate differences in function; Bayliss (1860-1924) and Starling (1866-1927) showed the existence of polarized reflexes operating in the intestine independent of extrinsic influences; John Langley defined the unusual features of the enteric nervous system and classified it as the "third division of the autonomic nervous system." *The enteric nervous system contains as many nerve cells as the spinal cord.* It is derived from neuroblasts of the neural crest that migrate to the gastrointestinal tract along the vagus nerve.

One major difference between the enteric nervous system and the sympathetic and parasympathetic branches of the ANS is its extraordinary degree of local autonomy. Digestion and peristalsis occur after spinal cord transection or during spinal anesthesia, although sphincter function may be impaired (see later).

Although functionally discrete, the gut is influenced by sympathetic and parasympathetic activity. The sympathetic preganglionic fibers from T5 through L1 are inhibitory to gut action; a spinal anesthetic to the midthoracic levels removes this inhibition, yielding a contracted small intestine that may afford superior surgical conditions in combination with the profound muscle relaxation of a spinal anesthetic. [19] The sphincters are relaxed, and peristalsis is normally active.

NE present within the gut is the transmitter of postganglionic sympathetic neurons to the gut. For example, if the contents of the upper intestine become overly acidic or hypertonic, an adrenergically mediated enterogastric reflex occurs, reducing the rate of gastric emptying. The adrenergic neurons, which run to the myenteric ganglia of the gastrointestinal tract from the thoracic and lumbar spinal segments, are usually inactive in the resting individual. Reflex pathways both within and external to the alimentary tract cause discharge of these neurons. During abdominal surgery, when the viscera are handled, a reflex firing of the adrenergic inhibitory nerves inhibits the motor activity of the intestine for an extended period of time. This adrenergic inhibition is thought to be the basis of the common condition known as postoperative ileus. Loss of parasympathetic nervous control usually decreases bowel tone and peristalsis, but, over time, compensation is provided by the increased activity of the enteric plexus. Spinal cord lesions may remove sacral parasympathetic input, but cranial *parasympathetics* may still be carried by the branches of the vagus nerve down to the end-organ ganglia: colonic dilatation and fecal impaction (which may precipitate hypertension in autonomic dysreflexia) occur more often than small intestinal dysfunction.

Enteric neurons can be *sensory* (monitoring such factors as tension in the wall of the intestine or the chemical nature of its contents), *associative* (acting like interneurons), or *motor* (activating intestinal functions, for example, causing muscles to contract, vessels to dilate, or water and electrolytes to be transported). The motor neurons in the enteric nervous system may be either excitatory or inhibitory.

Certain plexus play important roles in the enteric nervous system. The *myenteric plexus,* also called the Auerbach plexus, is a network of nerve strands and small ganglia lying in the plane between the external longitudinal and circular muscle coats of the intestine. The *submucus plexus* (Meissner plexus) consists of nerve cell bodies, glial cells, and glial and neuronal processes, but they do not contain connective tissue or blood vessels. Within the ganglia, many neuronal processes contain vesicles that are the presumed storehouses of neurotransmitters.

What is the organizational pattern of these neurons, which can contain up to a dozen neurotransmitters? Unlike the sympathetic and parasympathetic nervous systems, in which geographic location can confer selective action, this is anatomically impossible in the gut. Hence, an alternative pattern, that of chemical coding for function, assumes an important organizational role. The combination of amines and peptides within the enteric neuron is thought to code for its function.

ACh is the principal excitatory trigger of the nonsphincteric portion of the enteric nervous system, causing muscle contraction. Cholinergic neurons have several roles in the enteric nervous system, including excitation of external muscle, activation of motor neurons augmenting water and electrolyte secretion, and stimulation of gastric cells. Neural control of gastrointestinal motility is mediated through two types of motor neurons: excitatory and inhibitory. These neurons act in concert on the circular smooth muscle layer, on sphincteric and nonsphincteric regions throughout the digestive tract, and supply the muscle of the biliary tree and the muscularis mucosae. Although excitatory motor neurons supply the external longitudinal muscle, it is not well established that all regions of the longitudinal muscle are supplied by inhibitory motor neurons. Enteric motor neurons to the circular muscle of the small and large intestine are activated by local reflex pathways contained within the wall of the intestine. Distention evokes polarized reflexes, including contraction orally and relaxation anally, which in synchrony constitute peristalsis. Nicotinic antagonists abolish enteric reflexes, suggesting that the sensory neurons or interneurons in the pathway are cholinergic. Thus, in cases of cholinergic overload, such as insecticide poisoning or "overreversal" of muscle relaxants, there is a tendency for the gut (in which cholinesterase is inhibited) to become hyperreactive.

There are, however, many other compounds that also participate in intestinal function. These include SP, a variety of opiate peptides, VIP, and a growing population of peptide hormones. There is evidence for *nonadrenergic, noncholinergic (NANC)* neurons in the small intestine and for similar cells that mediate gastrin release. Evidence also indicates that nitric oxide (NO), the same compound that dilates the vasculature and is secreted by the endothelial cells, may be an important component of interneurons and may be cosecreted with VIP (NO-containing-NANC neurons also mediate penile erection. [20]) In the sphincters, SP, opioid peptides, and ACh may be involved in excitatory transmission, although their relative roles may vary from sphincter to sphincter.

FUNCTION

Organization and Integration

The sympathetic system, in response to internal or external challenges, acts to increase heart rate, blood pressure, and cardiac output, to dilate the bronchial tree, and to shunt blood away from the intestines and other viscera to better supply voluntary muscles: teleologically, the body is now better prepared to deal with the challenge. Parasympathetic nervous input acts primarily to conserve energy and maintain organ function and to support the vegetative processes.

Most organs of the body exhibit dual innervation, with input from the sympathetic and parasympathetic systems frequently mediating opposing effects (Table 14-1) (Table Not Available) . [21] Stimulation of one system may have an excitatory effect on the end organ, whereas stimulation of the other system may have an inhibitory effect. The eye, heart, bronchial tree, and gastrointestinal and genitourinary systems are thus innervated. For example, sympathetic stimulation acts on the heart to increase rate and vigor of contraction and to enhance conduction through the atrioventricular (AV) node, whereas parasympathetic stimulation acts to decrease rate and contractility and to slow conduction through the AV node. One of the two systems normally dominates the organ's function, providing its "resting tone" (Table 14-2) . In a few organs, the sympathetic system alone provides innervation: certain blood vessels, the spleen, and piloerector muscles are examples.

To predict the effects of drugs, the interaction of the sympathetic and parasympathetic system in different organs must be understood. *Blockade of sympathetic function unmasks preexisting parasympathetic activity, and the converse relation is true.* For example, administration of atropine blocks the resting muscarinic tone of the parasympathetically dominated heart, and unopposed sympathetic tone then causes tachycardia. Autonomic denervation, which may occur with neuraxial anesthesia, diabetes, and myocardial infarction (MI), can be assessed by traditional methods, such as orthostatic hypotension, or more recently by changes in the time interval between successive heart beats, that is, beat-to-beat or heart rate variability, as a measure of sympathovagal balance. [22]

Adrenergic Function

Overview of Effects of Epinephrine

The adrenergic neurons influence many bodily functions, but the effects on circulation and respiration are among the most important. The effects of sympathetic nervous stimulation on the body's physiology are designed to facilitate fight or flight (Table 14-3) . Ventilation is increased by both a central effect on the ventilatory centers and bronchodilation. Cardiac output is increased through an increase in the contractile force of the heart as well as in the rate of contraction,

TABLE 14-1 -- Responses Elicited in Effector Organs by Stimulation of Sympathetic and Parasympathetic Nerves

(Not Available)

From Ruffolo [21]

and perfusion pressure for vital organs is increased by constriction of vessels to nonvital organs. Function of both the gastrointestinal and genitourinary systems is decreased as a result of a relaxation of the smooth muscle in these organs and contraction of their sphincters. Gastrointestinal secretory activity is inhibited, and adrenal medullary output is increased. Metabolism is generally stimulated to provide more fuel for bodily function in the form of glucose and fatty acids.

Both endogenous catecholamines, NE and EPI, possess alpha- and beta-receptor agonistic activity. However, NE has minimal

TABLE 14-2 -- Usual Sympathetic or Parasympathetic Dominance at Specific Effector Sites

SITE	PREDOMINANT TONE
Ciliary muscle	Parasympathetic

Sweat glands	Sympathetic (cholinergic)

$beta_2$ -receptor activity, whereas EPI stimulates both the $beta_1$ - and $beta_2$ -receptors (Table 14-4) . Fundamental differences exist between infusion of exogenous catecholamines and release of endogenous catecholamines. For example, NE, when infused, can elicit bradycardia, but when released in response to stress, it evokes tachycardia.

The physiologic responses mediated by alpha-adrenoceptors are wide ranging and important. alpha-Receptor-mediated activity is responsible for most of the sympathetically induced smooth muscle contraction throughout the body, including the ciliary muscle of the eye, vascular smooth muscle, bronchial smooth muscle, and ureteral smooth muscle. [23] In addition, the gastrointestinal and genitourinary sphincter mechanisms are also stimulated by alpha-adrenergic receptors. alpha-Receptor agonism also mediates sympathetic nervous system control of pancreatic insulin secretion. In the peripheral vasculature, postjunctional alpha $_1$ - and $alpha_2$ -receptors are found on both arteries and veins and act to mediate vasoconstriction independent of nerve supply.

beta-Receptor agonism appears to be primarily responsible for sympathetic stimulation of the heart, relaxation of vascular and bronchial smooth muscle, stimulation of renin secretion by the kidney, and several metabolic consequences, including lipolysis and glycogenolysis. The beta $_1$ -receptor mechanism is thought to be primarily

involved in the cardiac effects [24] and release of fatty acids and renin, whereas the beta$_2$-receptors are primarily responsible for smooth muscle

TABLE 14-3 -- Effects of Sympathetic Nervous System Activation

	STIMULATION	INHIBITION
Heart	Rate, conduction, contractility	
Blood vessels	Vasoconstriction (skin, gut, liver, heart, kidney)	Vasodilation (skeletal muscle, heart, brain)

ADH, antidiuretic hormones or arginine vasopressin.

relaxation and hyperglycemia. In specialized circumstances, however, beta$_2$-receptors may also mediate cardiac activity (see later). Although acute changes in blood pressure or heart rate can be caused by NE or EPI, chronic hypertension does not appear to be related to levels of these hormones. [25] It is estimated that 85 percent of resting blood pressure is controlled by renin (Fig. 14-7) . An additional important effect of EPI includes increasing gap junctions in bone, causing an increase in circulating blood elements. [26] [27]

Psychologic and physical stimuli may evoke different compensatory responses. Whereas public speaking activates both the adrenal gland and the sympathetic nervous system, physical exercise elicits primarily a sympathetic response. [28]

TABLE 14-4 -- Adrenergic-Receptor Differentiation

1, mediated by beta$_1$-receptors; 2, mediated by beta$_2$-receptors; ?, controversial.

Thus, the stress response should not be conceived of as a uniform response, but it can vary in intensity and manifestations.

Blood Glucose

Catecholamines are released to mobilize glucose in the face of systemic hypoglycemia and thus normalize glucose values, providing cells with energy. Overall, sympathetic nervous stimulation via beta-receptor stimulation increases glycogenolysis in liver and muscle and liberates free fatty acids from adipose tissue, ultimately increasing blood glucose. In neonates, EPI plays an additional role in the exothermic breakdown of brown fat to maintain body temperature (nonshivering thermogenesis).

In addition, alpha$_2$- and beta$_2$-receptors are present in the pancreas. alpha$_2$-Receptor activation suppresses insulin secretion by pancreatic islets and inhibits lipolysis; blockade of these receptors may increase insulin release and may be associated with significant lowering of blood glucose levels. beta-Receptor stimulation increases glucagon and insulin secretion.

Potassium Shift

An additional function of plasma EPI involves regulation of serum potassium. beta-Adrenergic stimulation can initiate transient hyperkalemia, as potassium shifts out of hepatic cells with the glucose efflux produced by beta$_2$-stimulation. This effect is followed by a more prolonged hypokalemia as beta$_2$-stimulation drives potassium into red blood cells and muscle cells. Exogenously administered or endogenously released EPI stimulates the beta$_2$-receptors of red blood cells, activating adenylate cyclase and the sodium-potassium ATPase, driving potassium into cells. This leads to a reduction in serum potassium concentration and may contribute to the cardiac dysrhythmias accompanying MI and other stresses. beta$_2$-Adrenergic blockade has the theoretic advantage of inhibiting this potassium shift. However, the selective and nonselective beta blocker(s) have been shown to be equivalent in protecting the postinfarction heart against arrhythmias. [29] [30] [31] [32] [33]

Cholinergic Function

Overview of Effects of Acetylcholine

In contrast to the diffuse discharge of the sympathetic nervous system that constitutes the fight or flight response, the parasympathetic system is anatomically and functionally more localized in its effects. Parasympathetic activation conserves energy and maintains organ function. A massive parasympathetic response would only prostrate the organism, leaving it helplessly salivating, weeping, wheezing, vomiting, urinating, defecating, and seizing. Although the sympathetic system is needed for the emergency response to stressful situations, it is not necessary for survival; the parasympathetic system is, however, essential for the maintenance of life.

ACh release is the hallmark of parasympathetic activation. The actions of ACh are almost diametrically opposed to those of NE and EPI. In general, the muscarinic effects of ACh are qualitatively the same as the effects of vagal stimulation. *ACh is the only endogenous compound that causes simultaneous bradycardia and hypotension.*

The dose of ACh determines the effect or effects: a small intravenous (IV) dose of ACh causes generalized vasodilatation (including the coronary and pulmonary circulation), whereas a larger dose is required to demonstrate negative chronotropic and dromotropic effects. Significant numbers of muscarinic receptors exist in these vascular beds despite the apparent absence of cholinergic nerve supply to most vessels. Cholinergic receptor stimulation of the endothelium releases endothelium-derived relaxing factors (EDRF) causing vasodilation. However, if the endothelium is damaged, receptor stimulation by ACh causes vasoconstriction. A second mechanism of vessel relaxation by ACh is its inhibition of NE release from adrenergic nerve terminals.

ACh decreases the rate of cardiac contraction, the velocity of conduction in the sinoatrial (SA) and AV nodes, and contractility (although not as marked as the increase produced by sympathetic stimulation) in the atria. In the SA node, ACh causes membrane hyperpolarization, delaying resumption of the threshold potential and the ability to generate another action potential. This action slows the heart rate. Although the duration of the action potential and the effective refractory period are increased, the rate of conduction through atrial myocardium is unchanged. In the AV node, ACh decreases conduction velocity and increases the effective refractory period. This decrease in nodal conduction usually accounts for the complete heart block seen when large amounts of cholinergic agonists are given. In the ventricle, ACh decreases the Purkinje system automaticity, thereby increasing the fibrillation threshold. In the heart, muscarinic receptors present both pre- and postsynaptically are involved in these effects. ACh inhibits adrenergic stimulation of the heart, presynaptically by inhibiting the release of NE from sympathetic nerve endings and postsynaptically by opposing the effects of catecholamines on the myocardium.

Parasympathetic activation has many effects aside from the cardiovascular system. ACh stimulates the chemoreceptors of the carotid and aortic bodies. Cholinergic stimulation causes smooth muscle constriction, including that of bronchial walls. In the gastrointestinal and genitourinary tracts, there is constriction of the smooth muscle in the walls but relaxation of the sphincters. Topically administered, ACh constricts the smooth muscle of the iris, causing miosis.

Signs and symptoms of cholinergic overload reflect all these effects, with nausea and vomiting, intestinal cramps, belching, urination, and urgent defecation. All parasympathetic glands are stimulated to produce secretions, including the lacrimal, tracheobronchial, salivary, digestive, and exocrine glands.

Local Control of Vascular Tone

In addition to the pharmacologic effects of ACh that are mediated by the parasympathetic nervous system, ACh has a

significant effect on blood vessels, dilating virtually all vessels *in vivo.* In 1980, Furchgott and Zawadzki [34] noted that blood vessels that had intact endothelium would *dilate* when ACh was applied. If the endothelial cells were damaged, the vessels would *constrict.* Endothelial cells respond to ACh stimulation by producing one or more EDRF. [35] It now appears that the endothelial cells have receptors to numerous agonists including serotonin, adenosine, histamine, and catecholamines (Fig. 14-8) (Figure Not Available) . The radical NO is the first identified EDRF. It is produced by the endothelial cells in minute quantities, but it acts to relax the vascular smooth muscle cell and to limit or modify the actions of many vasoconstrictors. Nitroglycerin is degraded to NO in the vascular myo-cyte. The mechanism of this vasodilator action is mediated through activation of guanylate cyclase, through a protein phosphorylation cascade to phosphorylate actinomyosin directly. Thus, when the endothelium is damaged, as in ath-erosclerosis, there is diminished production of EDRF and increased constriction. This change explains why patients with damaged or diseased vessels react differently.

The biology of NO appears to be important. [36] It now appears that this simple compound, the mechanism of whose storage and release is still poorly understood, plays a prominent role in signal transduction and is a neurotransmitter in the cerebellum and gut (*N*-methyl- D-aspartate [NMDA] induces release of NO in cerebellum). [37] [38] NO is produced during the conversion of arginine to citrulline, by a class of enzymes known as NO synthases (NOS). This family of enzymes, now numbering five isoforms, has been identified, and the most common form, found in the cerebellum, has been cloned. [39] There is a requirement for flavins, reduced nicotinamide adenine dinucleotide phosphate (NADPH), and calmodulin. Some isoforms are inducible, and in septic (but not traumatic) shock or during chemotherapy, there is evidence that NO causes the hypotension that occurs. [40] Other isoforms of the enzyme, such as those in the brain, are constitutive and appear to reside in a population of cells that are tonically active. Curiously, the structure of NOS closely resembles that of cytochrome P-450. [41] There is also the suggestion that the head of the enzyme contains the NOS function, whereas the tail contains an NADPH diaphorase function. *Preclinical studies with NOS inhibitors suggest that the systemic vasculature is in a state of constant active vasodilation.*[42]

Endothelial cells exert important controls over the circulation in addition to producing NO. Endothelial cells metabolize many vasoactive amines, convert angiotensin I to angiotensin II, and secrete NO, prostacyclin, and the vasoconstrictive peptide endothelin-1 (ET-1). All three of these mediators (NO, ET-1, and prostacyclin) are local hormones released by endothelial cells to influence their immediate microenvironment. Prostacyclin and NO cause relaxation of underlying smooth muscle on the *abluminal* side, whereas in the lumen they act separately or in concert to prevent platelets from clumping onto the endothelium. There is clear synergism between the antiaggregating effect of prostacyclin and subthreshold concentrations of NO. Substances that activate prostacyclin generally stimulate NO release. Shear stress increases NO as an adaptive mechanism to dilate the circulation actively. Whereas NO works by the guanylate cyclase mechanism, prostacyclin works by activation of adenylate cyclase. Thus, although they work in concert, they activate different second messengers. [43]

Whereas prostacyclin and NO are short-lived vasodilators, injection of the vasoconstrictor ET-1 causes a powerful and long-lasting pressor effect. ET-1, which consists of 21 amino acids bound by 2 disulfide bonds, is enzymatically generated from the 39 amino acid pre-ET-1, known as big ET-1. The vasoconstrictor action of ET-1 is due to activation of endothelium receptors on smooth muscle. [44]

These three local hormones (NO, prostacyclin, and ET-1) appear to be operative in local control of the circulation. The prostacyclin system may be a mechanism reserved to reinforce the NO system in the presence of endothelial damage. Acting together, these two dilators provide an important defense mechanism against intravascular thrombosis.

Figure 14-8 (Figure Not Available) Schematic representation of potential modes of regulation of vascular tone by endothelial-related mechanisms. Norepinephrine (NA), adenosine triphosphate (ATP), calcitonin gene-related peptide (CGRP), substance P (SP), and vasoactive intestinal polypeptide (VIP) can be released from nerves in the adventitia (ADV) to act on their respective receptors in the media (MED) to cause vasoconstriction or vasodilation. ATP, acetylcholine (ACh), 5-hydroxytryptamine (5-HT), and SP released from endothelial cells (END) by shear stress or hypoxia act on their receptors on endothelial cells to cause release of endothelium-derived relaxing factors (EDRF) or prostaglandins (PG), which, in turn, act on the smooth muscle to cause relaxation. In areas denuded of endothelial cells, opposite effects may be produced by receptors on the smooth muscle. alpha, norepinephrine receptor; P_{2x} , P_{2x} -purinoceptor; P_{2y} , P_{2y} -purinoceptor; M, muscarinic receptor.

(Modified from Lincoln and Burnstock [13])

On the other hand, ET-1 can be produced locally in response to trauma such as wounds to the vessel wall. Long-term functions of these local hormones are of considerable interest in the pathophysiology of many disease states, including septic shock, pulmonary hypertension, and renal failure. [45] [46] [47]

PHARMACOLOGY

Adrenergic Pharmacology

Synthesis of Norepinephrine

NE is synthesized from tyrosine, which is actively transported into the varicosity of the postganglionic sympathetic nerve ending (Fig. 14-9) (Figure Not Available) . Tyrosine is synthesized from phenylalanine. One would therefore expect that in phenylketonuric patients, who lack phenylalanine hydroxylase, there would be a significant defect in the ANS. However, tyrosine is available from the diet as well as from phenylalanine, and no autonomic defect exists in phenylketonuric patients. In hypertensive rats, tyrosine may increase central adrenergic transmission, decreasing peripheral sympathetic outflow. [48] In hypotensive (hemorrhaged) rats, tyrosine may increase peripheral synthesis and release of catecholamines. Precursors are taken up in greater amounts in shock and may have beneficial effects on the efforts of the sympathetic nervous system to maintain perfusion pressure.

A series of steps results in the conversion of tyrosine to NE and (in the adrenal medulla) EPI. The first of these steps involves tyrosine hydroxylase (TH). *This cytoplasmic enzyme is the rate-controlling step for NE biosynthesis.* High levels of NE inhibit TH, and low levels stimulate the enzyme. Evidence indicates that during sympathetic nervous system stimulation, an increased supply of tyrosine also increases synthesis of NE. TH activity is modified by phosphorylation. TH depends on both a pteridine cofactor and the presence of molecular oxygen. Molecular oxygen, when in reduced quantity, may significantly reduce NE synthesis and may account for changes in wakefulness. Whereas acute control of TH occurs by altering enzyme activity, chronic stress can elevate TH levels by stimulating *synthesis* of new enzyme. Tyrosine is converted by the enzyme TH to dehydroxyphenylalanine (DOPA), which, in turn, is decarboxylated to dopamine by aromatic amino acid decarboxylase (DOPA decarboxylase), a relatively promiscuous enzyme in its substrate specificity. In Parkinson disease, central dopaminergic function is impaired. Administration of DOPA attempts to improve dopaminergic function in the

Figure 14-9 (Figure Not Available) Biosynthesis of norepinephrine and epinephrine in sympathetic nerve terminal (and adrenal medulla). (A) Perspective view of molecules. (B) Enzymatic processes. *(Modified from Tollenaere, [455] as modified by Vanhoutte [456])*

brain, because DOPA, but not dopamine, crosses the blood-brain barrier. Dopamine can and does act as a neurotransmitter in some cells, but in most adrenergic neurons dopamine is catabolized quickly by the enzyme monoamine oxidase (MAO), found particularly in mitochondria. Subsequently, dopamine is beta-hydroxylated within the vesicles to NE by the enzyme dopamine beta-hydroxylase (DBH).

In the adrenal medulla and to a limited extent in discrete regions of the brain, there is an additional enzyme, phenylethanolamine *N*-methyl transferase (PNMT), which methylates about 85 percent of the NE in the adrenal medulla to EPI. Glucocorticoids from the adrenal cortex pass through the adrenal medulla and can activate the system, so that stress-induced steroid release can cause increased EPI production. This local circulation amplifies the effects of glucocorticoid release. [49]

Storage of Norepinephrine

NE is stored within large, dense-core vesicles. Electron microscopy demonstrates that the dense cores in these vesicles are not due to NE but perhaps to other binding proteins also contained in the vesicle. The vesicles also contain calcium and a variety of peptides and ATP. Depending on the nature and frequency of physiologic stimuli, the ATP can be selectively released to cause an immediate postsynaptic effect via purinoreceptors.

Synaptic vesicles are heterogeneous and exist within functionally defined compartments. There appears to be an actively recycling population of synaptic vesicles and a reserve population of vesicles that is mobilized only on extensive stimulation. *Newly synthesized or taken up transmitters are preferentially incorporated into the actively recycling vesicles and thus are preferentially released on stimulation.* Therefore, drugs that mimic the neurotransmitter and are taken up presynaptically may be disproportionally represented in release. Functionally, NE is stored in compartments, of which 10 percent is readily releasable. *In general, 1 percent of stored NE is released with each depolarization, implying a significant functional reserve.* On stimulation, the contents of the vesicle are released into the synaptic cleft. Approximately 10 percent of stored NE is resistant to depletion, such as occurs with reserpine.

Synaptic vesicles have two fundamentally different functions: they take up and store neurotransmitters, and they both fuse with and bud from the presynaptic plasma terminal membrane. The proteins of synaptic vesicles can be divided into two functionally discrete classes. The first class consists of transport proteins providing the channels and pumps needed for the uptake and storage of neurotransmitters. The second class consists of proteins involved in the directed movement and docking reactions of the synaptic vesicle membrane.

Release of Norepinephrine

There are two fundamentally different processes by which the contents of the vesicle enter the synaptic cleft. The first of these occurs by leakage from the vesicles into the presynaptic cytoplasm and subsequent release. This mechanism, known as *indirect release,* occurs with drugs such as ephedrine or bretylium, which displace NE from the vesicles. Drugs that inhibit vesicular uptake, such as reserpine, also facilitate indirect release. Although it is easy to underestimate vesicular leakage, NE leakage from storage vesicles into the axoplasm actually exceeds leakage into the synaptic cleft by 100-fold and presynaptic reuptake by 10-fold, explaining the initial hypertension seen with drugs such as reserpine. [50]

The physiologic mechanism of release is known as exocytosis, in which the vesicle responds to the entry of calcium by initiating a process of vesicle docking, fusion, and endocytosis (the process by which vesicular membrane and proteins are recaptured) (Fig. 14-10) (Figure Not Available) . [47] Proof of the physiologic relevance of exocytosis in adrenergic release resides in numerous studies that demonstrate that the vesicular contents (DBH and NE) are present in the identical ratio in the stimulated superfusate as in the intact isolated vesicle preparations. Thus, the entire contents of the vesicle are liberated on nerve stimulation. Angiotensin II, prostacyclin, and histamine

Figure 14-10 (Figure Not Available) Release and reuptake of norepinephrine at sympathetic nerve terminals. aad, aromatic L-amino decarboxylase; DbetaH, dopamine beta-hydroxylase; dopa, L-dihydroxyphenylalanine; NE, norepinephrine; tyr hyd, tyrosine hydroxylase; solid circle, active carrier. *(Modified from Vanhoutte, [456] as modified by Shepherd and Vanhoutte [47])*

may potentiate release, whereas ACh and prosta-glandin E inhibit release. Because of its generalized importance in neurotransmitter release, the process of exocytosis has been extensively investigated in the past decade.

In this model, the vesicle merges with the cell membrane, a process dependent on microfilaments and influenced by calcium. A widely accepted view of the role of synaptic vesicles in transmitter release is as follows: when an action potential reaches a nerve terminal, the presynaptic plasma membrane depolarizes, and the voltage-gated calcium channels open at the active zone. Although only small amounts of calcium are required to initiate the process, the concentration of calcium in the specialized zones of active release, nanodomains, is very high. This concept of calcium nanodo-mains is postulated to represent the biologic explanation underlying augmentation and post-tetanic potentiation [51] in that the gradual diffusion of these high calcium levels from the nanodomains recruits new vesicles for release on subsequent stimulations (Ch. 20) . The dynamics of calcium levels in causing this phenomenon now appears well accepted. [52] The ensuing rise in intracellular calcium triggers exocytosis of synaptic vesicles, resulting in the release of neurotransmitters. [53] The synaptic vesicle membranes are reclaimed from the plasma membrane by endocytosis, and the vesicles eventually refill with neurotransmitters. A more detailed examination of this process can be seen in Figure 14-11 (Figure Not Available) . [54]

Various specific soluble and membrane-bound proteins have been identified that participate in docking, fusion, and endocytosis. There is increasing evidence that synaptotagmin serves as the intermediate between calcium entry and docking, because it binds calcium. [55] Microinjection of this protein participates in the step between docking and fusion, [56] and transgenic mice deficient in this protein exhibit attenuated neurotransmitter release. [57] Anatomic and molecular studies reveal vesicles that are predocked adjacent to the presynaptic membrane and permit rapid response. [54] [58] [59] The short latency between presynaptic excitation and vesicle release [60] has important functional implications, particularly in facilitating rapid transmission in the sympathetic nervous system.

The process by which docking and fusion occurs is incompletely understood, but it is thought to include two soluble proteins, *N*-ethylmaleimide-sensitive factor (NSF) and soluble NSF attachment protein (SNAP). These membrane proteins bind to cell membrane-bound SNAP receptors (SNARE), of which synaptobrevin, syntaxin, and 25-kd synaptasome-associated proteins (SNAP-25) have been identified. Syntaxin may serve to couple calcium channels and vesicle proteins. [61] It is now believed that the initial events involve activation of vesicles by the NSF-SNAP-SNARE complex, which synaptotagmin activates as soon as calcium entry reaches a critical level. [62] Evidence for the biologic relevance of these proteins derives from observations that tetanus toxin and botulinus toxin block vesicular release by binding to the docking and fusion proteins, [63] whereas microinjection of SNAP into neurons enhances exocytosis. [55] [64] Synaptic vesicles also contain guanosine triphosphate (GTP) binding proteins, which also participate in docking and fusion. [65] Recent evidence based on the uptake of fluorescent membrane dye and measurement of capacitance in nerve terminals demonstrates that the entire process of exocytosis, endocytosis, and vesicular reconstitution occurs in seconds. [66] [67] [68] [69]

The intimate chemistry of vesicular release is not a random event, but a highly differentiated process. The fact that exocytosis is so highly conserved from species to species indicates the biologic importance of this process. However, exocytosis is distinct from the generalized secretory process. First, exocytosis is a local pathway of the nerve terminal that is *independent* of organelles such as the Golgi complex, whereas regulated secretion, particularly of peptide hormones, typically requires repackaging of secretory vesicles via the Golgi complex. Second, exocytosis is far faster than secretion. Release of neurotransmitter from a single nerve

Figure 14-11 (Figure Not Available) Pathway of synaptic vesicle movement in the nerve terminal. Synaptic vesicles accumulate neurotransmitters (NT) by active transport (stage I) and then move to the plasma membrane (stage II), where they become docked at the active zone (stage III). Calcium (Ca^{2+}) influx after membrane depolarization triggers synaptic vesicle exocytosis and release of neurotransmitters (stage IV), after which the empty synaptic vesicles are endocytosed by clathrin-coated pits (stage V) and are recycled (stage VI) via an endosomal intermediate (stage VII). Stages V and VII have not been definitely proved, but they are probable on the basis of morphologic observations. *(Modified from Sudhof and Jahn [54])*

terminal can occur 50 times a second, requiring a coordinated and tightly linked regulation of underlying biochemical processes.

Although chromaffin cells in the adrenal medulla synthesize both EPI and NE, the two compounds are actually stored in and secreted from distinct chromaffin cell subtypes. Pharmacologic differences between cells containing NE and EPI have been described, and data suggest that there may be a preferential release from one or another form of chromaffin cell contingent on the nature of the stimulus. [70] Nicotinic agonists or depolarizing agents may cause the preferential release of NE, whereas histamine elicits predominantly EPI release. [71] [72] [73] Protein kinase C plays an important role in regulating catecholamine secretion from NE-containing chromaffin cells. [74]

Inactivation

Most of the NE released is rapidly removed from the synaptic cleft by either an amine uptake mechanism (uptake 1) or uptake by nonneuronal tissue (uptake 2). If a transmitter is to exert fine control over an effector system, as when NE controls blood pressure via the baroreceptor reflex, its half-life in the biophase (i.e., the extracellular space in close proximity of the receptor) must be very short. The uptake-1 mechanism represents the first and most important step in the inactivation of released NE. The majority of released NE is transported into the storage vesicle for reuse. This neurotransmitter uptake into synaptic vesicles is driven by an electrochemical proton gradient across the synaptic vesicle membrane. The vacuolar proton pump is a large, hetero-oligomeric complex, containing eight to nine different subunits. Following reuptake, the small amounts of NE not taken up into the vesicle are deaminated by MAO. There are several organ-specific forms of this enzyme.

In 1991, isolation and cloning of the human NE transporter were reported. [75] The cDNA sequence predicts a protein of molecular weight (MW) 69 kd with 12 to 13 highly hydrophobic regions compatible with membrane-spanning domains. The pharmacologic characteristics of this binding protein identify it as the cocaine binding site (K_i = 140 nm), although tricyclic antidepressants (desipramine and nortriptyline) were also potent antagonists.

Uptake of NE into the nerve varicosity and its return to the storage vesicle, albeit efficient, is not specific for the neurotransmitter. Some compounds structurally similar to NE may enter the nerve by the same mechanism and may result in depletion of the neurotransmitter. These false transmitters can be of great clinical importance. Moreover, some drugs that block reuptake either into the vesicle or into the synaptic ending itself may cause an enhanced response to catecholamines, that is, more NE is available to receptors. These drugs include cocaine and tricyclic antidepressants (Table 14-5). (Table Not Available)

Activity of the uptake-1 system varies greatly among different tissues. *Peripheral blood vessels, because of anatomic barriers, have almost no reuptake of NE, but they have the highest rate of synthesis in the body, whereas the highest rate of reuptake is found in the heart.* Thus, those drugs or disease states that alter biosynthesis or storage (e.g., alpha-methyldopa decreases storage) would be expected to have a more profound effect on blood pressure, whereas those that affect reuptake (e.g., cocaine) would be expected to affect cardiac rate and rhythm.

Typically, the lungs remove 25 percent of the NE that passes through their circulation, whereas EPI and dopamine pass through unchanged. Pulmonary uptake of NE appears to be a sodium-dependent, facilitated-transport process occurring in the endothelial cells of pre- and postcapillary vessels and pulmonary veins. There is no significant uptake by nerve endings. Pulmonary hypertension causes the diminution of NE uptake, presumably because of concomitant thickening of the pulmonary vasculature. [76] Diminished uptake is seen in patients with either primary or secondary pulmonary hypertension with elevated pulmonary vascular resistance. Although the functional significance of the endothelial uptake mechanism of the pulmonary vasculature is unknown, this occurs for other powerful vasoactive compounds, suggesting that the pulmonary endothelium functions

TABLE 14-5 -- Comparison of Direct- and Indirect-Acting Sympathomimetics

(Not Available)

to protect the left heart. Defects in the ANS are common in patients with congestive heart failure (CHF). The reuptake of NE is decreased, both at rest and during sympathetic activation, even more than with aging. Sustained sympathoexcitation results in increased neuronal release of NE. The spillover of cardiac NE is increased, predominantly attributable to increased rates of sympathetic nerve firing, rather than faulty neuronal reuptake of NE. [77] Cardiac NE spillover rates differ widely, even among patients with end-stage heart failure awaiting cardiac transplantation. [77] Studies of patients with CHF demonstrate that the heart is depleted of catecholamines. [78] Decreased vesicular leakage of NE in the failing heart because of depleted cardiac NE stores limits the increase in cardiac NE turnover that results from increased NE release. Because their ability to augment catecholamine release further is markedly impaired, patients with CHF compensate for decreases in systemic vascular resistance by further activation of the reninangiotensin system. Decreased clearance of catecholamines also occurs, and indeed some studies suggest that plasma catecholamine levels may provide a better guide to prognosis than traditional cardiovascular indices. [79] [80] Together, these events result in increased adrenergic drive, desensitization of beta-receptors, and depletion of NE stores, which contribute to insufficient inotropic function. [81] [82]

Metabolism

During storage and reuptake, a small amount of NE escapes uptake into the nerve ending and enters the circulation, where it is metabolized by MAO and/or catechol-*O*-methyl transferase (COMT). This metabolism occurs in the blood, liver, and kidney [83] (Fig. 14-12) (Figure Not Available) .

EPI, which is released by the adrenal medulla, is inactivated by the same enzymes. The final metabolic product of these inactivations is vanillylmandelic acid (VMA). The two catabolic enzymes and the vigorous uptake system account for an efficient clearance of catecholamines. *Because of this rapid clearance, the half-life of NE (and in fact most biogenic amines) in plasma is very short, less than 1 minute.* This short half-life necessitates administration of these agents by infusion. Another consequence of their short half-life is that measuring metabolic products, rather than catecholamines themselves, may be a more ideal measure of catecholamine production. For example, screening for an NE-producing pheochromocytoma is frequently done by measuring urine metanephrine and VMA. Only a small percentage of NE appears in the urine for assay.

Inhibition of MAO would be expected to have a great impact on the sympathetic function of a patient. MAO inhibitors (MAOI) are generally well tolerated, but the stability of the patient belies the fact that amine handling is fundamentally changed. Clinically important life-threatening drug interactions have been noted and are discussed in the section *Drugs and the Autonomic Nervous System.*

Other compounds can be metabolized by catabolic enzymes to produce "false transmitters." Although it is not used therapeutically, tyramine is the prototypic drug studied. Tyramine is present in many foods, particularly aged cheese and wines, or it can be synthesized from tyrosine. Tyrosine is decarboxylated in the liver and gut. Tyramine enters the sympathetic

Figure 14-12 (Figure Not Available) Metabolism of catecholamines. *(Modified from Lake et al [83])*

nerve terminal via the uptake-1 mechanism, displacing NE from the vesicles into the cytoplasm. This released NE leaks out from the cytoplasm and is responsible for the sympathomimetic effect of tyramine. However, a secondary effect can occur. In the vesicle, tyramine is converted by DBH into octopamine, which is eventually released as a false transmitter in place of NE, but without the expected effects, because it has only 10 percent of the potency of NE. [84] It is probably also clinically important to note that sodium plays a key role in the transport of NE into the cell. [85]

Adrenergic Receptors

Ahlquist originally identified alpha- and beta-receptors by their differing response to pharmacologic agents. Initially, alpha-adrenergic receptors were distinguished from beta-adrenergic receptors by their greater response to EPI and NE than to isoproterenol. The development of alpha- and beta-antagonists further supported the existence of separate alpha-receptors. The advent of radioligand binding techniques signaled an era of pharmacology in which subtypes of receptors could be more readily assessed.

Although it has long been traditional to classify adrenergic receptors as either alpha- or beta-, and more recently as alpha $_1$, alpha$_2$, beta$_1$, or beta$_2$ based on available drugs, the advent of molecular biology has suggested a more rational classification into three major subtypes and nine sub-subtypes [86] (Fig. 14-13) . Justification for such a scheme is derived from pharmacologic analyses of drug affinity patterns (see later), functional differences in signal transduction mechanisms, and primary structural differences in the receptors. Although such a classification is consistent with the available scientific evidence, the drugs currently available for clinical use may still be classified in the more traditional pattern. (Table 14-6) describes the distribution, response, typical agonists, and antagonists of the alpha $_1$ -, alpha$_2$ -, beta$_1$ -, and beta$_2$ -receptors.

alpha-Receptors

Whereas alpha$_1$ - and alpha$_2$ -receptors are traditionally differentiated based on pharmacologic characteristics, radioligand binding affinities have more recently been examined. At the alpha$_1$ -receptor prazosin is more potent than yohimbine, whereas the reverse is true at alpha $_2$ -receptors. Functional and binding assays and molecular biologic approaches have unequivocally confirmed the classification of alpha-adrenoceptors into subtypes. [87] Within alpha $_1$ -adrenergic receptors, alpha$_{1A/D}$ -, alpha$_{1B}$ - and alpha$_{1C}$ -receptors have been characterized. Several alpha $_2$ -isoreceptors (alpha$_{2A}$, alpha$_{2B}$, and alpha$_{2C}$) have been described. alpha$_2$ -Receptors can be expressed presynaptically or even in nonneuronal tissue. alpha $_2$ -Receptors are found in the peripheral nervous system and the CNS and in a variety of organs, including platelets, liver, pancreas, kidney, and the eye, where specific physiologic functions have been identified. [88] More recently, the predominant alpha$_2$ -receptor of the human spinal cord was identified as the alpha $_{2A}$ -subtype. [86] It appears that mammalian genomes contain two sets of at least three unique genes encoding the alpha-adrenoceptors. The genes encoding alpha $_2$ -receptors have been localized in chromosomes 2, 4, and 10.

There is more than theoretic relevance in subclassification of receptors. For example, the alpha-adrenergic receptors in the prostate gland are predominantly alpha $_{1A}$. Thus, therapy with selective alpha$_{1A}$ -antagonists for benign prostatic hypertrophy may avoid some of the postural hypotension and other deleterious effects that occur with less specific alpha-antagonists Localization of beta $_3$ -receptors to fat cells suggests a new therapy for obesity. Polymorphism of this beta-receptor subtype is associated with obesity and the potential for the development

Figure 14-13 Classification of adrenergic receptors.

TABLE 14-6 -- Distribution of alpha- and beta-Receptors

RECEPTOR	DISTRIBUTION	RESPONSE	AGONIST	ANTAGONIST
alpha$_1$	Smooth muscle	Constriction	Methoxamine Phenylephrine	Prazosin

of diabetes. [89] [90] [91] There are also examples of point mutations in genes encoding beta $_2$ -receptors that are correlated with decreased downregulation of beta-receptors and nocturnal asthma. [92] [93]

Amino acid sequence comparisons indicate that alpha- receptors are members of the seven transmembrane segment gene superfamily utilizing G protein for signal transduction. A core of 175 amino acids constitutes the seven transmembrane regions that are highly conserved among different family members. [94] The plethora of receptor subtypes remains incompletely explained, although the observation that different signal transduction mechanisms are used suggests finer control and physiologic significance. It may be important that there is considerable variability in alpha-adrenergic receptor subtypes among species. [95]

Receptors can be presynaptic as well as postsynaptic. Presynaptic receptors may act as either heteroreceptors or autoreceptors. An *autoreceptor* is a presynaptic receptor that reacts with the neurotransmitter released from its own nerve terminal, providing feedback regulation. A *heteroreceptor* is a presynaptic receptor that responds to substances other than the neurotransmitter released from that specific nerve terminal.

Although several presynaptic receptors have been identified, the alpha $_2$ -receptor may be of the greatest clinical import. Presynaptic alpha $_2$ -receptors regulate the release of NE and ATP through a negative feedback mechanism. [96] Thus, activation of presynaptic alpha $_2$ -receptors by NE inhibits subsequent NE release in response to nerve stimulation. Clonidine is a prototype alpha $_2$ -agonist. In the human brain, ligand studies reveal a high density of alpha $_2$ -receptors, particularly in cerebral cortex and medulla. [97] This latter distribution may account for the bradycardiac and hypotensive responses to alpha $_2$ -agonist drugs. Whereas presynaptic $alpha_2$ -receptors and cholinergic receptors inhibit release, presynaptic beta- receptors stimulate release of NE.

beta-Receptors

The structure of the beta-adrenergic receptor was among the first to be ascertained and is well characterized. Like the alpha-receptor, the beta-receptor is one of the superfamily of proteins that have seven helices woven through the cellular membrane. These transmembrane domains are labeled M $_1$ through M_7 ; antagonists have specific binding sites, whereas agonists are more diffusely attached to hydrophobic membrane-spanning domains (Fig. 14-14) (Figure Not Available) . The extracellular portion of the receptor ends in an amino group. A carboxyl group occupies the intracellular terminus, and it is here that phosphorylation occurs. At these cytoplasmic domains, interaction with G proteins and kinases, including beta-adrenergic receptor kinase, occurs (see later). Interestingly, the beta- receptor has mechanistic and structural similarities with muscarinic, but not nicotinic, receptors, primarily in the transmembrane sections. Both muscarinic and beta-receptors are coupled to adenylate cyclase through G proteins, and both can initiate the opening of ion channels.

beta-receptors have been further divided into beta $_1$ -, $beta_2$ -, and $beta_3$ -subtypes, all of which increase cyclic adenosine monophosphate (cAMP) through adenylate cyclase and the mediation of G proteins. [99] Traditionally, the beta $_1$ -receptors were thought isolated to cardiac tissue, and beta $_2$ -receptors were believed to be restricted to vascular and bronchial smooth muscle. Although this model of distribution is still useful because it reflects the primary clinical effects of pharmacologic manipulation of the $beta_1$ - and $beta_2$ -receptor subtypes, the role of beta $_2$ -receptors in cardiac function is more important than indicated by this model. The beta $_2$ -receptor population in human cardiac tissue is sizable, accounting for 15 percent of the beta-receptors in the ventricles and 30 to 40 percent in the atria. [100] These $beta_2$ -receptors may play an important role in compensation for disease, helping to maintain response to catecholamine stimulation as beta $_1$ -receptors are downregulated during chronic catecholamine stimulation and CHF. [101] The $beta_2$ -population is almost unaffected in end-stage congestive cardiomyopathy. [102] In addition to positive inotropic effects, beta $_2$ -receptors in the human atria participate in the regulation of heart rate. The generation of cAMP in the human heart appears to be mediated primarily by $beta_2$ -receptors, although this may be an artifact related to lability of beta $_1$ -receptors. [102] Thus, $beta_2$ -agonism may have significant effects on cardiac contractility and rate. [101]

Dopamine Receptors

Dopamine not only exists as an intermediate in NE biosynthesis, but also exerts alpha- or beta-effects (depending on the dose administered). Further, Goldberg and Rajfer [103] demonstrated physiologically distinct dopamine-1 (DA_1)- and dopamine-2 (DA_2)-receptors, the most important of the five dopamine receptors cloned to date (Fig. 14-15) (Figure Not Available) . DA_1 -receptors are postsynaptic and act on renal, mesenteric, splenic, and coronary vascular smooth muscle to mediate vasodilatation through stimulated adenylate cyclase and increased cAMP production. The vasodilatory effect tends to be strongest in the renal arteries. It is for this action, particularly

Figure 14-14 (Figure Not Available) Molecular structure of the beta-adrenergic receptor. Note the three domains. The transmembrane domains act as a ligand-binding pocket. Cytoplasmic domains can interact with G proteins and kinases, such as beta-adrenergic receptor kinase (beta-ARK). The latter can phosphorylate and desensitize the receptor. *(Modified from Opie [96])*

the redistribution of renal blood flow, that dopamine is most frequently used. Additional renal DA_1 -receptors located in the tubules modulate natriuresis through the sodium-potassium ATPase pump and the sodium-hydrogen exchanger. [103] [104] [105] [106] The DA_2 -receptors are presynaptic; their action may be to inhibit NE and perhaps ACh release. There are also central DA_2 -receptors that may mediate nausea and vomiting. The antiemetic activity of droperidol is thought to be related to its DA_2 activity.

G Proteins

After adrenergic receptor stimulation, the extracellular signal is transformed into an intracellular signal by a process known as *signal transduction* in which $alpha_1$ - and beta-receptors are coupled to G proteins. When activated, the G proteins can modulate either the synthesis or the availability of intracellular second messengers (Fig. 14-16) (Figure Not Available) . The activated second messenger diffuses through the cytoplasm and stimulates an enzymatic cascade. The sequence first messenger
receptor
G protein
effector
second messenger
enzymatic cascade is found in a wide variety of cells; the specific entities that fulfill the separate roles vary from cell to cell. [107] G proteins located on the inner surface of the cell membrane can also directly modify the activity of transmembrane ion channels.

The structure of G proteins has been the subject of intense scrutiny. Three types of subunits (alpha, beta, and gamma) have been described. The alpha-subunit is most variable and determines the

Figure 14-15 (Figure Not Available) Location of dopamine-1-(DA_1) receptors, $alpha_1$ - and $alpha_2$ -adrenoceptors on postganglionic vascular effector cells, and DA_2 -receptors and $alpha_2$ -adrenoceptors on the prejunctional sympathetic nerve terminal. When dopamine is administered, activation of DA_1 -receptors causes vasodilation, whereas activation of DA_2 -receptors causes inhibition (-) of norepinephrine (NE) release from storage granules. A larger dose of dopamine activates alpha $_1$ - and $alpha_2$ -adrenoceptors on the postjunctional effector cells to cause vasoconstriction and on $alpha_2$ -adrenoceptors on the prejunctional sympathetic terminal to inhibit release of NE. NE released from the prejunctional sympathetic terminal also acts on alpha $_1$ - and $alpha_2$ -adrenoceptors. *(Modified from Goldberg and Rajfer [103])*

Figure 14-16 (Figure Not Available) Epinephrine-stimulated glycogenolysis in a liver cell demonstrates the role of G proteins in cellular function. The first messenger (epinephrine) binds to its specific receptor, stimulating the G protein (in this case Gs) to activate the effector, adenylyl cyclase. This enzyme converts adenosine triphosphate (ATP) to cyclic adenosine monophosphate (cAMP), the second messenger, which then triggers a cascade of enzymatic reactions that stimulates the enzyme phosphorylase (phos-a) to convert glycogen into glucose, which the cell finally extrudes. *(Modified from Linder and Gilman [107])*

activity of the protein--whether it is stimulatory (G_s), inhibitory (G_i), G_o or the recently-described $G_{q/11}$. [108] [109] The alpha-subunit may split off and behave independently, whereas the beta- and gamma-subunits remain together. Although 20 alpha-subunits, 5 beta-subunits, and 6 gamma-subunits have been cloned, the constellation of G proteins used by any individual receptor is more limited. Each class of adrenergic receptor couples to a different major subfamily of G proteins, which are, in turn, linked to different effectors. The major subtypes of alpha$_1$ -, alpha$_2$ - and beta-receptors are linked to G_q, G_i, and G_s, respectively, which, in turn, are linked to phospholipase C activation (alpha$_1$), adenylyl cyclase inhibition (alpha$_2$), or adenylyl cyclase stimulation (beta) (see Fig. 14-13) . The pertussis-resistant G_q protein was identified in 1991 [109] and subsequently was observed to mediate alpha$_1$ -adrenergic receptor signal transduction by activation of phospholipase C and generation of inositol triphosphate (ITP) and diacylglycerol (DAG). [110] The physiologic relevance of the subunits is all the more important when one recognizes that the pharmacologic tools for dissecting signal transduction are all associated with diseases that have been scourges of humankind *(Bordetella pertussis, Vibrio cholerae,* and *Clostridium botulinum).*

In its resting state, the G protein is bound to guanosine diphosphate (GDP) and is not in contact with the receptor. When the receptor is activated by the first messenger, it stimulates the G protein to release GDP and bind GTP to its alpha-subunit, activating itself. The bound GTP signals the G protein to split into two parts consisting of the alpha-GTP structure and the beta-gamma-subunit. The released alpha-subunit binds to the effector and activates it, then converts its attached GTP to GDP thus returning itself to the resting state. The alpha- subunit joins with the beta-gamma-unit, and once again the reconstructed G protein waits at the inner membrane.

beta-Receptor stimulation activates G proteins, enhancing adenylate cyclase activity and cAMP formation. The briefest encounter of plasma membrane beta-adrenergic receptors with EPI or NE results in profound increases (up to 400-fold higher than the basal level within minutes) in the intracellular levels of cAMP. Increased cAMP synthesis, in turn, activates protein kinases, which phosphorylate target proteins. This phosphorylation elicits various cellular responses that complete the path between receptor and effect. Stimulation of alpha$_2$ -receptors results in G_i inhibition of the adenylate cyclase. There is a relative abundance of G proteins, resulting in amplification of receptor agonism at the signal transduction step. The number of G protein molecules greatly exceeds the number of beta-adrenergic receptors and adenylate cyclase molecules. Thus, it is the receptor concentration and ultimately adenylate cyclase activity that limit the response to catecholamines, perhaps providing an explanation for the efficacy of phosphodiesterase inhibitors. [111] [112]

Other transduction pathways are known. The alpha$_{1B}$ - receptor acts through G proteins, but it activates phospholipase C in the inner cell membrane, which then increases hydrolysis of the diphosphate form of phosphoinosotol (PIP_2) to the triphosphate and diacyglycerol. These two compounds then mobilize intracellular calcium stores from the sarcoplasmic reticulum and probably the subsarcolemma, resulting in a marked increase in intracellular calcium ion concentration. Ultimately, the calcium ions bind to calmodulin. This calcium-sensitive intracellular protein then activates a myosin light-chain kinase that phosphorylates the myosin light chain and facilitates the interaction between actin and myosin, resulting in the contraction of the smooth muscle. In other cells, calmodulin stimulates other kinases, resulting in effector activity.

Myocardial cells respond to receptor stimulation differently depending on the identity of the first messenger. Two opposing effects, inhibition or stimulation of contractility, are produced by the sequence of receptor
G protein
effector
enzymatic cascade, but the identity of the chemicals in the sequence differs. [113] NE causes myocardial cells to contract with more vigor when the alpha-subunit of the stimulatory protein (G_s) activates adenylate cyclase. The alpha-subunits of this protein cause potassium channels to open and permit efflux of potassium ion. The force of contraction is diminished when ACh acts as a first messenger, stimulating its receptor to activate the inhibitory protein G_i or G_o. Clinically important second-to-second changes in heart rate can be explained by the simultaneous activation of G_s and G_o. The current caused by G_o is larger than that of G_s, which explains the clinical impression that vagal inhibition of heart

---

rate is augmented in the presence of sympathetic stimulation, such as may occur in unpremedicated patients. [113]

Interaction of anesthetics with G proteins has been suggested as a mechanism for the negative inotropic effects of halothane and other volatile anesthetics. Although halothane attenuates neurotransmitter release from peripheral sympathetic neurons, [114] [115] [116] [117] other important postsynaptic effects may be involved in its negative inotropic action. [118] [119] [120] [121] [122]

Although an effect on cAMP formation would be a plausible explanation for halothane's negative inotropic effects, studies suggest that this effect is unrelated to adenylate cyclase. [123] Halothane blocks slow calcium channels in the heart, [124] [125] alters calcium fluxes in sarcoplasmic reticulum, [126] [127] and inhibits cAMP-dependent protein kinase. [119] Thus, at this time it appears that the negative inotropic effect of inhalational anesthetics occurs at several sites.

Upregulation and Downregulation

beta *-Adrenergic receptors are not fixed, but they change significantly in dynamic response to the amount of NE present in the synaptic cleft or in plasma.* For beta-adrenergic receptors, this response is fast: within 30 minutes of denervation or adrenergic blockade, there is an increased number of receptors. This upregulation may explain why sudden discontinuation of beta-adrenergic receptor blocking drugs causes rebound tachycardia and increases the incidence of myocardial infarction and ischemia. Many chronic phenomena, such as varicose veins [128] or aging, can decrease adrenergic receptor number or responsiveness systemically.

Clinically, and at the cellular level, responses to many hormones and neurotransmitters wane rapidly despite continuous exposure to adrenergic agonists. [129] This phenomenon, termed *desensitization,* has been particularly well studied for the stimulation of cAMP levels by plasma membrane beta-adrenergic receptors. [94] Mechanisms postulated for desensitization include uncoupling (phosphorylation), sequestration, and downregulation. The molecular mechanisms underlying *rapid* beta-adrenergic receptor desensitization do not appear to require internalization of the receptors, but rather an alteration in the functioning of beta-receptors themselves that uncouples the receptors from the stimulatory G_s protein. Agonist-induced desensitization involves phosphorylation of G protein-coupled receptors by two classes of serine-threonine kinases. One of these initiates receptor-specific or homologous desensitization. The other works through second messenger-dependent kinases, thus mediating a general cellular hyporesponsiveness, termed *heterologous desensitization.* Ultimately, an inhibitory arrestin protein binds to the phosphorylated receptor, causing desensitization by blocking signal transduction. Because GPK only phosphorylate receptors in the activated state, there has been an attempt to utilize transient beta blockade in states of receptor desensitization such as CHF or cardiopulmonary bypass in order to achieve a "a receptor holiday." [11] [95] [130] Regeneration of a functional beta-adrenergic receptor is contingent on sequestration of the receptor, with dephosphorylation and presumed recycling. There has been some evidence that the arrestins contribute to desensitization not only by uncoupling signal transduction, but also by contributing to the process of receptor internalization. [131] [132] Rapid changes in receptor populations can occur with such sequestration, which does not require protein synthesis. Downregulation may be distinguished from these rapid mechanisms because it occurs after hours of exposure to an agonist (e.g., as in chronic stress or CHF), and receptors are actually destroyed. New receptors must be synthesized before a return to a baseline state is possible.

Chronic CHF is one of the most important and best studied pathophysiologic situations in which tolerance or downregulation occurs. Initially, it was noted that the density of cardiac beta-receptors was markedly decreased in patients with terminal heart failure in response to the elevated plasma catecholamine levels. This finding explained why administration of exogenous beta-agonists was relatively ineffectual in this syndrome. Subsequently, with the demonstration that beta$_1$ - and beta$_2$ -receptors coexisted in human ventricles, Bristow and coworkers, [134] using radioligand techniques, documented that beta$_1$ -receptor density was decreased without

change in the density of beta$_2$ -receptors in human ventricles affected by CHF. Consequently, beta$_2$ -agonism accounted for 60 percent of the total inotropic response stimulated by isoproterenol in the failing heart, as contrasted with 40 percent in the nonfailing heart. [134]

Another disease in which adrenergic receptor function is altered is hyperthyroidism. The activity of the thyroid gland influences the receptor density, with hyperthyroidism increasing density and hypothyroidism decreasing density. There is some evidence that corticosteroids decrease receptor density. [24] Consequently, the reaction of the body to well-characterized sympathetic agonists may be considerably different, depending on the pathologic and environmental circumstances. [135] However, the structural similarity of thyroid hormone and tyrosine suggests that false transmitters may play a role. [136]

Cholinergic Pharmacology

Acetylcholine Synthesis

Many of our presumptions about cholinergic pharmacology are drawn from what is known about the neuromuscular junction, where detailed electrophysiologic information on cholinergic transmission is readily available. ACh is synthesized intraneurally from acetyl coenzyme A (CoA) and choline via the enzyme choline acetyl transferase in the synaptosomal mitochondria (Fig. 14-17) (Figure Not Available) . [137] Despite the presence of this enzyme, it should be noted that choline itself is not made in the brain, but it appears to be transported. Sources of choline include dietary phospholipids, hepatic synthesis of phosphatidylcholine from dietary precursors such as ethanolamines, and choline released by hydrolysis of ACh. Most choline originates in the liver. Choline is transported as the phospholipid and is taken up by a high-affinity transport system. This system appears to be largely responsible for determining ACh levels, although there is some evidence that precursor availability may limit cholinergic activity. The level of circulating choline can affect the release of ACh when rapid firing is taking place at cholinergic motor neurons. In one interesting experiment, plasma choline levels were measured in marathon runners before

Figure 14-17 (Figure Not Available) Synthesis of acetylcholine (ACh). Choline and acetyl coenzyme A (CoA) bind to the surface of choline acetyltransferase (ChAT). An imidazole on ChAT promotes proton removal and generates a more nucleophilic choline, thereby facilitating condensation with the acetyl group of acetyl CoA. The products of the reaction are CoA and ACh, which are rapidly packaged in vesicles for immediate release on proper stimulation. ChAT also catalyzes the reverse reaction between ACh and CoASH, although at a much slower rate than the forward reaction. *(Modified from Doukas [137])*

and immediately after a race; running a marathon decreased choline levels to well below those usually seen in fasting individuals, potentially lowering performance ability by possibly decreasing ACh release at the neuromuscular junction or cholinergic sites. [138] Choline analogues are being developed to enhance neuromuscular performance and to treat Alzheimer disease.

Storage and Release

The neuromuscular junction includes the nerve ending, the muscle, and the synaptic cleft, which is a space between the nerve and the muscle. On the nerve or presynaptic side, the nerve ending contains many synaptic vesicles (quanta) that contain ACh. On the muscle membrane, there are many infoldings of the postjunctional membrane. Studies have demonstrated that there are presynaptic release sites located opposite the junctional folds at the shoulders of the junctional folds. Vesicles containing ACh move toward these specific release sites and then fuse with the presynaptic membrane and open, spilling their contents across the synaptic cleft onto the receptors on the postsynaptic membrane (Fig. 14-18) (Figure Not Available) . [139]

ACh is stored in vesicles approximately 300 mum in diameter each containing 10,000 molecules of ACh. Central cholinergic transmission is different from the neuromuscular model in that few vesicles are present in the presynaptic terminal. These vesicles are "clear" on electron microscopy.

The spontaneous release of the ACh in one vesicle causes a miniature end-plate potential of 0.5 millivolts (mV) and 2,000 channels open in the membrane of a muscle cell, permitting sodium influx and potassium efflux. Twelve thousand ions enter the postsynaptic cell each millisecond each channel is open.

When a nerve impulse arrives at the presynaptic nerve terminal, it causes an influx of calcium ions across the membrane. This induces 100 to 300 synaptic vesicles to fuse with the presynaptic membrane at specific release sites at the active zone, resulting in the liberation of ACh from vesicles into the synaptic cleft.

Although the original hypothesis proposed by Katz of calcium as the exocytotic trigger has stood the test of time, *calcium entrance is necessary but not sufficient:* the presynaptic terminal must also be depolarized. Within 0.3 ms after the vesicle release occurs, the ACh in each vesicle causes 2,000 channels in the postsynaptic muscle cell membrane to open, with sodium entering the cell and potassium leaving. This ion flow gives rise to an electrical current and changes the normal resting potential of -90 mV. This nerve impulseinduced brief depolarization of 100 to 300 vesicles is known as an end-plate potential (EPP) but it is also a synaptic potential or an excitatory postsynaptic potential (EPSP), terms used to describe synaptic transmission in general. The EPP (50-100 mV) triggers a muscle action potential.

Normally, in the absence of a nerve impulse, there is a series of miniature end-plate potentials (MEPP) resulting from the spontaneous release of one quantum of ACh (10,000 molecules, or the contents of one vesicle). Each channel that is opened results in a depolarization of 0.00022 mV. The MEPP involves 1,500 ion channels being opened and causes a deflection of 0.5 mV. The EPP, which is summated, involves 500,000 ion channels opening and represents a depolarization of 50 to 100 mV.

Figure 14-18 (Figure Not Available) Acetylcholine (ACh) release, diffusion across the synaptic cleft, binding to receptors on end-plate membrane, and hydrolysis by acetylcholine esterase (AChE) in the absence of blocking drugs. *(From Stiller [135])*

Inactivation

ACh is an ester that hydrolyzes spontaneously in alkaline solutions into acetate and choline, neither of which has significant pharmacologic action. *In vivo,* the rate of hydrolysis is increased enormously by enzymatic catalysis. (Web sites: www.uoguelph.ca/GTI/urbanpst/cholin t.htm and www.biology.bnl.gov/disk$3/giles/che.html). The two most important enzymes are acetylcholinesterase and butyrylcholinesterase.

Sometimes called "tissue esterase" or "true esterase," *acetylcholinesterase* is a membrane-bound enzyme that is present in all cholinergic synapses, where it functions to destroy the neurotransmitter released from the nerve endings. Acetylcholinesterase is one of the most efficient of enzymes and destroys ACh, terminating transmission within milliseconds after its release. The enzyme also is present in tissues that are not innervated, such as erythrocytes. Its function in these tissues is not known.

Butyrylcholinesterase, sometimes called "plasma esterase" or "pseudocholinesterase," is a soluble enzyme that is made primarily in the liver and circulates in the blood. Its function in normal situations is not known; individuals who are genetically incapable of making the enzyme are normal in all other regards.

Of these two enzymes, acetylcholinesterase is the more important in terms of the function of ACh. Not only is it present in all cholinergic synapses, where it destroys neurally released ACh, but also it is the more efficient of the two enzymes. The substrate turnover is 2,500 molecules per second, and one catalytic event lasts 40 mus. Butyrylcholinesterase is important for the destruction of some cholinergic drugs, many of which are not destroyed by acetylcholinesterase.

Both forms of cholinesterase have been cloned. It is of more than passing interest that the first example of gene amplification in humans occurred in this enzyme system. The offspring of Israeli farmers exposed to insecticide expressed abnormal cholinesterase. [140] [141]

Traditionally, the catalytic part of the enzyme has been thought to contain two areas: an anionic site (which carries a strong negative charge) and an esteratic site (which contains electrophilic amino acids). It has been believed that, during its hydrolysis, ACh is attracted to the enzyme because the negative charge of the anionic

site attracts the positive charge in the quaternary nitrogen of ACh. The ester group of ACh aligns with the esteratic site of the enzyme. An electrophilic attack on the molecule occurs, and the acetate link is transferred from the choline to an amino acid in the enzyme. The choline drifts away, leaving a covalently bound, acetylated enzyme. The acetate link is subsequently attacked and broken by a hydroxyl group from water. The acetate drifts away, and the regenerated enzyme is ready to interact with another molecule of ACh.

However, the atomic structure of acetylcholinesterase has been found to be different from what had been previously thought, and our understanding of the binding of ACh to its

hydrolytic enzyme has altered. [142] The new model predicts that the quaternary ammonium binds to some of the 14 aromatic amino acids lining a deep gorge in the enzyme.

Inhibition of acetylcholinesterase prevents the destruction of ACh in cholinergic synapses and so can activate all cholinergic systems simultaneously. In addition to their therapeutic use, cholinesterase inhibitors are the active ingredients in insecticides and many nerve gases.

Cholinergic Receptors

Traditionally, cholinergic receptors have been organized into two major subdivisions, nicotinic and muscarinic, that predict most clinical effects. Muscarinic receptors are mostly present in peripheral visceral organs, whereas nicotinic receptors are present on parasympathetic and sympathetic ganglia and on the neuromuscular junctions of skeletal muscle.

Although these two structurally and functionally distinct classes of receptors have significantly different responses to ACh, ACh itself exhibits no specificity. However, specific antagonists can exploit the difference between the muscarinic and nicotinic receptors. As a result, structure-activity relationships have emerged. All cholinergic agonists appear to need a quaternary ammonium group as well as an atom capable of forming a hydrogen bond through an unshared pair of electrons. The distance between the two may determine whether the agonism is nicotinic or muscarinic. With muscarinic agonists, the distance appears to be about 4.4 A, whereas for nicotinic agonists, the distance is 5.9 A.

The nicotinic receptors on ganglia and motor end plates differ, and they are blocked by different drugs. *d*- Tubocurarine predominantly blocks the neuromuscular junction, whereas hexamethonium acts to block the ganglionic receptors. Methonium compounds were developed to explore the structure-activity relationships of the curare alkaloids. The most potent depolarizing neuromuscular blocking structure contained ten carbon atoms (decamethonium); in contrast, the structure containing six carbon atoms, hexamethonium, was an active ganglionic blocking agent but had little effect at the neuromuscular junction.

ACh receptors on the neuromuscular junctions of mature mammals belong to the superfamily of receptor-gated ion channels, which includes glutamate and glycine. The nicotinic receptors are pentameric membrane proteins, which form nonselective cation channels. There are two alpha-units, each 40 kd, and one each of the beta-, epsilon-, and delta-units (Fig. 14-19) (Figure Not Available) . Although different subunits may be expressed developmentally, the alpha-subunits represent the binding sites for ACh or nicotinic antagonists. At birth, a gamma-subunit occupies the position that will be taken by the epsilon-subunit within the first 2 weeks of life. This change in subunits converts the receptor from one with a low conductance and a relatively long duration of opening to a receptor with a high conductance but a brief duration of opening. [143] There are therefore important functional differences in ACh receptors during development, but the important drug-binding subunits remain constant.

These five subunits surround each ion channel through which sodium or calcium may enter the cell or potassium may exit. Each ion has its own separate channel, a unique characteristic of the neuromuscular junction. In order for the channel to open, ACh must occupy a receptor site on each of the two alpha-subunits. When ACh occupies both alpha-subunits, the channel opens; if only one site is occupied and the other is empty, the channel remains closed and there is no flow of ions and no change in electrical potential. In addition, if one site is occupied by ACh and the other site is occupied by an antagonist such as *d*-tubocurarine, the channel remains closed. If both sites are occupied by *d*-tubocurarine, the channel also remains closed. The ion channel response to ACh is instantaneous and usually lasts only a few milliseconds because ACh is rapidly destroyed by acetylcholinesterase in the synapse. This time course lends a rapidity and flexibility of response of motor end plates to neural stimulation that contributes profoundly not only to the viability of an organism, but also to its ability to control its own movements precisely and subsequently its environment.

In addition to binding of the alpha-subunit binding site by competing, non-ACh structures, there are two types of channel block (open and closed). With open-channel block, a drug enters a channel opened by ACh but cannot travel all the way through the channel. Thus, it impedes ionic flow and so prevents depolarization. Because only an open channel

Figure 14-19 (Figure Not Available) Sketch of postjunctional nicotinic acetylcholine receptors with an acetylcholinesterase (AChoE) molecule nearby. *(Modified from Standaert [457])*

may be entered, the intensity of this block depends on how often the channels are open and how active the system is; thus, it is "use dependent." Open-channel block is driven by the electrical potential difference across the membrane and the charge inherent in the molecular structure. In addition, drugs penetrating an open channel may temporarily bind at some point on the wall of the channel. The duration of effect, therefore, is partially dependent on the identity of molecule. Closed-channel blockade is harder to study and is less well understood. In this case, a drug may react with the mouth of a closed channel and prevent ion flow. Channel opening is not required, and blockade is, therefore, not use dependent. Because block does not occur at the ACh receptor site, closed-channel block is not due to a competitive antagonism of ACh. Therefore, the classic agents that inhibit cholinesterase may not be completely effective.

In adult skeletal muscle and postganglionic cells, cholinoceptors and their associated ion channels are present only in the immediate synaptic area and are absent from the rest of the cell membrane. The high density (10,000 molecules/mum^{-2}) of nicotinic acetylcholine receptors at the motor end plate is central to accomplishing successful neuromuscular transmission. Studies have demonstrated that agrin, a nerve-derived extracellular basal lamina protein, provides the signal that directs formation of presynaptic terminals [144] [145] and results in a 1,000-fold increase in nicotinic receptors in the motor end plate within hours of the presynaptic terminals reaching the myoctye. A series of ACh receptor (AChR)-associated proteins has been identified, but the precise way in which these extracellular [146] (agrin, laminin, and dystroglycan) and intracellular (utrophin and syntrophin) membrane-associated proteins maintain the necessary AChR clustering and integrity of motor end plate and bind to the cytoskeleton is unclear. Only the synaptic area is depolarized by ACh. This depolarization usually leads to the generation of action potentials that spread along the whole membrane of the cell and cause muscles to contract or neurons to transmit. However, if ACh action is prolonged, such as by inhibition of acetylcholinesterase, or if a longacting cholinomimetic drug is administered, the initial activation is quickly followed by blockade of transmission. This biphasic effect occurs because sodium channels in the membrane around the synapse, which are unaffected by ACh, accommodate to the continued depolarization of the synaptic membrane. They become inactivated and will not open again until the synaptic potential disappears. Propagated action potentials cannot be generated without sodium flow across the membrane, and so the message sent across the synapse is blocked from propagating through the postsynaptic cell.

Compared with adrenergic receptors, the cholinergic receptors turn over slowly. When a nerve to a muscle is transected, it takes 1 to 3 days to increase the number of cholinergic receptors. In the diaphragm, the number may increase 8 fold. These new receptors will no longer be confined to the motor end plate; that change has important clinical ramifications, especially in burn-induced denervation.

In contrast to the ion-gated nicotinic receptors, muscarinic receptors belong to the superfamily of G protein-coupled receptors. As noted earlier, it is of some interest that muscarinic receptors have a greater homology to alpha- and beta-adrenergic receptors than to nicotinic receptors. Like the other members of the family of receptors with seven helices (alpha$_2$, beta$_1$, beta$_2$, serotonin, rhodopsin, and opsin), muscarinic receptors utilize G proteins for signal transduction. Five muscarinic receptors (M_1 -M_5) exist with the primary structural variability residing in a huge cytoplasmic loop between the fifth and sixth membrane-spanning domains. Although molecular studies have described five forms, of which four are defined pharmacologically (M_1 , M_2 , M_3 , and M_4), selective muscarinic drugs are not available. The M_2 cholinergic postjunctional receptor predominates in visceral organs. M_2 and M_3 receptors have been identified in the airway smooth muscle of many species. *In vitro*

studies reveal that the M_3 receptor mediates the contractile and secretory response. However, the excess of M_2 receptors could explain the relative ineffectiveness of beta-adrenergic agonists in reversing cholinergic bronchoconstriction. [147]

The muscarinic receptors have diverse signal transduction mechanisms. The odd-numbered receptors (M_1, M_3, and M_5) work predominantly through the hydrolysis of polyphosphoinositide, whereas the even-numbered receptors work primarily through G_i proteins to regulate adenylate cyclase. [148]

When the M_3 muscarinic receptor is activated, G_q activates phospholipase C, which catalyzes the hydrolysis of phosphatidylinositol biphosphate into diacylglycerol and inositol triphosphate. Receptors in the muscarinic series are coupled to second messenger systems, such as cyclic nucleotides or phosphoinositides. These, in turn, are coupled to ion channels. In other cases, the influx of a cation is the trigger for cellular response. In some cases, however, an influx of calcium ions is initiated, and these ions act as messengers that react with and open other ion channels. The nature of the response is determined by the specific cation. If calcium or sodium is permitted to flow, then the membrane depolarizes; if only potassium is permitted to flow, then the membrane hyperpolarizes. In addition to affecting ion channels, the messenger calcium can stimulate various intracellular proteins to alter cell activity. In cardiac atria, activation of muscarinic receptors leads to the efflux of potassium and hyperpolarization of the cell membrane. This efflux slows conduction and slows or stops pacemakers. In glands, an influx of calcium and/or sodium activates intracellular events and causes the cells to secrete. Similarly, the influx of these ions into smooth muscle cells causes them to contract.

Muscarinic receptors are found on both central and peripheral neurons; a single neuron may have muscarinic receptors with excitatory as well as inhibitory effects. Prejunctional autoreceptors are perhaps not as well studied in the parasympathetic nervous system as in the sympathetic nervous system. Exogenous alpha $_2$ -agonists may act on prejunctional cholinergic receptors to decrease ACh release. As in the sympathetic system, presynaptic inhibition is of clinical relevance. Presynaptic muscarinic receptors may inhibit the release of ACh from postganglionic parasympathetic neurons, whereas prejunctional nicotinic receptors may act to increase the release of ACh.

Because of the complex coupling, the response of the muscarinic system is sluggish; no response is seen for seconds to minutes after the application of ACh. Similarly, the effect long outlives the presence of the agonist. Even though the transmitter is destroyed rapidly, the train of events it initiated causes the cellular response to continue for many minutes. Desensitization of muscarinic receptors occurs via agonist-dependent phosphorylation in a mechanism similar to that described earlier for beta-adrenergic receptors.

Ganglionic Pharmacology

Ganglia subserve far more complex functions than that of a simple connection between the nerve process of one cell and the cell body of its next connection. Integrative and processing functions may contribute to the subtlety of response and organization of the ANS. The electrophysiology of ganglionic stimulation is complex, with at least four different types of responses to electrical stimulation (Table 14-7) (Table Not Available) . [149] [150]

The central event at the ganglion is the EPSP, which occurs when ACh interacts with a nicotinic receptor to cause a rapid depolarization of the postsynaptic membrane. This depolarization primarily results from the influx of sodium ions through the nicotinic receptor channel, and it is sensitive to nondepolarizing nicotinic blocking drugs such as hexa-methonium. The other changes in electrical potential are related to secondary or subsidiary pathways that serve to augment or suppress; these pathways are insensitive to classic nicotinic antagonists.

The secondary pathways are indicated by the following changes in potential elicited by electrical stimulation of the ganglia:

1. A slow EPSP.
2. A late slow EPSP.
3. An inhibitory postsynaptic potential (IPSP).

The slow EPSP is slower in onset than the EPSP and lasts 30 to 60 seconds, because of a decrease in potassium ion conductance. The interaction of ACh with nicotinic receptors leads to closing of a potassium channel (m-channel). The slow EPSP is associated with the reduction or suppression of a potassium current through this channel. This wave is initiated by muscarinic receptor agonists and can be blocked by atropine and the selective M_1 muscarinic antagonists.

Like the slow EPSP, the late slow EPSP is due to a decrease in potassium ion conductance. It lasts for several minutes after being initiated by peptides in specialized ganglia. Peptides have special properties as neurotransmitters, showing prolonged stability and thus extending their influence to other postsynaptic sites, not just those in the immediate vicinity of the nerve ending. Depolarization of the membrane activates the potassium channel; the conductance of potassium ion has been labeled the "M current" and appears to act to regulate the cell's response to repetitive fast depolarizations.

The IPSP is inhibitory because the membrane is hyperpolarized and therefore is more resistant to depolarization. The slow IPSP seems to be mediated by the activation of an interneuron interposed between the preganglionic fiber and the ganglionic cell. The preganglionic nerve ending releases ACh, which stimulates the catecholamine-containing interneurons to release dopamine and NE. Catecholamine released by the interneuron then causes hyperpolarization of the ganglion cell membrane, or an IPSP. M_2 -receptors appear to be involved, as are SIF cells (*s*mall, *i*ntensely *f*luorescent cells). IPSP and catecholamine-induced hyperpolarization are both blocked by adrenergic blocking drugs. IPSP is not affected by classic nicotinic blocking agents, but is frequently sensitive to block by atropine.

The impact of the secondary pathways on the initial EPSP and the identity of the involved neurotransmitter varies among ganglia and differs between the parasympathetic and sympathetic ganglia. Many peptides have been identified in the ganglia and shown to be released on stimulation of preganglionic nerves, including gonadotropin-releasing hormone (GnRH), substance P, angiotensin, VIP, NPY, and the enkephalins. As mentioned, the peptides seem to be primarily associated with the late slow EPSP and inhibition of the M current. In addition, 5-HT and gamma-aminobutyric acid (GABA) appear to modify ganglionic transmission.

Autonomic ganglia may be stimulated by two groups of drugs, the nicotinic and muscarinic agonists. Nicotinic agonists cause the rapid onset of excitatory effects, mimic the initial EPSP, and are blocked by classic nondepolarizing ganglionic blocking drugs. Muscarinic agonists cause the delayed onset of these excitatory effects, are blocked by atropine, and mimic the slow EPSP.

Blockade of ganglionic transmission results primarily from action at the nicotinic receptor to stop or inhibit transmission. There are two groups of drugs that block ganglionic transmission. The first group is classically represented by nicotine and initially stimulates the receptor, then blocks it. This action is similar to the action of persistent depolarization. The second group causes no prior stimulation of the ganglia or change in ganglionic potentials and includes the drugs hexamethonium, trimethaphan, and mecamylamine. Trimethaphan appears to act by competing with ACh at the cholinergic receptor sites on the ganglia; hexamethonium blocks the channel when it is open. Either mechanism blocks the initial EPSP and ganglionic transmission.

Muscarinic antagonists or alpha-agonists are incapable of completely blocking transmission, but they may act to inhibit normal modulation of the nerve impulse. beta-Adrenergic stimulation appears to facilitate both nicotinic and muscarinic transmission, whereas alpha-adrenergic stimulation inhibits this transmission. 5-HT is mostly facilitative, but it can be inhibitory in certain areas. Dopamine may also be inhibitory through stimulation of the IPSP. It should be remembered that the adrenal medulla is a specialized ganglionic synapse and is therefore under influences similar to those arising on the autonomic ganglia.

DRUGS AND THE AUTONOMIC NERVOUS SYSTEM

The structure and function of the sympathetic and parasympathetic systems are discussed in the preceding sections. Pharmacologic manipulation of autonomic function is the basis of therapy in many acute and chronic illnesses. The complex pharmacology allows many points for intervention, including enhancement or inhibition of synthesis, storage, or receptor-mediated activity (Table 14-8) (Table Not Available) . [149] In the following section, specific autonomic drugs of interest to anesthesiologists and the mechanisms by which they work are discussed.

Drugs Affecting Adrenergic Transmission

Endogenous Catecholamines

The endogenous sympathetic transmitters NE, EPI, and dopamine are catecholamines and are an important subclass of the sympathomimetic drugs (Fig. 14-20) . The parent compound of this sympathomimetic group is beta-phenylethylamine, the structure of which includes a benzene ring and ethylamine side chain. Substitution of hydroxyl groups at the 3 and 4 positions of the benzene ring converts benzene to catechol, and thus these compounds are known as *catecholamines.* Although synthetic, isoproterenol and dobutamine are also catecholamines. Noncatecholamine drugs may also act as sympathomimetics and have a similar structure.

The catecholamines are primarily metabolized by catechol- *O*-methyl transferase (COMT). The loss of either hydroxyl group enhances oral effectiveness and duration of action because the drug is no longer metabolized by COMT. Noncatecholamines are primarily metabolized by MAO. The noncatecholamines that have a substituted alpha-carbon have a longer duration of action because they are not metabolized by either COMT or MAO. [151]

Epinephrine

EPI is used IV in life-threatening circumstances, including the treatment of cardiac arrest, circulatory collapse, and anaphylaxis, but it is also commonly used locally to limit the spread of local anesthetics or to reduce blood loss. The systemic effects of EPI are variable and are related to blood levels. Therefore, the choice of dosing and the route of administration are determined by the indication for use and its urgency.

EPI activates all adrenergic receptors: alpha $_1$, alpha $_2$, beta $_1$, beta $_2$, and beta $_3$. Potential therapeutic effects of EPI include positive intropy, chronotropy, and enhanced conduction in the heart (beta $_1$); smooth muscle relaxation in the vasculature and bronchial tree (beta $_2$); and vasoconstriction (alpha $_1$). As a result of

TABLE 14-8 -- Some Drugs and Toxins That Affect Autonomic Activity[a]

(Not Available)

Modified from Ganong [149]

[a] Only the principal actions are listed. Note that guanethidine is believed to have two principal actions.

Figure 14-20 Catecholamine structures. A benzene ring with two adjacent hydroxyl groups forms the catechol nucleus.

this vasoconstriction, aortic diastolic pressure is increased, promoting coronary flow during cardiac arrest, which may be the single most important determinant of survival. [152] Endocrine and metabolic effects of EPI include increased levels of glucose, lactate, and free fatty acids (see Table 14-1) (Table Not Available) .

EPI may be given IV as a bolus or by infusion. Usual bolus doses for pressure support begin at 2 to 8 mug IV; 0.02 mg/kg or approximately 1.0 mg is given for cardiovascular collapse, asystole, ventricular fibrillation, and electromechanical dissociation or anaphylactic shock. This higher dose range is recommended in these critical situations in order to maintain myocardial and cerebral perfusion through peripheral vasoconstriction. High-dose EPI (0.1-0.2 mg/kg) has been studied in resuscitation from cardiac arrest, but it does not appear to improve rates of survival in adults. High-dose EPI may be given in adults if usual doses fail to generate a response. [153] In pediatric patients, outcome from asystole and pulseless cardiac arrest is abysmal, and current recommendation is that high-dose EPI (0.1 mg/kg) be administered within 3 to 5 minutes after the initial dose (0.01 mg/kg) and repeated every 3 to 5 minutes throughout resuscitative attempts. [154] Doses as large as 0.2 mg/kg may be effective. [155] Endotracheal or intraosseous administration is an option in urgent situations such as cardiac arrest while IV access is obtained. Endotracheal doses should be at least tripled and diluted in 10 mL of normal saline in adult patients. [156] In pediatric patients, ten times the IV dose may be needed. [154] When continued cardiovascular support is required, infusion rates can be adjusted to elicit specific receptor stimulation. EPI should not be administered in alkaline solutions, because it is rapidly degraded to its biologically inactive metabolite, adrenochrome. If adrenochrome is present, the vial will have a pink hue and should be discarded. [151]

It should be remembered that patients vary tremendously in their response to these agents, and given rates of infusion cannot guarantee the expected serum levels in all patients; therefore, the "pressors" should be carefully titrated, and appropriate measures to monitor renal, cerebral, and myo-cardial perfusion are more critical than adherence to a rigid dosing scheme (Table 14-9) . A rate of 1 to 2 mug/min, though rarely used, should predominantly activate beta $_2$ -receptors with resulting vascular and bronchial smooth muscle relaxation. A rate of 2 to 10 mug/min (25-120 ng/kg/min) will, in addition, increase heart rate, contractility, and conduction through the AV node and decrease the refractory period. Doses in excess of 10 mug/min (100 ng/kg/min) cause marked alpha-stimulation with resultant generalized vasoconstriction. EPI is a potent renal vasoconstrictor acting directly by alpha- receptor stimulation and indirectly by stimulation of renin release. It is frequently used in combination with "renal dose" dopamine in an attempt to avoid renal ischemia. Although low-dose EPI increases heart rate by direct beta $_1$ - stimulation, reflex bradycardia is seen with higher doses, because of marked elevation of blood pressure through peripheral vasoconstriction.

In the past, inhaled EPI was used in a 1 percent (1 g:100 mL) solution to treat bronchospasm, but it has been largely supplanted by beta $_2$ -specific agonists. Racemic EPI (a mixture of the levo- and dextrorotary isomers) acts to constrict edematous mucosa and is used in the treatment of severe

TABLE 14-9 -- Dose-Dependent Actions of Inotropes and Chronotropes

DRUG[a] (PROPRIETARY NAME)	RECEPTORS	USUAL INFUSION RATE
Epinephrine (Adrenalin)	$beta_2$	1-2 mug/min
	$beta_1$ + $beta_2$	2-10 mug/min
	$alpha_1$	>10 mug/min[b] (bolus: 2-10 mug; 0.5-1.0 mg[c])
Norepinephrine (Levophed)	$alpha_1$, $beta_1$, $beta_2$	4-12 mug/min[b]
Dopamine (Intropin)	Dopaminergic	0-3 mug/kg/min
	beta	3-10 mug/kg/min
	alpha	>10 mug/kg/min[b]
Dobutamine (Dobutrex)	$beta_1$ $beta_2$, alpha	2.5-10 mug/kg/min[b]
Isoproterenol (Isuprel)	$beta_1$ > $beta_2$	0.5-10 mug/min
Amrinone (Inocor)	Increase cyclic adenosine monophosphate through phosphodiesterase inhibition	0.75 mg/kg/load over 2-3 min 5-10 mug/kg/min infusion

Data from Hoffman and Lefkowitz [151]

[a] All agents have elimination half-lives of a few minutes, except amrinone ($t_{½}$, 3.6 h; 5.8 h in congestive heart failure).

[b] Much higher doses have been used in clinical practice.

[c] With anaphylaxis or cardiac arrest.

croup [157] and of postextubation and traumatic airway edema. A 2.25 percent solution (microNefrin/Vaponefrin) is diluted with water or saline in a 1:8 ratio and is nebulized. Treatments may be given as frequently as every 2 hours, with effects lasting 30 to 60 minutes; the patient should remain under observation for at least 2 hours, because initial improvement may be followed by rebound swelling up to 2 hours after administration. [151] Although it is common clinical practice to utilize the racemic form of EPI for these clinical applications, data show that (levo)-EPI is 15 to 30 times more potent than the mixture [158] [159] and is equally effective and less expensive in treating these clinical complications. [160]

Bronchospasm may also be treated by subcutaneous (SQ) administration of EPI in doses of 300 mug every 20 minutes up to three doses. In addition to its direct bronchodilatory effects, EPI may decrease antigen-induced release of endogenous bronchospastic substances from mast cells and is particularly useful in anaphylactic reactions. [161] Relative contraindications include advanced age, significant tachycardia, hypertension, and coronary occlusive disease. Absorption of SQ EPI is extremely slow because of intense local vasoconstriction, and the effect of a very large SQ dose of 0.5 to 1.5 mg is roughly equivalent to an IV infusion of 10 to 30 mug/min. [151] IV injection of EPI in a dose appropriate for SQ administration can result in life-threatening ventricular arrhythmias, hypertension, and cerebral hemorrhage. Sus-Phrine, a sustained-release form of EPI, may be used in children by SQ injection but should never be given IV.

EPI is often applied locally to mucosal surfaces to decrease bleeding in the operative site. It is mixed with local anesthetics for infiltration into tissues or intrathecal injection. The alpha-mediated vasoconstriction decreases bleeding in the area and slows vascular uptake of local anesthetic, prolonging both the duration of effect and decreasing the peak serum level of the local anesthetic. Although clinicians express concern over the systemic effects of such injections, several studies have shown that, barring intravascular injection, resultant elevations in plasma levels due to vascular uptake are relatively modest and are substantially less than levels seen in psychologic stress. [28] [162]

Drug interactions with EPI are often predictable. Cocaine and other uptake inhibitors enhance the effect and duration of exogenous EPI. Preexisting alpha $_1$ -blockade can cause the paradoxic phenomenon of "EPI reversal" as the beta$_2$ -vasodilating effects are unmasked. Patients receiving nonselective beta blockers may demonstrate unopposed alpha-responses. Cardioselective (beta $_1$) blockade does not have this effect. [163]

Halothane is known to sensitize the heart to catecholamines, and the potential for troublesome arrhythmias under light inhalational anesthesia has long been appreciated by clinicians. EPI decreases the refractory period, rendering the heart more susceptible to arrhythmias. In adults, the EPI ED_{50} (dose required to produce three premature ventricular contractions in 50 percent of patients) at 1.25 minimum alveolar concentration (MAC) was 2.1 mug/kg for halothane, 6.7 mug/kg for isoflurane, and 10.9 mug/kg for enflurane. [164] Children appear to tolerate higher doses than do adults. It has been suggested that children receiving a halothane anesthetic can receive a maximum of 10 to 15 mug/kg SQ of EPI every 10 minutes. [157] Hypocapnia potentiates this drug interaction.

Norepinephrine

NE differs structurally from EPI only in its lack of a methyl group. Like EPI, NE acts at both alpha- and beta- receptors, but it is usually used for its potent alpha-agonism. It is frequently the pressor of last resort in supporting the systemic vascular resistance. Because of its short half-life of 2.5 minutes, a continuous infusion is preferred. Whereas less than 2 mug/min (30 ng/kg/min) may uncover beta $_1$ -stimulation effects, the usual infusion rates of greater than 3 mug/min (50 ng/kg/min) elicit peripheral vasoconstriction from alpha- stimulation. [165]

The peripheral vasoconstriction increases blood pressure and may cause reflex bradycardia. Venous return is increased by the powerful venoconstriction. Cardiac output is frequently unchanged or decreased; oxygen consumption is markedly increased. Pulmonary vascular resistance may be increased, and NE should be used with caution in patients with pulmonary hypertension. [166]

Like EPI, NE is a potent constrictor of the renal and mesenteric vascular beds and can cause renal failure,

mesenteric infarction, and peripheral hypoperfusion. The decrease in hepatic flow is of clinical relevance because plasma levels of hepatically metabolized drugs (such as lidocaine) are markedly increased. [167] To ameliorate the renal effects, low-dose dopamine infusion may be added to NE. [168] Extravasation can cause tissue necrosis and may be treated with local infiltration of phentolamine. Prolonged infusion has caused gangrene of the digits. The potential for profound vasoconstriction makes careful patient selection and close monitoring mandatory.

Dopamine

Dopamine acts at alpha-, beta-, and dopaminergic receptors; it also acts to release NE and therefore has mixed direct and indirect effects. Although dopamine is a precursor of NE, its most important effect may be to cause peripheral vasodilation. Improvement of blood flow through the renal and mesenteric beds in shock-like states is expected through its action at dopamine receptors on the postjunctional membrane. It is rapidly metabolized by MAO and COMT, and so has a short half-life of about 1 minute. Therefore, like other endogenous catecholamines, it is given as a continuous IV infusion and without a loading dose. At low doses (0.5-2.0 mug/kg/min), DA_1 -receptors are stimulated, and renal and mesenteric vascular beds dilate. [169] In addition to an improvement in renal blood flow, glomerular filtration

rate and sodium excretion increase. With an infusion rate of 2 to 10 mug/kg/min, beta $_1$ -receptor stimulation is seen, with resultant increases in cardiac contractility and output. Rates higher than 5 mug/kg/min stimulate release of endogenous NE, which contributes to cardiac stimulation. At higher doses, (10-20 mug/kg/min), both alpha- and beta$_1$ -receptors are stimulated, the alpha-vasoconstrictive effect predominates, and the benefit to renal perfusion may be lost. [170] Patients' responses to dopamine are extremely variable, and dosages must be individualized. Appropriate monitoring to ensure organ and peripheral perfusion is critical. The dose should be significantly decreased in patients treated previously with an MAOI or tricyclic antidepressant.

Dopamine is frequently the initial agent used in the treatment of shock, particularly in vasodilated states such as sepsis; as discussed earlier, it is frequently used to protect the kidney and also to aid in diuresis. It is particularly useful for this purpose in severe CHF. [171] Infusion in combination with dobutamine for the therapy of cardiogenic shock may be more effective than either agent given alone. [172]

Dopexamine hydrochloride (Dopacard), an inotropic vasodilator, is a synthetic parenteral dopamine analogue that may be of use in CHF. Intrinsic activity of dopexamine relative to dopamine is approximately 60 times more potent at beta$_2$ -adrenoreceptors and one-third at DA$_1$ -receptors and one-seventh at DA$_2$ -receptors. [173] [174] Unlike dopamine, it shows no alpha- and negligible beta $_1$ -adrenergic effects and is therefore devoid of any vasoconstrictive activity. [173] [175] Dopexamine has a reported half-life of 3 to 7 minutes in healthy patients and approximately 11 minutes in patients with low cardiac output. [176] beta$_2$ -Agonism produces systemic vasodilatation and indirect inotropic activity (via inhibition of neuronal uptake of NE). [173] [175] [177] [178] [179] The stimulation of dopaminergic receptors produces selective vasodilatation of renal and splanchnic vessels and increased glomerular filtration rate, diuresis, and natriuresis. [175] [180] [181] [182] [183]

The use of dopexamine seems preferable when vascular resistance is high. Within the dose range of 1 to 6 mug/kg/min, the combined inotropic, vasodilative, diuretic, and natriuretic effects have shown benefit in the management of CHF, [184] [185] [186] [187] but they have had an indeterminant outcome in the treatment of septic shock. [186] [188] [189] [190] [191] [192] Use of this agent has been limited by dose-dependent tachycardia, mainly at doses higher than 4 mug/kg/min. [193] [194] The effects of dopexamine on intestinal mucosal and hepatic perfusion remain controversial. [195] [196] [197] [198] [199] [200] In general, systemic vasodilatation appears more pronounced with dopexamine, and positive ino-tropic effects appear more marked with dopamine [201] and dobutamine. [202]

Fenoldopam is a selective DA$_1$ -agonist and potent vasodilator (6-9 times as potent as dopamine) that enhances natriuresis, diuresis, and renal blood flow. [203] [204] [205] [206] [207] Because of its poor bioavailability and varied results in clinical trials, fenoldopam is no longer being investigated as a candidate for therapy of chronic hypertension or CHF. Instead, IV fenoldopam, given by infusion at rates of 0.1 to 0.8 mug/kg/min with incremental titration at 0.1 mug/kg/min, has recently been approved to treat severe hypertension. It is an alternative to sodium nitroprusside, with potentially fewer side effects (no thiocyanate toxicity, rebound effect, or "coronary steal") and improved renal function. Its peak effects occur within 15 minutes. [208] [209]

Noncatecholamine Sympathomimetic Amines

Whereas the beta-agonist isoproterenol and the alpha-agonists phenylephrine and methoxamine act predominantly at only one type of receptor, most of the sympathomimetic drugs act at both alpha- and beta-receptors. Most noncatecholamine sympathomimetic amines act at alpha- and beta-receptors because they have two mechanisms of action: directly at a receptor and indirectly by releasing endogenous NE.

Mephentermine (Wyamine), ephedrine, and metaram-inol (Aramine) are mixed-acting drugs. Ephedrine increases blood pressure and has a positive inotropic effect. Because it does not have detrimental effects on uterine blood flow, ephedrine is widely used as a pressor in the hypotensive parturient patient. [210] Because of its beta$_1$ -stimulating effects, ephedrine is helpful in treating moderate hypotension, particularly if accompanied by bradycardia. It also has some direct beta $_2$ -stimulating effects and has been used orally as a bronchodilator. The usual dose is 2.5 to 25 mg IV, or 25 to 50 mg intramuscularly (IM). Mephentermine is similar to ephedrine in its effects, whereas metaraminol has relatively stronger direct alpha $_1$ -stimulating effects and may be associated with reflex bradycardia.

Tachyphylaxis to the indirect effect may develop through depletion of NE stores. Although all sympathomimetic amines are capable of producing tolerance or tachyphylaxis, the mechanism has been best studied with metaraminol. Metaraminol is taken up into the sympathetic nerve ending, displacing NE and producing the sympathomimetic effect. However, after a period of time, the drug acts as a false

transmitter, and subsequent sympathetic nerve stimulation results in much less effect. Consequently, the drug probably should not be used widely when other, more effective drugs are available. Indirect action is attenuated in the presence of long-term reserpine or cocaine use, but these drugs may still be efficacious, although at higher doses. Although indirect-acting agents are widely used as a first-line therapy for intraoperative hypotension, epidemiologic studies of adverse reactions under anesthesia suggest that dependence on these agents in life-threatening events may contribute to morbidity. [211]

alpha-Agonists

Phenylephrine and methoxamine are selective alpha$_1$ -agonists. These drugs are commonly used when peripheral vasoconstriction is needed, sometimes when cardiac output is adequate, as in the hypotension that may accompany spinal anesthesia, and at other times in patients with coronary artery disease or aortic stenosis to increase coronary perfusion pressure without chronotropic side effects. Phenyl-ephrine (Neo-Synephrine) has a rapid onset and a relatively short duration of action (5-10 min) when given intravenously. It may be given by bolus doses of 40 to 100 mug or by infusion at a starting rate of 10 to 20 mug/min. Higher doses of up to 1 mg may be used to slow supraventricular tachycardia through reflex action. Phenylephrine is also used as a mydriatic and nasal decongestant. In anesthetic practice, it is applied topically either alone or mixed with local anesthetic gel to prepare the nose for intubation. It is also added to local anesthetic to prolong subarachnoid block. In contrast, methoxamine (Vasoxyl) is a much longer-acting drug (30-60 min). [212] At high doses, the drug possesses some membrane-stabilizing properties and even beta-adrenergic blocking properties.

The alpha$_2$ -agonists are assuming greater importance as anesthetic adjuvants and analgesics. Their primary effect is sympatholytic. They reduce peripheral NE release by stimulation of prejunctional inhibitory alpha $_2$ -adrenoreceptors, and they inhibit central neural transmission in the dorsal horn, by both presynaptic and postsynaptic mechanisms, and directly in spinal preganglionic sympathetic neurons. Although traditionally they have primarily been used as antihypertensive drugs, new roles based on sedative, anxiolytic, and analgesic properties are being developed.

Clonidine, the prototypic drug of this class (Table 14-10) , is a selective partial agonist for alpha $_2$ -adrenoreceptors, with a ratio of approximately 200:1 (alpha $_2$:alpha$_1$). The antihypertensive effects are due to central and peripheral attenuation of sympathetic outflow and central activation of nonadrenergic imidazoline-preferring receptors. [164] [253] [254] [255] The decrease in central sympathetic outflow reduces activity in peripheral sympathetic neurons without affecting baroreceptor reflexes. [256] Arterial blood pressure is thereby decreased without the accompanying orthostatic hypotension seen with many antihypertensive drugs. [257] Because clonidine is lipid soluble, it is able to penetrate the blood-brain barrier to reach the hypothalamus and medulla, and thus, unlike alpha-methyldopa, it does not require transformation into another substance. [258] Clonidine withdrawal may precipitate hypertensive crises, and clonidine should be continued throughout the perioperative period (perhaps by patch) or at the least replaced by close monitoring of blood pressure and ready ability to treat hypertension. The administration of nonselective beta blockers during clonidine withdrawal could worsen hypertension by leaving alpha $_1$ -receptor- mediated vasoconstriction unopposed. Labetalol has been used to treat this withdrawal syndrome.

Although the use of alpha$_2$ -agonists as the sole anesthetic agents has not been demonstrated in humans, these drugs can reduce the anesthetic requirement and may provide a more stable cardiovascular course, presumably because of the sympatholytic effect of the drug and the need for lower doses of cardioactive anesthetic. [213] [214] [259] Clonidine reduced halothane MAC by up to 50 percent in a dosedependent fashion, [260] limited by alpha$_1$ -adrenoreceptor activation at higher concentrations, whereas dexmedetomidine, the prototype of novel superselective alpha $_2$ -agonists (alpha$_1$:alpha$_2$ of 10:1), decreased halothane MAC by more than 95 percent in animals. [260] [261] [262] Data suggest that oral, IV, epidural, and intrathecal administration of clonidine potentiates the anesthetic action of other agents, either volatile or injectable, and reduces both general and regional anesthetic requirements with correspondingly fewer side effects, [213] [214] [215] [222] [223] [224] [225] [238] [239] [240] [241] [242] [243] [260] [261] [262] [263] [264] [265] [266] [267] [268] [269] [270] [271] [272] although it has not been shown to reduce perioperative ischemia. [273] Clonidine also attenuates the rise in intraocular pressure associated with laryngoscopy and endotracheal intubation. [274] [275] [276]

alpha$_2$ -Agonists provide effective analgesia for acute and chronic pain, particularly as adjuncts to local anesthestics and opioids. The addition of clonidine results both in increased duration of analgesia and reduced doses of each component. [218] [219] [220] [222] [224] [225] [226] [277] [278] [279] [280] [281] [282] [283] [284] [285] [286] [287] [288] Epidural clonidine is indicated for the treatment of intractable pain, which is the basis for the approval of parenteral clonidine in the United States as an orphan drug. [289] Patients with intractable pain, unresponsive to maximal doses of oral or epidural opioids, benefit from oral, patch, IM, and neuraxial administration of clonidine, [228] [229] [230] [231] [232] as do patients with reflex sympathetic dystrophy [294]

TABLE 14-10 -- Clonidine Dosing

ROUTE	BOLUS	CONTINUOUS INFUSION	REFERENCES
Oral	150 mug, 4-5 mug/kg	--	[213] [214] [215] [216] [217]
Intramuscular	2 mug/kg	--	[218]
Intravenous	150 mug, 4-8 mug/kg	2 mug/kg/h	[219] [220] [221]
Epidural	150-450 mug	12.5-70 mug/h	[218] [222] [223] [224] [225] [226] [228] [229] [230] [231] [232] [233] [234] [235] [236]
	6-8 mug/kg	1-2 mug/kg/h	
Intrathecal	30-225 mug	8-400 mug/d	[237] [238] [239] [240] [241] [242] [243] [244] [245] [246] [247] [248] [249] [250] [251] [252]

and neuropathic pain. [229] [291] The intrinsic analgesic effects of alpha $_2$ -agonists have been demonstrated with large doses of clonidine alone, administered either intrathecally (as much as 450 mg) or epidurally (1-2 mug/kg/h) to control intraoperative and postoperative pain. Clonidine decreases postoperative oxygen consumption and adrenergic stress response. [292] [293] Although there are dose-dependent side effects such as hypotension and sedation and idiosyncratic side effects with clonidine such as bradycardia, it does not induce profound respiratory depression and only mildly potentiates opiate-induced respiratory depression. [216] [295] [298]

Aside from its role as an anesthetic adjuvant and antihypertensive agent, clonidine has been used to treat panic disorder; [296] symptoms of opiate, benzodiazepine, and ethanol withdrawal; [297] [298] cigarette craving after heavy smoking cessation; [299] [300] [301] and as an antiemetic in cancer chemotherapeutic regiment. Its use in diabetic diarrheas is based on the presence of alpha $_2$ -receptors on gut epithelial cells. Normally, stimulation of ileal mucosal alpha $_2$ -receptors by EPI promotes sodium chloride absorption and inhibits bicarbonate secretion. In diabetes, in which intractable diarrhea can be a major problem, there is a depletion of mucosal NE stores and a denervation hypersensitivity, resulting in increased numbers of postsynaptic alpha $_2$ -receptors. Clonidine may increase blood glucose concentrations by inhibiting insulin release. [302] Further, unlike spinal opioids, clonidine does not cause urinary retention and may actually hasten time to first micturition after spinal anesthesia. [244] [245] [246] [302]

beta-Agonists

Nonselective: Dobutamine

Although at clinical doses it can act at beta $_2$ - and alpha$_1$ - receptors, this synthetic analogue of dopamine has predominantly beta $_1$ -effects. Compared with isoproterenol, it is reported to have more inotropy than chronotropy, but it increases conduction velocity through nodal tissue to the same extent. [303] It exerts less beta$_2$ -effect than does isoproterenol and less alpha $_1$ -effect than NE. Unlike dopamine, it does not directly release endogenous NE, nor does it act at dopaminergic receptors.

Dobutamine is particularly useful in CHF and MI complicated by a low-output state, although in cases of severe hypotension it may not be effective because of a lack of a significant alpha$_1$ -pressor effect. Although dobutamine increases cardiac contractility in the failing heart, its ability to lower filling pressures contrasts with the effects of dopamine and NE. It is relatively safe to use in myocardial ischemia without increasing the size of the infarct or causing arrhythmias. [304] Tachycardia does not usually occur with doses less than 20 mug/kg/min, but in especially severe CHF, significant tachycardia may occur and is the primary side effect. Because dobutamine directly stimulates beta$_1$ -receptors, it does not rely on NE stores and may still be effective in catecholamine-depleted states such as chronic CHF. However, in severe chronic CHF, the downregulation of beta-adrenergic receptors may hamper its effectiveness.

The beta$_2$ -vasodilating effects of dobutamine are almost exactly offset by its alpha $_1$ -constricting effects, which experimentally can be revealed by administering a nonselective beta blocking drug. [305] Its modest ability to dilate the peripheral vasculature is probably more closely connected with its ability to relieve the high-adrenergic state of decompensated CHF than to a specific beta $_2$ -mediated vasodilative effect. [306] Clinical situations that call for distinct afterload reduction may be better served by an agent such as nitroprusside.

Prolonged treatment with dobutamine causes downregulation of beta-receptors; tolerance to its hemodynamic effects is significant after 3 days and may be temporarily offset by increasing the rate of infusion. [307] Intermittent infusions of dobutamine have been used in the long-term treatment of heart failure and have been shown to cause some persistent improvement in exercise tolerance, [308] but they do not improve survival. [309]

Nonselective: Isoproterenol

Isoproterenol (Isuprel) provides relatively pure nonselective beta-stimulation with no significant effect at alpha-receptors. Its beta $_1$ -stimulation is significantly stronger than beta$_2$, but it still causes more beta$_2$ -activity than does dobutamine. Since the development of other inotropes, its popularity has declined because of its side effects of tachycardia and arrhythmias. These side effects have limited its use in myocardial ischemia or when ventricular irritability is a concern. Isoproterenol has been used in aerosol form to treat bronchospasm, but it has been replaced by beta $_2$ -selective drugs with their lower risk of cardiac side effects. Its lack of alpha-agonist properties renders it ineffective to raise perfusion pressure in shock. In the past, isoproterenol was used in bradycardia or heart block resistant to atropine, but it is no longer part of the American Heart Association Advanced Cardiac Life Support protocol. Infusion rates start at 0.5 to 5 mug/min for adults. It is metabolized primarily by COMT. It is not taken up into adrenergic nerve endings, so its duration of action is slightly longer than that of the natural catecholamines.

Selectivebeta$_2$ -Agonists

As mentioned earlier, isoproterenol was used in the treatment of bronchospasm for its beta $_2$ -stimulating properties, but unpleasant and dangerous beta $_1$ -mediated side effects limited its use. The development of beta $_2$ -selective agents has made beta-stimulants a cornerstone of the treatment of bronchospasm. However, it should be noted that this beta$_2$ -selectivity is only relative, and it may be lost at higher doses; in addition, beta $_2$ - receptors in the SA node may cause tachycardia when stimulated. The structures of these drugs have also been modified to slow their metabolism, thus prolonging therapeutic benefit and enabling oral administration. In particular, the addition of bulky structures on the catecholamine amino group increases beta $_2$ -selectivity, decreases affinity for alpha-receptors, and protects against metabolism by COMT. These agents are preferentially given by inhalation aerosol both for reasons of rapid onset and to minimize systemic drug levels and side effects by reducing drug levels. However, a well-documented increase in the annual number of deaths from asthma has been described, and it has been suggested that this increase may be related to beta $_2$ -agonist use, [310] [311] [312] in part because of the

[c] Acebutolol is mainly eliminated by the liver, but its major metabolite, diacetolol, is excreted by the kidney.
[d] Half-life of the active metabolite, diacetolol, is 12 to 15 hours.

severity of illness and patient factors. A susceptibility to arrhythmia caused by these agents either by direct cardiac stimulation or by beta $_2$ -induced hypokalemia is one suggested mechanism, although it has been hypothesized that the long-term use of these drugs may increase airway hyperreactivity. Nonetheless, the safe use of these drugs in many thousands of patients is well documented. Commonly used drugs include metaproterenol (Alupent, Metaprel), terbutaline (Brethine, Bricanyl), and albuterol (Proventil, Ventolin). Metaproterenol is probably less beta $_2$ -selective than albuterol or terbutaline. Terbutaline is the only beta $_2$ -selective agent that can be given SQ and therefore may have particular use in status asthmaticus; the normal SQ dose is 0.25 mg, which may be repeated after 15 to 30 minutes.

beta$_2$ -Agonists are also used to treat premature labor. [313] Ritodrine (Yutopar) has been marketed for this purpose. beta $_1$ -side effects are common, particularly when the drugs are used IV. The other beta$_2$ -selective drugs have also been used as tocolytics, and all have been associated with significant beta $_1$ -side effects as well as the occasional incidence of pulmonary edema. [314] Their use for this purpose has recently been questioned. [315]

alpha-Receptor Antagonists

alpha$_1$ -Antagonists have long been utilized clinically as antihypertensives, but they have become less popular over the years. Alpha $_1$ -blockade vasodilates by blocking the effect of endogenous catecholamines on arterial and venous constriction. The effects are potentiated when standing or in the presence of hypovolemia. Reflex tachycardia and fluid retention can ensue. alpha $_2$ -Antagonists may act presynaptically to release NE.

Phenoxybenzamine (Dibenzyline) is a prototype alpha $_1$ - antagonist, although it irreversibly binds to both alpha $_1$ - and alpha$_2$ -receptors. New receptors must be synthesized before complete offset of its effects occurs. Its half-life after oral administration is unknown, but that after an IV dose is about 24 hours. Effects include a decrease in peripheral resistance and an increase in cardiac output; blood flow to skin and viscera is increased. As would be expected, its primary side effect is orthostatic hypotension; nasal stuffiness may occur. In addition to receptor blockade, phenoxybenzamine inhibits neuronal and extraneuronal uptake of the catecholamines. Phenoxybenzamine is used to treat pheochromocytoma through relatively long-term preoperative treatment ("chemical sympathectomy") that aids in blood pressure control, but also permits correction of a contracted plasma volume and protects against catecholamine-induced cardiac damage, yielding a smoother perioperative course. Total daily dose is 40 to 360 mg in two or three divided doses. When exogenous sympathomimetics are administered after alpha $_1$ -receptor blockade, their vasoconstrictive effects are inhibited. The effect of phenylephrine is completely blocked, whereas that of NE is limited to its beta $_1$ -effect of cardiac stimulation. There is potential "EPI reversal" caused by unopposed beta $_2$ -agonism, seen as severe hypotension and tachycardia. Despite its irreversible binding to the receptor, the recommended treatment for overdosage of phenoxybenzamine is NE infusion, because some receptors would still be free of the drug. [316]

Phentolamine (Regitine) is a shorter-acting agent that blocks both alpha $_1$ - and alpha$_2$ -receptors. Historically of use in pulmonary hypertension, it has been largely supplanted by nitroglycerin and nitroprusside. It is used to treat hypertension associated with clonidine withdrawal or with tyramine ingestion during MAOI therapy, but few real data have been collected on its efficacy and safety for these indications. The dose is 1 to 5 mg IM or slowly IV. Its plasma half-life is 19 minutes after IV administration. Phentolamine has also been infiltrated into affected tissues after extravasation of agents such as NE in an attempt to relax vasoconstriction: 5

to 10 mg is diluted in 10 mL of saline. Adverse effects of phentolamine include hypotension and gastrointestinal distress; reflex tachycardia and arrhythmias may be seen, at least partly resulting from action at alpha $_2$ -receptors. Coronary artery disease and peptic ulcer disease are relative contraindications. As in phenoxybenzamine overdosage, severe hypotension may require treatment with NE rather than EPI. Tolazoline (Priscoline) is a related drug used in persistent pulmonary hypertension of the newborn. [316]

Prazosin (Minipress) is a potent selective alpha $_1$ -adrenergic blocker often used as a prototypic antagonist in pharmacologic experiments. It antagonizes the vasoconstrictor effects of NE and EPI, causing a fall in peripheral vascular resistance and venous return to the heart. Although there is usually no increase in heart rate, orthostatic hypotension is a major problem. Unlike other antihypertensive drugs, prazosin improves lipid profiles, lowering lower-density lipid levels while raising the level of high-density lipids. It is primarily used to treat hypertension. It has also been used in CHF, but unlike the angiotensin-converting enzyme inhibitors (ACEI), prazosin does not prolong life. It is extensively hepatically metabolized. Supplied as 1-, 2-, and 5-mg tablets, its starting dose is usually 0.5 to 1 mg, given at bedtime only because of the orthostatic hypotension, and eventually it is given twice daily. [316]

alpha$_2$ -Antagonists, such as yohimbine, increase sympathetic outflow by enhancing release of NE. Although these drugs have proven to be of little clinical utility in anesthesia, they are used in urology.

beta-Receptor Antagonists

beta-Adrenergic receptor antagonists ("beta blockers") are among the most commonly prescribed drugs and are frequently taken by patients presenting for surgery. Current indications for the use of beta-blockade include ischemic heart disease, postinfarction management, arrhythmias, hypertrophic cardiomyopathy, hypertension, and prophylaxis of migraine headache. Initial concern that patients treated with beta blockers would be hemodynamically unstable under anesthesia has proven to be largely unjustified. In addition, these drugs are an important part of the armamentarium of the anesthesiologist in the ongoing attempt to limit stress responses perioperatively and to protect the cardiovascular system.

There is a confusing spectrum of beta blockers currently available to the clinician. The most important properties to consider in choosing a beta blocker for long-term use are cardioselectivity, intrinsic sympathomimetic activity, and lipid solubility. [317] [318] In anesthetic practice, cardioselectivity, duration of action, and a formulation suitable for IV use are crucial factors to consider (Table 14-11) . The beta-antagonists all resemble isoproterenol in structure and bind competitively to the beta-receptor, blocking access by more potent beta-agonists (Fig. 14-21) (Figure Not Available) . [316] Competitive inhibition at the beta-receptor can be overcome by increasing the available concentration of beta-agonist. In fact, the potency of a beta blocker is often determined

Figure 14-21 (Figure Not Available) Structures of isoproterenol and propranolol. *(From Tollenaere [455])*

by its ability to inhibit induction of tachycardia by isoproterenol. Propranolol is assigned a potency of 1, and the other drugs are evaluated in relation to it.

Nonselective beta blockers act at both the $beta_1$ - and $beta_2$ - receptors. The nonselective beta blockers include propranolol, nadolol, pindolol, sotalol, oxprenolol, penbutolol, and timolol. [306] [318] Cardioselective beta blockers have a stronger affinity for $beta_1$ - than for $beta_2$ -adrenergic receptors, and therefore the predominant effects are cardiac. Velocity of AV conduction, heart rate, and cardiac contractility are decreased, as well as the release of renin by the juxtaglomerular apparatus and lipolysis at the adipocytes. At higher doses, the relative selectivity for $beta_1$ -adrenergic receptors is lost, and $beta_2$ -receptors are also blocked, [319] with potential bronchoconstriction, peripheral vasoconstriction, and decreased glyco-genolysis. Cardioselective agents include atenolol, betaxolol, bevantolol, esmolol, and metoprolol. [306] [318] These drugs may be preferable in patients with obstructive pulmonary disease, peripheral vascular disease, Raynaud phenomenon, and diabetes mellitus. However, because the selectivity is only relative and may be lost at conventional clinical doses, extreme care must be used in administering a beta blocker in the presence of pulmonary disease, because death may result. Some beta-antagonists also have vasodilatory effects, making them particularly useful in the treatment of hypertension. [306] Labetalol vasodilates by blocking $alpha_1$ -receptors, as well as by direct $beta_2$ -agonism.

As mentioned, some beta blockers exert a partial agonist effect at the receptor while blocking access by more potent agonists and thus possess intrinsic sympathomimetic activity (ISA). Agents with ISA include acebutolol, carteolol, celiprolol, dilevalol, oxprenolol, penbutolol, and pindolol. [318] Of these, acebutolol and pindolol are more often used in the United States, but neither is commonly used in anesthetic practice. These agents lower blood pressure with less decrease in *resting* heart rate and left ventricular function. When sympathetic activity is high, such as during exercise, these drugs behave more like conventional beta blockers. The partial $beta_2$ -agonism of pindolol induces bronchodilation. [320] ISA may therefore be useful if beta blockade is required in a patient with bradycardia, peripheral vascular disease, or very mild hyperreactive airway disease. Beta blockers with ISA appear not to have the adverse effects on triglyceride and high-density lipoprotein levels seen after use of the other agents, although the clinical significance of this finding is unclear. [321] Agents with ISA may not be as effective in controlling symptoms in severe angina or in reducing mortality after MI. [322] ISA may protect against beta blocker withdrawal syndrome. [323]

The degree of lipid solubility greatly affects absorption and metabolism. Propranolol, metoprolol, and pindolol are the most lipid-soluble agents, are readily absorbed from the gastrointestinal tract, and are metabolized in the liver, undergoing extensive first-pass metabolism. Thus, propranolol and metoprolol are given IV in a much lower dose than that used orally because up to 70 percent of the orally administered drug is removed on the first pass of portal blood through the liver. [317] In addition, altered hepatic function may have a profound effect on plasma levels. The oral or IV dose of these agents required to reach a clinical end point varies greatly between patients. Because of a relatively short half-life, lipid-soluble agents are usually given at least twice a day. [316] The extremely short half-life of esmolol, however, is due to its metabolism by esterases.

The non-lipid-soluble, or hydrophilic, drugs are atenolol, sotalol, and nadolol. They are not as readily absorbed from the gastrointestinal tract, not as extensively metabolized, and are excreted unchanged by the kidneys. Because of a relatively long half-life, daily dosing may be adequate. There is less interpatient variability in plasma drug level and clinical effect because of the lack of hepatic metabolism and first-pass effect. [318] The lipid-insoluble drugs are slower to cross the blood-brain barrier and so may be chosen in an attempt to avoid the CNS side effects associated with beta blocker therapy (depression, sleep disturbances, nightmares, and fatigue). However, the relationship between lipid solubility and the occurrence of these symptoms is not consistent. [324] [325]

Propranolol and acebutolol possess membrane stabilizing activity (MSA), also referred to as the quinidine-like or local anesthetic effect. This reduces the rate of rise of the cardiac action potential. However, MSA is seen only at very high concentrations (ten times that required for blockade of beta receptors) [326] and is probably of little clinical consequence. Overdose with agents with MSA is associated with a higher incidence of fatality. [327]

Indications for Use

Myocardial Ischemia

Propranolol was initially introduced for treatment of myocardial ischemia three decades ago, and beta blocking drugs remain an important part of drug therapy for myocardial ischemia. This class of drugs reduces oxygen demand by decreasing heart rate and cardiac contractility. Both cardio-selective and nonselective beta blockers are effective: atenolol, metoprolol, nadolol, and propranolol have been approved in the United States for the treatment of angina; metoprolol and atenolol are the only beta blockers approved for IV use in acute MI. [316] Although initially there was concern that $beta_2$ -receptor blockade could worsen ischemia through unopposed alpha-mediated vasoconstriction, this phenomenon is rarely seen even in patients with variant angina. In usual clinical practice, the dose is increased until the heart rate is 60 to 80 beats/min at rest, and there is no tachycardia with exercise. Although in theory a nonselective antagonist may seem a better choice in acute MI, because the blockade of $beta_2$ -receptors may protect against stressinduced potassium shifts and hypokalemia-associated arrhythmias, cardioselective and nonselective drugs appear equally useful. [306] Agents with ISA are not as beneficial in this situation. [306] beta-antagonists are used both acutely in MI and on a long-term basis in postinfarction patients to reduce reinfarction and mortality. [328] [329] [330] [331] Early administration of IV beta blocking agents to patients receiving thrombolytic therapy appears to lower the incidence of ischemia and reinfarction [332] and may reduce the incidence of serious ventricular arrhythmias. [333] The long-term use of beta blockers (timolol, propranolol, metoprolol, and atenolol) has been shown unequivocally to decrease mortality after MI.

Hypertension

Although beta blockers are now recognized by the Joint National Council of the USA Guidelines as one of the two

preferred first-line therapies for hypertension (the other being diuretics), [334] the mechanisms by which beta-antagonists treat hypertension are incompletely understood. The blood pressure reduction is specific to hypertensive patients because long-term treatment of normotensive individuals does not lower blood pressure. Reduced cardiac output and renin release have been suggested as mechanisms. In hypertensive patients, beta-antagonists without ISA may cause a 15 to 20 percent reduction in cardiac output and a 60 percent reduction in renin release. However, pindolol, which has ISA and minimal effect on renin, is successful in treating hypertension. [335] In addition, maximum renin suppression precedes significant changes in arterial blood pressure. [336] Generally, beta blockade initially increases peripheral vascular resistance, then over time lowers it. [337] The decrease in cardiac output and eventual lowering of peripheral resistance may account for much of the antihypertensive efficacy of these drugs. However, this too is an incomplete explanation because labetalol is an effective antihypertensive despite its lack of effect on cardiac output. A primary CNS effect is not likely to be a major mechanism because of the similarity of antihypertensive efficacy of lipophilic and hydrophilic

compounds. Generally, beta blockade is ineffective as monotherapy in African-American patients more than 60 years of age.

Cardiac Arrhythmias

Beta blockers are also widely used in the therapy of tachyarrhythmias as class II agents (Ch.32) . Two possible mechanisms of action are blockade of catecholamine effects and MSA, although the latter is most likely not clinically significant, because antiarrhythmic effects are present in agents without MSA. [338] beta-Antagonists slow the rate of depolarization of the sinus node and any ectopic pacemakers, slow conduction through atrial tissue and the AV node, and increase the refractory period of the AV node. These drugs can convert atrial arrhythmias to sinus rhythm, [339] but beta blockade is primarily used to slow the ventricular response. Reentrant tachyarrhythmias and those associated with Wolff-Parkinson-White syndrome, mitral valve prolapse, and prolonged QT interval may also respond to these drugs. [326] Care should be exercised if AV block is present, as in digitalis toxicity, although these drugs are useful in the treatment of digitalis-associated tachyarrhythmias. [326] Sotalol, a beta blocker with added class III activity, is effective against ventricular tachyarrhythmias. A trial comparing racemic sotalol to *d*-sotalol in post-MI patients to protect against ventricular fibrillation showed an *increased* mortality with *d*-sotalol. [340] This finding suggests that beta-antagonists may perform differently as racemates than as optically pure agents.

Tachycardia

beta-Antagonists are frequently used as adjuvants to moderate the reflex tachycardia associated with vasodilators. This tachycardia can limit the effectiveness of blood pressure control or may cause myocardial ischemia. It is particularly crucial that appropriate beta blockade be administered during vasodilator therapy of aortic dissection because, in addition to potentiating blood pressure reduction, beta blockade reduces the velocity of left ventricular ejection (dp/dt) to attenuate the shearing force associated with tachycardia. [341] Nitroprusside used without concomitant beta blockade may propagate the dissection. Labetalol has been particularly useful in this situation. [342]

Perioperative Use

The safety of continuing beta blockade perioperatively is well established, and initial concerns regarding interaction with general anesthesia have not been confirmed. [343] In addition, attempts to discontinue beta blockers increase the risk of rebound tachycardia and myocardial ischemia in patients with coronary disease. These drugs should be given up to the time of surgery, and IV forms in appropriate dosages should be used whenever gastrointestinal absorption may be in question. As noted earlier, doses for IV administration vary less among patients because of the absence of first-pass hepatic effects. If beta blockers have been omitted from the preoperative regimen, esmolol or labetalol may be used acutely to blunt tachycardia and hypertension. Both cardio-selective and nonselective beta blockers appear effective in blocking chronotropic effects of endotracheal intubation and surgical stress. [344]

Thyrotoxicosis

Cardiac complications are a primary cause of morbidity in thyrotoxicosis. Beta blockade can suppress the tachycardia and rhythm disturbances, although very large doses may be required. beta-Antagonists also may be combined with digitalis for their synergistic effect on AV node conduction. Care should be exercised in the presence of CHF, but if the cause is tachyarrhythmia and ventricular function is adequate, beta blockers with or without digitalis may be helpful. Propranolol has been shown to inhibit conversion of thyroxine to the active form, triiodothyronine, in the periphery. [345]

Miscellaneous Conditions

Timolol (Timoptic) and betaxolol (Betoptic) are beta blocking drugs used topically in the eye to treat glaucoma through their reduction of the production of aqueous humor. Even topical use of these agents has been associated with significant systemic effects of beta blockade. Beta blockers are used in idiopathic hypertrophic subaortic stenosis in order to reduce the obstruction to left ventricular outflow and in the medical management of acute dissecting aortic aneurysm. The drugs are also effective in prophylaxis, but not therapy, of migraine headaches and in controlling acute panic symptoms and essential tremor.

Adverse Effects

The adverse effects of most concern are those involving cardiopulmonary function. Severe noncardiopulmonary reactions such as cutaneous reactions or anaphylaxis are extremely rare. Life-threatening bradycardia, even asystole, may occur; decreased contractility may precipitate CHF in

vulnerable individuals. Beta $_2$ blockade in patients with bronchospastic lung disease may be fatal. CNS effects, although an appropriate consideration in long-term therapy, are not a concern in the usual anesthetic use of these agents. Diabetes mellitus is a relative contraindication to the long-term use of beta-antagonists, because hypoglycemia in the face of sympathetic blockade is not accompanied by warning signs such as tachycardia and tremor, and compensatory glycogenolysis is blunted. However, most non-insulindependent diabetic patients can tolerate these drugs, although beta blockade may rarely cause insulin resistance. In addition to the potential worsening of peripheral perfusion by beta $_2$ blockade in patients with peripheral vascular disease, Raynaud phenomenon may be triggered in susceptible patients. Sudden withdrawal of beta blockers may cause myocardial ischemia and possibly infarction, although this is less of a problem with beta blockers with ISA such as pindolol. [323] [346] [347] Although beta-antagonists may reduce renal blood flow and glomerular filtration rate, these agents can be used in renal failure. In this case, the doses of lipidinsoluble drugs should be reduced. Use in pheochromocytoma should be avoided unless alpha-receptors have previously been blocked, to avoid worsening of hypertension. Hypertensive responses to nonselective agents may occur in cases of high sympathetic stimulation. [348]

Important drug interactions may occur. [316] [318] Verapamil has rate and contractility effects that are additive with those of the beta blockers, [349] [350] and care should be used in combining these agents, especially when using the IV forms in acute situations such as supraventricular tachycardia. The combination of digoxin and beta blockers can have powerful effects on heart rate and conduction and should be used with special care. Pharmacokinetic interactions are of note and are predictable from the degree of lipid solubility of the drug. Cimetidine and hydralazine may reduce hepatic perfusion, thereby increasing plasma levels and half-lives of the lipid-soluble beta-antagonists. Barbiturates, phenytoin, rifampin, and smoking may induce hepatic enzymes, thus enhancing metabolism. Propranolol may reduce hepatic clearance of lidocaine, increasing the risk of toxicity.

Overdose of beta blocking drugs may be treated with atropine, but isoproterenol, dobutamine, and/or glucagon infusions may be required, as well as cardiac pacing, to ensure an adequate rate of contraction.

Specific Drugs

The drugs propranolol, metoprolol, labetalol, and esmolol are particularly useful in anesthetic practice because they are widely available in IV formulation and have wellcharacterized effects. They are discussed in further detail in the following sections. If the drug the patient has taken on a long-term basis is propranolol, metoprolol, or labetalol, then that drug may be continued in IV form, if the clinical situation is relatively stable. In deciding which intravenous beta blocker to substitute in a patient taking a beta blocker on a long-term basis, the need for cardioselectivity is a primary consideration. Cardioselectivity is provided by metoprolol or esmolol. If the long-term agent has ISA, oxprenolol and acebutolol have IV forms, but they are not readily available. In many situations, esmolol may be substituted and titrated to effect, with the expectation that, if it is not well tolerated, its effects will fade relatively rapidly.

Propranolol

Propranolol (Inderal, Ipran) is the prototypic beta blocker, and its actions and its use are well characterized. [338] It is a nonselective beta blocking drug with MSA but no ISA. [318] It readily penetrates the CNS. Because of its high lipid solubility, it is extensively metabolized in the liver, but to an extent that varies greatly from patient to patient. Therefore, its effective dose is extremely variable: 10 mg to as much as 1 g may be given orally each day. Clearance of the drug can be affected by liver disease or altered hepatic blood flow. Renal impairment does not require adjustment of dosing. Despite its half-life of 4 hours, its antihypertensive effect is long-lived

enough to permit dosing once or twice a day. [338] [351] Inderal LA is a sustained-release formulation given once a day. [316]

Propranolol is available in IV form; although initially used as either bolus or infusion, the latter use has been largely supplanted by esmolol. For bolus administration, doses of 0.1 mg/kg may be given, although most practitioners initiate therapy with much smaller doses, typically 0.25 to 0.5 mg, and titrate to effect. Interestingly, propranolol shifts the oxyhemoglobin dissociation curve to the right, perhaps accounting for its efficacy in vasospastic disorders. [352] [353] [354]

Metoprolol

Metoprolol (Lopressor) is approved for the treatment of angina pectoris and is the only IV beta blocker formally approved by the U.S. Food and Drug Administration for treatment of acute myocardial infarction. Lacking either ISA or MSA, it is cardioselective. Because it is metabolized in the liver by the monooxygenase system, doses need not be adjusted in the presence of renal failure. [318] The usual oral dose is 100 to 200 mg per day, once or twice a day for hypertension and twice a day for angina pectoris. It may be administered IV in doses of 2.5 to 5 mg every 2 to 5 minutes up to about 15 mg, titrating to control of heart rate and acceptable blood pressure.

Labetalol

Labetalol (Trandate, Normodyne) is representative of a class of drugs that act as competitive antagonists at both alpha $_1$ - and beta-adrenergic receptors. Labetalol consists of four isomers that block the alpha$_1$ -, beta$_1$ -, and beta$_2$ -receptors, inhibit neuronal uptake of NE (uptake 1), act as a partial agonist at beta $_2$ -receptors, and possibly have some direct dilating abilities. [316] The potency of the mixture for beta blockade is 5- to 10-fold that for alpha blockade. [355] The usual oral dose of labetalol is 200 to 400 mg twice a day, although much larger doses have been used. It is hepatically metabolized, and therefore clearance is affected by hepatic perfusion. The dose need not be adjusted for renal dysfunction. [318] Labetalol may be given IV every 5 minutes in 5- to 10-mg doses or up to a 2-mg/min infusion. It significantly blunts cardiovascular responses

to tracheal intubation. [356] It can be effective in treatment of aortic dissection, [342] hypertensive emergencies, [357] [358] and postoperative cardiac surgical patients, [359] particularly because its vasodilatation is not accompanied by tachycardia. It may be used in pregnancy to treat hypertension, both on a long-term basis and in more urgent situations. [360] Uterine blood flow is not affected even with significant reduction of blood pressure. [361] Carvedilol, a mixed alpha- and beta-antagonist, has been introduced as therapy for mild to moderate hypertension, [362] [363] [364] [365] [366] [367] [368] [369] [370] for management of stable or unstable angina, and after acute MI. [371] [372] [373] [374] [375] Clinical trials of carvedilol use in the treatment of controlled CHF (New York Heart Association class II-IV) suggest a significant reduction in the risk of mortality, [376] [377] [378] [379] especially for patients with diabetes. [380]

Esmolol

Because of its hydrolysis by esterases, esmolol (Brevibloc) has a uniquely short half-life of 9 to 10 minutes, which makes it particularly useful in anesthetic practice. It is administered when beta blockade of short duration is desired or in critically ill patients for whom adverse effects of bradycardia, heart failure, or hypotension may necessitate rapid withdrawal of the drug. Peak effects of a loading dose are seen within 5 to 10 minutes and diminish rapidly (within 20-30 min). It is cardioselective. It may be given as a bolus of 0.5 mg/kg to blunt cardiovascular responses to tracheal intubation. If used as an infusion for the treatment of supraventricular tachycardia, 500 mug/kg is given over 1 minute, followed by an infusion of 50 mug/kg/min for 4 minutes. If the rate is not controlled, a repeat loading dose followed by a 4-minute infusion of 100 mug/kg/min is given, and this sequence is repeated, increasing the infusion in 50-mug/kg/min increments, up to 200 or 300 mug/kg/min if needed. It should be remembered that the clinical effect may persist for 20 to 30 minutes after discontinuation of the infusion. Compared with verapamil, esmolol may be more likely to convert atrial fibrillation to sinus rhythm. [339] Esmolol is safe and effective in treatment of intraoperative and postoperative hypertension and tachycardia. [381] [382] [383] If continuous use is required, it may be reasonably replaced by a longer-lasting cardioselective drug such as IV metoprolol. It has been used safely even in patients with compromised left ventricular function. [384] [385]

Drugs that Inhibit Synthesis, Storage or Release of Norepinephrine

Some early antihypertensive drugs acted by replacing NE in the nerve ending with a much less potent false transmitter. alpha-Methyldopa (Aldomet) is such a drug and was, in fact, the most popular nondiuretic antihypertensive used prior to the development of beta blockers. [317] Like DOPA, alpha- methyldopa enters the biosynthetic pathway for NE (see Fig. 14-9) (Figure Not Available) . It is then decarboxylated to alpha-methyl-NE. Initially, this chemical was thought to act as a false transmitter, but it was found to be almost as potent as NE. In the CNS, alpha-methyldopa may be further metabolized to alpha-methylepinephrine, [386] and it acts at alpha$_2$ -receptors to decrease sympathetic outflow, [387] thus reducing blood pressure. Because of its sedating qualities, fluid retention, postural hypotension, and occasional reports of hepatic necrosis, alpha-methyldopa is now used much less often. [317]

Methylparatyrosine (metyrosine, Demser) is a potent inhibitor of tyrosine hydroxylase, which catalyzes the formation of DOPA from tyrosine (see Fig. 14-9) (Figure Not Available) . Because this is the rate-limiting step in the biosynthesis of NE, the drug significantly decreases levels of endogenous catecholamines and is useful in treating inoperable or malignant pheochromocytomas. [388]

Reserpine affects the uptake of NE not at the neuronal membrane but at the vesicular membrane, thereby inhibiting transport and storage of NE and dopamine. Eventually, NE stores are depleted, and postsynaptic receptors increase in number, which may increase the effects of EPI in patients who have been given reserpine (see Table 14-5) (Table Not Available) . In these patients who require a sympathomimetic drug, direct-acting agents may be more useful, whereas mixed-acting drugs would only be efficacious at higher doses, if at all. Although the agent has central effects that lead to side effects such as sedation and depression, its peripheral effects are responsible for its utility as an antihypertensive drug.

Guanethidine (Ismelin) is taken up into adrenergic nerve endings by the uptake-1 mechanism and depletes NE stores, after initially blocking release of NE. It is used in therapy of hypertension, usually after trial of many other drugs. Its inability to cross the blood-brain barrier accounts for its lack of sedative effect. Guanadrel (Hylorel) is similar to guanethidine, but it has a shorter onset and duration of action.

Bretylium is a class III antiarrhythmic used parenterally to treat life-threatening ventricular tachyarrhythmias. Like guanethidine, it is taken up into adrenergic nerve terminals, but its mechanism of action is otherwise quite different. Bretylium initially causes NE release, then subsequently blocks that release by decreasing sympathetic nerve excitability. Unlike guanethidine, bretylium does not deplete NE stores. [389] The initial catecholamine release may worsen some arrhythmias, such as those associated with digitalis toxicity and myocardial ischemia. [326]

MAO and COMT are enzymes important in degradation of the catecholamines. MAOI bind irreversibly to the enzyme and cause increased amine concentration within the presynaptic terminal. This increase is associated with antihypertensive, antidepressant, and antinarcoleptic effects. [390] MAOI are thought to exert their antihypertensive effect through a false transmitter mechanism. Tyramine is usually oxidatively deaminated in the gut by MAO. With administration of an MAOI, tyramine levels rise. When tyramine is taken up into the sympathetic nerve terminal via uptake 1, it enters the varicosities and is transformed by DBH into octopamine. On its subsequent release in place of NE, octopamine is only weakly reactive at sympathetic receptors, resulting in a lowering of blood pressure. The MAOI are no longer used as antihypertensives because many other drugs with better risk-benefit ratios have been developed.

MAOI are now primarily used in psychiatric practice. The use of MAOI as antidepressants is based on the theory that depression is due to decreased amine in the synapses of the CNS. Inhibition of MAO thus makes more amine available

for release. MAOI currently available for treatment of depression include isocarboxazid (Marplan), phenelzine sulfate (Nardil), and tranylcypromine sulfate (Parnate).

There are at least two forms of this enzyme, based on substrate specificity. MAO-A acts on 5-HT, NE, and dopamine, whereas MAO-B is specific for tyramine. A specific MAO-B inhibitor, selegiline hydrochloride (deprenyl), has been developed for the treatment of Parkinson disease, in hopes that by blocking central dopamine breakdown, more dopamine will be preserved in the affected areas. [391]

Drug and food reactions have been of great concern in patients taking MAOI. Ingestion of tyramine-containing foods such as red wine and aged cheese must be avoided by patients taking these drugs. Consumption delivers a huge amount of tyramine to the adrenergic nerve terminal, with a subsequent massive release of NE. This is manifest clinically as a hypertensive crisis with potential for MI, cerebral hemorrhage, and death. Any intake of biogenic amine precursors would be expected to increase catecholamine levels greatly, as seen with the concurrent administration of levodopa with MAOI. The effects of sympathomimetic amines, particularly the indirect-acting drugs, are enhanced. [390] Of commonly used drugs, narcotics, in particular meperidine, have been associated with hyperpyrexic coma and death in patients treated with MAOI. Depressant effects of agents such as sedatives, alcohol, and general anesthetics are enhanced in these patients. Interaction between MAOI and tricyclic antidepressants can be disastrous. [390] Anesthetic interactions with deprenyl have not been reported, but experience with this drug is currently limited. [391] Great concern has been expressed that patients receiving long-term therapy with MAOI risk life-threatening drug interactions during anesthesia. Emergency surgery in patients given MAOI can be punctuated by marked hemodynamic instability. Severe reactions to narcotics and indirect-acting sympathomimetics, as well as altered metabolism of endogenous and exogenous catecholamines, make these patients potentially difficult to manage. Because of the possibly dangerous interactions of many drugs with MAOI, controversy exists over the best way to anesthetize these patients. [392] [393] It has been suggested that the level of concern expressed over the years may be excessive. Although prudence and custom dictate discontinuation of MAOI well in advance of elective procedures (2 weeks), there appear to be rational anesthetic choices based on pharmacology and risk-benefit considerations in patients in whom surgery cannot be delayed.

Drugs Affecting the Renin-Angiotensin System

The renin-angiotensin system is important in maintaining blood pressure and fluid balance (see Fig. 14-7) . The major end product of the system, angiotensin II, is a potent vasoconstrictor that stimulates the release of aldosterone from the adrenal cortex. Aldosterone causes salt and water retention by the kidney. The mechanism by which angiotensin II is produced is as follows. The juxtaglomerular cells of the renal cortex secrete the proteolytic enzyme called renin, which cleaves angiotensinogen, a protein produced in the liver, producing the decapeptide angiotensin I. Angiotensin I is converted almost immediately to angiotensin II by ACE. This converting enzyme is located predominantly in the endothelial tissue of the lung. In addition to its direct vasoconstrictive activity, angiotensin II enhances the prejunctional release of NE from the adrenergic nerve ending and increases efferent sympathetic nerve activity. Angiotensin II also affects sodium and water homeostasis by directly decreasing tubular reabsorption of sodium, increasing ADH and adrenocorticotropic hormone secretion, and stimulating the secretion of aldosterone. ACE is also a kinase that degrades the vasodilator bradykinin. Therefore, ACE inhibition blocks angiotensin II formation and delays bradykinin breakdown along with effects on associated prostaglandins. [394]

A few patients with hypertensive vascular disease have high circulating plasma renin levels, but many more, 70 percent of patients, respond to the antihypertensive effects of ACEI, and there is no dramatic difference in hypertensive response among patients with low or high renin levels. [317] The ACEI have proven to be useful in the treatment of hypertension and CHF and have decreased mortality after MI [395] (Table 14-12) . Captopril (Capoten), was the first active oral agent available, followed by enalapril (Vasotec) and lisinopril (Prinivil, Zestril). Four new ACEI have been marketed: benazepril (Lotensin), fosinopril (Monopril), quinapril (Accupril), and ramipril (Altace). The ACEI affect the renin-angiotensin aldosterone system by inhibiting ACE activity. [394] [396] [397] Enalapril is the only ACEI available in a parenteral dosage at this time. Lisinopril offers once-a-day dosing.

Although all the ACEI are approved for the treatment of hypertension, only captopril and enalapril are approved for the treatment of CHF. Both these agents have been shown to decrease morbidity and mortality in patients with CHF. Captopril is associated with more frequent adverse effects than enalapril, may have a few more drug interactions, and has a two- to three-times daily dosing regimen as compared with enalapril, which has a once-daily to twice-daily dosing regimen.

Some adverse effects observed with ACEI are common to the entire class, such as cough, angioedema, acute renal failure, and hyperkalemia. Angioedema has occurred, especially after the first dose, affecting the face, extremities, lips, mucous membranes, tongue, glottis, or larynx. [394] [398] [399] Some occurrences may be fatal. [394] [398] [400] This common side effect has led to the approval of the angiotensin II receptor antagonist, losartan. Rash and taste disturbance occur more frequently with captopril than with the other ACEI. Renal function impairment has occurred with ACEI, but it is usually reversible after withdrawal of the drug. Renal function should be monitored. [396] [399] Because hyperkalemia may result from inhibition of aldosterone secretion, it is recommended that serum potassium levels be monitored. [394] [397] [398] [399] ACEI have demonstrated fetal morbidity and mortality in humans. It is advised not to use these agents at all during the second or third trimester of pregnancy. [400]

Cholinergic Drugs

Overview of Mechanisms of Action

The cholinergic drugs act by mimicking, amplifying, or inhibiting the effects of ACh. Cholinergic drugs do not behave exactly as does ACh: their drug action is more specific, affecting

TABLE 14-12 -- Comparative Pharmacokinetics of Angiotensin-Converting Enzyme Inhibitors

fewer sites than ACh, and their duration of action is generally longer than that of ACh.

Unlike adrenergic pharmacology, in which the clinician can select from a wide choice of drugs, there is a relative paucity of drugs that influence parasympathetic function. In general, drugs that affect the parasympathetic system act in one of four ways:

1. As an agonist, stimulating cholinergic receptors.
2. As an antagonist, blocking or inhibiting the actions mediated by the cholinergic receptor.
3. Blocking or stimulating receptors on autonomic ganglia.
4. Inhibiting the metabolism of ACh, thus increasing and prolonging the effect of ACh.

There are currently no effective clinically used drugs that act through mechanisms affecting synthesis of ACh (e.g., by inhibiting choline acetyltransferase) or by causing indirect release of ACh (as tyramine, ephedrine, and amphetamine may release NE). Hemicholinium does interfere with choline uptake and could deplete ACh stores, but it is not used clinically. Adenosine may inhibit the release of ACh by decreasing the affinity of binding sites for calcium ions; aminoglycoside antibiotics may compete with calcium for membrane calcium channels, as does magnesium ion. Exocytotic release of ACh is inhibited by botulinum toxin; this toxin is sometimes given by local injection to treat strabismus and blepharospasm. In a full-blown botulism poisoning syndrome, fatalities may result from muscle weakness and respiratory failure.

Agonists

Cholinergic agonists have limited therapeutic use because of their detrimental effects. ACh, as a result of its diffuse, nonselective actions and rapid hydrolysis by both acetylcholinesterase and butyrylcholinesterase, has had almost no therapeutic use other than as an intraocular medication for transient constriction of the pupil during ophthalmic surgery.

Cholinergic agonists in clinical use have been derived from ACh, but they resist hydrolysis by cholinesterase, permitting a useful duration of action. The different systemic effects of the cholinergic agonists are more quantitative than qualitative, but some limited organ selectivity is useful therapeutically, as is seen with the synthetic choline esters bethanechol and carbachol. Methacholine and bethanechol are primarily muscarinic agonists; carbachol has significant nicotinic and muscarinic effects. The simple maneuver of adding a methyl group to the beta-position of the choline in ACh produces methacholine, which is almost purely muscarinic and is almost totally resistant to hydrolysis by either of the cholinesterases. An IV infusion of methacholine causes hypotension and bradycardia; a small SQ dose causes a more transient hypotension with a reflex increase in heart rate. The sole current use of methacholine (Provocholine) is as a provocative agent in diagnosing hyperreactive airways, making positive use of the deleterious bronchoconstrictive effect of muscarinic agonists. It is administered only by inhalation; serious side effects including gastrointestinal symptoms, chest pain, hypotension, loss of consciousness,

and complete heart block have occurred when the drug is given orally or parenterally. Excessive bronchoconstrictive response should be treated by an inhaled beta-agonist; coexisting beta blockade is considered a contraindication to the use of methacholine.

The carbamate derivative of methacholine, bethanecol (Urecholine), is occasionally used postoperatively to reinstitute peristaltic activity in the gut or to force the extrusion of urine from an atonic bladder. It is administered SQ or orally to avoid effects in other organ systems.

Carbachol is used topically or intraocularly to constrict the pupil, for long-term treatment of wide-angle glaucoma. When used topically, it is often better tolerated than the ophthalmic anticholinesterase agents, and it may be effective in patients resistant to pilocarpine and physostigmine. The rapid pupillary constriction is due to the combination of ganglionic block and muscarinic effects. Another natural alkaloid, pilocarpine, was used to treat glaucoma until the advent of more modern drugs.

Muscarinic Antagonists

Muscarinic antagonists are the active ingredients in some common plants used since antiquity for both medicinal and poisonous effects. It has been suggested that atropine poisoning figures in the American classic, *The Scarlet Letter.*[401] Despite their age, muscarinic antagonists still represent important drugs in anesthesia and critical care (Fig. 14-22) .

Muscarinic antagonists compete with neurally released ACh for access to muscarinic cholinoceptors and block its effects. They also antagonize the actions of muscarinic agonists at noninnervated, muscarinic cholinoceptors. Presyn-aptic muscarinic receptors on the adrenergic nerve terminal may inhibit NE release. Hence, muscarinic antagonists may enhance sympathetic activity. With the exception of quaternary ammonium compounds that do not readily cross the blood-brain barrier and so have few CNS actions, there is no significant specificity of action among these drugs; they block all muscarinic effects with equal efficacy, although some quantitative differences in effect may be seen (Table 14-13) . Research has revealed several subtypes of muscarinic receptors, and agonists and antagonists have been synthesized that bind preferentially to one or another. None of these selective agents is yet available commercially, but this is a rapidly developing area of research, and there will soon be drugs that selectively act on one site or another, such as the heart, bronchial system, smooth muscle, gastric mucosa, or some particular area of the CNS.

Historically, these drugs were used in peptic ulcer disease, various forms of "spastic bowel syndrome," upper respiratory illness, and asthma. However, with the availability of the specific histamine (H_2) drug cimetidine for peptic ulcer disease and inhaled beta-agonists and steroids for asthma, these uses have markedly decreased. Historically, atropine was one of the important drugs used to treat bronchospasm, but it was displaced with the introduction of beta $_2$ -agonist drugs that did not cause drying of secretions or diminished ciliary motility. Topical use of atropine analogues in ophthalmologic practice to dilate the pupil is still common.

The addition of a muscarinic anticholinergic drug to anesthetic premedication to decrease secretions and to prevent harmful vagal reflexes was mandatory in the era of ether anesthesia, but it is no longer necessary with modern inhalational agents. Scopolamine combined with an opiate, usually morphine, is still used by cardiac anesthesiologists to sedate a patient while minimizing cardiorespiratory effects. Routine preoperative use of these drugs as antisialogogues continues in some pediatric and otorhinolaryngologic cases.

Atropine is a tertiary structure that easily crosses the blood-brain barrier (see Fig. 14-22) . CNS effects have been seen with the relatively large doses (1-2 mg) given to block

Figure 14-22 Structural formulas of the clinically useful antimuscarinic drugs.

TABLE 14-13 -- Muscarinic Anticholinergic Drugs

	DURATION	CENTRAL NERVOUS SYSTEM[a]	ANTISIALAGOGUE	HEART RATE
Atropine	Short	Stimulation	+	++
Glycopyrrolate	Long	0	++	+

Scopolamine	Short	Sedation	++	0/+

0, no effect; +, mild effect, ++ moderate effect.

[a] Effects of atropine are limited with usual clinical doses, but they can be significant in the elderly.

the muscarinic side effects of the anticholinesterase drugs used for reversal or neuromuscular blockade reversal (Ch. 12) . In contrast, one of the synthetic antimuscarinic drugs, glycopyrrolate (Robinul), does not cross the blood-brain barrier and has gained popularity for this use. In addition, glycopyrrolate has a longer duration of action than does atropine.

Scopolamine, which resembles the others of this class in peripheral actions, has pronounced CNS effects. It is the active ingredient in most over-the-counter preparations sold as soporifics, and it is effective in preventing motion sickness. The patch preparation of scopolamine can be used prophylactically for motion sickness and postoperative nausea and vomiting, but like oral and parenteral forms, it may be associated with eye, bladder, skin and psychologic side effects. [402] [403]

The development of ipratropium (Atrovent) reestablished antimuscarinic drugs as an important therapeutic approach in asthma and bronchospastic disorders. [404] Although ipra-tropium is structurally similar to atropine and has essentially the same effects when administered parenterally, an important difference is that ipratropium is a quarternary ammonium compound. Thus, it is very poorly absorbed when delivered via inhalation and essentially has few extrapulmonary effects even when given in extremely large doses by this route. Ninety percent of inhaled drug is swallowed, but only 1 percent of the total dose is absorbed systemically.

When administered to normal volunteers, ipratropium provides almost complete protection against bronchospasm induced by a variety of provocative agents. However, in asthmatic patients, results are more variable. The bronchospastic effects of some agents, such as methacholine or sulfur dioxide, are completely blocked, whereas there is little effect on leukotriene-induced bronchoconstriction. Further, there is considerable variability among patients. The onset of bronchodilation is slow, and the maximal effect is less than that seen with beta-agonists. Unlike atropine, ipratropium has no negative effect on ciliary clearance. In general, more therapeutic effect from antimuscarinics, including ipra-tropium, is seen in patients with chronic obstructive pulmonary disease than in asthmatic patients. [404] [405] Ipra-tropium is supplied as a metered-dose inhaler supplying 18 mug per puff. Dosage is two puffs orally four times a day. Maximum bronchodilation occurs in 30 to 90 minutes, but the duration may be 4 hours. [405]

The toxic effects of the muscarinic antagonists are due to the blockade of muscarinic cholinoceptors in the periphery and the CNS. The peripheral effects (e.g., dry mouth) may be irritating, but not life-threatening, in healthy adults. However, children are more dependent than adults on sweating for thermoregulation and easily become dangerously hyperthermic. Moreover, older individuals may not be able to tolerate the cardiac, ocular, or urinary effects of muscarinic blockade.

The CNS effects are the usual cause of death or injury. Increasing doses of atropine or scopolamine cause greater distortions of mentation, progressing from thought disorders to hallucinations, delusions, delirium, and severe psychoses. These effects are reversible, but the mental dysfunction can persist for weeks. Left alone, the intoxicated individual will die of starvation, dehydration, and/or trauma. However, recovery will be complete if the individual receives appropriate supportive and protective care until the drug is eliminated. Volunteers have received more than 500 mg of atropine, more than 1,000 times the usual dose, and, although they have been disabled for weeks, they have recovered fully.

Small doses of atropine (0.05 mg) can evoke bradycardia, a finding that has led some clinicians to increase the dose in children. It was thought that a CNS effect of atropine could be responsible, but the time course, as well as the fact that it occurred in vagotomized animals, cast doubt on this mechanism. Whether this paradoxic bradycardia is a central or peripheral effect, or both, and the role of muscarinic subtypes, are still subjects of debate. [406]

Atropine and scopolamine toxicity have been treated for decades by the use of the naturally occurring alkaloid physostigmine (Antilirium), which is an anticholinesterase that penetrates the blood-brain barrier. [407] Consequently, the use of this drug in doses of 1 to 2 mg IV to treat the postoperative CNS effects of IV atropine or scopalamine has been successful. Physostigmine may also reverse the CNS effects of other compounds with anticholinergic activity, including the tricyclic antidepressants, several major tranquilizers, and antihistamine drugs. [408] Physostigmine may antagonize the sedative effects of the benzodiazepines as well, but the specific benzodiazepine antagonist, flumazenil (Romazicon), will undoubtedly supplant physostigmine for this use. [409] [410] Physostigmine must be administered with care because of its potentially lethal nicotinic effects, which are not prevented by the muscarinic antagonists, and because its half-life rarely matches that of the intoxicant.

Cholinesterase Inhibitors

Anticholinesterase drugs provide the most commonly used means of producing sustained systemic cholinergic agonism. These drugs are used to reverse neuromuscular blockade, to treat myasthenia gravis, and to treat certain tachyarrhythmias.

The first anticholinesterase agent available was physostigmine (see earlier). There are currently three chemical

classes of compounds used as cholinesterase inhibitors: carbamates, organophosphates, and quaternary ammonium alcohols. Neostigmine was first used as a gastrointestinal tract stimulant and later as a treatment for myasthenia gravis.

Physostigmine, neostigmine, and pyridostigmine are carbamates, whereas edrophonium is a quaternary ammonium alcohol. The cholinesterase enzyme is inhibited so long as the esteratic site is bound to an acetate, carbamate, or phosphate. Carbamate and phosphate bonds are much more resistant to attack by hydroxyl groups than are acetate bonds. The acetylated form lasts for only microseconds, whereas the carbamylated form lasts for 15 to 20 minutes. Organophosphates include diisopropylfluorophosphate, parathion, malathion, soman, sarin, VX, and a variety of other compounds used as insecticides. Although the toxicity of the organophosphate insecticides is primarily related to their anticholinesterase activity, the mechanism of this effect is different from the clinically used anticholinesterase drugs. The organophosphates produce an irreversible enzyme inhibition and have CNS effects as well. [411] Consequently, treatment of organophosphate insecticide poisoning relies on chemical compounds capable of displacing the insecticides from the enzyme and therefore of reactivating the cholinesterase activity. The best-documented of these chemicals is pralidoxime (2-PAM). Physostigmine and most of the organophosphates are not quaternary ammonium compounds and have major effects on cholinergic functions in the CNS.

Edrophonium is unique in that it lacks an acetate, carbamate, or a phosphate group. It acts because the positive charge of the nitrogen is attracted strongly by the anionic site and physically blocks the esteratic site. Thus, the edrophonium molecule is postulated to be held in place only by an ionic bond. The duration of inhibition provided by each molecule is short (e.g. milliseconds), but because they are not changed in the reaction, the molecules can hop onto and off the enzyme repeatedly and consequently render the enzyme unavailable to ACh.

Aside from reversal of neuromuscular blockade, there are few other therapeutic uses of these compounds. Because these compounds can increase the effect and duration of neurally released ACh, they are useful in situations in which such release is deficient, such as myasthenia gravis. Further, anticholinesterase drugs are occasionally used to stimulate intestinal function and topically in the eye as a miotic. An irreversible organophosphate anticholinesterase that is used clinically is echothiophate iodide (Phospholine), which is available as topical drops for the treatment of glaucoma. Its major advantage over other topical agents is its prolonged duration of action. Because this chemical also inactivates plasma cholinesterase, it may prolong the action of succinylcholine. Although prudence dictates discontinuation of echothiophate for 1 week prior to surgery, there are numerous case reports of successful anesthesia performed under emergency conditions.

Ganglionic Drugs

Agonists

The agonists are essential for analyzing the mechanism of ganglionic function, but they have no therapeutic use. Nicotine is the classic ganglionic agonist, and its

effects have been well described. [412]

Parasympathetic drugs stimulate ganglia, but this action is usually masked by the other parasympathomimetic effects. Experimentally, relatively large doses of ACh administered IV after blockade of muscarinic receptors by atropine causes ganglionic stimulation and release of EPI by the adrenal medulla. [412]

Antagonists

The ganglionic antagonists were the first effective therapy for the management of hypertension and were used extensively during the 1950s and 1960s. However, because of interference with transmission through both sympathetic and parasympathetic ganglia, antihypertensive action was accompanied by numerous undesirable side effects. Hexa-methonium is the prototypic drug of this class, and it has minimal neuromuscular and muscarinic activity. Paton [413] provided a vivid description of the clinical effects of chronic ganglionic blockade with his "hexamethonium man." The systemic effects of ganglionic blockade are determined by the "resting tone" of a specific body system prior to the application of ganglionic blockade (see Table 14-2) .

Although not as reliable or as potent as nitroprusside, trimethaphan has a quick onset and short duration of action that makes it useful in situations in which moment-to-moment control of blood pressure is critical, while avoiding some of the toxicity and side effects associated with agents such as nitroprusside and beta blockers. Because it does not increase cerebral blood flow, it may be used in hypertensive encephalopathy without worsening cerebral edema and also in intracranial hem-orrhage associated with hypertension. In acute aortic dissection, trimethaphan may lower blood pressure without causing significant tachycardia, avoiding the increase in shearing forces (dp/dt) seen with increased heart rate. [341]

Trimethaphan may be used for controlled hypotension under certain circumstances, as an alternative to or in combination with nitroprusside. The two agents combined may avoid the sympathoadrenal stimulation and rebound hypertension seen with nitroprusside alone. The dosages are also decreased with the use of combination therapy, thus avoiding cyanide toxicity in patients who have renal insufficiency or who require large cumulative doses of trimethaphan. Side effects and rapidly developing tolerance limit its use. Other noncardiovascular side effects related to effects of ganglionic blockade include blurred vision, persistent pupillary dilatation (which may interfere with neurologic evaluation), and gastrointestinal and urinary atony. Orthostatic hypotension occurs, but it may not be a serious concern in these usually critically ill patients. Histamine release also occurs at clinically relevant concentrations.

AUTONOMIC DYSFUNCTION

Plasma Catecholamines

Accurate and sensitive techniques for measuring plasma catecholamines have existed for three decades, but interpretation of the data they yield has been controversial. Plasma EPI and NE levels are typically in the 100 to 400 pg/mL normal range, but they can easily increase 6-fold or more in stress.

Plasma concentrations of EPI reflect adrenal medullary activity, [414] if not overall sympathetic activity, and are labile. The uncontrolled stress experienced by experimental subjects has clouded the meaning of measured levels. Significant isolated adrenal medullary secretion can occur in certain stressful situations, such as public speaking. [28] Moreover, venous samples may reflect the EPI kinetics in the organ being sampled rather than in the whole body, and arterial samples may be more reliable. [415]

The significance of plasma NE concentration is even more controversial. Although the adrenal medulla secretes some NE, plasma NE levels generally reflect spillover from sympathetic stimulation because most of the plasma NE released at the nerve ending is taken up again by the nerve terminal. Although reuptake may be tissue-specific and markedly influenced by alterations in physiology or diseases, this spillover in humans is 10 to 20 percent of the NE synthesis rate at baseline and may be greatly enhanced in periods of sympathetic activation. [416] The most compelling argument for use of plasma NE as a marker for sympathetic activity comes from animal studies in which plasma NE levels directly mirrored nerve stimulation. [417] Many important studies have correlated elevations in plasma catecholamines with acute and chronic stress and have led to the concept of stress-free anesthesia. The landmark study showing a striking relationship between mortality in CHF and plasma NE levels resulted in attempts to utilize beta-adrenergic antagonists in the treatment of ventricular dysfunction. [79] [418] [419]

The development of experimental radiotracer techniques to assess the *in vivo* kinetics of catecholamines has provided additional information that is of clinical importance, particularly in relation to regional kinetics. For example, studies relying only on arterial and venous catecholamines suggested that the hepatomesenteric bed contributed significantly to the total body clearance of catecholamines but only minimally (<8%) to the spillover. However, more recent studies of regional NE kinetics demonstrate that the gut release of NE (
25% of the total body) is largely obscured by efficient extraction (>80%) in the liver. Similarly, selective elevations in NE release from the heart, which may be associated with ischemia, the early onset of CHF, and tachyarrhythmias may not be apparent in measuring arterial or venous levels. [420] The observations involving regional spillover have led to the realization that although stress may activate a generalized sympathetic response, there may be different patterns contingent on the stimulus. Thus, it is possible that the lack of association of plasma NE levels in the presence of clinically significant sympathetic activation may be a function of the measurement technique or the particular stressor. Although there are increasing data that many anesthetic techniques, including inhalational, opiate, and regional, can attenuate the stress response, the question whether this represents a benefit or liability in patient care remains a matter of controversy. [421] [422] Until recently, there were few data to suggest that the attenuation of the stress response altered outcome, with the exception of prolonged postoperative epidural anesthesia or special surgical situations. However, results of several studies in infants and adults undergoing heart surgery suggest that the use of high-dose opiates or other strategies to diminish perioperative stress may improve outcome. [423] [424] [425] [426] Since the last edition of this book, several studies have reported that the ability of neur-axial analgesia to attenuate the sustained increase in perioperative catecholamines usually associated with general anesthesia leads to decreased ischemic and thrombotic complications. [427] [428] [429] [430]

It is our belief that, given the effects of age, posture, and hydration, small changes in plasma catecholamines levels correlate poorly with hemodynamic changes and merit cautious interpretation, whereas significant increases (>1,000 pg) in levels are good markers of sympathetic nervous system activation.

Clinical Syndromes

Diabetes Mellitus

Diabetes mellitus is the most common cause of autonomic neuropathy. Early small-fiber damage is revealed by loss or impairment of vagally controlled normal heart rate variability, decreased peripheral sympathetic tone with subsequent increase in blood flow, and diminished sweating. The diabetic neuropathic foot demonstrates early loss of pain and temperature sense before loss of touch or vibration. With sympathetic denervation, sympathetic nerves normally found supplying small arterioles are either entirely absent or are abnormally distant from their effector sites. The neuropathic foot may show increased blood flow with arteriovenous shunting, whereas peripheral arteries are dilated and stiff; despite the total increase in flow, capillaries may be "missed," with distal ischemia the result. The arterial walls may be stiff from calcification in the media; interestingly, calcification has been reported after surgical sympathectomy.

Mechanisms maintaining normal standing blood pressure are altered, and normal precapillary vasoconstriction in the foot on standing may be diminished. When healthy people stand, roughly 700 mL of the blood volume may pool in the legs and splanchnic circulation, with an associated 20 percent decrease in cardiac output. In healthy individuals, baroreceptors in the carotid sinus and aortic arch detect the decrease and mediate sympathetic impulses to the heart and blood vessels. The sympathetic denervation associated with diabetes may cause loss of the normal compensatory vasoconstriction in the peripheral and gut tissues, and this may be potentiated also by a failure of appropriate acceleration of heart rate and reduced cardiac output. Diabetic patients with orthostatic hypotension usually have lower NE levels.

Most clinicians recognize that diabetic patients with autonomic neuropathy may be at additional risk in general anesthesia. The increased cardiovascular casualty is shown in a number of case reports and at least one prospective study. [431] Gastroparesis is most probably due to vagal degeneration and is of clinical relevance, because awake or rapidsequence intubation may be required.

Autonomic Changes with Aging

Although numerous studies have examined the effects of maturation and aging on vascular reactivity, the human paradigm is one of exaggerated changes in blood pressure. [432] Aging is associated with alterations in vascular reactivity manifest clinically as exaggerated changes in blood pressure, namely, hypertension and orthostatic hypotension. Orthostatic hypotension is quite common (
20%) in the elderly

and may result largely from diminished baroreceptor responsiveness. Heart rate response to changes in blood pressure, Valsalva maneuver, and the respiratory cycle are blunted with aging. [433] [434] [435] [436] [437]

Resting and exercise-induced NE levels increase with age in healthy subjects (by 13% per decade), [438] in part owing to decreased clearance. [438] [439] Previously a matter of controversy, it now appears that besides the well-documented reduction in vagal function associated with aging, [440] [441] the primary autonomic defect in aging is an impairment in NE reuptake, perhaps as a function of decreased nerve density. Although there is no apparent age-dependent decrement in nerve firing rates from sympathetic efferents in skeletal muscle, [442] kinetic studies reveal selective and dramatic increases in cardiac NE spillover attributable to decreased reuptake in elderly patients subjected to mental stress or exercise. [416] The augmented synaptic concentration of NE in the setting of age-related reduction in vagal function can precipitate clinical complications (arrhythmogenesis and sudden cardiac death) in patients with cardiac disease. However, end-organ responsiveness is blunted by compensatory downregulation of the beta $_1$ -adrenoreceptors (decreased receptor density and affinity) and uncoupling of beta $_2$ -adrenoreceptors (via decreased G_s activity). [443] [444] [445] Despite increased cardiac spillover cardiac oxygen consumption was not altered. [446]

Attenuation of presynaptic alpha$_2$ -adrenoreceptor-mediated inhibition of neuronal NE release [447] [448] [449] also accounts for increased NE levels observed with age. Reduced postsynaptic alpha$_2$ -adrenoreceptor activity decreases contractile responses and further attenuates vasoconstrictor tone. In a seemingly vicious cycle, the increase in circulating NE levels are associated with downregulation of platelet alpha $_2$ -adrenoreceptor density and responsiveness. [450] The loss of adrenergic control via the reduction of alpha$_2$ - and beta-receptor-mediated responses with age causes a loss in the efficacy of the sympathetic system to control cardiovascular responsiveness with advancing age, implying a relationship with or an explanation of the increased incidence of cardiovascular disorders, such as CHF, in the elderly.

Autonomic Changes in Spinal Cord Transection

The most drastic of all alterations in the ANS an anesthesiologist may encounter is complete spinal cord transection. Spinal cord transection not only may affect motor and sensory function, but also may exhibit profound alterations and autonomic activity that can alter anesthetic care. As is obvious from the anatomy of the sympathetic and parasympathetic outflow, spinal cord injuries or transection can cause varying degrees of autonomic dysfunction, depending on the site, extent, and timing of the lesion.

In patients with cervical spinal cord transection, both sympathetic and parasympathetic outflows are detached from central control mechanisms. Thus, in addition to expected motor and sensory changes, there are profound abnormalities altering the cardiovascular, thermoregulatory, gastrointestinal, and urinary systems. The autonomic consequences of transection are not always apparent because the distal portion of the spinal cord may retain some function, resulting in unanticipated autonomic abnormalities.

There are fundamental differences between the acute and chronic effects of spinal cord transection. Initially, a transient state of decreased excitability occurs. This phenomenon, known as "spinal shock," usually occurs immediately after the lesion and may last from days to weeks. In these patients, the periphery is generally atonic, and the peripheral blood vessels are largely dilated. Investigators have suggested that methylprednisolone may be of some use in treating this phase of spinal shock. [451] In patients with high thoracic lesions who have sustained recent injury, the basal supine blood pressure is usually low and is accompanied by plasma catecholamine levels that are approximately 35 percent of normal. [452] Patients with recent low spinal injuries may exhibit compensatory tachycardia from intact parts of the ANS.

In contrast, patients with high spinal lesions may fail to respond to hypovolemia with an increased heart rate and may actually exhibit bradycardia. The only intact efferent component of baroreflex pathways in quadriplegic patients is the vagus. Bradycardia occurs not only with changes in position, but also with Valsalva maneuvers or increased intrathoracic pressure. [453]

One aspect of care that is frequently overlooked is the effect of tracheal suctioning on patients with high spinal transection. Given that many of these patients are dependent on artificial respiration because of their respiratory muscle paralysis, there may be unopposed vagal stimuli contributing to profound bradycardia in these patients. This vagal response is particularly accentuated during hypoxemia.

Because the sympathetic nervous system may be dysfunctional in these patients, there is a compensatory enhancement of the renin-angiotensin-aldosterone system for the maintenance of blood pressure. Therefore, patients who have spinal cord transection may be exquisitely sensitive to ACEI, even with modest changes in intravascular volume or posture. It should be emphasized that the release of renin may be independent of sympathetic stimulation and may be due to renal baroreceptor stimulation that accompanies the fall in renal perfusion pressure.

Although pressure stimuli above the lesion do not usually cause a change in blood pressure, the phenomenon of *autonomic dysreflexia* can occur when stimulation occurs below the lesion. Thus, bladder or bowel distention can elicit the so-called "mass reflex." This autonomic reflex includes a dramatic rise in blood pressure, a marked reduction in flow to the periphery, and flushing and sweating in areas above the lesion. The patient's heart rate may fall as a reflex. Surprisingly, evidence from microneurography studies indicates that there is only a modest rise in sympathetic nerve activity during activation of the mass reflex, [454] and plasma levels increase only modestly. Thus, speculation has arisen that the exaggerated blood pressure response may be due to supersensitivity of adrenoreceptors. As would be anticipated, there is an increase in sensitivity to exogenously administered pressors in quadriplegic patients. [452] It is interesting to note, however, that quadriplegic patients may exhibit a 5- to 10-fold increase in blood pressure in response to the exogenous administration of angiotensin as well as to catecholamines. It is thus possible that impairment of descending inhibitory reflex pathways that are activated during hypertension may contribute to the supersensitivity. This hypothesis is supported by the finding that lesions below T5 only infrequently exhibit the increased sensitivity. Further,

there is apparently a normal level of adrenoreceptors even in patients with chronic quadriplegia.

The management of autonomic dysreflexia is of clinical importance. Although the anesthesiologist may be tempted to utilize minimal anesthesia in a patient without sensory or motor function, significant visceral reflexes can be evoked. For these reasons, one may utilize spinal anesthesia, general anesthesia, or a vasodilator such as nitroprusside or nitroglycerin to attenuate this reflex even if pain is not appreciated. There has been some enthusiasm for using clonidine prophylactically to diminish this response.

An additional problem arising from the autonomic denervation occurring with spinal cord transection involves thermogenesis. Hypothermia may occur readily in such patients resulting from cutaneous vasodilatation and the inability to shiver. Similarly, hyperthermia can occur because the normal sweating mechanism can be impaired. It is therefore important to monitor temperature assiduously in these patients during the course of anesthesia.

Chapter 15 - Respiratory Physiology and Respiratory Function During Anesthesia

Jonathan L. Benumof

INTRODUCTION

Respiratory Physiology

Understanding normal respiratory physiology is a prerequisite to understanding mechanisms of impaired gas exchange during anesthesia and surgery. Toward this end, the normal (gravity-determined) distribution of perfusion and ventilation, the major nongravitational determinants of resistance to perfusion and ventilation, the transport of the respiratory gases, and the pulmonary reflexes and special functions are presented first in this chapter. These processes and concepts are then discussed in relation to the general mechanisms of impaired gas exchange during anesthesia and surgery.

Normal (Gravity-Determined) Distribution of Perfusion, Ventilation, and the Ventilation/Perfusion Ratio

Distribution of Pulmonary Perfusion

Contraction of the right ventricle imparts kinetic energy to the blood in the main pulmonary artery. As the kinetic energy in the main pulmonary artery is dissipated in climbing a vertical hydrostatic gradient, the absolute pressure in the pulmonary artery (Ppa) decreases by 1 cm H_2O per centimeter of vertical distance up the lung (Fig. 15-1) (Figure Not Available) . At some height above the heart, Ppa becomes zero (atmospheric), and still higher in the lung, the Ppa becomes negative. [1] In this region, alveolar pressure (P_A) then exceeds Ppa and pulmonary venous pressure (Ppv), which is very negative at this vertical height. Because the pressure outside the vessels is greater than the pressure inside the vessels, the vessels in this region of the lung are collapsed, and there is no blood flow (zone 1, $P_A > Ppa > Ppv$). Because there is no blood flow, no gas exchange is possible, and the region functions as alveolar dead space, or "wasted" ventilation. Little or no zone 1 exists in the lung under normal conditions, [2] but the amount of zone 1 lung may be greatly increased if Ppa is reduced, as in oligemic shock, or if P_A is increased, as in positive-pressure ventilation.

Further down the lung, absolute Ppa becomes positive, and blood flow begins when Ppa exceeds P_A (zone 2, $Ppa > P_A > Ppv$). At this vertical level in the lung, P_A exceeds Ppv, and blood flow is determined by the mean Ppa - P_A difference rather than by the more conventional Ppa - Ppv difference (see later). [3] The zone 2 blood flow-alveolar pressure relationship has the same physical characteristics as a waterfall flowing over a dam. The height of the upstream river (before reaching the dam) is equivalent to Ppa, and the

Figure 15-1 (Figure Not Available) Schematic diagram showing distribution of blood flow in the upright lung. In zone 1, alveolar pressure (P_A) exceeds pulmonary artery pressure (Ppa), and no flow occurs because the intra-alveolar vessels are collapsed by the compressing alveolar pressure. In zone 2, Ppa exceeds P_A, but P_A exceeds venous pressure (Ppv). Flow in zone 2 is determined by the Ppa-P_A difference (Ppa - P_A) and has been likened to an upstream river waterfall over a dam. Because Ppa increases down zone 2 and P_A remains constant, the perfusion pressure increases, and flow steadily increases down the zone. In zone 3, Ppv exceeds P_A, and flow is determined by the Ppa-P_A difference (Ppa - Ppv), which is constant down this portion of the lung. However, the transmural pressure across the wall of the vessel increases down this zone so that the caliber of the vessels increases (resistance decreases), and therefore flow increases. Finally, in zone 4 pulmonary interstitial pressure becomes positive and exceeds both Ppv and P_A. Consequently, flow in zone 4 is determined by the Ppainterstitial pressure difference (Ppa - P_{ISF}). *(Modified from West [14])*

height of the dam is equivalent to P_A. The rate of water flow over the dam is only proportional to the difference between the height of the upstream river and the dam (Ppa - P_A), and it does not matter how far below the dam the downstream river bed (Ppv) is. This phenomenon has various names, including the waterfall, Starling resistor, weir (dam made by beavers), and "sluice" effect. Because mean Ppa increases down this region of the lung but mean P_A is relatively constant, the mean driving pressure (Ppa - P_A) increases linearly, and therefore mean blood flow increases linearly. However, respiration and pulmonary blood flow are cyclic phenomena. Therefore, absolute instantaneous Ppa, Ppv, and P_A are changing continuously, and the relationships among Ppa, Ppv, and P_A are dynamically determined by the phase lags between the cardiac and respiratory cycles. Consequently, a given point in zone 2 may actually be in either a zone 1 or a zone 3 condition at a given moment, depending on whether the patient is in respiratory systole or diastole or in cardiac systole or diastole.

Still lower in the lung, there is a vertical level at which Ppv becomes positive and also exceeds P_A. In this region, blood flow is governed by the pulmonary arteriovenous pressure difference (Ppa - Ppv) (zone 3, $Ppa > Ppv > P_A$), for here both these vascular pressures exceed the P_A, and the capillary systems are thus permanently open and blood flow is continuous. In descending zone 3, gravity causes both absolute Ppa and Ppv to increase at the same rate, so that the perfusion pressure (Ppa - Ppv) is unchanged. However, the pressure outside the vessels, namely, pleural pressure (Ppl), increases less than Ppa and Ppv, so that the transmural distending pressures (Ppa - Ppl and Ppv - Ppl) increase down zone 3, the vessel radii increase, vascular resistance decreases, and blood flow therefore increases further.

Finally, whenever pulmonary vascular pressures are extremely high, as they are in a severely volume-overloaded patient, in a severely restricted and constricted pulmonary vascular bed, in an extremely dependent lung (far below the vertical level of the left atrium), and in patients with pulmonary embolism or mitral stenosis, fluid may transude out of the pulmonary vessels into the pulmonary interstitial compartment. In addition, pulmonary interstitial edema can be caused by extremely negative Ppl and perivascular hydrostatic pressure, such as may occur in a vigorously spontaneously breathing patient with an obstructed airway (upper airway masses [tumors, hematoma, abscess, edema], laryngospasm [most common], strangulation, infectious processes [epiglottitis, pharyngitis, croup], and vocal cord paralysis), by rapid reexpansion of lung, and by application of very negative Ppl during thoracentesis. [4] [5] Transuded pulmonary interstitial fluid may significantly alter the distribution of pulmonary blood flow.

When the flow of fluid into the interstitial space is excessive and cannot be cleared adequately by lymphatics, it accumulates in the interstitial connective tissue compartment around the large vessels and airways, forming peribronchial and periarteriolar edema fluid cuffs. The transuded pulmonary interstitial fluid fills the pulmonary interstitial space and may eliminate the normally present negative and radially expanding interstitial tension on the extra-alveolar pulmonary vessels. The expansion of the pulmonary interstitial space by fluid causes pulmonary interstitial pressure (P_{ISF}) to become positive and to exceed Ppv (zone 4, $Ppa > P_{ISF} > Ppv > P_A$). [6] [7] In addition, the vascular resistance of

extra-alveolar vessels may be increased at a very low lung volume (i.e., the residual volume), at which the tethering action of the pulmonary tissue on the vessels is also lost, causing P_{ISF} to increase positively (see lung volume discussion later). [8] [9] Consequently, zone 4 blood flow is governed by the arteriointerstitial pressure difference (Ppa - P_{ISF}), which is less than the Ppa - Ppv difference, and therefore zone 4 blood flow is less than zone 3 blood flow. In summary, zone 4 is a region of the lung from which a large amount of fluid has transuded into the pulmonary interstitial compartment or is possibly at a very low lung volume. Both these circumstances produce a positive interstitial pressure, causing extra-alveolar vessel compression, increased extra-alveolar vascular resistance, and decreased

regional blood flow.

It should be evident that as Ppa and Ppv increase, three important changes take place in the pulmonary circulation, namely, recruitment or opening of previously unperfused vessels, distention or widening of previously perfused vessels, and transudation of fluid from very distended vessels. [10] [11] Thus, as mean Ppa increases, zone 1 arteries may become zone 2 arteries, and as mean Ppv increases, zone 2 veins may become zone 3 veins. The increase in both mean Ppa and Ppv distends zone 3 vessels according to their compliance and decreases the resistance to flow through them. Zone 3 vessels may become so distended that they leak fluid and become converted to zone 4 vessels. In general, recruitment is the principal change as Ppa and Ppv increase from low to moderate levels; distention is the principal change as Ppa and Ppv increase from moderate to high levels; and finally, transudation is the principal change when Ppa and Ppv increase from high to very high levels.

Distribution of Ventilation

Gravity also causes vertical Ppl differences that, in turn, cause regional alveolar volume, compliance, and ventilation differences. The vertical gradient of Ppl can be best understood by imagining the lung as a plastic bag filled with semifluid contents; in other words, it is a viscoelastic structure. Without the presence of a supporting chest wall, the effect of gravity on the contents of the bag would cause the bag to bulge outward at the bottom and inward at the top (it would assume a globular shape). With the lung inside the supporting chest wall, the lung cannot assume a globular shape. However, gravity still exerts a force on the lung to assume a globular shape; the force creates a relatively more negative pressure at the top of the pleural space (where the lung pulls away from the chest wall) and a relatively more positive pressure at the bottom of the lung (where the lung is compressed against the chest wall) (Fig. 15-2) . The magnitude of this pressure gradient is determined by the density of the lung. Because the lung has about one-fourth of the density of water, the gradient of Ppl (in cm H_2O) is about one-fourth the height of the upright lung (30 cm). Thus, Ppl increases positively by 30/4 = 7.5 cm H_2O from the top to the bottom of the lung. [12]

Because P_A is the same throughout the lung, the Ppl gradient causes regional differences in transpulmonary distending pressures (P_A - Ppl). Because Ppl is most positive (least negative) in the dependent basilar lung regions, alveoli in these regions are more compressed and therefore are considerably

Figure 15-2 Schematic diagram of the lung within the chest wall, showing the tendency of the lung to assume a globular shape owing to the lung's viscoelastic nature. The tendency of the top of the lung to collapse inward creates a relatively negative pressure at the apex of the lung, and the tendency of the bottom of the lung to spread outward creates a relatively positive pressure at the base of the lung. Thus, pleural pressure increases by 0.25 cm H_2O per centimeter of lung dependency.

smaller than superior, relatively noncompressed apical alveoli (there is an approximately fourfold volume difference). [13] If the regional differences in alveolar volume are translated to a pressure-volume curve for normal lung (Fig. 15-3) , the dependent small alveoli are on the midportion and the nondependent large alveoli are on the upper portion of the S-shaped pressure-volume curve. Because the different regional slopes of the composite curve are equal to the different regional lung compliances, dependent alveoli are relatively compliant (steep slope), and nondependent alveoli are relatively noncompliant (flat slope). Thus, most of the tidal volume (V_T) is preferentially distributed to dependent alveoli, because they expand more per unit pressure change than do nondependent alveoli.

Distribution of the Ventilation/Perfusion Ratio

Both blood flow and ventilation (both on the left-hand vertical axis of Fig. 15-4) (Figure Not Available) increase linearly with distance down the normal upright lung (horizontal axis, reverse polarity). [14] Because blood flow increases from a very low value and more rapidly than ventilation with distance down the lung, the ventilation/perfusion (V_A/Q) ratio (right-hand vertical axis) decreases rapidly at first and then more slowly.

The V_A/Q ratio best expresses the amount of ventilation relative to perfusion in any given lung region. Thus, alveoli at the base of the lung are overperfused in relation to their ventilation ($V_A/Q < 1$). Figure 15-5 (Figure Not Available) shows the calculated ventilation (V_A) and blood flow (Q) in liters per minute, the V_A/Q ratio, and the alveolar partial pressure of oxygen (P_{AO_2}) and partial pressure of carbon dioxide (P_{ACO_2}) in mm Hg for horizontal slices from the top (7% of lung volume), middle (11% of lung volume), and bottom (13% of lung volume) of the

Figure 15-3 Pleural pressure increases by 0.25 cm H_2O every centimeter down the lung. The increase in pleural pressure causes a fourfold decrease in alveolar volume. The caliber of the air passages also decreases as lung volume decreases. When regional alveolar volume is translated over to a regional transpulmonary pressure-alveolar volume curve, small alveoli are on a steep (large slope) portion of the curve, and large alveoli are on a flat (small slope) portion of the curve. Because the regional slope equals regional compliance, the dependent small alveoli normally receive the largest share of the tidal volume. Over the normal tidal volume range (lung volume increases by 500 mL from 2,500 mL [normal functional residual capacity] to 3,000 mL), the pressure-volume relationship is linear. Lung volume values in this diagram relate to the upright position.

Figure 15-4 (Figure Not Available) Distribution of ventilation and blood flow (left-hand vertical axis) and the ventilation/perfusion ratio (V_A/Q, right-hand vertical axis) in normal upright lung. Both blood flow and ventilation are expressed in liters per minute per percentage of alveolar volume and have been drawn as smoothed-out linear functions of vertical height. The closed circles mark the /V_A/Q ratios of horizontal lung slices (three of which are shown in Fig. 15-5) (Figure Not Available) . A cardiac output of 6 L/min and a total minute ventilation of 5.1 L/min was assumed. *(Modified from West [14])*

Figure 15-5 (Figure Not Available) The ventilation/perfusion ratio (V_A/Q) and the regional composition of alveolar gas. Values for the regional flow (Q), ventilation (V_A), P_{O_2} , and P_{CO_2} were derived from Figure 15-4 (Figure Not Available) . P_{N_2} was obtained by what remains from the total gas pressure (which, including water vapor, equals 760 mm Hg). The volumes [Vol. (%)] of the three lung slices are also shown. Compared with the top of the lung, the bottom of the lung has a low V_A/Q and is relatively hypoxic and hypercarbic. *(From West [15])*

lung. [15] The P_{AO_2} increases by more than 40 mm Hg from 89 mm Hg at the base to 132 mm Hg at the apex, whereas P_{CO_2} decreases by 14 mm Hg from 42 mm Hg at the bottom to 28 mm Hg at the top. Thus, in keeping with the regional V_A/Q , the bottom of the lung is relatively hypoxic and hypercarbic as compared with the top of the lung.

V_A/Q inequalities have different effects on arterial P_{CO_2} (Pa_{CO_2}) as compared with arterial P_{O_2} (Pa_{O_2}). Blood passing through underventilated alveoli tends to retain its CO_2 and does not take up enough O_2 ; blood traversing overventilated alveoli gives off an excessive amount of CO_2 but cannot take up a proportionately increased amount of O_2 , owing to the flatness of the oxyhemoglobin (oxy-Hb) dissociation curve in this region (see Fig. 15-25) . Hence, a lung with uneven V_A/V relationships can eliminate CO_2 from the overventilated alveoli to compensate for the underventilated alveoli. Thus, with uneven V_A/Q relationships, P_{ACO_2} to Pa_{CO_2} gradients are small, and P_{AO_2} to Pa_{O_2} gradients are usually large.

In 1974, Wagner and colleagues [16] described a method of determining the continuous distribution of V_A/Q ratios within the lung based on the pattern of elimination of a series of intravenously infused inert gases. Gases of differing solubility are dissolved in physiologic saline solution and infused into a peripheral vein until a steady state is achieved (20 minutes). Toward the end of the infusion period, samples of arterial and mixed expired gas are collected, and total ventilation and cardiac output (Q_T) are measured. For each gas, the ratio of arterial to mixed venous concentration (retention) and the ratio of expired to mixed venous concentration (excretion) are calculated, and retention-solubility and excretion-solubility curves are drawn. The retention- and excretion-solubility curves can be regarded as fingerprints of the particular distribution of V_A/Q ratios that give rise to them.

Figure 15-6 (Figure Not Available) shows the type of distributions found in young, healthy subjects breathing air in the semirecumbent position. [17] The distributions of both ventilation and blood flow are relatively narrow. The upper and lower 95 percent limits shown (vertical interrupted lines) correspond to V_A/Q ratios of 0.3 and 2.1, respectively. Note that these young, healthy subjects had no blood flow perfusing areas with very low V_A/Q ratios, nor did they have any blood flow to unventilated or shunted areas ($V_A/Q = 0$) or unperfused areas ($V_A/Q =$

). Figure 15-6 (Figure Not Available) also shows P_{AO_2} and P_{ACO_2} in respiratory units having different V_A/Q ratios. Within the 95 percent range of V_A/Q ratios (0.3-2.1), the P_{O_2} ranges from 60 to 123 mm Hg, whereas the corresponding P_{CO_2} range is 44 to 33 mm Hg.

Other (Nongravitational) Important Determinants of Pulmonary Vascular Resistance and Blood Flow Distribution

Cardiac Output

As Q_T increases, pulmonary vascular pressures increase [18] (Fig. 15-7) (Figure Not Available) . Because the pulmonary vasculature is distensible, an increase in Ppa increases the radius of the pulmonary vessels, causing pulmonary vascular resistance to decrease. Exactly the opposite effect applies to the passive effect of a

Figure 15-6 (Figure Not Available) (A) The average distribution of ventilation/perfusion ratios (V_A/Q) in young semirecumbent normal subjects. The 95 percent range covers V_A/Q from 0.3 to 2.1 (between dashed lines). (B) The corresponding variations of P_{O_2} and P_{CO_2} in the alveolar gas. *(From West [17])*

decrease in Q_T on the pulmonary circulation. As Q_T decreases, pulmonary vascular pressures decrease. The decrease in pulmonary vascular pressure reduces the radii of the pulmonary vessels, causing pulmonary vascular resistance to increase.

Understanding the relationship among Ppa, pulmonary vascular resistance, and Q_T during passive events is a prerequisite to recognition of active vasomotion in the pulmonary circulation. Active vasoconstriction occurs whenever Q_T decreases, and Ppa either remains constant or increases. Increased Ppa and pulmonary vascular resistance have been found to be "a universal feature of acute respiratory failure." [19] Active pulmonary vasoconstriction can increase Ppa and Ppv, thereby contributing to the formation of pulmonary edema, and in that way has a role in the genesis of the adult respiratory distress syndrome (ARDS). Active vasodilation occurs any time Q_T increases and Ppa either remains constant or decreases. When deliberate hypotension is achieved with sodium nitroprusside, Q_T often remains constant or increases, but Ppa decreases and, therefore, so does pulmonary vascular resistance.

Alveolar Hypoxia

Alveolar or environmental hypoxia of *in vivo* and *in vitro* whole lung, unilateral lung, lobe, or lobule of lung causes localized

Figure 15-7 (Figure Not Available) Passive changes in pulmonary vascular resistance (PVR) as a function of pulmonary artery pressure (Ppa) and pulmonary blood flow (Q_T) (PVR = Ppa/Q_T). As Q_T increases, Ppa also increases, but to a lesser extent, so that PVR decreases. As Q_T decreases, Ppa also decreases, but to a lesser extent, so that PVR increases. *(Modified from Fishman [18])*

pulmonary vasoconstriction. This phenomenon is called hypoxic pulmonary vasoconstriction (HPV) and is present in all mammalian species.

The HPV response occurs primarily in the pulmonary arterioles of about 200-mum diameter. These vessels are advantageously situated anatomically in close relation to the small bronchioles and alveoli, which permits rapid and direct detection of alveolar hypoxia. Indeed, blood may actually become oxygenated in small pulmonary arteries, owing to the ability of oxygen to diffuse directly across the small distance between the contiguous air spaces and vessels. [20] This direct access that gas in the airways has to small arteries makes possible a rapid and localized vascular response to changes in gas composition.

The oxygen tension at the HPV stimulus site (Ps_{O_2}) is a function of both P_{AO_2} and mixed venous O_2 pressure (Pv_{O_2}). [21] The Ps_{O_2} - HPV response is sigmoid, with a 50 percent response when P_{AO_2}, Pv_{O_2}, and Ps_{O_2} are approximately 30 mm Hg. Usually, P_{AO_2} has a much greater effect than Pv_{O_2}, because O_2 uptake is from the alveolar space to the blood in the small pulmonary arteries. [21] However, in those regions of the lung that are atelectatic, the only stimulus for HPV is Pv_{O_2}.

There are two major theories how alveolar hypoxia may cause pulmonary vasoconstriction. [22] [23] [24] [25] [26] First, alveolar hypoxia may cause the release of vasoconstrictor substances into the pulmonary interstitial compartment, where the substances may then cause vasoconstriction. Over the past years, many vasoactive substances have been proposed as the mediators of HPV (e.g., leukotrienes, prostaglandins, catecholamines, serotonin, histamine, angiotensin, and bradykinin), but none has been proved to be involved primarily in the process. In 1992, nitric oxide (endothelialderived relaxing factor) was proposed to have a pivotal role in modulating pulmonary vascular resistance. [27]

Although the precise mediator of HPV is not known, it is certain that the prostaglandin products of arachidonic acid metabolism can inhibit the HPV response, and it is possible that the leukotriene products of arachidonic acid metabolism mediate, or are at least required for, the HPV response. The general scheme of arachidonic acid metabolism is shown in Figure 15-8 . On an appropriate stimulus, such as alveolar hypoxia, phospholipase A_2 converts the phospholipid in the cell membrane (possibly in all 40 lung cell types) [28] to arachidonic acid. The released arachidonic acid can be metabolized in two ways. First, the enzyme cyclooxygenase can convert arachidonic acid to prostaglandins; the major prostaglandin is prostaglandin I_2 (prostacyclin). [29] [30] Prostacyclin is a potent pulmonary vasodilator, which can abolish HPV. [29] [30] The cyclooxygenase pathway can also produce thromboxane; this product is not shown in Figure 15-8 because it is thought not to be important with regard to HPV. [31] [32] Second, the enzyme lipoxygenase can convert arachidonic acid to leukotrienes. All the leukotrienes are potent pulmonary vasoconstrictors and can enhance HPV; indeed, the leukotrienes have received considerable attention as the mediator of HPV. [32] The amount of pulmonary vasoconstriction caused by hypoxia is regulated by a balance between leukotriene agonist and prostaglandin antagonist effects.

There are many experimental data that support and are consistent with the foregoing relationship between the products of arachidonic acid metabolism and HPV (see Fig. 15-8) . Blockage of cyclooxygenase with acetylsalicylic acid, [30] [33] [34] [35] indomethacin, [33] [34] [35] [36] meclofenamate, [37] [38] or ibuprofen [39] [40] results in increased HPV (predominance of leukotrienes). Infusion of prostaglandins [41] [42] and prostacyclin [40] during regional HPV and prostacyclin during regional pneumonia [33] [36] [43] [44] decreases HPV (predominance of prostaglandins). Blockage of lipoxygenase results in decreased HPV (predominance of prostaglandins). [45] [46] [47] Blockage of leukotriene receptors with FPL 55713 causes decreased HPV (predominance of prostaglandins). [30] [48] [49] If both the cyclooxygenase-prostaglandin and the lipoxygenase-leukotriene systems are inhibited (as with BW755C), but the cyclooxygenase-prostaglandin system is inhibited to a greater extent (resulting in predominance of leukotrienes), HPV is increased. [50] If cyclooxygenase is already blocked by ibuprofen, addition of BW755C relatively selectively blocks lipoxygenase (relative increase in the cyclooxygenase-prostaglandin system), and

Figure 15-8 The leukotriene products of arachidonic acid metabolism can increase hypoxic pulmonary vasoconstriction (HPV), and the prostaglandin products of arachidonic acid metabolism can decrease HPV. The amount of HPV is determined by a balance between these agonist and antagonist effects of the leukotrienes and prostaglandins, respectively.

HPV is relatively decreased. [39] Thus, maneuvers that promote the use of the cyclooxygenase-prostaglandin pathway decrease HPV, and maneuvers that promote the use of the lipoxygenase-leukotriene pathway increase HPV. Although most studies support the cyclooxygenase-prostaglandin-decreased HPV and lipoxygenase-leukotriene-increased HPV theory, a few studies do not. [51] [52] [53] [54] [55]

Second and/or alternatively, hypoxia also appears to stimulate metabolic activity of pulmonary vascular smooth muscle directly and to accelerate production of adenosine triphosphate (ATP), whereas in systemic vascular beds, the action of hypoxia on metabolism is depressant. Low O_2 tension also maintains the membrane of pulmonary vascular smooth muscle cells in a state of partial depolarization and influences the role of calcium in excitation-contraction coupling. [26] Thus, alveolar hypoxia may directly cause ion fluxes, which cause or contribute to the vasoconstriction. In this way, elements of the vascular wall could serve both as a sensor and as an effector of vasoconstriction. [32] In summary, HPV may be due to either a direct action of alveolar hypoxia on pulmonary vasculature or an alveolar hypoxia-induced release of vasoactive substances. These two mechanisms for the production of HPV are not necessarily mutually exclusive.

There are three ways in which HPV operates in humans. First, life at high altitude or whole-lung respiration of a low inspired concentration of O_2 (F_{IO_2}) increases

Ppa. This is true for newcomers to high altitude, for the acclimatized, and for natives. [26] The vasoconstriction is considerable, and in healthy people breathing 10 percent O_2, Ppa doubles, whereas pulmonary wedge pressure remains constant. [56] The increased Ppa increases perfusion of the apices of the lung (recruitment of previously unused vessels) and results in gas exchange in a region of lung not normally utilized (i.e., zone 1). Thus, with a low F_{IO_2}, the Pa_{O_2} is greater and the alveolar-arterial O_2 tension difference and V_T/V_T ratio are less than would be expected or predicted on the basis of a normal (sea level) distribution of ventilation and blood flow. High-altitude pulmonary hypertension is an important component in the development of mountain sickness subacutely (hours to days) and cor pulmonale chronically (weeks). [57] In fact, there is now good evidence that in patients with chronic obstructive pulmonary disease, even nocturnal episodes of arterial O_2 desaturation (caused by episodic hypoventilation) are accompanied by elevations in Ppa and may account for or lead to sustained pulmonary hypertension and cor pulmonale. [58] Second, hypoventilation (low V_A/Q), atelectasis, or nitrogen ventilation of any region of the lung (one lung, lobe, lobule) generally causes a diversion of blood flow away from the hypoxic to the nonhypoxic lung (40-50%, 50-60%, 60-70%, respectively) [59] [60] (Fig. 15-9) . The regional vasoconstriction and blood flow diversion are of great importance in minimizing transpulmonary shunt and in normalizing regional V_A/Q ratios during disease of one lung, one-lung anesthesia (Ch. 48) , and inadvertent intubation of a main stem bronchus. Third, in patients who have chronic obstructive pulmonary disease, asthma, pneumonia, or mitral stenosis but not bronchospasm, administration of pulmonary vasodilator drugs such as isoproterenol, sodium nitroprusside, and nitroglycerin causes a decrease in Pa_{O_2} and pulmonary vascular resistance and an increase in right-to-left transpulmonary shunt. [61] The mechanism for

Figure 15-9 Schematic drawing of regional hypoxic pulmonary vasoconstriction (HPV); one-lung ventilation is a common clinical example of regional HPV. HPV in the hypoxic atelectatic lung causes a redistribution of blood flow away from the hypoxic lung to the normoxic lung, thereby diminishing the amount of shunt flow (Q_S/Q_T) that can occur through the hypoxic lung. Inhibition of hypoxic lung HPV causes an increase in the amount of shunt flow through the hypoxic lung, thereby decreasing Pa_{O_2}.

these changes is thought to be deleterious inhibition of preexisting and, in some of the lesions, geographically widespread HPV without a concomitant and beneficial bronchodilation. [61] In accordance with the latter two lines of evidence (one-lung or regional hypoxia and vasodilator drug effects on whole-lung or generalized disease), HPV is thought to divert blood flow away from hypoxic regions of the lung, thereby serving as an autoregulatory mechanism that protects Pa_{O_2} by favorably adjusting regional V_A/Q ratios. Factors that inhibit regional HPV are extensively discussed elsewhere. [62]

Lung Volume

The functional residual capacity (FRC) is the volume of lung that exists at the end of a normal exhalation after a normal V_T and when there is no muscle activity or pressure difference between alveoli and atmosphere. Total pulmonary vascular resistance is increased when lung volume is either increased or decreased from FRC (Fig. 15-10) . [63] [64] [65] The increase in total pulmonary vascular resistance above FRC is due to alveolar compression of small intra-alveolar vessels, which results in an increase in small vessel pulmonary vascular resistance (i.e., creation of zone 1 or zone 2). [66] As a relatively small mitigating or counterbalancing effect to the small vessel compression, the large extra-alveolar vessels may be expanded by the increased negativity of the perivascular pressure at high FRC. The increase in total pulmonary vascular resistance below FRC is due to an increase in pulmonary vascular resistance of large extraalveolar vessels. The increase in large vessel pulmonary vascular resistance was previously thought to be due to a mechanical tortuosity or kinking of these vessels. However, small or grossly atelectatic lungs are hypoxic, and it has been shown that the

Figure 15-10 An asymmetric U-shaped curve relates total pulmonary vascular resistance to lung volume. The trough of the curve occurs when lung volume equals functional residual capacity (FRC). Total pulmonary resistance is the sum of resistance in small vessels (increased by increasing lung volume) and the resistance in large vessels (increased by decreasing lung volume). The end point for increasing lung volume (toward total lung capacity [TLC]) is the creation of zone 1 conditions, and the end point for decreasing lung volume (toward residual volume [RV]) is the creation of low ventilation/perfusion (V_A/Q) and atelectatic (atel) areas that have hypoxic pulmonary vasoconstriction (HPV). The curve represents a composite of data from Benumof, [62] Simmons et al, [63] and Burton and Patel. [64]

mechanism of increased large-vessel pulmonary vascular resistance in these lungs is due entirely to HPV. [67] This conclusion has been found to be true whether the chest is open or closed and whether ventilation is by positive pressure or is spontaneous. [68]

Alternate (Nonalveolar) Pathways of Blood Flow Through the Lung

There are several possible pathways for blood to travel from the right side of the heart to the left side of the heart without being fully oxygenated or oxygenated at all. Blood flow through poorly ventilated alveoli (low V_A/Q regions at F_{IO_2} <0.3 have a right-to-left shunt effect on oxygenation) and blood flow through nonventilated alveoli (atelectatic or consolidated regions;V_A/Q = 0 at all F_{O_2}) are sources of right-to-left shunt. Low V_A/Q and atelectatic lung units occur in conditions in which the FRC is less than the closing capacity of the lung (see the section *Lung Volumes, Functional Residual Capacity, and Closing Capacity*).

There are several right-to-left blood flow pathways through the lungs and heart that do not pass by or involve alveoli at all. The bronchial and pleural circulations originate from systemic arteries and empty into the left side of the heart without being oxygenated, constituting the 1 to 3 percent true right-to-left shunt normally present. With chronic bronchitis, the bronchial circulation may carry 10 percent of the cardiac output, and with pleuritis, the pleural circulation may carry 5 percent of the cardiac output. Consequently, there may be as much as a 10 percent and a 5 percent obligatory right-to-left shunt present, respectively, under these conditions. Intrapulmonary arteriovenous anastomoses are normally closed, but in the face of acute pulmonary hypertension, such as may be caused by a pulmonary embolus, they may open and may cause a direct increase in right-to-left shunt. The foramen ovale is patent in 20 to 30 percent of individuals, but it normally remains functionally closed because left atrial pressure exceeds right atrial pressure. However, any condition that causes right atrial pressure to be greater than left atrial pressure may produce a right-to-left shunt, with resultant hypoxemia and possible paradoxic embolization. Such conditions include the use of high levels of positive end-expiratory pressure (PEEP), pulmonary embolization, pulmonary hypertension, chronic obstructive pulmonary disease, pulmonary valvular stenosis, congestive heart failure, and postpneumonectomy states. [69] Indeed, even such common events as mechanical ventilation [70] and breath-holding and reaction to the presence of an endotracheal tube during the excitement phase of emergence from anesthesia [71] [72] have caused right-to-left shunting across a patent foramen ovale and severe arterial desaturation (with the potential for paradoxic embolization). [72] Esophageal to mediastinal to bronchial to pulmonary vein pathways have been described and may explain in part the hypoxemia associated with portal hypertension and cirrhosis. There are no known conditions that selectively increase thebesian channel blood flow (thebesian vessels nourish the left portion of the myocardium and originate and empty into the left side of the heart.)

Other (Nongravitational) Important Determinants of Pulmonary Compliance, Resistance, Lung Volume, and Ventilation

Pulmonary Compliance

For air to flow into the lungs, a pressure gradient (DeltaP) must be developed to overcome the elastic resistance of the lungs and chest wall to expansion. These structures are arranged concentrically, and their elastic resistances are therefore additive. The relationship between the DeltaP and the resultant volume increase (DeltaV) of the lungs and thorax is independent of time and is known as total compliance (C_T), as expressed in the following equation:

The C_T of lung plus chest wall is related to the individual compliances of lungs (C_L) and chest wall (C_{CW}) according to the following expression:

Normally, C_L and C_{CW} each equal 0.2 L/cm H_2O; thus, C_T = 0.1 L/cm H_2O. To determine C_L, DeltaV and the *transpulmonary pressure gradient* (P_A - Ppl, the DeltaP for the lung) must be known; to determine C_{CW}, DeltaV and the *transmural pressure gradient* (Ppl - Pambient, the DeltaP for the chest wall) must be known; to determine C_T, DeltaV and the *transthoracic pressure gradient* (P_A - Pambient, the DeltaP for the lung and chest wall together) must be known. In clinical practice, only C_T is measured, which can be done dynamically or statically, depending on whether a peak or plateau inspiratory DeltaP (respectively) is used for the C_T calculation.

During a positive or negative pressure inspiration of sufficient duration, the transthoracic DeltaP first increases to a peak value and then decreases to a lower plateau value. The peak transthoracic pressure value is due to pressure required to overcome both elastic and airway resistance (see the section *Airway Resistance*). The transthoracic pressure decreases to a plateau value following the peak value, because with time, gas redistributes from stiff alveoli (which expand only slightly and therefore have only a short inspiratory period) into more compliant alveoli (which expand a great deal and therefore have a long inspiratory period). Because the gas redistributes into more compliant alveoli, less pressure is required to contain the same amount of gas, and this explains why the pressure decreases. In practical terms, dynamic compliance is the volume change divided by the peak inspiratory transthoracic pressure, and static compliance is the volume change divided by the plateau inspiratory transthoracic pressure. Therefore, static C_T is usually greater than dynamic C_T, because the former calculation uses a smaller denominator (lower pressure) than the latter. However, if the patient is receiving PEEP, this must be first subtracted from the peak or plateau pressure before calculating thoracic compliance (i.e., compliance = volume delivered/ peak or plateau pressure - PEEP).

The P_A deserves special comment. The alveoli are lined with a layer of liquid. The lining of a curved surface (sphere or cylinder, as are the alveoli, bronchioles, and bronchi) with liquid creates a surface tension that tends to make the surface area that is exposed to the atmosphere as small as possible. Simply stated, water molecules crowd much closer together on the surface of a curved layer of water than elsewhere in the fluid. As lung or alveolus size decreases, the degree of curvature and the retractive surface tension increase.

According to the Laplace equation, the pressure in an alveolus (P, in dynes per square centimeter) is higher than ambient pressure by an amount depending on the surface tension of the lining liquid (T, in dynes per centimeter) and the radius of curvature of the alveolus (R, in centimeters). This is expressed in the following equation:

Although surface tension contributes to the elastic resistance and retractive forces of the lung, two difficulties must be resolved. First, the pressure inside small alveoli should be higher than that inside large alveoli, a conclusion that stems directly from the Laplace equation (R in the denominator). From this reasoning, one would expect a progressive discharge of each small alveolus into a larger one, until eventually only one gigantic alveolus would be left (Fig. 15-11 A). The second problem concerns the relationship between lung volume and the transpulmonary DeltaP (P_A - Ppl). Theoretically, the retractive forces of the lung should increase as the lung volume decreases. If this were true, lung volume should decrease in a vicious circle, with the tendency to collapse

Figure 15-11 Relationship among surface tension (T), alveolar radius (R), and alveolar transmural pressure (P). (A) The pressure relationship in two alveoli of different size but with the same surface tension in their lining fluids. The direction of gas flow is from the higher-pressure small alveolus to the lower-pressure large alveolus, and the result is one large alveolus (Rfinal = SigmaRinitial). (B) The pressure relationships of two alveoli of different size when allowance is made for the expected changes in surface tension (less tension in smaller alveolus). The direction of gas flow is from the larger alveolus to the smaller alveolus until the two alveoli are of equal size and are volume stable (R_K). SigmaR, sum of all individual radii; K, constant.

increasing progressively as the lung volume diminished.

These two problems are resolved by the fact that the surface tension of the fluid lining the alveoli is variable and decreases as its surface area is reduced. The surface tension of alveolar fluid can reach levels that are well below the normal range for body fluids such as water and plasma. When an alveolus decreases in size, the surface tension of the lining fluid falls to an extent greater than the corresponding reduction of radius, so that the transmural pressure gradient (= 2T/R) diminishes. This explains why small alveoli do not discharge their contents into large alveoli (Fig. 15-11 B) and why the elastic recoil of small alveoli is less than that of large alveoli.

The substance responsible for the reduction (and variability) of alveolar surface tension is secreted by the intraalveolar type II pneumocyte and is a lipoprotein called *surfactant,* which floats as a 50-A-thick film on the surface of the fluid lining the alveoli. When the surface film is reduced in area and the concentration of surfactant at the surface is increased, there is an increased surface-reducing pressure, which counteracts the surface tension of the fluid lining the alveoli.

Airway Resistance

For air to flow into the lungs, a DeltaP must also be developed to overcome the nonelastic airway resistance of the lungs to airflow. The relationship between the DeltaP and the rate of airflow (V) is known as airway resistance (R):

The DeltaP along the airway depends on the caliber of the airway and the rate and pattern of airflow. There are three main patterns of airflow. Laminar flow occurs when the gas passes down parallel-sided tubes at less than a certain critical velocity. With laminar flow, the pressure drop down the tube is proportional to the flow rate and may be calculated from the equation derived by Poiseuille: $P = V \times 8L \times mu/pir^4 \times 980$, where P = pressure drop (in cm H_2O), V = volume flow rate (in mL/s), L = length of tube (in cm), r = radius of tube (in cm), and mu = viscosity (in poises).

When flow exceeds the critical velocity, it becomes turbulent. The significant feature of turbulent flow is that the pressure drop along the airway is no longer directly proportional to flow rate but is proportional to the square of flow rate according to the equation $P = V^2 pfL/4pi^2 r^5$, where p is a gas or fluid density term and f is a friction factor that depends on the roughness of the tube wall. [73] Thus, with increases in turbulent flow (and/or orifice flow; see the next paragraph), P increases much more than V, and therefore R increases, as shown in equation 4.

Orifice flow occurs at severe constrictions such as a nearly closed larynx. In these situations, the pressure drop is also proportional to the square of the flow rate, but density replaces viscosity as the important factor in the numerator. This explains why a low-density gas such as helium diminishes the resistance to flow (by threefold as compared with air) in severe obstruction of the upper airway.

Because the total cross-sectional area of the airways increases as branching occurs, the velocity of airflow decreases; laminar flow is therefore chiefly confined to the airways below the main bronchi. Orifice flow occurs at the larynx, and flow in the trachea is turbulent during most of the respiratory cycle. Viewing the components that constitute each of the preceding airway pressure equations, one can see that many factors obviously may affect the pressure drop down the airways during respiration. However, variations in diameter of the smaller bronchi and bronchioles are particularly critical (bronchoconstriction may convert laminar flow to turbulent

flow), and the pressure drop along the airways may become much more closely related to flow rate.

Different Regional Lung Time Constants

So far, the compliance and airway resistance properties of the chest have been discussed separately. In the following analysis, the pressure at the mouth is assumed to increase suddenly to a fixed positive value [74] (Fig. 15-12) (Figure Not Available) that overcomes both elastic and airway resistance and to be maintained at this value during inflation of the lungs. The DeltaP required to overcome nonelastic airway resistance is the difference between the fixed mouth pressure and the instantaneous height of the dashed line in Figure 15-12 (Figure Not Available) and is proportional to the flow rate during most of the respiratory cycle. Thus, the DeltaP required to overcome nonelastic airway resistance is maximal initially but then decreases exponentially (Fig. 15-12 (Figure Not Available) A), hatched lines). The rate of filling therefore also declines in an approximately exponential manner. The remainder of the pressure gradient overcomes the elastic resistance (the instantaneous height of the dashed line in Fig. 15-12 (Figure Not Available) A) and is proportional to the change in lung volume. Thus, the DeltaP required to overcome elastic resistance is minimal initially but then increases exponentially, as does lung volume. Alveolar filling ceases (lung volume remains constant) when the pressure resulting from the retractive elastic forces balances the applied (mouth) pressure (see Fig. 15-12 (Figure Not Available) A, dashed line).

Because there is only a finite time available for alveolar filling and because alveolar filling occurs in an exponential manner, the degree of filling obviously depends on the duration of the inspiration. The rapidity of change in an exponential curve can be described by its time constant tau, which is the time required to complete 63 percent of an exponentially changing function if the total time allowed for the function change is unlimited (2tau = 87%, 3tau = 95%, and 4tau = 98%). For lung inflation, tau = $C_T \times R$; normally, C_T = 0.1 L/cm H_2O, R = 2.0 cm H_2O/L/s, tau = 0.2 second, and 3tau = 0.6 second.

When this equation is applied to individual alveolar units, the time taken to fill such a unit clearly increases as airway resistance increases. The time to fill an alveolar unit also increases as compliance increases, because a greater volume of air will be transferred into a more compliant alveolus before

Figure 15-12 (Figure Not Available) (A-C) Artificial ventilation by intermittent application of a constant pressure (square wave). Expiration is passive. The pressure required to overcome airway resistance (hatched lines, A) and airflow rate (V of Equation 4, C), which are proportional to one another, decreases exponentially. The pressure required to overcome elastic resistance (height of dashed line, A) and lung volume (B), which are proportional to one another, increases exponentially. Values shown are typical for an anesthetized supine paralyzed patient: total dynamic compliance, 50 mL/cm H_2O; pulmonary resistance, 3 cm H_2O/L/s; apparatus resistance, 7 cm H_2O/L/s; total resistance, 10 cm H_2O/L/s; time constant, 0.5 second. *(From Nunn [74])*

the retractive force equals the applied pressure. The compliance of individual alveoli differs from top to bottom of the lung, and the resistance of individual airways varies widely depending on their length and caliber. Therefore, various time constants for inflation exist throughout the lung.

Pathways of Collateral Ventilation

Collateral ventilation is another nongravitational determinant of the distribution of ventilation. There are four known pathways of collateral ventilation. First, interalveolar communications (pores of Kohn) exist in most species; they may range from 8 to 50 per alveolus and may increase with age and with the development of obstructive lung disease. Their precise role has not been defined, but they probably function to prevent hypoxia in neighboring but obstructed lung units. Second, distal bronchiolar-to-alveolar communications are known to exist (channels of Lambert), but their function *in vivo* is speculative (may be similar to pores of Kohn). Third, respiratory bronchiole-to-terminal bronchiole connections have been found in adjacent lung segments (channels of Martin) in healthy dogs and in humans with lung disease. Fourth, there are interlobar connections; the functional characteristics of interlobar collateral ventilation through these connections have been described in dogs, [75] and they have been observed in humans as well. [76]

The Work of Breathing

The pressure-volume characteristics of the lung also determine the work of breathing.Because

and ventilatory work may be analyzed by plotting pressure against volume. [77] In the presence of increased airway resistance or decreased C_L, increased transpulmonary pressure is required to achieve a given V_T with consequent increase in the work of breathing. The metabolic cost of the work of breathing at rest constitutes only 1 to 3 percent of the total O_2 consumption in healthy subjects, but it is increased considerably (up to 50%) in patients with pulmonary disease.

Two different pressure-volume diagrams are shown in Figure 15-13. During normal inspiration (left graph), transpulmonary pressure increases from 0 to 5 cm H_2O while 500 mL of air is drawn into the lung. Potential energy is stored by the lung during inspiration and is expended during

Figure 15-13 Lung volume plotted against transpulmonary pressure in a pressure-volume diagram for an awake (healthy) and an anesthetized patient. The lung compliance of the awake patient (slope of line AB = 100 mL/cm H_2O) equals that shown for the small dependent alveoli in Figure 15-3. The lung compliance of the anesthetized patient (slope of line AB = 50 mL/cm H_2O) equals that shown for the medium midlung alveoli in Figure 15-3 . and for the anesthetized patient in Figure 15-12 (Figure Not Available) The total area within the oval and triangles has the dimensions of pressure multiplied by volume and represents the total work of breathing. The hatched area to the right of lines AB and AB represents active inspiratory work necessary to overcome resistance to airflow during inspiration (INSP). The hatched area to the left of the triangle AB C represents active expiratory work necessary to overcome resistance to airflow during expiration (EXP). Expiration is passive in the healthy subject because sufficient potential energy is stored during inspiration to produce expiratory airflow. The fraction of total inspiratory work necessary to overcome elastic resistance is shown by the triangles ABC and AB C. The anesthetized patient has a decreased compliance and increased elastic resistance work (triangle AB C) compared with the healthy patient's compliance and elastic resistance work (triangle ABC). The anesthetized patient shown in this figure has an increased airway resistance to both inspiratory and expiratory work.

expiration; as a consequence, the entire expiratory cycle is passive. The hatched area plus the triangular area ABC represents pressure multiplied by volume and is the work of breathing. Line AB is the lower section of the pressurevolume curve of Figure 15-13 . The triangular area ABC is the work required to overcome elastic forces (C_T), whereas the hatched area is the work required to overcome airflow or frictional resistances (R). The graph on the right applies to an anesthetized patient with diffuse obstructive airway disease resulting from the accumulation of mucous secretions. There is a marked increase in both the elastic (triangle AB C) and airway (hatched area) resistive components of respiratory work. During expiration, only 250 mL of air leaves the lungs during the passive phase when intrathoracic pressure reaches the equilibrium value of 0 cm H_2O. Active effort-producing work is required to force out the remaining 250 mL of air, and intrathoracic pressure actually becomes positive.

For a constant minute volume, the work done against elastic resistance is increased when breathing is deep and slow. On the other hand, the work done against airflow resistance is increased when breathing is rapid and shallow. If the two components are summated and the total work is plotted against respiratory frequency, there is an optimal respiratory frequency at which the total work of breathing is minimal [78] (Fig. 15-14) (Figure Not Available) . [79] In patients with diseased lungs in which elastic resistance is high (pulmonary fibrosis, pulmonary edema, infants), the optimum frequency is increased, and rapid, shallow breaths are favored. When airway resistance is high (asthma, obstructive lung disease), the optimum frequency is decreased, and slow, deep breaths are favored.

Figure 15-14 (Figure Not Available) The diagrams show the work done against elastic and airflow resistance separately and summated to indicate the total work of breathing at different respiratory frequencies. The total work of breathing has a minimum value at about 15 breaths/min under normal circumstances. For the same minute volume, minimum work is performed at higher frequencies with stiff (less compliant) lungs and at lower frequencies when the airflow resistance is increased. *(Modified from Nunn [75])*

Lung Volumes, Functional Residual Capacity, and Closing Capacity

Lung Volumes and Functional Residual Capacity

The FRC is defined as the volume of gas in the lung at the end of a normal expiration when there is no airflow and P_A equals the ambient pressure. Under these conditions, expansive chest wall elastic forces are exactly balanced by retractive lung tissue elastic forces [80] (Fig. 15-15) (Figure Not Available) .

The expiratory reserve volume is part of the FRC; it is that additional gas beyond the end-tidal volume that can be consciously exhaled, resulting in the minimum volume of lung possible, known as the residual volume. Thus, the FRC equals the residual volume plus the expiratory reserve volume (Fig. 15-16) . With regard to the other lung volumes shown in Figure 15-16 , V_T, vital capacity, inspiratory capacity, inspiratory reserve volume, and expiratory reserve volume can all be measured by simple spirometry. Total lung volume, FRC, and residual volume all contain a fraction (the residual volume) that cannot be measured by simple spirometry. However, if one of these three volumes is measured, the others can be easily derived because the other

Figure 15-15 (Figure Not Available) (A) The resting state of normal lungs when they are removed from the chest cavity; that is, elastic recoil causes total collapse. (B) The resting state of a normal chest wall and diaphragm when the thoracic apex is open to the atmosphere and the thoracic contents are removed. (C) The lung volume that exists at the end of expiration is the functional residual capacity (FRC). At FRC, the elastic forces of lung and chest walls are equal and in opposite directions. The pleural surfaces link these two opposing forces. *(Modified from Shapiro et al [80])*

lung volumes, which relate these three volumes to one another, can be measured by simple spirometry.

FRC can be measured by one of three techniques. The first method is to wash the nitrogen out of the lungs by several minutes of O_2 breathing and to measure the total quantity of nitrogen eliminated. Thus, if 2 L of nitrogen is eliminated and the initial alveolar nitrogen concentration was 80 percent, the initial volume of the lung was 2.5 L. The second method uses the washin of a tracer gas such as helium. If 50 mL of helium is introduced into the lungs and, after equilibration, the helium concentration is found to be 1 percent, the volume of the lung is 5 L. The third method uses Boyle's law (i.e., PV = K, where P = pressure, V = volume, and K = a constant). The subject is confined within a gas-tight box (plethysmograph), so that changes in the volume of the body may be readily determined as a change in pressure within the box. Disparity between FRC as measured in the body plethysmograph and by the helium method is often used as a way of detecting large, nonventilating air-trapped blebs. [81] Obviously, there are difficulties in applying the body plethysmograph to anesthetized patients.

Airway Closure and Closing Capacity

As discussed earlier in the section on the distribution of ventilation, Ppl increases from the top to the bottom of the lung and determines regional alveolar size, compliance, and ventilation. Of even greater importance to the anesthesiologist is the recognition that these gradients in Ppl may lead to airway closure and collapse of alveoli.

Airway Closure in Patients with Normal Lungs

Figure 15-17 (Figure Not Available) A illustrates the normal resting endexpiratory (FRC) position of the lung-chest wall combination. The distending transpulmonary and the intrathoracic air passage transmural DeltaP are 5 cm H_2O, and the airways remain patent. During the middle of a normal inspiration (Fig. 15-17, (Figure Not Available) B) there is an increase in the transmural DeltaP (to 6.8 cm H_2O), which encourages distention of intrathoracic air passages. During the middle of a normal expiration (Fig. 15-17 (Figure Not Available) C), expiration is passive; P_A is attributable only to the elastic recoil of the lung (2 cm H_2O), and there is a decrease (to 5.2 cm H_2O) but still a favorable (distending) intraluminal transmural DeltaP. During the middle of a severe forced expiration (Fig. 15-17 (Figure Not Available) D), Ppl increases far higher than atmospheric pressure and is communicated to the alveoli, which have a pressure that is higher still owing to the elastic recoil of the alveolar septa (an additional 2 cm H_2O). At high gas flow rates, the pressure drop down the air passage is increased, and there will be a point at which intraluminal pressure equals either surrounding parenchymal pressure or Ppl; that point is termed the *equal pressure point* (EPP). If the EPP occurs in small intrathoracic air passages (distal to the 11th generation, the airways have no cartilage and are called *bronchioles*), they may be held open at that particular point by the tethering effect of the elastic recoil of the immediately adjacent or surrounding lung parenchyma. If the

Figure 15-16 The dynamic lung volumes that can be measured by simple spirometry are the tidal volume, inspiratory reserve volume, expiratory reserve volume, inspiratory capacity, and vital capacity. The static lung volumes are the residual volume, functional residual capacity, and total lung capacity. The static lung volumes cannot be measured by observation of a spirometer trace and require separate methods of measurement.

EPP occurs in large extrathoracic air passages (proximal to the 11th generation, the airways have cartilage and are called *bronchi*), they may be held open at that particular point by their cartilage. Downstream of the EPP (in either small or large airways), the transmural DeltaP is reversed (-6 cm H_2O) and results in airway closure. Thus, the patency of airways distal to the 11th generation is a function of lung volume, and the patency of airways proximal to the 11th generation is a function of intrathoracic (pleural) pressure. In extrathoracic bronchi with cartilage, the posterior membranous sheath appears to give first by invaginating into the lumen. [82] If lung volume were abnormally decreased (for example, owing to splinting) and expiration were still forced, the caliber of the airways would be relatively reduced at all times, causing the EPP and point of collapse to move progressively from larger to smaller air passages (closer to the alveolus).

In patients with normal lungs, airway closure may still occur even if exhalation is not forced, provided residual volume is approached closely enough. Even in patients with normal lungs, as lung volume decreases toward residual volume during expiration, the small airways (0.5-0.9 mm in diameter) show a progressive tendency to close, whereas larger airways remain patent. [83] [84] Airway closure occurs first in the dependent lung regions (as directly observed by computed tomography [CT]), [85] because the distending transpulmonary pressure is less and the volume change during expiration is greater. The airway closure is most likely to occur in

Figure 15-17 (Figure Not Available) Pressure gradients across the airways. The airways consist of a thin-walled intrathoracic portion (near the alveoli) and a more rigid (cartilaginous) intrathoracic and extrathoracic portion. During expiration, the pressure due to elastic recoil is assumed to be +2 cm H_2O in normal lungs (A-D) and +1 cm H_2O in abnormal lungs (E and F). The total pressure inside the alveolus is pleural pressure plus the elastic recoil. The arrows indicate direction of airflow. EPP, equal pressure point. See text for explanation. *(Modified from Benumof [189])*

the dependent regions of the lung whether the patient is in the supine or lateral decubitus position, [85] and whether ventilation is spontaneous or positive-pressure ventilation. [86] [87]

Airway Closure in Patients with Abnormal Lungs

Airway closure occurs with milder active expiration, lower gas flow rates, and higher lung volumes and occurs closer to the alveolus in patients with emphysema, bronchitis, asthma, and pulmonary interstitial edema. In all four conditions, airway resistance is increased, causing a larger pressure decrease from the alveoli to the larger bronchi, thereby creating the potential for negative intrathoracic transmural DeltaP and narrowed and collapsed airways. In addition, the structural integrity of the conducting airways may be diminished owing to inflammation and scarring, and therefore these airways may close more readily for any given lung volume or transluminal DeltaP.

In emphysema, the elastic recoil of the lung is reduced (to 1 cm H_2O in Fig. 15-17 (Figure Not Available) E), the air passages are poorly supported by the lung

parenchyma, the point of airway resistance is close to the alveolus, and the transmural DeltaP can become negative quickly. Therefore, during only a *mild* forced expiration in an emphysematous patient, the EPP and the point of collapse are near the alveolus (see Fig. 15-17 (Figure Not Available) E). Use of pursed lip or grunting expiration (the equivalents of partly closing the larynx during expiration), PEEP, and a continuous positive airway pressure in an emphysematous patient restores a favorable (distending) intrathoracic transmural air DeltaP (Fig. 15-17 (Figure Not Available) F). In bronchitis, the airways are structurally weakened and may close when only a small negative transmural DeltaP is present (as with a mild forced expiration). In asthma, the middle-size airways are narrowed by bronchospasm, and if expiration is forced, they are further narrowed by a negative transmural DeltaP. Finally, with pulmonary interstitial edema, perialveolar interstitial edema compresses alveoli and acutely decreases FRC; the peribronchial edema fluid cuffs (within the connective tissue sheaths around the larger arteries and bronchi) compress the bronchi and acutely increase closing volume. [88] [89] [90]

Measurement of Closing Capacity

Closing capacity (CC) is a sensitive test of early smallairway disease and is performed by having the patient exhale to residual volume [91] (Fig. 15-18). (Figure Not Available) An inhalation from residual volume toward total lung capacity is begun, and at the beginning of the inhalation a bolus of tracer gas (xenon-133 [^{133} Xe], helium) is injected into the inspired gas. During the initial part of this inhalation from residual volume, the first gas to enter the alveolus is the V_D gas and the tracer bolus. The tracer gas will only enter alveoli that are already open (presumably the apices of the lung; see hatched lines, Fig. 15-18) (Figure Not Available) . and does not enter alveoli that are already closed (presumably the bases of the lung; see no hatched lines, Fig. 15-18) (Figure Not Available) As the inhalation continues, apical alveoli complete filling and basilar alveoli begin to open and fill, but with gas that does not contain any tracer gas.

Figure 15-18 (Figure Not Available) Measurement of closing capacity by the use of a tracer gas such as xenon-133 (^{133} Xe). The bolus of tracer gas is inhaled near residual volume and, owing to airway closure in the dependent lung, is distributed *only* to those nondependent alveoli whose air passages are still open (shown crosshatched in diagram). During expiration, the concentration of the tracer gas becomes constant after the dead space is washed out. This plateau (phase 3) gives way to a rising concentration of tracer gas (phase 4) when there is once again closure of the dependent airways because the only contribution made to the expired gas is by the nondependent alveoli with a high ^{133} Xe concentration. *(Modified from Nunn [91])*

A differential tracer gas concentration is thus established; the gas in the apices has a higher tracer concentration (see Fig. 15-18 (Figure Not Available) , hatched lines) than that in the bases (see Fig. 15-18 (Figure Not Available) , no hatched lines). As the subject exhales and the diaphragm ascends, a point is reached at which the small airways just above the diaphragm start to close, limiting airflow from these areas. The airflow now comes more from the upper lung fields, where the alveolar gas has a much higher tracer concentration, which results in a sudden increase in the tracer gas concentration toward the end of exhalation (phase 4)

The closing volume (CV) is the difference between the onset of phase 4 and residual volume; because it represents part of a vital capacity maneuver, it is expressed as a percentage of the vital lung capacity. The CV plus the residual volume is known as the CC and is expressed as a percentage of total lung capacity. Smoking, obesity, aging, and the supine position increase the CC. [92] In healthy individuals at a mean age of 44 years, CC = FRC in the supine position, and at a mean age of 66 years, CC = FRC in the upright position. [93]

Relationship Between Functional Residual Capacity and Closing Capacity

The relationship between FRC and CC is far more important than consideration of the FRC or CC alone because

it is this relationship that determines whether a given respiratory unit is normal or atelectatic or has a low V_A/Q ratio. The relationship between FRC and CC is as follows. When the volume of lung at which some airways close is greater than the whole of the V_T, lung volume never increases enough during tidal inspiration to open any of these airways. Thus, these airways stay closed during the entire tidal respiration. Airways that are closed all the time are equivalent to atelectasis (Fig. 15-19) (Figure Not Available) . If the CV of some airways lies within the V_T, then as lung volume increases during inspiration, some previously closed airways will open for a short time until lung volume recedes once again below the CV of these airways. Because these opening and closing airways are open for a shorter time than normal airways, they have less chance or time to participate in fresh gas exchange, a circumstance equivalent to a low V_A/Q region. If the CV of the lung is below the whole of tidal respiration, no airways are closed at any time during tidal respiration; this is a normal circumstance. Anything that decreases FRC relative to CC or increases CC relative to FRC will convert normal areas to low V_A/Q and atelectatic areas, [94] which causes hypoxemia.

Mechanical intermittent positive-pressure breathing (IPPB) may be efficacious because it can take a previously spontaneously breathing patient with a low V_A/Q relationship (in which CC is greater than FRC but still within the tidal volume, as depicted in Fig. 15-20 , right panel) and increase the amount of inspiratory time that some previously closed (at end exhalation) airways spend in fresh gas exchange and thereby increase the V_A/Q relationship (Fig. 15-20 , middle panel). However, if PEEP is added to the IPPB, the PEEP increases FRC to or above a lung volume greater than CC, thereby restoring a normal FRC to CC relationship, so that no airways are closed at any time during the tidal respiration depicted in Figure 15-20 (left panel) (IPPB + PEEP). Thus, anesthesia-induced atelectasis (CT scan shows crescent-shaped densities) in the dependent regions of patients' lungs has not been reversed with IPPB alone but has been reversed with IPPB plus PEEP (5-10 cm H_2O). [85]

Figure 15-19 (Figure Not Available) Relationship between the functional residual capacity (FRC), which is the percentage of total lung capacity that exists at the end of exhalation, shown by the level of each trough of the sine wave tidal volume, and the closing capacity (CC) of the lung (three different closing capacities are indicated by the three different straight lines). See text for explanation of why the three different FRC to CC relationships depicted result in normal or low ventilation/perfusion relationships (V_A/Q) or atelectasis. The abscissa is time. *(From Benumof [189])*

Figure 15-20 The functional residual capacity to closing capacity relationship during spontaneous ventilation (SPON), intermittent positive-pressure breathing (IPPB), and intermittent positive-pressure breathing and positive end-expiratory pressure (IPPB + PEEP). See text for explanation of the effect of the two ventilatory maneuvers (IPPB and PEEP) on the functional residual capacity to closing capacity relationship. TLC, total lung capacity.

Oxygen and Carbon Dioxide Transport

Alveolar and Dead Space Ventilation and Alveolar Gas Tensions

In patients with normal lungs, approximately two-thirds of each breath reach perfused alveoli to take part in gas exchange. This constitutes the effective or alveolar ventilation. The remaining one-third of each breath takes no part in gas exchange and is therefore termed the total (or effective or physiologic) dead space ventilation. The total V_D ventilation may be divided into two components: a volume of gas that ventilates the conducting airways (the anatomic V_D ventilation) and a volume of gas that ventilates unperfused alveoli (e.g., as in zone 1, pulmonary embolus, and destroyed alveolar septa) and therefore does not take part in gas exchange (the alveolar dead space ventilation). Figure 15-21 shows a two-compartment model of the lung in which the anatomic and alveolar dead space compartments have been combined into the total (physiologic) dead space compartment; the other compartment is the alveolar ventilation compartment, whose idealized V_A/Q ratio is 1.0. *

* Figure 15-21 indicates that in a steady state, the volume of CO_2 entering the alveoli (V_{CO_2}) must equal the volume of CO_2 eliminated in the expired gas (V_E) (FE_{CO_2}). Thus $V_{CO_2} = (V_E)(FE_{CO_2})$. However, the expired gas volume consists of alveolar gas (V_A)(F_{ACO_2}) and V_D gas (V_D)(F_{ICO_2}). Thus, $V_{CO_2} = (V_A)(F_{ACO_2}) + (V_D)(F_{ICO_2})$. Setting the first equation equal to the second equation and using the relationship $V_E = V_A + V_D$, subsequent algebraic manipulation (including setting $P_{ACO_2} = Pa_{CO_2}$) results in the V_D equation:

Figure 15-21 Two-compartment model of the lung in which the anatomic and alveolar dead space compartments have been combined into the total (physiologic) dead space (V_D).V_A, alveolar ventilation; V_E, expired minute ventilation; V_{CO_2}, carbon dioxide (CO_2) production; F_{ICO_2}, inspired CO_2 fraction; F_{ACO_2}, alveolar CO_2 fraction; FE_{CO_2}, mixed expired CO_2 fraction;$V_A/Q = 1$, equal

ventilation and perfusion in liters per minute. Normally, the amount of CO_2 eliminated at the airway ($V_E \times FE_{CO_2}$) equals the amount of CO_2 removed by alveolar ventilation ($V_A \times F_{ACO_2}$) because there is no CO_2 elimination from alveolar dead space ($F_{ICO_2} = 0$).

The anatomic dead space varies with lung size and is approximately 2 mL/kg of body weight. In the healthy patient lying supine, the anatomic and total dead space are approximately equal to each other because alveolar dead space is minimal. In the erect posture, the uppermost alveoli may not be perfused (zone 1), and alveolar dead space may increase from a negligible amount to 60 to 80 mL.

In severe lung disease, the physiologic V_D/V_T provides a useful expression of the inefficiency of ventilation. In the healthy patient, this ratio is usually less than 30 percent; that is, ventilation is more than 70 percent efficient. In the patient with obstructive airway disease, V_D/V_T may increase to 60 to 70 percent. Under these conditions, ventilation is obviously grossly inefficient. Figure 15-22 shows the relationship between minute ventilation (V_E) and Pa_{CO_2} for several V_D/V_T values. As V_E decreases, Pa_{CO_2} increases for all V_D/V_T. As V_D/V_T increases, a given decrease in V_E causes a much greater increase in Pa_{CO_2}. If Pa_{CO_2} is to remain constant while V_D/V_T increases, V_E must increase.

The alveolar concentration of a gas is equal to the difference between the inspired concentration of a gas and the ratio of the output (or uptake) of the gas to the V_A. Thus, for gas X during dry conditions, $P_{AX} = (Pdry\ atm)(F_{IX}) \pm V_X$ (output or uptake)$/V_A$, where P_{AX} = alveolar partial pressure of gas X; F_{IX} = inspired concentration of gas X; Pdry atm = dry atmospheric pressure = Pwet atm - PH_2O = 760 - 47 = 713 mm Hg; V_X = output or uptake of gas X; V_A = alveolar ventilation. For CO_2, $P_{ACO_2} = 713(F_{ICO_2} + V_{CO_2}/V_A)$. Because $F_{ICO_2} = 0$ and using standard conversion factors

For example, 36 mm Hg = (713)(200/4,000).

For O_2,

For example, 100 mm Hg = 713(0.21 - 225/3,200).

Figure 15-23 (Figure Not Available) shows the hyperbolic relationships expressed in equations (7) and (8) between Pa_{CO_2} and V_A (and Fig. 15-22) and between P_{AO_2} and V_A for different levels of V_{CO_2} and V_{O_2}, respectively. Pa_{CO_2} is substituted for P_{ACO_2}, because P_{ACO_2} to Pa_{CO_2} gradients are small (as opposed to P_{AO_2} to Pa_{O_2} gradients, which can be large). Note that as V_A increases, the second term of the right-hand side of equations 7 and 8 approaches zero and the composition of the alveolar gas approaches that of the inspired gas. In addition, it should be noted from Figures 15-22 through 15-24 that because anesthesia is usually administered with an oxygen-enriched gas mixture, hypercarbia is a more common result of hypoventilation than hypoxemia.

Oxygen Transport

Overview of Oxygen Transport

The principal function of the heart and lungs is supporting O_2 delivery to, and CO_2 removal from, the tissues in accordance

Figure 15-22 Relationship between the minute ventilation (V_E, L/min) and Pa_{CO_2} for a family of ratios of total dead space to tidal volume (V_D/V_T). These curves are hyperbolic (see equation 7) and rise steeply at low V_E values.

Figure 15-23 (Figure Not Available) Relationship between alveolar ventilation and P_{AO_2} and Pa_{O_2} for a family of different O_2 consumption (V_{O_2}) and CO_2 production (V_{CO_2}) is derived from Equations 7 and 8 in the text and is hyperbolic. As alveolar ventilation increases, the P_{AO_2} and Pa_{CO_2} approach inspired concentrations. Decreases in alveolar ventilation to less than 4 L/min are accompanied by precipitous decreases in P_{AO_2} and increases in Pa_{CO_2}. *(From Nunn [79])*

with metabolic requirements while maintaining arterial blood O_2 and CO_2 partial pressures within a narrow range. The respiratory and cardiovascular systems are series-linked to accomplish this function over a wide range of metabolic requirements, which may increase 30-fold from rest to heavy exercise. The steps in this functional linkage are as follows: (1) ventilation and distribution of ventilation with respect to perfusion, (2) diffusion of O_2 into blood, (3) chemical reaction of O_2 with Hb, (4) Q_T of arterial blood, and (5) distribution of blood to tissues and release of O_2 (Table 15-1) (Table Not Available) . The system is seldom stressed except at exercise, and the earliest symptoms of cardiac or respiratory diseases are often seen only during exercise.

The maximum functional capacity of each link can be determined independently. Table 15-1 (Table Not Available) lists these measured functional capacities for healthy, young men. Because theoretical maximum O_2 transport at the ventilatory step or the diffusion and chemical reaction steps (about 6 L/min in healthy humans at sea level) exceeds the O_2 transportable by maximum cardiac output and distribution steps, the limit to O_2 transport is the cardiovascular system. Respiratory diseases would not be expected to limit maximum O_2 transport until their functional capacities were reduced nearly 40 to 50 percent.

Oxygen-Hemoglobin Dissociation Curve

As a red blood cell (RBC) passes by the alveolus, O_2 diffuses into the plasma, increasing the Pa_{O_2}. As Pa_{O_2} increases, O_2 diffuses into the RBC and combines with Hb. Each Hb molecule consists of four heme molecules attached

Figure 15-24 For any given O_2 concentration in the inspired gas, the relationship between alveolar ventilation and P_{AO_2} is hyperbolic. As the inspired O_2 concentration is increased, the amount that alveolar ventilation must decrease to produce hypoxemia is greatly increased.

TABLE 15-1 -- Functional Capacities and Potential Maximum Oxygen (O_2) Transport of Each Link in the O_2 Transport Chain in Normal Humans[a] at Sea Level

(Not Available)

From Cassidy SS: Heart-lung interaction in health and disease. Am J Med Sci 30:451-461, 1987.

[a] Hemoglobin = 15 g/dL; physiologic dead space in percentage of tidal volume = 0.25; partial alveolar pressure of oxygen > 110 mm Hg.

to a globin molecule. Each heme molecule consists of glycine, alpha-ketoglutaric acid, and iron in the ferrous (Fe^{++}) form. Each ferrous ion has the capacity to bind with one O_2 molecule in a loose, reversible combination. As the ferrous ions bind to O_2, the Hb molecule begins to become saturated.

The oxy-Hb dissociation curve relates the saturation of Hb (rightmost Y axis in Fig. 15-25) to the Pa o_2. Hb is fully saturated (100%) by a P o_2 of about 700 mm Hg. The normal arterial point on the right side and flat part of the oxy-Hb curve in Figure 15-25 is 95 to 98 percent saturation by a Pa o_2 of about 90 to 100 mm Hg. When the P o_2 is less than 60 mm Hg (90% saturation), the saturation falls steeply, so that the amount of Hb uncombined with O_2 increases greatly for a given decrease in P o_2. Mixed venous blood has a P o_2 (Pv o_2) of about 40 mm Hg and is approximately 75 percent saturated; this is indicated by the middle of the three points on the oxy-Hb curve in Figure 15-25.

The oxy-Hb curve can also relate the O_2 content (C o_2) (volume percent, mL of O_2 /0.1 L of blood; secondmost right Y axis in Fig. 15-25) to the P o_2. Oxygen is carried in solution in the plasma, 0.003 mL of O_2 /mm Hg P o_2 /0.1 L, and is combined with Hb, 1.39 mL of O_2 /g of Hb * to the extent (percentage) Hb is saturated. Thus

For a patient with an Hb of 15 g/0.1 L, Pa o_2 of 100 mm Hg, and Pv o_2 of 40 mm Hg, arterial O_2 content (Ca o_2) = (1.39) (15)(1) + (0.003)(100) = 20.9 + 0.3 = 21.2 mL of O_2 /0.1 L; mixed venous O_2 content (Cv o_2) = (1.39)(15)(0.75) - (0.003)(40) = 15.6 + 0.1 = 15.2 mL of O_2 /0.1 L. Thus, the normal arteriovenous O_2 content difference is approximately 5.5 mL/0.1 L.

The oxy-Hb curve can also relate the O_2 transport (L/min) to the peripheral tissues (see thirdmost right Y axis in Fig. 15-25) to the P o_2. This value is obtained by multiplying O_2 content by the Q t (O_2 transport = Q t × Ca o_2). To do this multiplication, one must convert the content unit of mL/0.1 L to mL/L by multiplying the usual O_2 content by 10 (results in ml of O_2 /L of blood); subsequent multiplication of mL/L against Q t in L/min yields mL/min. Thus, if Q t = 5 L/min and Ca o_2 = 20.4 mL of O_2 /0.1 L, then the arterial point corresponds to 1,060 mL/min going to the periphery and the venous point corresponds to 785 mL/min returning to the lungs, with V o_2 = 275 mL/min.

The oxy-Hb curve can also relate the O_2 actually available to the tissues (see leftmost Y axis in Fig. 15-25) as a function of P o_2. Of the 1,000 mL/min of O_2 normally going to the periphery, 200 mL/min of O_2 cannot be extracted because it would lower the P o_2 below the level (see rectangular dashed line in Fig. 15-25) at which organs such as the brain can survive; the O_2 available to the tissues is therefore 800 mL/min. This amount is approximately three to four times the normal resting V o_2. When Q t = 5 L/min and the arterial saturation is less than 40 percent, the total flow of O_2 to the periphery is reduced to 400 mL/min, so that the available O_2 is now 200 mL/min and O_2 supply just equals O_2 demand. Consequently, with low arterial saturation, tissue demand can only be met by an increase in Q t or, in the longer term, by an increase in Hb concentration.

The position of the oxy-Hb curve is best described by the P o_2 level at which Hb is 50 percent saturated (P_{50}). The normal adult P_{50} (see the point on the left side and steep portion of the oxy-Hb curve in Fig. 15-24) is 26.7 mm Hg.

The effect on Hb saturation of a shift in the position of the oxy-Hb curve depends greatly on the P o_2. In the region of the normal Pa o_2 (75 to 100 mm Hg), the curve is relatively horizontal, so that shifts of the curve have little effect on saturation. In the region of the mixed venous P o_2, where the curve is relatively steep, a shift of the curve leads to a much greater difference in saturation. A P_{50} lower than 27 mm Hg describes a left-shifted oxy-Hb curve, which means that at any given P o_2, Hb has a higher affinity for O_2 and is therefore more saturated than normal. This lower P_{50} may require a higher than normal tissue perfusion to produce the normal amount of O_2 unloading. The causes of a left-shifted oxy-Hb curve are alkalosis (metabolic and respiratory-- the Bohr effect), hypothermia, abnormal and fetal Hb, carboxyhemoglobin, methemoglobin, and decreased RBC 2,3-diphosphoglycerate (2,3-DPG) content (which may occur with transfusion of old acid-citrate-dextrose [ACD]-

* Controversy exists over the magnitude of this number. Originally, 1.34 had been used, [95] but with the determination of the molecular weight of Hb (64,458), the theoretic value of 1.39 has become popular. [96] Following extensive human studies, Gregory [97] observed in 1974 that the applicable value was 1.306 mL/g% in human adults. Most of the literature still, however, uses 1.39.

Figure 15-25 The oxygen-hemoglobin dissociation curve. Four different ordinates are shown as a function of oxygen partial pressure (the abscissa). In order from right to left, they are: saturation (%), O_2 content (mL of O_2 /0.1 L) of blood; O_2 supply to the peripheral tissues (mL/min); and O_2 available to the peripheral tissues (mL/min), which is O_2 supply minus approximately 200 mL/min that cannot be extracted below a partial pressure of 20 mm Hg. Three points are shown on the curve: a, normal arterial; v, normal mixed venous; and P_{50}, the partial pressure (27 mm Hg) at which hemoglobin is 50 percent saturated.

stored blood; storage of blood in citrate-phosphate-dextrose [CPD] minimizes changes in 2,3-DPG with time).

A P_{50} higher than 27 mm Hg describes a right-shifted oxy-Hb curve, which means that at any given P o_2, Hb has a low affinity for O_2 and is less saturated than normal. This higher P_{50} may allow a lower tissue perfusion than normal to produce the normal amount of O_2 unloading. The causes of a right-shifted oxy-Hb curve are acidosis (metabolic and respiratory--the Bohr effect), hyperthermia, abnormal Hb, increased RBC 2,3-DPG content, and inhalation anesthetics (see later).

Abnormalities in acid-base balance result in alteration of 2,3-DPG metabolism to shift the oxy-Hb curve to its normal position. This compensatory change in 2,3-DPG requires between 24 and 48 hours. Thus, with acute acid-base abnormalities, O_2 affinity and the position of the oxy-Hb curve change. However, with more prolonged acid-base changes, the altered levels of 2,3-DPG shift the oxy-Hb curve and therefore O_2 affinity back toward normal.

Many inhalation anesthetics have been shown to shift the oxy-Hb dissociation curve to the right. [98] [99] Isoflurane shifts the P_{50} to the right by 2.6±0.07 mm Hg at a vapor pressure of approximately 1 MAC (1.25 percent). [100] On the other hand, high-dose fentanyl, morphine, and meperidine do not alter the position of the curve.

Effect of QS/QT on the PaO_2

Figure 15-26 (Figure Not Available) shows the relationship between F IO_2 and Pa o_2 for a family of right-to-left transpulmonary shunts (Q s/Q t); the calculations assume a constant and normal Q t and Pa co_2. With no Q s/Q t, a linear increase in F IO_2 results in a linear increase in Pa o_2 (solid straight line). As the shunt is increased, the Q s/Q t lines relating F IO_2 to Pa o_2 become progressively flatter. [101] With a shunt of 50 percent of Q t, an increase in F IO_2 results in almost no increase in Pa o_2. The solution to the problem of hypoxemia secondary to a large shunt is not increasing the F IO_2, but rather causing a reduction in the shunt (fiberoptic bronchoscopy, PEEP, patient positioning, antibiotics, suctioning, diuretics).

Effect of QT and Vo_2 on Cao_2

In addition to an increased Q s/Q t, the Ca o_2 is decreased by a decreased Q t (for a constant V o_2) and by an increased V o_2 (for a constant Q t). In either case (decreased Q t or increased

Figure 15-26 (Figure Not Available) Effect of changes in inspired oxygen concentration on Pa o_2 for various right-to-left transpulmonary shunts. Cardiac output (Q t), hemoglobin (Hb), oxygen

consumption (V O_2), and arteriovenous oxygen content differences [C(a - v) O_2] were assumed to be normal. *(From Nunn [75])*

Figure 15-27 Effect of a decrease in cardiac output or an increase in oxygen consumption on mixed venous and arterial oxygen contents. Mixed venous blood (v) either perfuses ventilated alveolar (ALV O_2) capillaries and becomes oxygenated end-pulmonary capillary blood (c
) or perfuses whatever true shunt pathways exist and remains the same in composition (desaturated). These two pathways must ultimately join together to form mixed arterial (a) blood. If the cardiac output (Q T) decreases and/or the oxygen consumption (V O_2) increases, the tissues must extract more oxygen per unit volume of blood than under normal conditions. Thus, the primary effect of a decrease in Q T or an increase in V O_2 is a decrease in mixed venous oxygen content. The mixed venous blood with a decreased oxygen content must flow through the shunt pathway as before (which may remain constant in size) and lower the arterial content of oxygen. Thus, the secondary effect of a decrease in Q T or an increase in V O_2 is a decrease in arterial oxygen content.

V O_2), along with a constant right-to-left shunt, the tissues must extract more O_2 from the blood per unit blood volume, and therefore, the Cv O_2 must primarily decrease (Fig. 15-27) . When the blood with lower Cv O_2 passes through whatever shunt exists in the lung and remains unchanged in its O_2 composition, it must inevitably mix with oxygenated end-pulmonary capillary blood (c
flow) and secondarily decrease the Ca O_2 (Fig. 15-27) * The larger the intrapulmonary shunt, the greater is the decrease in Ca O_2 because more venous blood with lower Cv O_2 can admix with end-pulmonary capillary blood [102] [103] (see Fig. 15-37) (Figure Not Available) . Thus, the P(A - a) O_2 is a function both of the size of the Q S/Q T and of what is flowing through the Q S/Q T, namely, Cv O_2 , and Cv O_2 is a primary function of Q T and V O_2 .

Figure 15-28 shows the equivalent circuit of the pulmonary circulation in a patient with a 50 percent shunt, a normal Cv O_2 of 15 vol percent, and a moderately low Ca O_2 of 17.5 vol percent. Decreasing Q T and/or increasing V O_2 causes a larger primary decrease in Cv O_2 to 10 vol percent and a smaller, but still significant, secondary decrease in Ca O_2 to 15 vol percent; the ratio of change in Cv O_2 to Ca O_2 in this example of 50 percent Q S/Q T is 2:1.

Figure 15-28 The equivalent circuit of the pulmonary circulation in a patient with a 50 percent right-to-left shunt. Oxygen content is in mL/100 mL of blood (vol percent). A decrease in cardiac output (Q T) or an increase in O_2 consumption (V O_2) can cause a decrease in mixed venous oxygen content (from 15 to 10 vol percent in this example), which, in turn, will cause a decrease in the arterial content of oxygen (from 17.5 to 15.0 vol percent). In this 50 percent shunt example, the decrease in mixed venous oxygen content was twice the decrease in arterial oxygen content.

If a decrease in Q T or an increase in V O_2 is accompanied by a decrease in Q S/Q T, there may be no change in Pa O_2 (a decreasing effect on Pa O_2 is offset by an increasing effect on Pa O_2) (Table 15-2) . These changes sometimes occur in diffuse lung disease. If a decrease in Q T or an increase in V O_2 is accompanied by an increase in Q S/Q T, Pa O_2 may be greatly decreased (a decreasing effect on Pa O_2 is compounded by another decreasing effect on Pa O_2) (see Table 15-2) . These changes sometimes occur in regional ARDS and atelectasis. [105]

Fick Principle

The Fick principle allows calculation of V O_2 and states that the amount of O_2 consumed by the body (V O_2) is equal

TABLE 15-2 -- Cardiac Output (Q T), Shunt (Q S/Q T), and Venous (Pv O_2) and Arterial PaO_2 Oxygenation

CHANGES	CLINICAL SITUATION
If Q T	Classic theory, normal lung
Pv O_2 and Q S/Q T = K Pa O_2	
If Q T	Diffuse lung disease

Pv O_2 and Q S/Q T Pa O_2	

ARDS, adult respiratory distress syndrome; K, constant;
, decrease;
, increase.

* The amount of O_2 flowing through any given channel per minute in Figure 15-27 is a product of the blood flow times the O_2 content. Thus, from Figure 15-27 Q TCa O_2 = Qc
Cc
O_2 + QsCv O_2 . With Qc
= Q T - Qs and further algebraic manipulation [104]

to the amount of O_2 leaving the lungs (Q T)(Ca O_2) minus the amount of O_2 returning to the lungs (Q T)(Cv O_2). Thus

Condensing the content symbols yields the usual expression of the Fick equation:

This equation states that O_2 consumption is equal to the Q_T times the arteriovenous O_2 content difference. Normally, (5 L/min)(5.5 mL)/0.1 L = 0.27 L/min (see the section *Oxygen-Hemoglobin Dissociation Curve*).

Similarly, the amount of O_2 consumed by the body (V_{O_2}) is equal to the amount of O_2 brought into the lungs by ventilation (V_I)(F_{IO_2}) minus the amount of O_2 leaving the lungs by ventilation (V_E)(FE_{O_2}), where V_E is expired minute ventilation and FE_{O_2} is mixed expired O_2 fraction. Thus, $V_{O_2} = (V_I)(F_{IO_2}) - (V_E)(FE_{O_2})$. Because the difference between V_I and V_E is due to the difference between V_{O_2} (normally 270 mL/min) and V_{CO_2} (normally 200 mL/min) and is only 70 mL/min (see below), V_I essentially equals V_E. Substituting V_E for V_I:

Normally, V_{O_2} = 5.0 L/min (0.21 - 0.16) = 0.25 L/min. In determining V_{O_2} in this way, V_E can be measured with a spirometer, F_{IO_2} can be measured with an O_2 analyzer or from known fresh gas flows, and FE_{O_2} can be measured by collecting expired gas in a bag for a few minutes. A sample of the mixed expired gas is used to measure PE_{O_2}. To convert PE_{O_2} to FE_{O_2}, simply divide PE_{O_2} by dry atmospheric pressure: $PE_{O_2}/713 = FE_{O_2}$.

Additionally, the Fick equation is useful in understanding the impact of changes in Q_T on Pa_{O_2} and Pv_{O_2}. If V_{O_2} remains constant (K) and Q_T decreases (
), the arteriovenous O_2 content difference has to increase (
):

The $C(a - v)_{O_2}$ difference increases because a decrease in Q_T causes a much larger and primary decrease in Cv_{O_2} as compared with a smaller and secondary decrease in Ca_{O_2}:

Thus, the Cv_{O_2} (and Pv_{O_2}) are much more sensitive indicators of Q_T, because they change more with the changes in Q_T than does Ca_{O_2} (or Pa_{O_2}) (see Figs. 15-27 and 15-37) (Figure Not Available) .

Carbon Dioxide Transport

The amount of CO_2 circulating in the body is a function of both CO_2 elimination and production. Elimination of CO_2 depends on pulmonary blood flow and alveolar ventilation. Production of CO_2 parallels O_2 consumption according to the respiratory quotient (R):

Under normal resting conditions, R is 0.8; that is, only 80 percent as much CO_2 is produced as O_2 is consumed. However, this value changes as the nature of the metabolic substrate changes. If only carbohydrate is utilized, the respiratory quotient is 1.0. Conversely, with the sole use of fat, more O_2 combines with hydrogen to produce water and the R value drops to 0.7.

CO_2 is transported from the mitochondria to the alveoli in a number of forms. In plasma, CO_2 exists in physical solution, hydrated to carbonic acid (H_2CO_3) and as bicarbonate (HCO_3^-). In the RBC, CO_2 combines with Hb as carbaminohemoglobin (Hb-CO_2). The approximate relative values of H_2CO_3 ($H_2O + CO_2$), HCO_3^-, and Hb-CO_2 to the total CO_2 transported are 7, 80, and 13 percent, respectively.

In plasma, CO_2 exists both in physical solution and as H_2CO_3:

The CO_2 in solution can be related to P_{CO_2} by use of Henry's law [106]:

where alpha is the solubility coefficient of CO_2 in plasma (0.03 mmol/L/mm Hg at 37°C). However, the major fraction of CO_2 produced passes into the RBC. As in plasma, CO_2 combines with water to produce H_2CO_3. However, unlike the slow reaction in plasma, in which the equilibrium point lies toward the left, the reaction in the RBC is catalyzed by the enzyme carbonic anhydrase. This zinc-containing enzyme moves the reaction to the right at a rate 1,000 times faster than in plasma. Furthermore, nearly 99.9 percent of the H_2CO_3 dissociates to the HCO_3^- and hydrogen ions (H^+):

The H^+ produced from H_2CO_3 in the production of HCO_3^- is buffered by Hb (H^+ + Hb i HHb). The HCO_3^- produced passes out of the RBC into the plasma to perform its function as a buffer. To maintain electrical neutrality within the RBC, chloride ion (Cl^-) moves in as HCO_3^- moves out (Cl^- shift). Finally, CO_2 can combine with Hb in the erythrocyte (to produce Hb-CO_2). Again, as in the HCO_3^- release, an H^+ ion is formed in the reaction of CO_2 and Hb. This H^+ ion is also buffered by Hb.

Bohr and Haldane Effects

Just as the percent saturation of Hb with O_2 is related to P_{O_2}, so is the total CO_2 in blood related to P_{CO_2}. The Bohr effect is the dependence of the position of the oxy-Hb curve

on P $_{CO_2}$ and pH; hypercapnia and acidosis shift the curve to the right, and hypocapnia and alkalosis shift the curve to the left. The Haldane effect is the shift in the relationship of P $_{CO_2}$ to total CO_2 (i.e., the CO_2 dissociation curve) caused by altered levels of O_2. Low P $_{O_2}$ shifts the CO_2 dissociation curve to the left so that the blood is able to pick up more CO_2.

Pulmonary Microcirculation, Pulmonary Interstitial Space, and Pulmonary Interstitial Fluid Kinetics (Pulmonary Edema)

The ultrastructural appearance of an alveolar septum [107] is schematically depicted in Figure 15-29 (Figure Not Available) . Capillary blood is separated from alveolar gas by a series of anatomic layers: capillary endothelium, endothelial basement membrane, interstitial space, epithelial basement membrane, and alveolar epithelium (of the type I pneumocyte).

On one side of the alveolar septum (the thick, upper [see Fig. 15-29] (Figure Not Available) , fluid- and gas-exchanging side), the epithelial and endothelial basement membranes are separated by a space of variable thickness containing connective tissue fi-brils, elastic fibers, fibroblasts, and macrophages. This connective tissue is the backbone of the lung parenchyma; it forms a continuum with the connective tissue sheaths around the conducting airways and blood vessels. Thus, the pericapillary perialveolar interstitial space is continuous with the interstitial tissue space that surrounds terminal bronchioles and vessels, and both spaces constitute the connective tissue space of the lung. There are no lymphatics in the interstitial space of the alveolar septum. Instead, lymphatic capillaries first appear in the interstitial space surrounding terminal bronchioles, small arteries, and veins.

The opposite side of the alveolar septum (the thin, down [see Fig. 15-29] (Figure Not Available) , gas-exchanging-only side) contains only

Figure 15-29 (Figure Not Available) Schematic summary of the ultrastructure of the pulmonary capillary. The upper side of the capillary has the endothelial and epithelial basement membranes separated by an interstitial space, whereas the lower side of the capillary contains only fused endothelial and epithelial basement membranes. The dashed arrows indicate a potential pathway for fluid to move from the intravascular space to the interstitial space (through loose junctions in the endothelium) and from the interstitial space to the alveolar space (through tight junctions in the epithelium). RBC, red blood cell; ENDO, endothelium; BM, basement membrane; IS, interstitial space; EPI, epithelium; LJ, loose junction; TJ, tight junction; ALV, alveolus. *(From Fishman [107])*

fused epithelial and endothelial basement membranes. The interstitial space is thus greatly restricted on this side owing to fusion of the basement membranes. Interstitial fluid cannot separate the endothelial and epithelial cells from one another, and as a result the space and distance barrier to fluid movement from the capillary to alveolar compartment is reduced and is composed only of the two cell linings with their associated basement membranes. [108] [109]

Between the individual endothelial and epithelial cells are holes or junctions that provide a potential pathway for fluid to move from the intravascular space to the interstitial space and finally from the interstitial space to the alveolar space. The junctions between endothelial cells are relatively large and are therefore termed *loose;* the junctions between epithelial cells are relatively small and therefore termed *tight.* Pulmonary capillary permeability (K) is a direct function of and essentially equivalent to the size of the holes in the endothelial and epithelial linings.

To understand how pulmonary interstitial fluid is formed, stored, and cleared, it is necessary to first develop the concepts that (1) the pulmonary interstitial space is a continuous space between a periarteriolar and peribronchial connective tissue sheath and the space between the endothelial and epithelial basement membranes in the alveolar septum, and (2) the space has a progressively negative distal to proximal DeltaP.

The concepts of a continuous connective tissue sheath-alveolar septum interstitial space and a negative interstitial space DeltaP are prerequisite to understanding interstitial fluid kinetics (Fig. 15-30) (Figure Not Available) . After entering the lung parenchyma, both the bronchi and arteries run within a connective tissue sheath, which is formed by an invagination of the pleura at the hilum and which ends at the level of the bronchioles (Fig. 15-30 (Figure Not Available) A). Thus, there is a potential perivascular and peribronchial space, respectively, between the arteries and the bronchi and the connective tissue sheath. The negative pressure in the pulmonary tissues surrounding the perivascular connective tissue sheath exerts a radial outward traction force on the sheath. The radial traction creates a negative pressure within the sheath, which is transmitted to the bronchi and arteries, tending to hold them open and increase their diameters (see Fig. 15-30). (Figure Not Available) [219] The alveolar septum interstitial space is the space between the capillaries and alveoli (or more precisely, the space between the endothelial and epithelial basement membranes) and is continuous with the interstitial tissue space that surrounds the larger arteries and bronchi (see Fig. 15-30 (Figure Not Available) A). Studies indicate that the alveolar interstitial pressure is also uniquely negative but not as much as the negative interstitial space pressure around the larger arteries and bronchi. [110]

The forces governing net transcapillary-interstitial space fluid movement are as follows. The net transcapillary flow of fluid (F) out of pulmonary capillaries is equal to the difference between pulmonary capillary hydrostatic pressure (Pinside) and the interstitial fluid hydrostatic pressure (Poutside) and to the difference between the capillary colloid oncotic pressure (piinside) and the interstitial colloid oncotic pressure (pioutside). These four forces produce a steady-state fluid flow (F) during a constant capillary permeability (K).

Figure 15-30 (Figure Not Available) (A) Schematic diagram of the concept of a continuous connective tissue sheath-alveolar septum interstitial space. The entry of the main stem bronchi and pulmonary artery into the lung parenchyma invaginates the pleura at the hilum, forming a surrounding connective tissue sheath (heavy black line). The connective tissue sheath ends at the level of the bronchioles. The space between the pulmonary arteries and bronchi and the interstitial space is continuous with the alveolar septum interstitial space. The alveolar septum interstitial space is contained within the endothelial and epithelial basement membranes of the capillaries and alveoli, respectively. (B) Schematic diagram showing how interstitial fluid moves from the alveolar septum interstitial space to the connective tissue interstitial space. The mechanisms are a negative pressure gradient (sump), the presence of one-way valves in the lymphatics, and the massaging action of arterial pulsations. *(Modified from Benumof [185])*

K is a capillary filtration coefficient expressed in mL/min/mm Hg/100 g. The filtration coefficient is the product of the effective capillary surface area in a given mass of tissue and the permeability per unit surface area of the capillary wall to filter the fluid. Under normal circumstances and at a vertical height in the lung that is at the junction of zones 2 and 3, the intravascular colloid oncotic pressure (
26 mm Hg) acts to keep water in the capillary lumen, and working against this force, the pulmonary capillary hydrostatic pressure (
10 mm Hg) acts to force water across the loose endothelial junctions into the interstitial space. If these were the only operative forces, the interstitial space, and consequently the alveolar surfaces, would be constantly dry, and there would be no lymph flow. In fact, alveolar surfaces are moist, and lymphatic flow from the interstitial compartment is constant (
500 mL/d). This can be explained in part by the pioutside (8 mm Hg) and in part by the negative Poutside (
8 mm Hg). Negative (subatmospheric) interstitial space pressure would promote, by suction, a slow loss of fluid across the endothelial holes. [111] Indeed, extremely negative pleural (and perivascular hydrostatic) pressure, such as may occur in a vigorously spontaneously breathing patient with an obstructed airway, can cause pulmonary interstitial edema [112] (Table 15-3) . Relative to the vertical level of the junction of zones 2 and 3, as lung height decreases (lung dependency), absolute Pinside increases, and fluid has a propensity to transudate; as lung height increases (lung nondependency), absolute Pinside decreases, and fluid has a propensity to be reabsorbed. However, fluid transudation induced by an increase in Pinside is limited by a concomitant dilution of proteins in the interstitial space and therefore a decrease in pioutside. [113] Any change in the size of the endothelial junctions, even if the foregoing four forces remain constant, changes the magnitude and perhaps even the direction of fluid movement; increased size of endothelial junctions (increased permeability) promotes transudation, and decreased size of endothelial junctions (decreased permeability) promotes reabsorption.

There are no lymphatics in the interstitial space of the alveolar septum. Instead, lymphatic capillaries first appear in the interstitial space sheath surrounding terminal bronchioles and small arteries. Interstitial fluid is normally removed from the alveolar interstitial space into the lymphatics by a sump (pressure gradient) mechanism, which is caused by the presence of the more negative pressure surrounding the larger arteries and bronchi. [114] [115] The sump mechanism is aided by the presence of valves in the lymph vessels. In addition, because the lymphatics run in the same sheath as the pulmonary arteries, they are exposed to the massaging action of the arterial pulsations. The differential negative pressure, the lymphatic valves, and the arterial pulsations all help to propel the lymph proximally toward the hilum through the lymph nodes (pulmonary to bronchopulmonary to tracheobronchial to paratracheal to scalene and cervical nodes) to the central venous circulation depot (Fig. 15-30 (Figure Not Available) B). An increase in central venous pressure, which is the back pressure for lymph to flow out of the lung, would decrease lung lymph flow

and perhaps promote pulmonary interstitial edema.

If the rate of entry of fluid into the pulmonary interstitial space exceeds the capability of the pulmonary interstitial space to clear the fluid, the pulmonary interstitial space will fill with fluid; the fluid, now under an increased and positive

TABLE 15-3 -- Causes of Extremely Negative Pulmonary Interstitial Fluid Pressure (Poutside) Pulmonary Edema

Vigorous spontaneous ventilation against an obstructed airway
Upper airway mass (tumor, hematoma, abscess, foreign body, etc.)
Laryngospasm
Infection, inflammation, edema
Vocal cord paralysis
Strangulation
Rapid reexpansion of lung
Vigorous pleural suctioning (thoracentesis, chest tube)

driving force (P_{ISF}), will cross the relatively impermeable epithelial wall holes and the alveolar space will fill. Intra-alveolar edema fluid will additionally cause alveolar collapse and atelectasis, thereby promoting further fluid accumulation.

RESPIRATORY FUNCTION DURING ANESTHESIA

Introduction

Arterial oxygenation is impaired in most patients during anesthesia, with either spontaneous or controlled ventilation. [116] [117] [118] [119] [120] [121] In otherwise normal patients it is generally accepted that the impairment of arterial oxygenation during anesthesia is more severe in the elderly, [122] [123] the obese, [124] and smokers. [125] In various studies of healthy young to middle-aged, generally anesthetized patients, venous admixture (shunt) has been found to average 10 percent, and the scatter in V_A/Q ratios has been found to be small to moderate [123] [126] whereas in patients with more marked deterioration in preoperative pulmonary function, general anesthesia causes considerable widening of V_A/Q distribution and large increases in both low V_A/Q ($0.005 < V_A/Q < 0.1$) (underventilated) regions and shunt. [122] [125] [127] The magnitude of shunt correlates closely with the degree of atelectasis. [122] [127]

In addition to the foregoing generalizations concerning respiratory function during anesthesia, the effect of a given anesthetic on respiratory function depends on the depth of general anesthesia, the patient's preoperative respiratory condition, and the presence of special intraoperative anesthetic and surgical conditions.

Effect of Anesthetic Depth on Respiratory Pattern

The respiratory pattern is altered by the induction and deepening of anesthesia. When the depth of anesthesia is inadequate (less than minimum alveolar concentration [MAC]), the respiratory pattern may vary from excessive hyperventilation and vocalization to breathholding. As anesthetic depth approaches or equals MAC (light anesthesia), irregular respiration progresses to a more regular pattern, which is associated with a larger than normal V_T. However, during light but deepening anesthesia, the approach to a more regular respiratory pattern may be interrupted by a pause at the end of inspiration (a "hitch" in the inspiration), followed by a relatively prolonged and active expiration in which the patient seems to exhale forcefully rather than passively. As anesthesia deepens to moderate levels, respiration becomes faster and more regular but shallower. The respiratory pattern is a sine wave losing the inspiratory hitch and lengthened expiratory pause. There is little or no inspiratory or expiratory pause, and the inspiratory and expiratory periods are equivalent. Intercostal muscle activity is still present, and there is normal movement of the thoracic cage with lifting of the chest during inspiration. The respiratory rate is generally slower and the V_T larger with nitrous oxide-narcotic anesthesia as compared with anesthesia with halogenated drugs. During deep anesthesia with halogenated drugs, increasing depression of respiration is manifested by even more rapid, shallow breathing (panting). On the other hand, with deep nitrous oxide-narcotic anesthesia, respirations become slower but may remain deep. With very deep anesthesia with all drugs, respirations are jerky or gasping in character and irregular in pattern. This situation results from loss of active intercostal muscle contribution to inspiration. As a result, a rocking boat movement occurs in which there is an out-of-phase depression of the chest wall during inspiration, a flaring of the lower chest margins, and a billowing of the abdomen. The reason for this type of movement is that inspiration is dependent solely on diaphragmatic effort. Independently of anesthetic depth, similar chest movements may be simulated by upper and lower airway obstruction and by partial paralysis.

Effect of Anesthetic Depth on Spontaneous Minute Ventilation

Despite the variable changes in respiratory pattern and rate as anesthesia deepens, overall spontaneous V_E progressively decreases. The normal awake response to breathing CO_2 (the X axis in Fig. 15-31 (Figure Not Available) shows increasing end-tidal concentration of CO_2) causes a linear increase in V_E (see the Y axis in Fig. 15-31) (Figure Not Available) . In Figure 15-31 (Figure Not Available) the slope of the line relating V_E to end-tidal CO_2 concentration in awake individuals is 2 L/min/mm Hg. (There is a large variation in the slope of this response in healthy individuals.) Figure 15-31 (Figure Not Available) also shows that increasing halothane concentration displaces the end-tidal CO_2 concentration P_{CO_2} -ventilation response curve progressively to the right (meaning that at any CO_2 concentration, ventilation is less than before), decreases the slope of the curve, and shifts the apneic threshold to a higher end-tidal CO_2 concentration level. [128] Similar alterations are observed with other halogenated anesthetics and

Figure 15-31 (Figure Not Available) In conscious controls (heavy solid line), increasing end-expiratory P_{CO_2} increases pulmonary minute volume. The dashed line is an extrapolation of the CO_2 -response curve to zero ventilation and represents the apneic threshold. An increase in anesthetic (halothane) concentration (end-expiratory concentration) progressively diminishes the slope of the CO_2 -response curve and shifts the apneic threshold to a higher P_{CO_2} . The heavy line interrupted by dots shows the decrease in minute ventilation and the increase in P_{CO_2} that occur with increasing depth of anesthesia. *(Modified from Munson et al [128])*

narcotics. Figures 15-22 to 15-24 show that decreases in V_E cause increases in Pa_{CO_2} and decreases in Pa_{O_2} . In healthy, unstimulated, spontaneously breathing male volunteers, 1 MAC halothane, isoflurane, and enflurane causes a Pa_{CO_2} of approximately 46, 48, and 62 mm Hg, respectively.

Effect of Preexisting Respiratory Dysfunction on the Respiratory Effects of Anesthesia

Anesthesiologists are frequently required to care for (1) patients with acute chest disease (pulmonary infection, atelectasis) or systemic diseases (sepsis, cardiac and renal failure, or multiple trauma) who require emergency operations; (2) heavy smokers with subtle pathologic airway and parenchymal conditions and hyperreactive airways; (3) patients with classic emphysematous and bronchitic problems; (4) obese people prone to decreases in FRC during anesthesia; [129] [130] (5) patients with chest deformities; and (6) extremely old patients.

The nature and magnitude of these preexisting respiratory conditions determine, in part, the effect of a given standard anesthetic on respiratory function. For example, in Figure 15-32 , the FRC-CC relationship is depicted for normal, obese, bronchitic, and emphysematous patients. In the healthy patient, FRC exceeds CC by approximately 1 L. In the latter three respiratory conditions, CC is 0.5 to 0.75 L less than FRC. If anesthesia causes a 1-L decrease in FRC, the healthy patient will have no change in the qualitative relationship

Figure 15-32 The lung volume (ordinate) at which the tidal volume is breathed decreases (by 1 L) from the awake state to the anesthetized state. The functional residual capacity (FRC), which is the volume of lung existing at the end of the tidal volume, therefore also decreases (by 1 L) from the awake to the anesthetized state. In healthy, obese, bronchitic, and emphysematous patients, the awake FRC considerably exceeds the closing capacity (CC). In obese, bronchitic, and emphysematous patients, the anesthetized state causes FRC to be less than CC. In healthy patients, anesthesia causes the FRC to equal the CC.

between FRC and CC. In the patients with special respiratory conditions, a 1-L decrease in FRC will cause CC to exceed FRC and will change the previous marginally normal FRC-CC relationship to either a grossly low V_A/Q or an atelectatic FRC-CC relationship. Similarly, patients with chronic bronchitis, who have copious airway secretions, may suffer more from an anesthetic-induced decrease in mucus velocity flow than other patients. Finally, if an anesthetic drug inhibits HPV,

the drug may increase shunting more in patients with than in those without preexisting HPV. Thus, the effect of a standard anesthetic can be expected to produce varying degrees of respiratory change among patients who have different degrees of preexisting respiratory dysfunction.

Effect of Special Intraoperative Conditions on the Respiratory Effects of Anesthesia

Some special intraoperative conditions (such as surgical position, massive blood loss, and surgical retraction on the lung), may cause impaired gas exchange. For example, some of the surgical positions (i.e., the lithotomy, jackknife, and kidney rest positions) and surgical exposure requirements may decrease Q_T, may cause hypoventilation in a spontaneously breathing patient, and may reduce the FRC. The respiratory depressant effects of any anesthetic will be magnified by the type and severity of preexisting respiratory dysfunction as well as by the number and severity of special intraoperative conditions that can embarrass respiratory function.

Mechanisms of Hypoxemia During Anesthesia

Malfunction of Equipment

Mechanical Failure of Anesthesia Apparatus to Deliver Oxygen to the Patient

Hypoxemia resulting from mechanical failure of the O_2 supply system (also see Ch. 7) or the anesthesia machine is a recognized hazard of anesthesia. Disconnection of the patient from the O_2 supply system (usually at the juncture of the endotracheal tube and elbow connector) is by far the most common cause of mechanical failure to deliver O_2 to the patient. Other reported causes of O_2 supply failure during anesthesia include the following: an empty or depleted O_2 cylinder; substitution of a nonoxygen cylinder at the O_2 yoke because of absence or failure of the pin index; an erroneously filled O_2 cylinder; insufficient opening of the O_2 cylinder (which hinders a free flow of gas as pressure decreases); failure of gas pressure in a piped O_2 system; faulty locking of the piped O_2 system to the anesthesia machine; inadvertent switching of the Schrader adapters on piped lines; crossing of piped lines during construction; failure of a reducing valve or gas manifold; inadvertent disturbance of the setting of the O_2 flowmeter; employment of the fine O_2

flowmeter instead of the coarse flowmeter; fractured or sticking flowmeters; transposition of rotameter tubes; erroneous filling of a liquid O_2 reservoir with nitrogen; and fresh gas line disconnection from machine to in-line hosing. [131] [132] [133] [134] [135] Monitoring of the inspired O_2 concentration with an in-line F_{IO_2} analyzer and monitoring of airway pressure should detect most of these causes of failure to deliver O_2 to the patient. [131] [132] [133] [134] [135]

Mechanical Failure of Endotracheal Tube: Main Stem Bronchus Intubation

Esophageal intubation results in almost no ventilation. Virtually all other mechanical problems (except disconnect) with endotracheal tubes (such as kinking, secretion blockage, and herniated or ruptured cuffs) cause an increase in airway resistance and may result in hypoventilation. Intubation of a main stem bronchus (also see Ch. 39) results in the absence of ventilation of the contralateral lung. Although potentially minimized by HPV, some perfusion to the contralateral lung always remains, and shunting increases and Pa_{O_2} decreases. A tube previously well positioned in the trachea may enter a bronchus after the patient or a patient's head is turned or moved into a new position. [136] Flexion of the head causes caudad movement, and extension of the head causes cephalad movement of an endotracheal tube. [136] A high incidence of main stem bronchial intubation following institution of a 30-degree Trendelenburg position has been reported. [137] Cephalad shift of the carina during the Trendelenburg position caused the previously "fixed" endotracheal tube to become located in a main stem bronchus. A main stem bronchial intubation may obstruct the ipsilateral upper lobe in addition to the contralateral lung. [138] [139] Infrequently, the right upper bronchus or one of its segmental bronchi branches from the lateral wall of the trachea and may be occluded by a properly positioned, endotracheal tube.

Hypoventilation (Decreased Tidal Volume)

Patients under general anesthesia may have a reduced spontaneous V_T for two reasons. First, it may be more difficult to breathe during general anesthesia because of increased airway resistance and decreased C_L. Airway resistance may be increased because of reduced FRC, endotracheal intubation, the presence of external breathing apparatus and circuitry, and possible airway obstruction in patients whose tracheas are not intubated. [140] [141] [142] C_L is reduced owing to some (or all) of the factors that can decrease FRC. [143] Second, the patients may be less willing to breathe spontaneously during general anesthesia (decreased chemical control of breathing) (see Fig. 15-31) (Figure Not Available) .

There are two ways a decreased V_T may cause hypoxemia. First, shallow breathing may promote atelectasis and cause a decrease in FRC (see the section *Ventilation History*). [144] [145] Second, decreased V_E decreases the overall V_A/Q ratio of the lung, which decreases Pa_{O_2} (see Figs. 15-23 (Figure Not Available) and 15-24) . This is likely to occur with spontaneous ventilation during moderate to deep levels of anesthesia, in which the chemical control of breathing is significantly altered.

Hyperventilation

Hypocapnic alkalosis (hyperventilation) may result in a decreased Pa_{O_2} via several mechanisms. These mechanisms are decreased Q_T, [102] [103] and increased O_2 consumption [146] [147] (see the section *Decreased Cardiac Output and Increased Oxygen Consumption*), a left-shifted oxy-Hb curve (see the section *Oxygen-Hemoglobin Dissociation Curve*), decreased HPV [148] (see the section *Inhibition of Hypoxic Pulmonary Vasoconstriction*), and/or increased airway resistance and decreased compliance [149] (see the section *Increased Airway Resistance*).

Decrease in Functional Residual Capacity

Induction of general anesthesia is consistently accompanied by a significant (15-20%) decrease in FRC, [85] [94] [150] which usually causes a decrease in compliance. [143] The maximum decrease in FRC appears to occur within the first few minutes of anesthesia [85] [151] [153] and in the absence of any other complicating factor does not seem to decrease progressively during anesthesia. During anesthesia, the reduction in FRC is of the same order of magnitude whether ventilation is spontaneous or controlled. Conversely, in awake patients FRC is only slightly reduced during controlled ventilation. [153] The reduction of FRC continues into the postoperative period. [154] For individual patients, the reduction in FRC correlates well with an increase in the alveolar-arterial P_{O_2} gradient during anesthesia with spontaneous breathing, [155] during anesthesia with artificial ventilation, [152] and in the postoperative period. [154] The reduced FRC may be restored to normal or above normal by application of PEEP. [84] [156] The following discussion considers all possible causes of reduced FRC.

Supine Position

Anesthesia and surgery are usually performed with the patient in the supine position (Ch. 26) . In changing from the upright to the supine position, FRC decreases by 0.5 to 1.0 L [85] [94] [150] because of a 4-cm cephalad displacement of the diaphragm by the abdominal viscera (Fig. 15-33) (Figure Not Available) . Pulmonary vascular congestion may also contribute to the decrease in FRC in the supine position, particularly in patients who experienced orthopnea preoperatively.

Induction of General Anesthesia: Change in Thoracic Cage Muscle Tone

At the end of a normal (awake) exhalation, there is slight tension in the inspiratory muscles and no tension in the expiratory muscles. Thus, at the end of a normal exhalation, there is a force tending to maintain lung volume and no

Figure 15-33 (Figure Not Available) Anesthesia and surgery may cause a progressive cephalad displacement of the diaphragm. The sequence of events involves assumption of the supine position,

induction of anesthesia, causation of paralysis, the assumption of several surgical positions, and displacement by retractors and packs. The cephalad displacement of the diaphragm results in a decreased functional residual capacity (
FRC). P_{ab} , pressure of the abdominal contents. *(Modified from Benumof [189])*

force decreasing lung volume. After induction of general anesthesia, there is a loss of the inspiratory tone and an appearance of end-expiratory tone in the abdominal expiratory muscles at the end of exhalation. The end-expiratory tone in the abdominal expiratory muscles increases intra-abdominal pressure, forces the diaphragm cephalad, and decreases FRC [151] [157] (see Fig. 15-33) (Figure Not Available) . Thus, after the induction of general anesthesia, there is loss of a force tending to maintain lung volume and gain of a force tending to decrease lung volume. Indeed, Innovar (droperidol and fentanyl citrate) may increase tone in expiratory muscles to such an extent that the reduction in FRC with Innovar anesthesia alone is greater than that with Innovar plus paralysis induced by succinylcholine. [157] [158]

With emphysema, exhalation may be accompanied by pursing the lips or grunting (partially closed larynx). The emphysematous patient exhales in either of these ways because both these maneuvers cause an expiratory retard that produces PEEP in the intrathoracic air passage and decreases the possibility of airway closure and decrease in FRC (see Fig. 15-17 (Figure Not Available) F). Endotracheal intubation bypasses the lips and glottis and may abolish normally present pursed-lip or grunting exhalation and in that way contribute to airway closure and a loss in FRC in some spontaneously breathing patients.

Paralysis

In the upright subject, the FRC and the position of the diaphragm are determined by the balance between the lung elastic recoil pulling the diaphragm cephalad and the weight of the abdominal contents pulling it caudad. [159] There is no transdiaphragmatic pressure gradient.

The situation is more complex in the supine position. The diaphragm separates two compartments of markedly different hydrostatic gradients. On the thoracic side, pressure increases by approximately 0.25 cm H_2O/cm of lung height, [6] [7] and on the abdominal side by 1.0 cm H_2O/cm of abdominal height. [159] This means that in horizontal postures, progressively higher transdiaphragmatic pressures must be generated toward dependent parts of the diaphragm to keep the abdominal contents out of the thorax. In the unparalyzed patient, this tension is developed either by passive stretch and shape changes of the diaphragm (causing an increased contractile force) or by neurally mediated active tension. With acute muscle paralysis, neither of these two mechanisms can operate, and a shift of the diaphragm to a more cephalad position occurs [160] (see Fig. 15-33) (Figure Not Available) . The latter position must express the true balance of forces on the diaphragm, unmodified by any passive or active muscle activity.

The cephalad shift in the FRC position of the diaphragm owing to expiratory muscle tone during general anesthesia is equal to the shift observed during paralysis (awake or anesthetized patients). [151] [161] The equal shift suggests that the pressure on the diaphragm caused by an increase in expiratory muscle tone during general anesthesia is equal to the pressure on the diaphragm caused by the weight of the abdominal contents during paralysis. It is quite probable that the magnitude of these changes in FRC due to paralysis also depends on the body habitus.

Light or Inadequate Anesthesia and Active Expiration

The induction of general anesthesia can result in increased expiratory muscle tone, [157] but the increased expiratory muscle tone is not coordinated and does not contribute to the exhaled volume of gas. In contrast, spontaneous ventilation during light general anesthesia usually results in a coordinated and moderately forceful active exhalation and larger exhaled volumes. Excessively inadequate anesthesia (relative to a given stimulus) results in very forceful active exhalation, which may produce exhaled volumes of gas equal to an awake expiratory vital capacity.

As during an awake expiratory vital capacity maneuver, a forced expiration during anesthesia raises the intrathoracic and alveolar pressures considerably above atmospheric pressure (see Fig. 15-17) (Figure Not Available) . This results in a rapid outflow of gas, and because part of the expiratory resistance lies in the smaller air passages, a pressure drop occurs between the alveoli and the main bronchi. Under these circumstances, the intrathoracic pressure rises considerably above the pressure within the main bronchi. Collapse will occur if this reversed pressure gradient is sufficiently high to overcome the tethering effect of the surrounding parenchyma on the small intrathoracic bronchioles or the structural rigidity of cartilage in the large extrathoracic bronchi. Such collapse occurs in the normal subject during a maximal forced expiration and is responsible for the associated wheeze in both awake and anesthetized patients. [162]

In the paralyzed anesthetized patient, use of a subatmospheric expiratory pressure phase is analogous to a forced expiration in the conscious subject; the negative phase may set up the same adverse DeltaP, which can cause airway closure, gas trapping, and a decrease in FRC. An excessively rapidly descending bellows of a ventilator during expiration has caused a subatmospheric expiratory pressure and resulted in wheezing. [163]

Figure 15-34 (Figure Not Available) The anesthetized patient in the supine position has an increased airway resistance owing to decreased functional residual capacity, decreased caliber of the airways, endotracheal intubation, and connection of the endotracheal tube to external breathing apparatus and circuitry. *(Modified from Benumof [189])*

Increased Airway Resistance

The overall reduction in all components of lung volume during anesthesia results in a reduced caliber of airway, which increases airway resistance and any tendency toward airway collapse (Fig. 15-34) (Figure Not Available) . The relationship between airway resistance and lung volume is well established (Fig. 15-35). (Figure Not Available) The decreases in FRC caused by the supine position (
0.8 L) and the induction of anesthesia (
0.4 L) are often sufficient to explain the increased resistance seen in the healthy anesthetized patient. [140]

In addition to this expected increase in airway resistance in anesthetized patients, there are a number of additional special potential sites of increased airway resistance. These consist of the endotracheal tube (if present), the upper and lower airway passages, and the external anesthesia apparatus. Endotracheal intubation reduces the size of the trachea, usually by 30 to 50 percent (see Fig. 15-34) (Figure Not Available) . Pharyngeal obstruction, which can be considered to be a normal feature of unconsciousness, is most common. A minor degree of this

Figure 15-35 (Figure Not Available) Airway resistance is an increasing hyperbolic function of decreasing lung volume. Functional residual capacity (FRC) decreases in changing from the upright to the supine position. *(From Nunn [91])*

type of obstruction occurs in snoring. Laryngospasm and obstructed endotracheal tubes (secretions, kinking, herniated cuffs) are not uncommon and may be life-threatening.

Respiratory apparatus often causes resistance that is considerably higher than the resistance in the normal human respiratory tract [91] (see Fig. 15-34) (Figure Not Available) . When certain resistors such as those shown in Figure 15-34 (Figure Not Available) are joined in a series to form an anesthetic gas circuit, they generally add to produce a larger resistance (as with resistances in series in an electrical circuit). The increase in resistance associated with commonly used breathing circuits and endotracheal tubes may impose an additional work of breathing that is two to three times normal. [142]

Supine Position, Immobility, and Excessive Intravenous Fluid Administration

Patients undergoing anesthesia and surgery are often kept supine and immobile for long periods of time. Thus, some of the lung may be continually dependent and below the left atrium and therefore in zone 3 or 4 condition. Being in a dependent position, the lung is predisposed to fluid accumulation. Coupled with excessive fluid administration, conditions sufficient to promote transudation of fluid into the lung are present and will result in pulmonary edema and a decreased FRC. When mongrel dogs were placed in a lateral decubitus position and were anesthetized for several hours (Fig. 15-36 (Figure Not Available) , bottom horizontal axis), expansion of the extracellular space with fluid (top horizontal axis) caused the P_{O_2} (left-hand axis) of blood draining the dependent lung (closed circles) to decrease precipitously to mixed venous levels (no O_2 uptake). [164] Blood draining the nondependent lung maintained its P_{O_2} for a period of time but in the face of the extracellular fluid expansion also suffered a decline in its P_{O_2} after 5 hours. Transpulmonary shunt (right-hand axis) progressively increased. If the animals were

turned every hour (and received the same fluid challenge), only the dependent lung, at the end of each hour period, suffered a decrease in oxygenation. If the animals were turned every half-hour and received the same fluid challenge, neither lung suffered a decrease in oxygenation. In patients undergoing surgery in the lateral decubitus position (e.g., pulmonary resection, in which they have, or will have, a restricted pulmonary vascular

Figure 15-36 (Figure Not Available) Mongrel dogs anesthetized with pentobarbital (bottom axis), placed in a lateral decubitus position, and subjected to progressive extracellular fluid expansion (top axis) have a marked decrease in the P_{O_2} (left vertical axis) of blood draining the dependent lung (solid circles) and a smaller, much slower decrease in P_{O_2} of blood draining the nondependent lung (open circles). The pulmonary arteriovenous shunt (right vertical axis) rises progressively (triangles). *(From Ray et al [164])*

bed) who receive excessive intravenous fluids, the risk of the dependent lung becoming edematous is certainly increased. These considerations also explain, in part, the beneficial effect of a continuously rotating (side-to-side) bed on the incidence of pulmonary complications in critically ill patients. [165]

High Inspired Oxygen Concentration and Absorption Atelectasis

General anesthesia is usually administered with an increased F_{IO_2}. In patients who have areas of moderately low V_A/Q ratios (0.1 to 0.01), administration of F_{IO_2} greater than 0.3 adds enough O_2 into the alveolar space in these areas to eliminate the shunt-like effect that they have, and total measured right-to-left shunt decreases. However, when patients with a significant amount of blood flow perfusing lung units with very low V_A/Q ratios (0.01-0.0001) have a change in F_{IO_2} from room air to 1.0, the very low V_A/Q units virtually disappear, and a moderately large right-to-left shunt appears. [16] [17] [166] In these studies, the increase in shunting was equal to the amount of blood flow previously perfusing the areas with low V_A/Q ratios during the breathing of air. Thus, in these studies the effect of breathing O_2 was to convert units that had low V_A/Q ratios into shunt units. The pathologic basis for this data is the conversion of low V_A/Q units into atelectatic units.

The cause of the atelectatic shunting during O_2 breathing is presumably a large increase in O_2 uptake by lung units with low V_A/Q ratios. [166] [167] A unit that has a low V_A/Q ratio during breathing of air will have a low P_{AO_2}. When an enriched O_2 mixture is inspired, P_{AO_2} rises, causing the rate at which O_2 moves from the alveolar gas to the capillary blood to increase greatly. The O_2 flux may increase so much that the net flow of gas into the blood exceeds the inspired flow of gas, and the lung unit will become progressively smaller. Collapse is most likely to occur if the F_{IO_2} is high, the V_A/Q ratio is low, the time of exposure of the unit with low V_A/Q to high F_{IO_2} is long, and the Cv_{O_2} is low. Thus, given the right V_A/Q ratio and time of administration, an F_{IO_2} as low as 50 percent can produce absorption atelectasis. [166] [167] This phenomenon is of considerable significance in the clinical situation for two reasons. First, enriched O_2 mixtures are often used therapeutically, and it is important to know whether this therapy is causing atelectasis. Second, the amount of shunt is often estimated during breathing of 100 percent O_2, and if this maneuver results in additional shunt, the measurement will be hard to interpret.

Surgical Position

In the supine position, the abdominal contents force the diaphragm cephalad and reduce FRC (Ch. 26). [94] [151] [157] [161] The Trendelenburg position allows the abdominal contents to push the diaphragm further cephalad, so that the diaphragm not only must ventilate the lungs, but it also must lift the abdominal contents out of the thorax. The result is a predisposition to decreased FRC and atelectasis. [168] Increased pulmonary blood volume and gravitational force on the mediastinal structures are additional factors that may decrease pulmonary compliance and FRC. In the steep Trendelenburg position, most of the lung may be below the left atrium and therefore in a zone 3 or 4 condition. As such, the lung may be susceptible to the development of pulmonary interstitial edema. Thus, patients with elevated Ppa, such as those with mitral stenosis, do not tolerate the Trendelenburg position well. [169]

In the lateral decubitus position, the dependent lung experiences a moderate decrease in FRC and is predisposed to atelectasis, whereas the nondependent lung may have an increased FRC. The overall result is usually a slight to moderate increase in total lung FRC. [170] The kidney and lithotomy positions also cause small decreases in FRC above that caused by the supine position. The prone position may increase FRC moderately. [170]

Ventilation History (Rapid Shallow Breathing)

Rapid shallow breathing is often a regular feature of anesthesia. Monotonous shallow breathing may cause a decrease in FRC, promote atelectasis, and decrease compliance. [144] [145] [171] These changes with rapid shallow breathing are likely due to progressive increases in surface tension. [171] Initially, these changes may cause hypoxemia with normocarbia and may be prevented and/or reversed by periodic large mechanical inspirations, spontaneous sighs, and/or PEEP. [171] [172] [173]

Decreased Removal of Secretions (Decreased Mucociliary Flow)

Tracheobronchial mucous glands and goblet cells produce mucus, which is swept by cilia up to the larynx, where

it is swallowed or expectorated. This process clears inhaled organisms and particles from the lungs. The secreted mucus consists of a surface gel layer lying on top of a more liquid sol layer in which the cilia beat. The tips of the cilia propel the gel layer toward the larynx (upward) during the forward stroke. As the mucus streams upward and the total cross-sectional area of the airways diminishes, absorption takes place from the sol layer to maintain a constant depth of 5 mm. [174]

Poor systemic hydration and low inspired humidity reduce mucociliary flow by increasing the viscosity of secretions and by slowing the ciliary beat. [175] [176] [177] Mucociliary flow varies directly with body or mucosal temperature (low inspired temperature) over a range of 32 to 42°C. [178] [179] A high F_{IO_2} decreases mucociliary flow. [180] Inflation of an endotracheal tube cuff suppresses tracheal mucous velocity, [181] an effect that occurs within 1 hour, and apparently it does not matter whether a low- or high-compliance cuff is used. Passage of an uncuffed tube through the vocal cords and keeping it *in situ* for several hours does not affect tracheal mucous velocity. [181]

The mechanism for endotracheal tube cuff suppression of mucociliary clearance is speculative. In the report of Sackner et al, [181] mucous velocity was decreased in the distal trachea, whereas the cuff was inflated in the proximal portion. Thus, the phenomenon cannot be attributed solely to damming of mucus at the cuff site. One possibility is that the endotracheal tube cuff caused a critical increase in the thickness of the layer of mucus proceeding distally from the cuff. Another possibility is that mechanical distention of the trachea by the endotracheal tube cuff initiated a neurogenic reflex arc, which altered mucous secretions or frequency of ciliary beating.

Other investigators showed that when all the foregoing factors are controlled, halothane reversibly and progressively decreases, but does not stop, mucus flow over an inspired concentration of 1 to 3 MAC. [182] The halothaneinduced depression of mucociliary clearance was likely due to depression of the ciliary beat, an effect that caused slow clearance of mucus from the distal and peripheral airways. In support of this hypothesis is the finding that cilia are morphologically similar throughout the animal kingdom, and in clinical dosages, inhaled anesthetics, including halothane, have been found to cause reversible depression of the ciliary beat of protozoa. [183]

Decreased Cardiac Output and Increased Oxygen Consumption

A decreased Q_T in the presence of a constant O_2 consumption (V_{O_2}), or an increased V_{O_2} in the presence of a constant Q_T, or a decreased Q_T and an increased V_{O_2} must all result in a lower Cv_{O_2}. The venous blood with lowered Cv_{O_2} then flows through whichever shunt pathways exist, mixes with the oxygenated end-pulmonary capillary blood, and lowers the Ca_{O_2} (see Figs. 15-27 and 15-28). Figure 15-37 (Figure Not Available) shows these relationships quantitatively for several different intrapulmonary shunts. [102] [103] The larger the intrapulmonary shunt, the greater the decrease in Ca_{O_2} because more venous blood with lower Cv_{O_2} can admix with end-pulmonary

Figure 15-37 (Figure Not Available) Effects of changes in cardiac output (Q) on the O_2 content of end-pulmonary capillary, arterial, and mixed venous blood for a family of different transpulmonary

right-to-left shunts. The magnitude of the right-to-left shunt is indicated by the various numbered percent symbols for arterial (solid line) and mixed venous (dashed line) blood; the oxygen content of end-capillary blood is unaffected by the degree of shunting. Note that a decrease in Q results in a greater decrease in the arterial content of O_2, the larger the shunt. *(From Kelman et al [102])*

capillary blood. Decreased Q_T may occur with myocardial failure and hypovolemia; the specific causes of these two conditions are beyond the scope of this chapter. Increased V_{O_2} may occur with excessive sympathetic nervous system stimulation, hyperthermia, or shivering and can further contribute to impaired oxygenation of arterial blood. [184]

Inhibition of Hypoxic Pulmonary Vasoconstriction

Decreased regional P_{AO_2} causes regional pulmonary vasoconstriction, which diverts blood flow away from hypoxic regions of the lung to better ventilated normoxic regions of the lung. The diversion of blood flow minimizes venous admixture from the underventilated or nonventilated lung regions. Inhibition of regional HPV could impair arterial oxygenation by permitting increased venous admixture from hypoxic or atelectatic areas of the lung (see Fig. 15-9) .

Because the pulmonary circulation is poorly endowed with smooth muscle, any condition that increases the pressure against which the vessels must constrict (i.e., the Ppa) will decrease HPV. There are numerous clinical conditions that can increase Ppa and therefore decrease HPV. Mitral stenosis, [185] volume overload, [185] low (but >room air) F_{IO_2} in nondiseased lung, [186] a progressive increase in the amount of diseased lung, [186] thromboembolism, [186] hypothermia, [187] and vasoactive drugs [188] can all increase Ppa. Direct vasodilating drugs (such as isoproterenol, nitroglycerin, and sodium nitroprusside), [61] [188] inhaled anesthetics, [189] and hypocapnia [148] [188] can directly decrease HPV. The selective application of PEEP to only the nondiseased lung can selectively increase nondiseased lung pulmonary vascular resistance and may divert blood flow back into the diseased lung. [190]

Paralysis

In the supine position, the weight of the abdominal contents pressing against the diaphragm is greatest in the dependent or posterior part of the diaphragm and is least in the nondependent or anterior part of the diaphragm. In the awake patient breathing spontaneously, the active tension in the diaphragm is capable of overcoming the weight of the abdominal contents, and the diaphragm moves the most in the posterior portion (because the posterior diaphragm is stretched higher into the chest, it has the smallest radius of curvature and therefore it contracts most effectively) and least in the anterior portion. This is a healthy circumstance because the greatest amount of ventilation occurs where there is the most perfusion (posteriorly or dependently), and the least amount of ventilation occurs where there is the least perfusion (anteriorly or nondependently). During paralysis and positive-pressure breathing, the passive diaphragm is displaced by the positive pressure preferentially in the anterior nondependent portion (where there is the least resistance to diaphragmatic movement) and is displaced minimally in the posterior dependent portion (where there is the most resistance to diaphragmatic movement). This is an unhealthy circumstance because the greatest amount of ventilation now occurs where there is the least perfusion, and the least amount of ventilation now occurs where there is the most perfusion. [161] However, the magnitude of the change in the diaphragmatic motion pattern with paralysis varies with body position. [191] [192]

Right-to-Left Interatrial Shunting

Acute arterial hypoxemia from a transient right-to-left shunt through a patent foramen ovale has been described, particularly during emergence from anesthesia. [193] [194] However, unless there is a real-time technique of imaging the cardiac chambers (color-flow Doppler mapping), it is difficult to document an acute and transient right-to-left intracardiac shunt as a cause of arterial hypoxemia. Nevertheless, right-to-left shunting through a patent foramen ovale has been described in virtually every conceivable clinical situation that afterloads the right heart and increases right atrial pressure.

Involvement of Mechanisms of Hypoxemia in Specific Diseases

In any given pulmonary disease, many of the mechanisms of hypoxemia listed earlier may be involved. Pulmonary embolism (air, fat, thrombi) (Fig. 15-38) (Figure Not Available) (Ch. 52) and the evolution of ARDS (Ch. 72) (Fig. 15-39) (Figure Not Available) will be used to illustrate this point. A significant pulmonary embolus can cause severe increases in pulmonary artery pressure, and these increases can cause right-to-left transpulmonary shunting through opened arteriovenous anastomoses and the foramen ovale (possible in 20% of patients), pulmonary edema in nonembolized regions of the lung, and inhibition of HPV.

Figure 15-39 (Figure Not Available) Mechanisms of hypoxemia during the adult respiratory distress syndrome (ARDS). See text for explanation of pathophysiologic flow diagram. CAP PERM, capillary permeability; CC, closing capacity; FRC, functional residual capacity; HPV, hypoxic pulmonary vasoconstriction; PA, pulmonary artery. *(Modified from Benumof [189])*

The embolus may cause hypoventilation via increased dead space ventilation. If the embolus contains platelets, serotonin may be released, and this release can cause hypoventilation via bronchoconstriction and pulmonary edema via increased pulmonary capillary permeability. Finally, the pulmonary embolus can increase pulmonary vascular resistance and decrease the cardiac output.

After major hypotension, shock, or blood loss, respiratory failure often ensues, and this is the syndrome called ARDS (Chs. 71 and 72) . The syndrome can evolve during and after anesthesia and has the hallmark characteristics of decreased FRC and compliance and hypoxemia. Following shock and trauma, plasma levels of serotonin, histamine, plasmakinins, lysozymes, superoxides, fibrin degradation products, products of complement metabolism, and fatty acids increase. Sepsis and endotoxemia may be present. Increased levels of activated complement activate neutrophils into chemotaxis in patients with trauma and pancreatitis; activated neutrophils can damage endothelial cells. These factors, along with pulmonary contusion (if it occurs), may individually or collectively increase pulmonary capillary permeability. After shock, acidosis, increased circulating catecholamines and sympathetic nervous system activity, leukotriene and prostaglandin release, histamine release, microembolism (with serotonin release), increased intracranial pressure (with head injury), and alveolar hypoxia may occur and may individually or collectively, particularly after resuscitation, cause a moderate increase in Ppa. After shock, the normal compensatory response to hypovolemia is movement of a protein-free fluid from the interstitial space into the vascular space to restore vascular volume. The dilution of vascular proteins by protein-free interstitial fluid can cause a decreased capillary colloid oncotic pressure. Increased pulmonary capillary permeability and Ppa along with decreased capillary colloid oncotic pressure will cause fluid transudation and pulmonary edema. Additionally, decreased Q_T, inhibition of HPV, immobility, supine position, excessive fluid administration, and an excessively high F_{IO_2} can contribute to the development of ARDS.

Mechanisms of Hypercapnia and Hypocapnia During Anesthesia

Hypercapnia

Hypoventilation, increased dead space ventilation, increased CO_2 production, and inadvertent switching off of a CO_2 absorber can all cause hypercapnia (Fig. 15-40) (Figure Not Available) .

Hypoventilation

Patients spontaneously hypoventilate during anesthesia because it is more difficult to breathe (abnormal surgical position, increased airway resistance, decreased compliance) and they are less willing to breathe (decreased respiratory drive due to anesthetics). Hypoventilation results in hypercapnia (see Figs. 15-22 and 15-23) (Figure Not Available) .

Increased Dead Space Ventilation

A *decrease* in Ppa, as during deliberate hypotension, [195] may cause an increase in zone 1 and alveolar dead space ventilation. An *increase* in *airway pressure* (as with PEEP) may cause an increase in zone 1 and alveolar dead space ventilation. *Pulmonary embolus, thrombosis,* and *vascular obliteration* (kinking, clamping, blocking of pulmonary artery during surgery) may increase the amount of lung that is ventilated but unperfused. Vascular obliteration may be

Figure 15-40 (Figure Not Available) Schematic diagram of the causes of hypercapnia during anesthesia. An increase in carbon dioxide (CO_2) production (V_{CO_2}) will increase Pa_{CO_2} with a constant minute ventilation (V_E). There are several events that can increase alveolar dead space, and they consist of a decrease in pulmonary artery pressure (Ppa), the application of positive end-expiratory pressure, thromboembolism, and mechanical interference with pulmonary arterial flow (ligatures and kinking of vessels). A decrease in V_E causes an increase in Pa_{CO_2} with a constant V_{CO_2}. It is possible for some anesthesia systems to cause rebreathing of CO_2. Finally, the anesthesia apparatus may increase the anatomic dead space, and inadvertent switching off of a CO_2 absorber in the presence of low fresh gas flows can increase Pa_{CO_2}. *(Modified from Benumof [185])*

responsible for the increase in dead space ventilation with age (V_D/V_T = 33 + age/3). *Rapid short inspirations* may be distributed preferentially to noncompliant (short time constant for inflation) and badly perfused alveoli, while a slow inspiration allows time for distribution to more compliant (long time constant for inflation) and better perfused alveoli. Thus, rapid, short inspirations may have a dead space ventilation effect.

The *anesthesia apparatus* increases total dead space (V_D/V_T) for two reasons. First, the apparatus simply increases the anatomic dead space. Inclusion of normal apparatus dead space increases the total V_D/V_T ratio from 33 percent to about 46 percent in intubated patients and to about 64 percent in patients breathing via a mask. [196] Second, anesthesia circuits cause rebreathing of expired gases, which is equivalent to dead space ventilation. The rebreathing classification by Mapleson is widely accepted. [197] The order of increasing rebreathing (decreasing clinical merit) with spontaneous ventilation with Mapleson circuits is A (Magill), D, C, and B. The order of increasing rebreathing (decreasing clinical merit) with controlled ventilation is D, B, C, and A. There will be no rebreathing in system E (Ayre T-piece) if the patient's respiratory diastole is long enough to permit washout with a given fresh gas flow (common event) or if the fresh gas flow is greater than the peak inspiratory flow rate (uncommon event).

The effects of an increase in dead space can usually be counteracted by a corresponding increase in the respiratory V_E. If, for example, the V_E is 10 L/min and the V_D/V_T ratio is 30 percent, the alveolar ventilation will be 7 L/min. If a pulmonary embolism occurred, resulting in an increase of the V_D/V_T ratio to 50 percent, the V_E would need to be increased to 14 L/min to maintain an alveolar ventilation of 7 L/min (14 L/min × 0.5).

Increased Carbon Dioxide Production

All the causes of increased O_2 consumption also increase CO_2 production: hyperthermia, shivering, catecholamine release (light anesthesia), hypertension, and thyroid storm. If V_E, total dead space, and V_A/Q relationships are constant, an increase in CO_2 production will result in hypercapnia.

Inadvertent Switching Off of a Carbon Dioxide Absorber

Many factors, such as patient ventilatory responsiveness to CO_2 accumulation, fresh gas flow, circle system design, and CO_2 production, determine whether hypercapnia will result from accidental switching off or using up of a circle CO_2 absorber (Ch. 7) . However, high fresh gas flows (> 5 L/min) minimize the problem with almost all systems for almost all patients.

Hypocapnia

The mechanisms of hypocapnia are the reverse of those that produce hypercapnia. Thus, all other factors being equal, hyperventilation (spontaneous or controlled ventilation), decreased V_D ventilation (change from mask airway to endotracheal tube airway, decreased PEEP, increased Ppa, or decreased rebreathing), and decreased CO_2 production (hypothermia, deep anesthesia, hypotension) will lead to hypocapnia. By far the most common mechanism of hypocapnia is passive hyperventilation by mechanical means.

Physiologic Effects of Abnormalities in the Respiratory Gases

Hypoxia

The end products of aerobic metabolism (oxidative phosphorylation) are CO_2 and water, both of which are easily diffusible and lost from the body. The essential feature of hypoxia is the cessation of oxidative phosphorylation when mitochondrial P_{O_2} falls below a critical level. Anaerobic pathways, which produce energy (ATP) inefficiently, are then utilized. The main anaerobic metabolites are hydrogen and lactate ions, which are not easily excreted. They accumulate in the circulation, where they may be quantified in terms of the base deficit and the lactate/pyruvate ratio.

Because the various organs have different blood flow and O_2 consumption rates, the presentation and clinical diagnosis of hypoxia is usually related to symptoms arising from the most vulnerable organ. This organ is usually the brain in an awake patient and the heart in an anesthetized patient (see later), but in special circumstances it may be the spinal cord (aortic surgery), kidney (acute tubular necrosis), liver (hepatitis), or limb (claudication, gangrene).

The cardiovascular response to hypoxemia [198] [199] [200] is a product of both reflex (neural and humoral) and direct effects (Table 15-4) . The reflex effects occur first and are excitory and vasoconstrictive. The neuroreflex effects result from aortic and carotid chemoreceptor, baroreceptor, and central cerebral stimulation, and the humoral reflex effects result from catecholamine and renin-angiotensin release. The direct local vascular effects of hypoxia are inhibitory and vasodilatory and occur late. The net response to hypoxia in a subject depends on the severity of the hypoxia, which determines the magnitude of and balance between the inhibitory and excitory components; the balance may vary according to the type and depth of anesthesia and the degree of preexisting cardiovascular disease.

Mild arterial hypoxemia (arterial saturation less than normal but still 80 percent or higher) causes a general activation of the sympathetic nervous system and release of catecholamines. Consequently, heart rate, stroke volume, Q_T, and myocardial contractility (as measured by a shortened preejection period [PEP], left ventricular ejection time [LVET], and a decreased PEP/LVET ratio) are increased [201] (Fig. 15-41) (Figure Not Available) . Changes in systemic vascular resistance are usually slight. However, in patients under anesthesia with beta-blockers, hypoxia (and hypercapnia when present) may cause circulating catecholamines to have only an alpha-receptor effect, the heart may be unstimulated (even depressed by a local hypoxia effect), and systemic vascular resistance may be increased. Consequently, Q_T may be decreased in these patients. With moderate hypoxemia (arterial O_2 saturation

TABLE 15-4 -- Cardiovascular Response to Hypoxemia

O_2 SATURATION (%)	HEMODYNAMIC VARIABLE					PREDOMINANT RESPONSE
	HR	***BP***	***SV***	***CO***	***SVR***	
>80					No change	Reflex, excitatory

<60						Local, depressant

BP, systemic blood pressure; CO, cardiac output; HR, heart rate; SV, stroke volume; SVR, systemic vascular resistance;
, increase;
, decrease.

60 to 80 percent), local vasodilation begins to predominate and systemic vascular resistance and blood pressure decrease, but heart rate may continue to be increased owing to a systemic hypotension-induced stimulation of baroreceptors. Finally, with severe hypoxemia (arterial saturation less than 60 percent), local depressant effects dominate and blood pressure falls rapidly, the pulse slows, shock develops, and the heart either fibrillates or becomes asystolic. Significant preexisting hypotension will convert a mild hypoxemia-hemodynamic profile into a moderate hypoxemia-hemodynamic profile and a moderate hypoxemia-hemodynamic profile into a severe hypoxemia-hemodynamic profile. Similarly, in well anesthetized and/or sedated patients, early sympathetic nervous system reactivity to hypoxemia may be reduced and the effects of hypoxemia may be expressed only as bradycardia with severe hypotension and ultimately, circulatory collapse. [202]

Hypoxemia may also cause cardiac arrhythmias which may in turn potentiate the already mentioned deleterious cardiovascular effects. Hypoxemia-induced arrhythmias may be caused by multiple mechanisms; the mechanisms are interrelated because they all cause a decrease in the myocardial O_2 supply/demand ratio, which in turn increases myocardial irritability. First, arterial hypoxemia may directly decrease myocardial O_2 supply. Second, early tachycardia may cause an increased myocardial O_2 consumption, and a decreased diastolic filling time may cause a decreased myocardial O_2 supply. Third, early increased systemic blood pressure may cause an increased afterload on the left ventricle, which increases left ventricular O_2 demand. Fourth, late systemic hypotension may decrease myocardial O_2 supply owing to decreased diastolic perfusion pressure. Fifth, coronary blood flow reserve may be exhausted by a late maximally increased coronary blood flow due to maximal coronary vasodilation). [203] The level of hypoxemia that will cause cardiac arrhythmias cannot be predicted with certainty because the myocardial O_2 supply and demand relationship in a given patient is not known (i.e., the degree of coronary artery atherosclerosis may not be known). However, if a myocardial area (or areas) become hypoxic and/or ischemic, unifocal or multifocal premature ventricular contractions, ventricular tachycardia, and ventricular fibrillation may occur.

The cardiovascular response to hypoxia includes a number of other important effects. Cerebral blood flow increases (even if hypocapnic hyperventilation is present). Ventilation will be stimulated no matter why hypoxia exists (see Fig. 15-41) (Figure Not Available) . The pulmonary distribution of blood flow is more homogeneous owing to an increased pulmonary artery pressure. Chronic hypoxia causes an increased Hb concentration and a right-shifted oxy-Hb curve (due to either an increase in 2,3-DPG or acidosis), which tends to raise tissue P_{O_2}.

Hyperoxia (Oxygen Toxicity)

The dangers associated with the inhalation of excessive O_2 are multiple (Ch. 67) . Exposure to a high O_2 tension clearly causes pulmonary damage in healthy individuals. [204] [205] A dose-time toxicity curve for humans is available from a number of studies. [204] [205] [206] Because the lungs of normal human volunteers cannot be directly examined to determine the rate of onset and course of toxicity, indirect measures such as the onset of symptom formation have been

employed to construct the dose-time toxicity curves. Examination of the curve indicates that 100 percent O_2 should not be administered for more than 12 hours, 80 percent O_2 should not be administered for more than 24 hours, and 60 percent O_2 should not be administered for more than 36 hours. [204] [205] [206] No measurable changes in pulmonary function or blood-gas exchange occur in humans during exposures to less than 50 percent O_2 even for long periods. [206] Nevertheless, it is important to note that in the clinical setting, these dose-time toxicity relationships are often generally obscured, [207] owing to the complex multivariable nature of the clinical setting.

The dominant symptom of O_2 toxicity in human volunteers is substernal distress, which begins as a mild irritation in the area of the carina and may be accompanied by occasional coughing. [208] As exposure continues, pain becomes more intense, and the urge to cough and to deep breathe also becomes more intense. These symptoms will progress to severe dyspnea, paroxysmal coughing, and decreased vital capacity when the F_{IO_2} has been 1.0 for longer than 12 hours. At this point, recovery of mechanical lung function usually occurs within 12 to 24 hours, but it may require more than 24 hours in some individuals. [206] As toxicity progresses, other pulmonary function studies such as compliance and blood gases deteriorate. Pathologically, in animals, the lesion progresses from tracheobronchitis (exposure for 12 hours to a few days), to involvement of the alveolar septa with pulmonary interstitial edema (exposure for a few days to 1 week), to pulmonary fibrosis of the edema (exposure for more than 1 week). [209]

Ventilatory depression may occur in those patients who, by reason of drugs or disease, have been ventilating in response to a hypoxic drive. By definition, ventilatory depression resulting from removal of a hypoxic drive by increasing the inspired O_2 concentration will cause hypercapnia but does not necessarily produce hypoxia (owing to the increased F_{IO_2}).

Absorption atelectasis is previously earlier (see the section *High Inspired Oxygen Concentration and Absorption Atelectasis*). Retrolental fibroplasia, an abnormal proliferation of the immature retinal vasculature of the prematurely born infant, can occur after exposure to hyperoxia. Extremely premature infants are most susceptible to retrolental fibroplasia (i.e., those of less than 1.0 kg birth weight and 28 weeks' gestation). The risk of retrolental fibroplasia exists whenever an F_{IO_2} causes Pa_{O_2} to be more than 80 mm Hg for more than 3 hours in an infant whose gestational age plus life age combined is less than 44 weeks. If the ductus arteriosus is patent, arterial blood samples should be drawn from the right radial artery (umbilical or lower extremity Pa_{O_2} is lower than the Pa_{O_2} to which the eyes are exposed owing to ductal shunting of unoxygenated blood).

The mode of action of toxicity of O_2 in tissues is complex, but interference with metabolism seems to be widespread. Most importantly, there is O_2-derived free radicals inactivation of many enzymes, particularly those with sulfhydryl groups. [207] Neutrophil recruitment and release of mediators of inflammation occur next and greatly accelerate the extent of endothelial and epithelial damage and impairment of the surfactant systems. [207] The most acute toxic enzyme effect of O_2 in humans is a convulsive effect, which occurs during exposure to pressures in excess of 2 atm absolute.

High inspired O_2 concentrations can be of use therapeutically. Clearance of gas loculi in the body may be greatly accelerated by inhalation of 100 percent O_2. Inhalation of 100 percent O_2 creates a large nitrogen gradient from the gas space to the perfusing blood. As a result, nitrogen leaves the gas space and the space diminishes in size. Administration of O_2 to remove gas may be used to ease intestinal gas pressure in patients with intestinal obstruction, to hasten recovery from pneumoencephalography, to decrease the size of an air embolus, and to aid in absorption of pneumoperitoneum and pneumothorax.

Hypercapnia

The effects of CO_2 on the cardiovascular system are as complex as those of hypoxia. Like hypoxemia, hypercapnia appears to cause direct depression of both the cardiac muscle and vascular smooth muscle, but at the same time it causes reflex stimulation of the sympathoadrenal system, which compensates to a greater or lesser extent for the primary cardiovascular depression [200] [203] (see Fig. 15-41) (Figure Not Available) . With moderate to severe hypercapnia a hyperkinetic circulation results with increased Q_T and systemic blood pressure (see Fig. 15-41) (Figure Not Available) . [201] Even in patients under halothane anesthesia, plasma

catecholamine levels increase in response to increased CO_2 levels in much the same way as conscious subjects. Thus, hypercapnia, like hypoxemia, may cause increased myocardial O_2 demand (tachycardia, early hypertension) and decreased myocardial O_2 supply (tachycardia, late hypotension).

Table 15-5 summarizes the interaction of anesthesia with hypercapnia in humans; increased Q_T and decreased systemic vascular resistance should be emphasized. [210] [211] The increase in Q_T is most marked during anesthesia with drugs that enhance sympathetic activity and least marked with halothane and nitrous oxide. The decrease in systemic vascular resistance is most marked during enflurane anesthesia and hypercapnia. Hypercapnia is a potent pulmonary vasoconstrictor even after inhalation of 3 percent isoflurane for 5 minutes. [212]

Arrhythmias have been reported in unanesthetized humans during acute hypercapnia, but they have seldom been of serious import. A high Pa_{CO_2} level is, however, more dangerous during general anesthesia. With halothane anesthesia, arrhythmias frequently occur above a Pa_{CO_2} arrhythmic threshold that is often constant for a particular patient.

The maximal stimulant respiratory effect is attained by a Pa_{CO_2} of about 100 mm Hg. With a higher Pa_{CO_2}, stimulation is reduced, and at extremely high levels, respiration is depressed and later ceases altogether. The P_{CO_2}-ventilation response curve is generally displaced to the right, and its slope is reduced by anesthetics and other depressant drugs. [213] With profound anesthesia, the response curve may be flat or even sloping downward, and CO_2 then acts as a respiratory depressant. In patients with ventilatory failure, CO_2 narcosis occurs when the Pa_{CO_2} rises to more than 90 to 120 mm Hg. A 30 percent CO_2 concentration is sufficient for the production of anesthesia, and this concentration causes total but reversible flattening of the electroencephalogram. [214] As expected, hypercapnia causes bronchodilation in both healthy persons and patients with lung disease. [215]

TABLE 15-5 -- Cardiovascular Responses to Hypercapnia (Pa_{CO_2} = 60 to 83 mm Hg) during Various Types of Anesthesia (1 MAC Equivalent Except for Nitrous Oxide)[a]

ANESTHESIA	HEART RATE	CONTRACTILITY	CARDIAC OUTPUT	SYSTEMIC VASCULAR RESISTANCE
Conscious	++	++	+++	-
Nitrous oxide	0	+	++	--
Fluroxene	+	+++	+++	-
Halothane	0	+	+	-
Enflurane	+	+	++	---
Isoflurane	++	+++	+++	-

+, <10% increase; ++, 10 to 25% increase; +++, >25% increase; 0, no change; -, <10% decrease; -- 10 to 25% decrease; ---, >25% decrease; MAC, minimum alveolar concentration for adequate anesthesia in 50% of subjects.

[a] The increase in partial arterial pressure of carbon dioxide (Pa_{CO_2}) in the conscious subjects was 11.5 mm Hg from a normal level of 38 mm Hg.

Quite apart from the effect of CO_2 on ventilation, it exerts two other important effects that influence the oxygenation of the blood. First, if the concentration of nitrogen (or other inert gas) remains constant, the concentration of CO_2 in the alveolar gas can only increase at the expense of O_2, which must be displaced. Thus, P_{AO_2} and Pa_{O_2} may decrease. Second, hypercapnia shifts the oxy-Hb curve to the right, facilitating tissue oxygenation.

Chronic hypercapnia results in increased resorption of bicarbonate by the kidneys, further raising the plasma bicarbonate level and constituting a secondary or compensatory metabolic alkalosis. Chronic hypocapnia decreases renal bicarbonate resorption, resulting in further fall of plasma bicarbonate and producing a secondary or compensatory metabolic acidosis. In each case arterial pH returns toward the normal value, but the bicarbonate ion concentration departs even further from normal.

Hypercapnia is accompanied by a leakage of potassium from the cells into the plasma. Much of the potassium comes from the liver, probably from glucose release and mobilization, which occur in response to the rise in plasma catecholamine levels. [216] Because the plasma potassium level takes an appreciable time to return to normal, repeated bouts of hypercapnia at short intervals result in a stepwise rise in plasma potassium.

Hypocapnia

In this section, hypocapnia is considered to be produced by passive hyperventilation (by the anesthesiologist or ventilator). Hypocapnia may cause a decrease in Q_T by three separate mechanisms. First, if it is present, an increase in intrathoracic pressure will decrease the cardiac output. Second, hypocapnia is associated with a withdrawal of sympathetic nervous system activity, and this can decrease the ionotropic state of the heart. Third, hypocapnia can increase pH, which can in turn decrease ionized calcium, which may, in turn, decrease the ionotropic state of the heart. Hypocapnia with an alkalosis also shifts the oxy-Hb curve to the left, which increases the Hb affinity for O_2, impairing O_2 unloading at the tissue level. The decrease in peripheral flow and impaired ability to unload O_2 to the tissues is compounded by an increase in whole body O_2 consumption caused by an increased pH-mediated uncoupling of oxidation from phosphorylation. [217] A Pa_{CO_2} of 20 mm Hg will increase tissue O_2 consumption by 30 percent. Consequently, hypocapnia may simultaneously increase tissue O_2 demand and decrease tissue O_2 supply. Thus, to have the same amount of O_2 delivery to the tissues, Q_T or tissue perfusion has to increase at a time when it may not be possible to do so. The cerebral effects of hypocapnia may be related to a state of cerebral acidosis and hypoxia, because hypocapnia may cause a selective reduction in the cerebral blood flow and also shifts the oxy-Hb curve to the left.

Hypocapnia may cause V_A/Q abnormalities by inhibiting HPV or by causing bronchoconstriction and decreased C_L. Finally, passive hypocapnia produces apnea.

Chapter 16 - Cardiac Physiology *

Thomas J. J. Blanck
David L. Lee

INTRODUCTION

Cardiac physiology today concerns a broad range of issues extending from systems physiology to molecular biology. In this chapter, we examine a few of the issues pertinent to the understanding of cardiac contraction, the regulation of contraction, and the assessment of cardiac contractility.

The heart is a pump that works continuously from before birth until death; this requires approximately 2.6 billion contractions over a lifetime (assuming a life-span of 73 years and a heart rate of 70 beats/min). With a cardiac output of 3 to 5 L/min, the heart is required to pump 100 to 200 million L of blood in a lifetime in order to deliver approximately 9.6 billion L of oxygen to the tissues of the body. Obviously, the heart is a pump that is dependable and durable, and it is quite remarkable that more problems related to cardiac dysfunction do not appear in view of the incredible workload the heart must perform. The following discussion deals with the average mechanisms of cardiac contraction and does not consider the differences that exist in cardiac function at the extremes of youth and old age (Chs. 58 , 59 , and 61).

CELLULAR STRUCTURE

Anatomic Considerations

The heart can be considered as two parallel pumps, each consisting of an atrium and a ventricle, acting in unison to propel blood into the pulmonary and systemic circulations from the right and left sides, respectively. Anatomically, the walls of the cardiac chambers consist of three parts: the endocardium, a thin inner layer of endothelial cells in direct contact with the blood; the myocardium, a middle layer consisting predominantly of muscle tissue; and the epicardium, an outer layer that is actually the inner portion of the double-layered pericardium, a fibrous sheath composed of mesothelial cells encasing the heart.

Blood return from the body enters the right atrium (RA) through the superior and inferior vena cava. It is then pumped through the tricuspid valve into the right ventricle (RV) and through the pulmonic valve into the pulmonary circulation, where oxygen-carbon dioxide exchange occurs within lung alveoli. Newly oxygenated blood returns to the left atrium (LA) via the pulmonary veins and passes through the mitral valve into the left ventricle (LV). The blood is then propelled through the aortic valve into the systemic circulation in order to meet the metabolic demands of peripheral tissues. Elaborate nervous and endocrine feedback loops carefully regulate the function of the heart and circulatory systems.

Structurally, the atria are thin-walled, low-pressure chambers that essentially serve as conduits to the ventricles. [1] The interatrial septum, which divides the two chambers, is embryologically derived from the foramen ovale and is the thinnest portion of the heart. Pacemaker activity of the conduction system of the heart originates in the sinoatrial (SA) and atrioventricular (AV) nodes, both of which are located within the RA. RA and LA chamber pressures vary anywhere from 0 to 10 mm Hg. [2]

Between each atrium and its respective ventricle lies an AV valve. As its name implies, the tricuspid valve, which separates the RA from the RV, is composed of three leaflets (anterior, medial, and posterior) arranged to open into the ventricle to allow one-way flow of blood from the atrium. The normal tricuspid valve has an 8- to 11-cm^2 area. [2] At the tip of each leaflet are the chordae tendineae, strong fibrous filaments that are anchored within the papillary muscles of the ventricles. They act to hold the leaflets together in a closed position during ventricular ejection to prevent prolapse of the valves and regurgitation of the blood back into the atria.

---

* *See Practice Guideliness for Pulmonary Artery Catheterization*

The mitral valve, which separates the LA from the LV, is composed of two leaflets (anterior and posterior), also arranged in an inverted fashion connected by chordae tendineae to the papillary muscles. The normal mitral valve has a 6- to 8-cm^2 area. [3]

The ventricles are thick-walled, muscular, high-pressure chambers that serve to propel blood forward into the pulmonary and systemic circulations. Because the LV must pump against higher pressure, its walls are considerably thicker than those of the RV. *In utero,* the ratio of LV to RV thickness is approximately 1:1. After delivery, pulmonary vascular resistance rapidly decreases with expansion of the lungs and increased oxygen saturation, and systemic vascular resistance increases with loss of the placenta, such that over the first month of extrauterine life, the LV/RV thickness ratio increases to 2:1, which is similar to that of the adult. [4] The ventricles are separated by the interventricular septum, consisting of a thinner membranous portion along the uppermost segment of the septum, which is contiguous with the RA, and a thicker muscular portion, which forms the major body of the septum and is structurally identical to the rest of the LV free wall. Normal RV pressures are in the ranges 15 to 30/0 to 10 mm Hg, whereas normal LV pressures are in the ranges 100 to 140/3 to 12 mm Hg.

Between each ventricle and its respective outflow tract is a semilunar (half-moon-shaped) valve. The pulmonic valve, which separates the RV from the pulmonary artery, comprises three cusps (anterior, right, and left), which are arranged to allow unidirectional flow of blood by pushing the individual cusps up and outward into the pulmonary artery during ventricular systole, only to have them snap back together during diastole. Normal pulmonic valve area is 4 cm^2. A similar arrangement occurs in the aortic valve, which separates the LV from the aorta, except that the three cusps (posterior, right, and left) are slightly thicker, owing to the increased stress placed on the valve by higher systemic pressures. Normal aortic valve area is 3 to 4 cm^2. Normal pulmonary artery pressures are 15 to 30/3 to 12 mm Hg, and normal aortic pressures are 100 to 140/60 to 90 mm Hg. [2]

Behind the cusps of the aortic valve and, to a lesser extent, the pulmonic valve, small outpouchings in the aorta and pulmonary artery known as the *sinuses of Valsalva* produce tiny eddy currents, which tend to keep the cusps away from the vessel walls. These sinuses are of significance because they prevent occlusion of the right and left coronary ostia, which originate behind the right and left aortic cusps, respectively. [1]

The right coronary artery originates from the aorta behind the right aortic cusp and travels anteriorly behind the pulmonary artery into the groove between the RA and RV [5] (Fig. 16-1). (Figure Not Available) It gives off several branches, including the acute marginal, and continues circumferentially until it reaches the posterior interventricular groove. It is primarily responsible for blood supply to the RA and RV, and in 50 percent of the population, it gives rise to the posterior descending artery, which courses along the interventricular septum, providing blood supply to the AV node and the posterior third of the septum. This is termed a right dominant distribution pattern despite some overlapping blood supply from the left circumflex artery in an additional 30 percent of individuals. [6] [7]

The left main coronary artery originates from the aorta behind the left cusp of the aortic valve and courses laterally behind the pulmonary artery, where it divides into the left anterior descending artery and the left circumflex artery (see Fig. 16-1). (Figure Not Available) The left anterior descending artery travels anteriorly and courses down the anterior interventricular groove toward the apex, where it gives off branches, including the ramus intermedius, septal perforators, and diagonals, that are responsible for the blood supply to the anterior free wall of the LV and the anterior two-thirds of the septum. Meanwhile, the left circumflex artery extends posteriorly along the groove between the LA and the LV, giving off the obtuse marginal branches, until it connects with the right coronary artery at the posterior interventricular groove. It is primarily responsible for blood supply to the LA and posterolateral segments of the LV, and in 20 percent of individuals, it gives rise to the posterior descending artery. This is termed a left dominant distribution pattern. Blood supply to the SA node is provided by a branch of either the right coronary artery (59% of cases) or the left circumflex artery (38% of cases). [8] Blood supply to the AV node is provided by a branch of the right coronary artery (90% of cases) or the left circumflex artery (10% of cases). [8A]

Most venous blood from the heart returns to the RA via the coronary sinus, which drains the great and middle cardiac veins and the posterior LV vein. However, some return occurs via the anterior coronary veins, in addition to direct blood return into the cardiac chambers via arteriosinusoidal, arterioluminal, and thebesian vessels. [9] Arteriosinusoidal channels are small arteries that divide into endothelium-lined sinuses that connect with other sinuses and capillaries and filter into the chambers. Arterioluminal vessels are small arterioles in direct communication with the chambers. Thebesian vessels are small veins that connect capillaries directly to the chambers as well as between other capillaries and cardiac veins. All three vessel types form an extensive subendocardial vascular network, which possibly plays a

role in added myocardial oxygen and nutrient delivery.

Cellular Anatomy

At the cellular level, the heart itself can be divided into the cardiac muscle tissue, the conduction system, and the extracellular connective tissue, which consists mainly of collagen. The cardiac muscle cell is unique in that it incorporates characteristics present in both skeletal and smooth muscle, yet it remains morphologically distinct. As in skeletal muscle, cross-striations or Z lines are present in cardiac tissue, demarcating the sarcomere borders. The sarcomeres are the smallest units of the contractile complex and are separated from one another at each end by Z lines; each sarcomere consists of an ordered array of thick (myosin molecules) and thin (actin molecules) filaments [10] [11] (Fig. 16-2) (Figure Not Available) and a third filament system that imparts stiffness to the myocyte (see (Fig. 16-2) (Figure Not Available) A, B). The third filament system consists of the giant protein, titin, with a molecular weight of
30,000 kd, that imparts structural integrity and passive tension response to stretched muscle. [12] Titin is the third most abundant muscle protein after myosin and actin, and it constitutes approximately 10 percent of muscle protein. Titin has two important domains that appear to impart elastic and passive tension properties to the protein and the muscle: an immunoglobulin domain (Ig) and a PEVK domain consisting of repeating residues of proline (P), glutamate (E), valine (V), and lysine (K). Cardiac muscle is the stiffest of the striated muscles, and its stiffness appears related

Figure 16-1 (Figure Not Available) The anatomic distribution of the coronary arteries and veins along the surface of the heart and their relationship to the great vessels. *(From Berne and Levy [5])*

to the smaller complement of Ig and PEVK residues relative to skeletal muscle. Unlike the fibers of striated muscle, the individual muscle fibers in the heart are contained within discrete cell membranes. These membranes contain extensive networks of interdigitating folds, which link the ends of individual fibers together along their Z lines in areas known as *intercalated disks.* These disks form a tight connection between longitudinally arranged fibers and allow for tension to be transferred uniformly between cells in that particular axis. In addition, the presence of fused cell membranes, or gap junctions, between laterally adjacent muscle fibers provides a low-resistance pathway for propagation of depolarization potentials between fibers. The gap junction connects adjacent myocytes and is responsible for the electrical continuity that exists between cells in the heart. [13] [14]

The gap junction has a permeability that is several orders of magnitude greater than that of normally juxtaposed plasma membranes. The major protein component of the gap junction is connexin, which appears to make up the six subunits of the channel structure (the *connexon*) that links

Figure 16-2 (Figure Not Available) (A) Contractile elements of the sarcomere. Individual actin fibers form the thin filament, a double helical structure that houses the troponin and tropomyosin complex. Individual myosin molecules form the thick filament, the articulated region that allows for cross-bridging of the two structures during contraction. *(Fig. A from Langer [10])* (B) Electron micrograph of mammalian cardiac muscle in longitudinal section. A sarcomere, the smallest contractile unit, is defined from Z line to Z line. The light areas adjacent to the Z line are made up of thin filaments (actin filaments), which are anchored to the Z line, and the dark central zone is due to the interdigitation of thick (myosin molecules) and thin filaments. The H zone is due solely to thick filaments. The section on the left shows muscle at the optimum length on its length-tension curve (no H zone), and that on the right is muscle that has been stretched. *(Fig. B from Fawcett and McNutt [11])*

the cytoplasm of adjacent cells. [15] The connexins consist of a family of related proteins that contain conserved and unique regions. Connexin 40, connexin 43, and connexin 45 are all found in cardiomyocytes. The individual connexins form channels with different permeability, voltage dependence, and conductance properties. [16] The gating properties (i.e., the regulation of opening) of these channels are under intense investigation, but the channels appear to remain in an open conformation for more time than do other ion channels found in the myocyte plasma membrane. [17] The gap

junction effectively allows for cardiac muscle to act in a synchronous manner as a syncytium, similar to that of smooth muscle, while maintaining cellular integrity.

The myocardial cell is surrounded by its plasma membrane, which has proteoglycans and connective tissue attached to its outer surface. Together, the plasma membrane and its outer constituents comprise the sarcolemma. The plasma membrane is typical of lipid bilayers found in mammalian cells. Imbedded within this lipid bilayer and extending from the extracellular to the intracellular space are receptors, ion channels, and ionic pumps that allow the cells to communicate with each other and their extracellular environment.

In the myocardial cell, invaginations of the plasma membrane result in the extension of extracellular space into more central portions of the myocardial cell [11] (Fig. 16-3) (Figure Not Available) . These invaginations are called *transverse tubules* (T tubules). The T tubules are in close proximity to an intracellular membrane system, the sarcoplasmic reticulum (SR), which is the major storage area for ionized calcium (Ca^{2+}) within the cell. Although the SR is a contiguous membrane structure, it can be further divided into two functional types, longitudinal and junctional SR. A large protein complex termed the *calcium release channel* resides within the junctional SR membrane. It responds to the depolarization-stimulated influx of Ca^{2+} through the sarcolemmal L-type Ca^{2+} channel

Figure 16-3 (Figure Not Available) Electron micrograph of mammalian cardiac muscle in cross-section. TT indicates the T tubule, which extends into the body of the muscle from the outer sarcolemma. *(From Fawcett and McNutt [11])*

by releasing large amounts of Ca^{2+} from the SR stores into the myoplasm, resulting in an increase in intracellular Ca^{2+} concentration from 10^{-7} to 10^{-5} mol/L.

Electrical Activity and Conduction System

As seen in Figure 16-4 , the conduction system of the heart consists of the SA and AV nodes, the bundle of His, and Purkinje fibers of the right and left bundle branches, which initiate, transmit, and propagate impulses and subsequent contraction in a sequential fashion. [18]

Electrophysiology

In the normal heart the action potential originates at the SA node. Contraction of the heart is initiated by the action potential, of which two types present within the heart: fast-response action potentials, which occur in most myocardial tissue, including the atria, ventricles, and Purkinje cells of the conduction system; and slow-response action potentials, which are found in the specialized cells responsible for the internal automaticity or pacemaker activity of the heart, namely the SA and AV nodes. [19] The difference between the two types of action potential lies in the resting membrane potential (V_m) present in the various cells and the rate of rise

Figure 16-4 The components of the conduction system and their anatomic relationship to the chambers of the heart. *(From Berne and Levy [18])*

Figure 16-5 (Figure Not Available) The four phases of an action potential and the various ion movements that occur along electrostatic and electrochemical gradients with membrane depolarization.

(Modified from Berne and Levy [18])

of upstroke of the action potential, which subsequently determines the propagation velocity of the action potential through the heart. [19]

The action potential can be divided into four phases, [18] as depicted in Figure 16-5 (Figure Not Available) . In the fast-response action potential, the resting V_m in a cardiac muscle cell is -80 to -90 mV, and phase 0 represents initial depolarization of the cell through the voltage-dependent fast sodium (Na^+) channels. [20] These sarcolemmal Na^+ channels operate in a double-gated fashion in which initially the outer, or m-gate (activation gate) is closed until a threshold V_m of -60 to -70 mV is achieved [21] (Fig. 16-6) (Figure Not Available) . The gate then opens, and Na^+

Figure 16-6 (Figure Not Available) Schematic of sodium channel dynamics that occur during a cardiac cycle. The channel is initially closed but not inactivated; depolarization leads to activation, which opens the m-gate, allowing entry of ions. Subsequently the h-gate closes, inactivating the channel and preventing ion flow. Deactivation then occurs, with both the m-gate and h-gate closed. This is followed by removal of inactivation, with opening of the h-gate, priming the channel for voltagesensitive activation. *(Modified from Levitan and Kazcmarek [21])*

is allowed to enter the cell along its concentration and electrostatic gradient, contributing to the brisk upstroke seen in the V_m. As the V_m reaches +30 mV, the inner, or h-gate (inactivation gate) closes, preventing further influx of Na^+ (inhibition of Na^+ channels) and effectively ending phase 0. At a V_m of 0, there are no further electrostatic forces pulling Na^+ into the cell, but Na^+ nonetheless continues to enter the cell because of the persistent concentration gradient, which accounts for the overshoot seen in the V_m. These fast Na^+ channels are inhibited by tetrodotoxin. [22]

Partial repolarization (phase 1) and the plateau (phase 2) at a V_m of around 0 are dominated by the influx of Ca^{2+} through slow L-type voltage-dependent Ca^{2+} and to a lesser extent, of Na^+ along its slow channel. These channels open initially at a V_m of -30 mV during the rapid depolarization upstroke of phase 0 and allow Ca^{2+} and to a lesser extent, Na^+, to enter the cell along its concentration gradient. [23] The entry of Ca^{2+} via these channels triggers further release of Ca^{2+} from the SR. [24] Free intracellular Ca^{2+} is then able to bind contractile proteins and to initiate contractile force. Catecholamines, such as epinephrine and norepinephrine, increase slow inward Ca^{2+} currents, and this represents one of the mechanisms by which catecholamines increase contractile force. These slow Ca^{2+} channels are inhibited by manganese and by dihydropyridine and phenylalkylamine-type Ca^{2+} channel antagonists. [25]

Repolarization, or phase 3, occurs as the ionized potassium (K^+) permeability increases, leading to an efflux of K^+ along its concentration gradient out of the cell. This has the effect of lowering V_m to its resting potential and causing the closure and inactivation of the slow Ca^{2+} and Na^+ channels. During this period, which is known as the *effective* or *absolute refractory* period, no further depolarization of the cell can take place. Restoration of Na^+ and K^+ to their preexcitation concentration gradients occurs via an active transport Na^+/K^+ membrane adenosine triphosphatase (ATPase) pump at a ratio of 6 Na^+ ions out for every 3 K^+ ions in. Ca^{2+} homeostasis is achieved by the SR, Ca^{2+}, Mg^{2+} ATPase and the sarcolemmal Ca^{2+} ATPase and Na^+, Ca^{2+} exchange mechanism.

Finally, phase 4 represents the period between completion of repolarization and initiation of the next action potential. During this period, K^+ continues to leak slowly from the cell along its concentration gradient.

In contrast, in the slow-response action potential, cell resting V_m are approximately -60 mV [18] (Fig. 16-7) (Figure Not Available) . Fast Na^+ channel activation is virtually absent, and depolarization occurs in a manner similar to that of phase 2 of the fast-response action potential, with the predominance of slow inward Ca^{2+} and Na^+ currents. [26] Phase 3 repolarization and phase 4 are virtually identical between the two types of action potentials, although the absolute refractory period in cells exhibiting slow-type action potentials is much longer.

Components of the Conduction System

The SA node is a disk-shaped structure, approximately 15 × 5 × 2 mm, which lies in the sulcus terminalis at the junction of the superior vena cava and the RA on the posterior

Figure 16-7 (Figure Not Available) An example of the slow-response action potential seen in a pacemaker-type cell. Note the resting transmembrane potential of -60 mV. The slope of diastolic depolarization is dependent on the degree of sympathetic (a) and parasympathetic (b) stimulation. *(From Berne and Levy [18])*

aspect of the heart. [27] Anatomically, it developed from right-sided embryologic structures, and this origin accounts for the predominance of right vagal innervation to it. [28] As noted earlier, its action potential tracing is characteristic of the slow-response type, with a V_m of -60 mV and a slower velocity upstroke of phase 1, indicating little involvement of the fast Na^+ channels. However, in contrast to the constant V_m seen in phase 4 of fast-response action potentials, such as that of ventricular free wall muscle, the SA node exhibits a slow, steady depolarization of phase 4, known as *prepotential* or *pacemaker potential,* which continues until the next action potential threshold is reached and triggered. During phase 4 in the slow-response tissue, a steady increase in net inward current is occurring. This phase 4 pattern is characteristic and represents the internal automaticity present among pacemaker-type cells. [29]

Automaticity

The basis of automaticity lies in the outward K^+ current, which serves to return the V_m to its resting baseline during phase 3 repolarization. As mentioned earlier, K^+ continues to leak out of the cell during phase 4, but its membrane permeability is markedly reduced, a factor that contributes to this steady depolarization. [29] Factors that alter the frequency of pacemaker depolarization include changes in the rate (slope) of phase 4 depolarization and changes in the resting potential. For example, sympathetic stimulation from catecholamines, such as norepinephrine, act to raise heart rate by increasing the rate of phase 4 depolarization. [30] Conversely, parasympathetic (vagal) stimulation from cholinergics, such as acetylcholine, act to hyperpolarize pacemaker cells, an action that lengthens the time of phase 4 depolarization [31] (see Fig. 16-7) (Figure Not Available) .

A phenomenon known as *overdrive suppression* occurs when the automaticity of pacemaker-type cells is depressed after a period in which action potentials are triggered at a frequency greater than its intrinsic rate. [18] For example, an ectopic atrial pacemaker site may fire at a rate of 150 times per minute, causing overdrive suppression of the SA node, which normally fires at a rate of between 60 and 100 times per minute. As the ectopic site stops firing, a brief period, called the *sinus node recovery time,* may intervene between the end of the period of overdrive suppression and the resumption of pacemaker activity by the SA node. This concept

is important in understanding the origin of conduction abnormalities, such as sick sinus syndrome, in which rapid heart rates inhibit normal SA node pacemaker activity and lead to periods of asystole in which the ectopic focus discharge slows. [18]

The SA nodal discharges are passed through the atria via three bundles of fibers, which conduct impulses to the AV node: the anterior internodal tract of Bachmann, the middle internodal tract of Wenckebach, and the posterior internodal tract of Thorec. [32] [33] [34] Of these, the most important is probably the anterior pathway, which also conducts impulses directly to the LA. [32] The atrial muscle tissue for the most part exhibits the fast-response-type action potentials, with a shorter phase 2 plateau and a slightly slower rate of phase 3 repolarization as compared with ventricular muscle tissue.

The AV node is a button-shaped structure approximately 22 × 10 × 3 mm, which lies on the right posterior side of the interatrial septum near the ostium of the coronary sinus. [35] Anatomically, it developed from left-sided embryologic structures, an origin that accounts for the predominance of left vagal innervation to the AV node. [28] Impulses from the three internodal tracts converge on the AV node, which is divided into three discrete functional zones: the AN region, joining the atrium to the node; the nodal (N) region; and the NH region, joining the node to the bundle of His. [36] The AN and, to a lesser degree, the N regions, are important because of the delay that occurs in transmission of the atrial impulses to the distal conduction system, allowing for adequate filling time for the ventricle between the onset of

atrial and ventricular contraction. This area is responsible for the PR interval on the electrocardiogram (ECG).

As with the pacemaker-type cells, the action potential tracing of AV nodal cells is of the slow-response type, with a V_m of -50 to -60 mV and a very slow phase 1 upstroke, particularly in the N region. In addition, the absolute and relative refractory periods tend to be prolonged in the AV node. This property acts as a protective mechanism against rapid ventricular depolarization, which could otherwise occur in rapid atrial rhythms such as atrial fibrillation and flutter.

Like the SA node, the AV node is also subject to overdrive suppression. Its intrinsic pacemaker rate is approximately 60 per minute, so its automaticity tends to be suppressed by the higher SA nodal discharge rate. Moreover, the AV node is also subject to similar autonomic regulation of conduction. For example, sympathetic stimulation from norepinephrine decreases conduction time through the AV node, enhancing the rhythmicity, or regularity, of pacemaker activity of the node. As in the SA node, it also increases the rate of rise of phase 4 depolarization. Meanwhile, parasympathetic stimulation from acetylcholine acts in an opposite manner, to delay or block impulses through the node. [28]

The AV node gives rise distally to the bundle of His, which travels subendocardially along the right side of the interventricular septum, divides, and continues as the right bundle branch (see Fig. 16-4) . Meanwhile, the left bundle branch arises in a perpendicular path from the bundle of His, passes through the interventricular septum, and is further divided into a thin anterior fascicle and a thick posterior fascicle, which courses subendocardially along the left side of the interventricular septum. Ultimately, the right bundle and two left fascicles continue to subdivide to form the complex Purkinje fiber network, which allows conduction of impulses to all parts of the ventricle. Because of their somewhat thicker cellular diameter, the Purkinje fibers have a faster conduction velocity than any other portion of the conduction system. [18] This property allows for rapid propagation of action potentials to all regions of the ventricular myocardium to coordinate contraction. The action potential configuration for Purkinje fibers and for ventricular muscle is virtually identical; both are of the fast-response type.

As the action potential passes through the Purkinje fibers, the myocardial tissue of the interventricular septum and papillary muscle are the first to contract. Septal contraction serves to anchor the heart as the rest of the ventricular free wall begins contracting, and papillary muscle tightening prevents prolapse of the tricuspid and mitral valves during the early portion of systole. Excitation of muscle fibers spreads outward from endocardium to epicardium, and owing to the relative differences in wall thickness, the RV contracts earlier than the LV. [18]

CARDIAC CYCLE

As seen in Figure 16-8 (Figure Not Available) , the cardiac cycle can be divided into four distinct segments. It begins in the latter half of diastole with ventricular filling (points A to B). Blood returns to the RA and LA from the pulmonary and systemic circulations, respectively, and accumulates during the time of the previous ventricular systole. When the atrial pressure exceeds that within the ventricle, the AV valves open, and blood enters the ventricular chambers. This passive flow accounts for roughly 75 percent of total ventricular filling, with the balance contributed by active atrial contraction, also known as the atrial "kick." [37] This occurs with atrial systole, which begins with the depolarization of the sinus

Figure 16-8 (Figure Not Available) The cardiac cycle and its phases. *(From Berne and Levy [1])*

node and propagation of the action potential through the atria along the internodal tracts, and corresponds to the P wave on ECG (Fig. 16-9) (Figure Not Available) . The shape of the curve of the ventricular filling segment (see Fig. 16-8 (Figure Not Available) , A to B) is dependent on the compliance or elasticity of the ventricular wall muscle. Certain conditions or disease states, such as after cardiopulmonary bypass or in LV hypertrophy secondary to aortic stenosis or prior myocardial infarction, can make the ventricle stiffer and less compliant, a property that impedes passive filling. In these circumstances, the atrial kick may be very important in achieving adequate ventricular filling.

While the ventricles fill, the valves are displaced upward, and ventricular systole begins with the closure of the tricuspid and mitral valves, corresponding to the end of the R wave on the ECG (point B). Ventricular systole can be divided into two parts. In the first part, known as *isovolumic* or *isometric contraction* (points B to C), the initial impulse has traveled through the AV node and down the right and left bundles into the Purkinje fibers, which stimulate the ventricular muscle to contract. The AV valves are held closed by the initial tightening of the papillary muscles, and pressure within the ventricle increases as progressively more ventricular myocardium is stimulated to contract. When the developed pressures within the two ventricles exceed the pulmonary artery and aortic pressures (point C), the pulmonic and aortic valves open to allow flow into their respective circulations. The latter portion of systole, termed *ventricular ejection* (points C to E), has an initial rapid phase (points C to D), characterized by maximal forward flow and developed artery and aortic pressures, which tapers while systole progresses (points D to E).

With ejection of blood from the heart, the pressures within the RV and LV fall, and ventricular diastole begins with the closure of the pulmonic and aortic valves (point E). Ventricular diastole can also be divided into two periods. Initially during the first half, known as *isovolumic* or *isometric relaxation* (points E to A), the conduction system and myocardial cells have repolarized and are in the relative refractory period, corresponding to the end of the T wave on ECG. The ventricular pressures continue to drop until they fall below that of the RA and LA, at which point the tricuspid and mitral valves reopen (point A), ventricular filling commences, and the cycle repeats itself.

MECHANISMS OF MYOCARDIAL CONTRACTION

Biochemical Components

The heartbeat is initiated at the SA node, which is a strip of fine muscle fibers located posteriorly near the junction of the superior vena cava with the RA. [37] The nodal cells undergo spontaneous depolarization. The impulse passes out from the SA node to the atria and down the conduction system through the AV node into the ventricular cells. Phase 0 of the action potential in both atrial and ventricular cells is due to the opening of Na^+ channels and the rapid influx of

Figure 16-9 (Figure Not Available) A single cardiac cycle. AORTA, PULM. A., L.V., R.V. indicate the pressures in the respective vessels and chambers of the heart. The hatched lines mark the periods of isovolumic contraction and relaxation. Heart sounds and the ECG are pictured in register with the pressure and flow curves. *(From Patton HD et al (eds): Textbook of Physiology, vol. 2. Philadelphia, WB Saunders, 1989.)*

Na^+ . Soon thereafter, as a result of depolarization, Ca^{2+} channels open. The Ca^{2+} channel, designated the L-type channel because it is activated by low voltage, allows entry of Ca^{2+} into the myoplasm (see Fig. 16-5) (Figure Not Available) .

Sarcoplasmic Reticulum

The SR is the intracellular storage site of Ca^{2+} used for contraction. The Ca^{2+} entering through the sarcolemma is scant and acts solely as a trigger to initiate Ca^{2+} release from the SR. [38]

Electron micrographs have shown that L-type Ca^{2+} channels are closely associated with the Ca^{2+} release channel (CRC) of the junctional SR. The CRC is a huge protein of 565,000 molecular weight with foot processes that appear to be involved in release, perhaps by giving directionality to the outflow of Ca^{2+} (Fig. 16-10) (Figure Not Available) . The short distance from the L-type Ca^{2+} channel in the T-tubular membrane to the foot process of the CRC in the junctional SR allows Ca^{2+} entry through the L channel to immediately initiate Ca^{2+} release from the SR CRC. [39] The rise of Ca^{2+} as measured by luminescent or fluorescent intracellular Ca^{2+} dyes indicates that little, if any, measurable lag exists between the initiation of the action potential and the increase in intracellular Ca^{2+} . Measurements of myoplasmic Ca^{2+} by luminescent and fluorescent techniques measure free Ca^{2+} ; the quantity and time course of Ca^{2+} that is bound to troponin C qualitatively follows the time course of free Ca^{2+} . [40] Approximately 99 percent of cytosolic Ca^{2+} is bound to Ca^{2+} buffering proteins, so the measurement of free Ca^{2+} by spectroscopic means underestimates the Ca^{2+} that is available for contraction. As noted earlier, the CRC is localized to the heavy or junctional SR and is responsible for release of Ca^{2+} stores from the SR during contraction.

The other equally important function of the SR is the reaccumulation of Ca^{2+} . This is accomplished by a 105,000-molecular weight Ca/Mg-ATPase pump, which is imbedded in the membrane of the longitudinal SR. Because removal of free intracellular Ca^{2+} from the myoplasm to generate a Ca^{2+} gradient is an active, energy-consuming process, hydrolysis of ATP is required. The myoplasmic Ca^{2+} concentration is restored to 10^{-7} mol/L at diastole, and a high Ca^{2+} concentration within the SR membrane space results. The activity of the SR Ca^{2+} pump can be augmented by the cyclic adenosine monophosphate (cAMP)-dependent phosphorylation

Figure 16-10 (Figure Not Available) Model of the approximation of the dihydropyridine receptor in the T tubule to the calcium release channel (ryanodine receptor) in the junctional sarcoplasmic reticulum. Ca^{2+} , which enters through the dihydropyridine receptor or L-type Ca^{2+} channel, acts upon the ryanodine receptor to initiate calcium release channel opening and the efflux of Ca^{2+} into the myoplasm. Calsequestrin in the SR binds Ca^{2+} and adds to the storage capacity of the SR. *(From McPherson and Campbell [39])*

of an associated SR protein, phospholamban. beta-Adrenergic stimulation leads to increased phospholamban phosphorylation, increased Ca^{2+} pump activity, and a shorter relaxation time. [41]

The continuity of the SR membrane, from junctional to longitudinal, and the separation of CRC and the Ca^{2+} pump from each other along the course of the SR membrane suggests the importance of movement of Ca^{2+} within the SR membrane space from the longitudinal to the junctional region. This movement could simply depend on diffusion of Ca^{2+} down a concentration gradient and suggests a temporal limitation to the availability of the Ca^{2+} for contraction.

Contractile Elements

The purpose of the elaborate system of Ca^{2+} delivery and removal is to control the availability of Ca^{2+} for the contractile process (see Fig. 16-2) (Figure Not Available) . For cardiac muscle to contract, actin and myosin must interact. These two contractile proteins make up, respectively, the thin and thick filaments seen in electron micrographs of cardiac and skeletal muscle. Actin is a small protein with a molecular weight of 43,000. Individual actin molecules combine to form long polymer chains in a double-helical structure that make up the thin filament. Interposed at a regular spacing along the thin filament is a complex of tropomyosin (Tm) and troponin (Tn). Tm is a linear protein of approximately 70,000 molecular weight that lies within the sulcus of the thin filament. Tn is a protein consisting of three distinct polypeptides: TnT, TnI, and TnC. It is found at the amino-terminal of Tm, with which it forms a complex. Each polypeptide of troponin fulfills a different function in the regulation of contraction. TnT binds to Tm, TnI is believed to inhibit the reaction of actin with myosin, and TnC binds Ca^{2+} , which results in a conformational change of several proteins and leads to contraction.

TnC, a small protein (molecular weight 18,000), is the target at which Ca^{2+} activates contraction. This protein is similar to TnC found in skeletal muscle, but cardiac TnC has one less Ca^{2+} binding site, which leads to the less steep Ca^{2+} concentration dependence of tension development found in cardiac muscle. [42] TnC is an example of a ubiquitous class of Ca^{2+} binding proteins called EF-hand proteins, all of which contain a particular amino acid sequence that results in a pocket with multiple oxygen atoms to coordinate the binding of the Ca^{2+} ion with high specificity and affinity. [43] Another example of this class of proteins is calmodulin, which confers Ca^{2+} sensitivity on many enzymatic processes in the heart and central nervous system. The binding of Ca^{2+} to TnC is the trigger that initiates a chain reaction of conformational changes and leads to the development of mechanical activity.

The thick filament observed in electron micrographs of cardiac muscle is made up of myosin, which is a large, asymmetric molecule consisting of two heavy chains,

each of 220,000 molecular weight, and four light chains, each of approximately 20,000 molecular weight. The functions of the light chains are still uncertain but may include regulation of cross-bridge formation. The myosin molecule consists of two globular heads containing the enzymatic ATPase activity, a hinge area, and a tail area resulting from the intertwining of the two heavy chains [44] (Fig. 16-11) (Figure Not Available) . The head interacts with actin to form cross-bridges and hydrolyse ATP, the hinge area appears to be involved in tension development, and the tail anchors the molecule to other myosin molecules in the thick filament.

A complex cycle of actin-myosin interactions, shortening, and tension development occurs on binding of Ca^{2+} to TnC. This active process requires ATP and utilizes approximately 70 percent of the ATP available in the myocyte. [45] The hydrolysis of ATP to adenosine diphosphate (ADP) and the formation of a high-energy phosphate intermediate of actin-myosin

Figure 16-11 (Figure Not Available) Diagram of a possible mechanism of force generation due to the interaction of the myosin head (S1) with the actin thin filament. Upon attachment of the head, P_i is released, followed by release of ADP during the power stroke. This results in a change in the angle of attachment of the head, S1, and the hinge area S2. The binding of another ATP molecule leads to detachment, and the cycle of hydrolysis and reattachment begins again. *(Modified from Stryer [44])*

ATPase drives the three parts of the contractile cycle: (1) detachment of the myosin head from actin; (2) reattachment of myosin to actin with a different conformation and higher free energy at the beginning of the work stroke; and (3) development of force and the performance of mechanical work. [46]

The transduction of the energy released by ATP hydrolysis into mechanical force occurs during the release of ADP and inorganic phosphorus (P_i) from the myosin head. The substrate, Mg^{2+} ATP, causes the dissociation of the actomyosin complex by binding to the ATPase active site of myosin. Myosin hydrolyses ATP, forming a complex with ADP and P_i . Actin is able to recombine with another myosin head, displacing ADP and P_i . Force is generated in this last step. [47]

Metabolic Considerations

The metabolic function of the cardiac myocyte serves a 2-fold purpose: to generate energy to maintain cell integrity by maintaining ionic gradients across membranes and to generate energy to maintain a physiologic pump that must work nonstop for, on average, 73 years.

Substrates and Energy Sources

The heart is able to metabolize glucose, carbohydrates, lactate, and fatty acids to form its metabolic energy source, ATP. During fasting, free fatty acids (FFA) are elevated in the serum, and the substrates utilized by the heart in fasting patients are mainly FFA and glucose. In fact, FFA in these circumstances inhibit the utilization of glucose. [48] These substrates are used to form ATP and creatine phosphate, molecules with high energy, which are then used by the heart to perform mechanical and chemical work, such as contraction and ion transport.

Mitochondria

The mitochondrion contains the enzymatic constituents to synthesize the ATP used by the cell for all its energy requirements. Approximately 23 percent of the volume of the myocardial cell is occupied by mitochondria, a finding that reflects the importance of a continuous supply of ATP for continuous cardiac function (Fig. 16-12) (Figure Not Available) . The mitochondrion is an elongated structure with an outer and inner membrane system. The inner membrane system consists of a multiplex of folds, which contain the enzymes for aerobic metabolism and the cytochromes involved in electron transport. Modified FFA and the intermediary products of glucose metabolism are further metabolized by the mitochondria, yielding reduced nictotinamide adenine dinucleotide (NADH) and reduced flavin adenine dinucleotide (FADH), which are fed into the electron transport chain.

Utilization Pathways

Glucose and FFA are the primary substrates. Glucose is metabolized by the glycolytic pathway to yield pyruvate when the oxygen supply is sufficient and lactate when oxygen is in short supply. Pyruvate then enters the citric acid cycle in the mitochondrion, where it is broken down to carbon dioxide and water and ATP is generated. Pyruvate is enzymatically transformed to acetylcoenzyme A (acetyl-CoA) and NADH. The enzyme responsible for this transformation is pyruvate dehydrogenase, which is a highly regulated enzyme found in the inner mitochondrial membrane. Acetyl-CoA enters the citric acid cycle in the mitochondrion, where it is oxidized, yielding NADH, $FADH_2$, and two ATP molecules from what is called substrate level phosphorylation. The NADH and $FADH_2$ then enter the respiratory chain, where they are oxidized and provide reducing equivalents (a reducing equivalent is a hydrogen atom

Figure 16-12 (Figure Not Available) Mammalian cardiac muscle in crosssection, demonstrating the large number of mitochondria (MI) found in cardiac muscle in order to fulfill the metabolic requirements of contraction. The mitochondria are surrounded by myofilaments (MfI). *(From Fawcett and McNutt [11])*

[$H^+ + e^-$]). The basic equations of oxidative phosphorylation are as follows:

which is coupled to the oxidation of ADP

such that three molecules of ATP are formed for each atom of oxygen. This refers to the concept of a phosphate/oxygen (P/O) ratio of 3, but in fact, depending on the energy substrate, the ratio varies from 2.83 to 3.17. For example, with FFA as substrates, the P/O ratio is 2.83 because one of the products of FFA metabolism is $FADH_2$ rather than NADH alone. $FADH_2$ enters the respiratory chain at one phosphorylation site further downstream than NADH, yielding less ATP per molecule of FFA than per molecule of glucose (Fig. 16-13) (Figure Not Available) . The function of oxygen in this metabolic scheme is to act as an acceptor of electrons, allowing the cycling of the electron transport chain to continue.

Regulators

FFA, which are normally present in the blood, are elevated during fasting, and, as noted earlier, the result is in an inhibition of glucose metabolism and a preferential metabolism of FFA. FFA metabolism accounts for approximately 60 to 70 percent of the oxygen utilized, whereas glucose accounts for the remaining 30 to 40 percent. [49] FFA are found in the blood highly bound to albumin. Myocardial cells have albumin receptors, which permit the interaction of FFAs with the sarcolemma. Because the FFA are lipid soluble, they can cross the sarcolemma freely and enter the cytoplasm of the cell, where they are transformed by thiokinase to acyl-CoA derivatives. The enzyme, acylcarnitine transferase, then adds a carnitine moiety to the FFA. An enzymatic translocation system, carnitine translocase, transports

CARDIAC OUTPUT

Definition

Cardiac output is defined as the rate of blood flow (Q), or the amount of blood pumped by the heart per unit time. It has been traditionally calculated by the Fick principle, derived from the law of conservation of mass, which states that the amount of oxygen present in the blood returned to the heart from the body plus the amount of oxygen transported across the alveoli into the blood equals the amount of oxygen carried away from the heart. [50] This concept is diagrammed in Figure 16-14 (Figure Not Available) , [51] where q_1 represents the rate of oxygen delivery to the alveoli via the pulmonary artery, which is equivalent to a certain rate of blood flow Q multiplied by the mixed venous oxygen content ($[O_2]_{ven}$). Meanwhile, q_3 represents the rate of oxygen delivery to the left side of the heart and subsequent peripheral tissues via the pulmonary vein, which is equivalent to the same rate of Q multiplied by the arterial oxygen content ($[O_2]_{art}$). The difference between the two, q_2 , represents the rate of oxygen consumption by the body and is equivalent to the rate of oxygen transported across the alveoli.

Thus, mathematically by the Fick principle

which converts to

Therefore, the rate Q, or cardiac output, is equivalent to

At a resting basal oxygen consumption rate of 250 mL/min, with an average arterial oxygen content of 20 vol percent and an average venous oxygen content of 15 vol percent, the cardiac output is 5,000 mL/min. [52]

Determinants

Cardiac output can also be thought of in anatomic terms. Because stroke volume reflects the amount of blood ejected from the heart per beat, cardiac output is mathematically equal to the stroke volume multiplied by the heart rate, or number of beats per minute. Stroke volume is defined as the difference between LV end-diastolic volume and LV end-systolic volume, corresponding to the change in volume seen during the ejection phase of the cardiac cycle. Typical values for stroke volume in healthy adults range from 60 to 90 mL per beat.

Thus, based on the foregoing definitions, cardiac output changes to accommodate changes in oxygen consumption, as reflected by alterations in oxygen delivery (arterial oxygen content) or oxygen utilization (venous oxygen content), and this may be manifested as a change in stroke volume, heart rate, or both.

Classic teaching has been that cardiac output is determined by four separate parameters: preload, afterload, heart rate, and contractility. *Preload* is defined as the end-diastolic fiber length or end-diastolic volume of the heart. It is influenced by intravascular volume status, capacity of the venous system, and ventricular function as related to compliance, afterload, and contractility. *Afterload* is defined as the force opposing ventricular ejection and translates into the wall tension developed as ventricular muscle fibers shorten during both isovolumic contraction and ejection phases of systole. It is influenced by ventricular size and volume, including chamber radius and wall thickness, as well as by systemic vascular

Figure 16-14 (Figure Not Available) An illustration of the Fick principle, in which q_1 represents the rate of oxygen delivery to the alveoli (venous return) and q_3 represents the rate of oxygen delivery to the periphery (systemic circulation). By the law of conservation of mass, q_2 must represent the rate of oxygen consumption that is equivalent to the rate of oxygen transport across the alveoli. *(Modified from Berne and Levy [51])*

resistance and aortic compliance. *Heart rate,* as previously discussed, is defined as the number of beats per minute and is heavily influenced by the autonomic nervous system. Increases in heart rate increase cardiac output up until the point at which a rapid heart rate does not permit for adequate ventricular filling during diastole, and cardiac output consequently falls. This occurs at a heart rate of approximately 160 beats/min. [53] *Contractility* is defined as the inherent inotropic ability of the heart independent of changes in the other codeterminants of cardiac output. It is influenced by the regulation of intracellular calcium concentration, as discussed previously, and ventricular compliance, including relaxation, which determines the ability of the ventricle to fill. Indices of contractility include the rate of change of ventricular pressure with respect to time (dP/dt), the rate of shortening of mean circumferential fiber length during ejection, ventricular function curves, and the cardiac cycle pressure-volume loops and force-velocity curves, as discussed later. *Ejection fraction,* a term often associated with the discussion of contractility, is defined as the stroke volume divided by the left ventricular end-diastolic volume, or the percentage of blood ejected with each beat during systole. Typical values for ejection fraction in healthy adults range from 60 to 70 percent, whereas values lower than 40 percent represent severe ventricular contractile dysfunction.

Several other factors influence the actual cardiac output primarily through changes in contractility. The term *heterometric autoregulation* refers to adaptive adjustments used by the heart that improve ventricular function dependent on changes in myocardial fiber length. The Frank-Starling curve, as described later, is an example of heterometric autoregulation, in which an increase in preload or stretch on the heart results in an increase in cardiac output.

Conversely, the term *homeometric autoregulation* refers to compensatory mechanisms that result in improved ventricular performance that is independent of changes in myocardial fiber length. The Anrep effect is an example of homeometric autoregulation. It occurs when afterload or systemic vascular resistance increases abruptly and produces a resultant increase in LV end-diastolic and diastolic pressures. These increased values are transient and return to baseline as contractile function

increases in response to the pressure challenge. [54]

Another example of homeometric autoregulation is the treppe (staircase) effect. This phenomenon was first described by Bowditch in frog ventricle, in which he noted a negative correlation between time interval between stimuli (heart rate) and developed myocardial tension (as a measure of contractile function). This finding is believed to be due to an increased intracellular calcium concentration, as noted by studies using aequorin, a Ca^{2+} -sensitive bioluminescent protein indicator, which demonstrated an increased signal in response to an increased heart rate. [55] A related contradictory phenomenon is the reverse, or negative, staircase effect in which myocardial performance increases in response to a long pause between beats, as is seen with the compensatory pause following premature ventricular contractions. [56]

Moreover, there are also several factors that worsen myocardial performance and hence cardiac output. These include hypoxia, myocardial ischemia or infarction, acidosis, cardiomyopathy, volatile anesthetics, and various negative inotropic drugs.

Measurement

In addition to the Fick principle described earlier, cardiac output can be measured by several other techniques. Injection of an indicator dye such as indocyanine green into the venous blood allows determination of cardiac output by calculating the area under the dye dilution curve as measured by densitometry of the arterial blood. The major limitation of this method is the recirculation of dye, which then requires extrapolation of the downward slope of the dilution curve to estimate the area under the peak and hence cardiac output. Thus, repeated injections cause build-up of dye levels and further hinder the usefulness of this method. This problem, however, has a hidden advantage in that it can be used to determine the presence of shunts. The initial bolus of dye injected into the blood normally produces a second or recirculation peak after the primary dilution curve from the second passage of dye through the heart. The presence of a right-to-left shunt results in the appearance of a more prominent initial peak as well as a secondary recirculation peak, which occurs much earlier than normal. Conversely, the presence of a left-to-right shunt results in the appearance of a diminished initial dye curve and a barely detectable recirculation peak, which occurs much later than normal, with marked prolongation of dye elimination.

Another method of determining cardiac output is Doppler echocardiography. This noninvasive technique is based on measuring the cross-sectional area of the aortic valve and the velocity of blood flow by ultrasound. Although it has shown good experimental correlation with other methods of determining cardiac output, its use in clinical situations has been limited by reliability issues. [57]

Currently, the most widely used technique for measuring cardiac output is the thermodilution method. Like the dye method, it relies on dilutional measurements of a substance injected as a bolus. In this case, a thermistor sensor measures changes in temperature of a known quantity of injectate of normal saline or dextrose at either 4°C or room temperature and calculates the cardiac output as the area under the curve. Although it only measures output from the right side of the heart, this is assumed to correlate well with that of the left. Thus, the limitations of this method include the presence of shunts, the use of varying quantities of injectate, the speed of injection, and the baseline temperature, all of which may overestimate or underestimate the actual cardiac output.

CONTROL OF CARDIAC FUNCTION

Neural Regulation of the Heart

Control of Heart Rate

As described earlier, the SA and AV nodes receive autonomic nervous system input via parasympathetic and sympathetic innervation to the heart, eliciting changes in heart rate in response to physiologic changes within the body that vary with a person's age and particular situation [58] (ch. 14) .

In the adult, the normal heart rate varies between 60 and 80 beats/min. The SA node, because of its origin from right-sided embryologic structures, receives its innervation predominantly

from the right vagus nerve and right stellate ganglion, although there is usually some overlap of distribution between right and left sides. Cholinergic parasympathetic simulation from the vagus nerve causes a decrease in the heart rate via muscarinic receptors, which hyperpolarize pacemaker cells and slow phase 4 depolarization. Meanwhile, adrenergic sympathetic stimulation from the cardiac accelerator fibers via the stellate ganglion causes an increase in the heart rate via beta receptors that speed phase 4 depolarization.

Most changes in heart rate usually involve a coordinated reciprocal action between the two branches of the autonomic nervous system, such that situations that increase sympathetic activity (e.g., exercise) elicit a concomitant decrease in parasympathetic activity and vice versa. Under normal resting circumstances in the adult heart, parasympathetic tone predominates. When parasympathetic and sympathetic innervation is completely blocked through denervation (e.g., transplant surgery) or pharmacologic intervention, the underlying or intrinsic heart rate has been found to average around 105 beats/min.

There are three types of parasympathetic reflex receptors found in the atria that function to regulate changes in heart rate or volume status. Type A receptors are innervated by myelinated vagal afferent fibers and are located throughout the atria as well as at the junction between the vena cava and the RA and the pulmonary vein and the LA. [58A] [58B] [58C] These receptors seem to be more responsive to heart rate rather than atrial chamber volume, and they discharge impulses continuously throughout the normal cardiac cycle that correspond to the timing of the a wave. Type B receptors are also innervated by myelinated vagal afferent fibers and occur in a similar distribution to that of type A receptors. These receptors seem to be more responsive to atrial stretch and changes in intravascular volume than to heart rate, and they discharge impulses late in systole that correspond to the timing of the v wave. [58C] These receptors are normally inactive in atrial contraction, but they increase their activity in conditions such as tachyarrhythmias, in which the rate of rise of intra-atrial pressure increases. Finally, a group of receptors innervated by group C parasympathetic fibers and located throughout the atria respond to changes in atrial pressure with a threshold of 2 to 3 mm Hg, but in general they are much less responsive and have a lower rate of activity than type B receptors. [59]

There are also ventricular receptors mediated by myelinated vagal afferent fibers, which are located throughout the ventricular chambers and coronary arteries and respond to changes in pressure either by bradycardia and hypotension or by reflexive sympathetic cardiovascular stimulation. These receptors are sensitive to changes in the rate of rise of ventricular pressure and fire impulses at the onset of ventricular ejection. They may play a role in the reported myocardial depressant effects seen with parasympathetic stimulation, as discussed later. In addition, there are two types of receptors innervated by unmyelinated vagal afferent fibers: chemoreceptors that respond to capsaicin or veratridine and mechanoreceptors that respond to aortic constriction and ventricular stimuli.

Most sympathetic afferent nerves are unmyelinated, although the significance of myelinated versus unmyelinated nerve fibers remains unclear. [60] Both myelinated and unmyelinated spinal afferents have been detected in the atria, fire throughout the cardiac cycle, and appear to be sensitive to both mechanical and chemical stimulation including K^+ and bradykinin. [61] The myelinated nerve fibers in the ventricles are also sensitive to mechanical and chemical stimuli, with increased firing during periods of increased ventricular pressure and with the detection of vasoactive peptides such as bradykinin and veratridine. [62]

The pain of myocardial ischemia is presumably related to stimulation of spinal afferent pathways. Specifically, various compounds, such as bradykinin, are released by ischemic myocardium and activate both chemosensitive and mechanosensitive sympathetic afferent fibers. [63] This effect is attenuated by vagal afferents, which can modulate the sensation of cardiac pain, and it serves as an explanation for silent ischemia and infarction. [64] In humans, myocardial ischemic pain can be relieved by the bilateral removal of the T1 to T5 sympathetic ganglia. [65]

Control of Myocardial Performance

As would be expected, left-sided structures in the heart are predominantly autonomically innervated by the left vagus and left stellate ganglion. Distribution of the left vagus nerve terminates near the AV node, where it elicits its greatest influence, producing variable degrees of nodal conduction block. Meanwhile, the branches of the left stellate ganglion form an extensive plexus network over the epicardium of the heart and penetrate the myocardium along the various branches of the coronary vessels. Thus in general, sympathetic adrenergic activity from the cardiac augmenter fibers via the left stellate ganglion has a greater effect on contractility, whereas the accelerator fibers from the right have a greater effect on heart rate. [66] The tissue concentration of norepinephrine in the atria is roughly three times that in the ventricle, reflecting the differences in the relative density of sympathetic innervation to those respective areas of the heart. Moreover, if the heart is denervated, as in transplanted hearts, the tissue levels of norepinephrine are virtually nonexistent.

Stimulation of beta receptors increases heart rate and contractility via increases in cyclic adenosine monophosphate (cAMP) [67] (Fig. 16-15) (Figure Not Available) . This process occurs as norepinephrine, the neurotransmitter released by postganglionic sympathetic nerve terminals, binds the receptor and causes a conformational change that subsequently activates a specific guanylnucleotide-binding stimulatory coupling protein (G_s). G proteins are a family of heterotrimeric structures composed of alpha-, beta-, and gamma-subunits, of which the alpha-subunits vary in molecular weight and function. Binding of the beta receptor causes dissociation of the alpha-subunit of G_s (molecular weight 43,000) from the betagamma complex (molecular weight 35,000) with the concomitant expenditure of guanosine triphosphate, and this alpha-subunit then stimulates adenylate cyclase to increase intracellular cAMP levels. [68] Increases in cAMP, in turn, act on certain protein kinases that function to phosphorylate various intracellular proteins, especially those related to the SR, that ultimately raise intracellular Ca^{2+} concentration.

Although both $beta_1$ - and $beta_2$ -receptors cause increases in heart rate and contractility, $beta_1$ -receptors specifically increase

Figure 16-15 (Figure Not Available) A schematic of the coupling of the beta receptor (R_s) via a stimulatory guanyl-nucleotide-binding protein (G_s) to adenylate cyclase. Note the heterotrimeric structure of the G protein. The muscarinic receptor (R_i) is also coupled to adenylate cyclase via an inhibitory guanyl-nucleotide-binding protein (G_i). Ultimately, cAMP levels are affected by the balance of stimulatory and inhibitory input from sympathetic and parasympathetic influences. *(From Susanni et al [67])*

conduction velocity of the heart, whereas $beta_2$-receptors specifically cause smooth muscle relaxation, which is responsible for its usefulness in the control of asthma and reactive airway diseases as well as in premature labor [69] (ch. 72) . This becomes important when selecting certain drugs that have preferentially selective $beta_1$- and $beta_2$-agonist and antagonist activity.

As mentioned earlier, parasympathetic stimulation also seems to influence contractility, even though the parasympathetic nervous system has a relatively low level of innervation to the ventricles as compared with that of the sympathetic nervous system. The specific mechanism by which the parasympathetic neurotransmitter acetylcholine acts is unclear; however, there are several potential pathways, all of which ultimately lower the levels of intracellular cAMP. [70] Binding of acetylcholine to muscarinic receptors on myocardial cells has a dual effect. The first is to elevate cyclic guanosine monophosphate (cGMP) levels by activation of guanylate cyclase. Increases in this nucleotide have been shown to accelerate the breakdown of cAMP, perhaps by activation of phosphodiesterase, although the exact mechanism by which this occurs is not known. The second effect occurs via an inhibitory G protein (G_i). Like G_s, the corresponding stimulatory coupling protein linking the beta receptor to adenylate cyclase, G_i couples the muscarinic receptor to adenylate cyclase. However, unlike G_s, the alpha- subunit of G_i (molecular weight 41,000), which dissociates from the betagamma complex on binding of the muscarinic receptor, then inhibits adenylate cyclase, leading to a decrease in cAMP synthesis. [71] Finally, acetylcholine released from parasympathetic postganglionic nerve terminals that lie in close proximity to sympathetic postganglionic nerve terminals may actually inhibit their release of norepinephrine, and this, in turn, decreases beta receptor stimulation and ultimately cAMP levels. [72]

Starling's Law of the Heart

As mentioned earlier, ventricular function curves illustrate the principle of heterometric autoregulation wherein an increase in stretch on a muscle fiber produces an increase in the tension developed. This serves as the basis for Starling's Law of the heart, or the Frank-Starling relationship, as it is more commonly known. [73] Experimentally, maximal developed tension in cardiac muscle fibers occurs at a resting sarcomere length of 2.0 to 2.3 mum, which allows for optimal cross-bridge formation between the contractile proteins that make up the thick and thin filaments. Clinically, this translates into peak ventricular output occurring at filling pressures of 10 to 12 mm Hg. [74] If the sarcomere length is less than ideal, the thin filaments may be compressed or may overlap, and this may interfere with adequate cross-bridge formation and generation of force. Conversely, if the sarcomere length is greater than optimal, there may be insufficient cross-bridges formed between thick and thin filaments, and this may result in impaired contractile performance. In fact, at a sarcomere length of 3.6 mum, there are no cross-bridges formed, and developed tension in these cardiac muscle fibers is zero [75] (Fig. 16-16) .

There exists some ambiguity regarding the applicability of the Frank-Starling relationship to periods, such as exercise, when the myocardial contractile state is high. This is related to the interaction of reflexive mechanisms in healthy persons (i.e., catecholamines) that regulate heart rate, vascular tone, coronary blood flow, and overall myocardial performance. With the diminution of catecholamine modulation of myocardial performance that occurs with advancing age, however, the heart reverts back to increased reliance on augmenting end-diastolic volume to improve cardiac output. [76] [77]

In addition, experimental evidence using Ca^{2+} and other inotropic substances suggests that changes in myocardial performance are closely linked to the effectiveness of excitation-contraction coupling. [78] Moreover, these pharmacologic interventions appear to depend on length and are more effective at longer rather than shorter resting muscle fiber lengths. [79]

Assessment of Contractile Function

Systolic Properties

Assessment of contractile function in the intact heart *in vivo* is a complex task because many factors such as preload, afterload, heart rate, and autonomic activity can modify contractility and are difficult to control. To measure the intrinsic contractile activity of the heart, several strategies have been attempted, with varying degrees of success. The simplest and most straightforward means of assessing contractile function is by differentiating the ventricular pressure (P) trace with respect to time (t). Maximum positive dP/dt has been used frequently to judge contractile function of the left

Figure 16-16 (A) Schematic diagram of the thick (myosin) and thin (actin) filaments, and of the spacing lateral projections from myosin that attach to actin to form cross-bridges. Sarcomere length is the distance between two lines, which are dense areas resulting from the overlap of actin fibers of sarcomeres in series. Note that when the sarcomere length is 3.65 mum, no cross-bridge attachment between thick and thin filaments can occur; when sarcomere length is 2.20 to 2.25 mum, the maximum number of bridges is formed. Reduction of sarcomere length from 2.20 to 2.05 mum does decrease the number of cross-bridges, because the central part of myosin (C band) has no projections. Reduction of sarcomere length from 2.05 mum to 1.85-1.65 mum does not reduce the number of cross-bridges from the maximum number but does result in double actin overlap. (B) Force measured during a tetanic activation at 0°C as a function of sarcomere length (as in 1 to 5 in Fig. A) in tetanized skeletal muscle. Note that force is zero at zero myofilament overlap, that is, at sarcomere length of 3.6 mum at which no cross-bridges exist between myosin and actin. Maximum force occurs when the number of cross-bridges is maximum and no double overlap of actin occurs (2.0 to 2.25). Force decreases 20 percent when sarcomere length is reduced from 2.0 to 1.65 mum, a length range where the *number* of cross-bridges does not change.

ventricle. Although this value is simple to obtain, its interpretation must be made with several caveats. Of primary importance is the measurement system. The passage of a high-fidelity micromanometer into the LV is required for accurate assessment of dP/dt. The micromanometer can be passed into the LV in at least three ways: (1) retrograde through the aorta and aortic valve; (2) through the pulmonary veins into the LA and across the mitral valve into the LV; and (3) through the apex of the LV. Each of these procedures obviously has its own set of drawbacks. The disadvantage of using dP/dt as a measure of contractility is that it is dependent on heart rate, afterload, and preload. If all these factors can be controlled during the course of the measurement, changes in dP/dt can be used to monitor contractile function.

Although dP/dt gives one an initial assessment of contractile activity, other methods have been developed to assess contractility independently of the effects of preload and afterload. In 1895, Frank published the first pressure-volume loops for frog hearts. He showed the extremes of curves for isovolumic maxima and isobaric maxima curves. He concluded that a simple relationship between length and tension did not exist, but the history (i.e., the preexisting conditions of the contractile process) were important in determining the instantaneous contractile activity. [80] An interest in pressure-volume curves was revived in the 1960s and 1970s. In 1978, when it became clear that a linear relationship existed between the end-systolic volume and the end-systolic ventricular pressure, Sagawa [81] suggested the use of the end-systolic pressure-volume relationship (ESPVR) as a means of comparing intrinsic contractile activity (Fig. 16-17) (Figure Not Available) . These studies [82] were performed in isolated hearts, and the linear relationship obtained in both the ejecting mode and the isovolumic contracting mode was formulated as follows:

where P_{ES} and V_{ES} are end-systolic pressure and end-systolic volume, respectively, E_{ES} is the slope, and V_d is the volume axis intercept. This linear formulation and its relation to the pressure-volume curve are demonstrated in Figure 16-17 (Figure Not Available) . [82] Although extensive use has been made of the concepts of the pressure-volume curve and the ESPVR as a

Figure 16-17 (Figure Not Available) Pressure-volume loops of the left ventricle, demonstrating the difference between the ESPVR in the control and epinephrine-treated isolated heart. The ESPVR is represented by the straight solid line connecting the upper left-hand corners of the pressure-volume loops obtained at different filling volumes of the heart. Epinephrine shifts the pressure-volume loops such that the ESPVR is shifted to the left with a steeper slope, indicating the positive inotropic effect. *(Modified from Suga et al [82])*

means of assessing contractile activity, the application of these tools to intact animals and humans has had less convincing results. [83] Investigations have, in fact, demonstrated that the ESPVR is dependent on heart rate, showing a 25 percent change over a heart rate of 60 to 160 beats/min. Furthermore, E_{ES} was found to yield inconsistent and statistically nonsignificant results when comparing control and inotropic-stimulated hemodynamics in the conscious dog. Overall, the results in intact animals and humans have been inconsistent in terms of assessing contractility changes with either E_{ES} or V_d alone. [83] [84] [85]

As a result, investigators have continued to search for other indices of contractility based on the ESPVR with more complete use of all the data available in a pressure-volume loop (i.e., not using either E_{ES} or V_d alone). Crottogini et al [83] demonstrated the utility of the area under the ESPVR within defined limits. They pointed out that in the positive inotropic state the ESPVR is always above and to the left of the control line, whereas in the negative inotropic state, the ESPVR is always below and to the right of the control loop. These investigators therefore calculated the area under the ESPVR from an upper limit defined by the end-systolic volume of the animal with no manipulations of volume status to a lower limit obtained from the occlusion of the inferior vena cava to limit preload during measurement of control ESPVR. Figure 16-18 (Figure Not Available) demonstrates the two trapezoidal areas calculated to compare inotropic states. [85] This determination of the $ESPVR_{area}$ as an index of contractility resulted in a statistically significant determination of positive and negative inotropic activity even when either the slope E_{ES} or the volume intercept V_d alone gave inconsistent results. Using the area under the ESPVR within defined limits as a means of assessing contractile states allowed Pagel et al [85] to obtain a dose-dependent and statistically significant decrease in this index of contractility in response to halothane and isoflurane while observing no consistent change in either E_{ES} or V_d from the ESPVR. In this set of experiments, consistent and dose-dependent decreases were also noted in dP/dt_{50} (i.e., the time derivate of pressure when pressure has reached one-half of its maximal value).

Some investigations have employed a new index of contractility, which is based on the speculation of Sarnoff and Berglund [86] that a linear relationship should exist between stroke work and end-diastolic volume. Because of the technical difficulties in measuring end-diastolic volume, these investigators were unable to obtain this linear relationship. However, in 1985, Glower et al, [87] using the best current technology, demonstrated that a linear relationship did in fact exist between stroke work and end-diastolic volume, and they termed this relationship the *preload recruitable stroke work* (PRSW) (Fig. 16-19) (Figure Not Available) . In fact, they used both global and regional measures of end-diastole and showed that linearity was maintained with either measure. Global ventricular volume was measured by placing dimensional transducers on the epicardial surface across the longitudinal and transverse axes of the LV, assuming that the volume of the ventricle could be represented by an ellipsoid. Global stroke work was then calculated as the integral of the LV pressure curve (i.e., the area within the curve). Regional stroke work was determined by employing segment length measurements and integrating the LV pressure over the segment length for a contractile cycle. Changes in preload and afterload were achieved with occlusions of the inferior vena cava and infusions of phenylephrine or nitroprusside, respectively. The resulting relationship remained linear over extremes of diastolic filling and ventricular pressure. However, these experimental conditions required autonomic blockade with 2 mg/kg of propranolol and 3 mg/kg of atropine and 20 mg/kg of hexamethonium to prevent the interference of hemodynamic reflexes from confounding the assessment of the factors regulating contractility.

Figure 16-18 (Figure Not Available) Pressure-segment length loops were generated with a transducer in the left ventricle and sonomicrometry crystals on the ventricular surface by occluding the inferior vena cava. The area under the curve was obtained by integration from the minimum segment length (L_m) to the maximum segment length (L_M) beneath the slope of the end-systolic pressure-length relationship. *(Modified from Pagel et al [85])*

Figure 16-19 (Figure Not Available) Example of the preload recruitable stroke work (PRSW) relationship. Pressure-length loops were obtained as in Figure 16-18 (Figure Not Available) . The shaded area represents regional stroke work and, as shown in the insert, was plotted versus the corresponding end-diastolic length (EDL, large dot). *(From Pagel et al [85])*

The concept of PRSW has appeared in the anesthesia literature and has been used as a means of demonstrating the negative inotropic effects of several anesthetics, in particular, halothane, isoflurane, and propofol. [85] [88] [89] Pagel and Warltier [88] compared the ESPVR, $ESPVR_{area}$, and PRSW in autonomically blocked, chronically instrumented canines. These investigators found that either the slope or the volume intercept of the ESPVR gave inconsistent results, whereas both $ESPVR_{area}$ and the PRSW gave results that were consistent and demonstrated the dose-dependent negative inotropic effects of the volatile anesthetics halothane and isoflurane and the intravenous anesthetic propofol.

Current data suggest that we have two load-insensitive measures of contractility, $ESPVR_{area}$ and PRSW; however, both indices, while giving valuable and reproducible measures of contractility, cannot, at this time be directly applied to clinical evaluation of the patient because of the invasive requirements of the measurements. Thus, as the quantitative aspects of transesophageal echocardiography improve, allowing accurate dimensional measurements to be performed, and as the reliability and use of volume catheters increase, and as the placement of high-fidelity transducers into the ventricular cavities becomes less an experimental procedure, clinical monitoring will likely benefit from these concepts.

Diastolic Properties

Intense investigations have demonstrated that alterations in diastole can markedly alter cardiac performance. It has been shown that diastolic function can be modified directly by certain pathologic processes such as ischemia and hypertrophy and also indirectly by alterations in systolic function. Diastole is a complex process, which can be divided into four phases: (1) isovolumic relaxation; (2) rapid ventricular filling; (3) diastasis or slow filling; and (4) atrial systole. Each phase is the result of independent mechanisms, but it is interrelated with the other processes [90] (Fig. 16-20) (Figure Not Available) .

Assessment of diastole can be performed in a number of ways, most requiring invasive monitoring for accurate measures of chamber pressure, segment length, and transcardiac pressure. One index of diastolic function is the maximum rate of fall of LV pressure, maximum negative dP/dt. Unfortunately, this index is highly dependent on the maximum ventricular pressure and loading conditions, is only measured at a single time point, and, therefore, disregards much of the available data that are obtainable during relaxation. A second, more encompassing index reflecting the

Figure 16-20 (Figure Not Available) The phases of left ventricular diastole: (1) isovolumic relaxation from aortic valve closure to initial valve opening; (2) rapid filling time from mitral valve opening to plateau of ventricular volume curve; (3) slow filling period; and (4) atrial systole. *(From Plotnick [90])*

Figure 16-21 (Figure Not Available) Determination of the time constant for relaxation obtained from a plot of dP/dt versus left ventricular pressure during one heart beat. The slope of the line from maximum negative dP/dt to mitral valve opening yields the constant T as the negative inverse of the slope. *(From Humphrey et al [91])*

rate of pressure decline is tau, or its inverse, T, which describes the time constant of the exponential decay of LV pressure from maximum -dP/dt to its asymptote. The following equation and method were developed by Thompson et al [91] to describe exponential decay of ventricular pressure:

where P(t) is the pressure at variable time, P_0 is the initial pressure, P_{asym} is the asymptotic pressure as t approaches infinity, and A is the reciprocal of the time

constant T. [91] This formula can be reconfigured by differentiation and substitution to yield

and plotting dP/dt versus P will result in a straight line with a slope of -1/T ms $^{-1}$ and an intercept of P_{asym} [92] (Fig. 16-21) (Figure Not Available) . The time constant T has the units of milliseconds, and an increase in T indicates prolongation of the relaxation process. Volatile anesthetics have been shown to prolong T, as do hemodynamic factors such as ischemia. [93] [94]

The relaxation processes reflected by T include the basic mechanisms of Ca^{2+} sequestration by the SR, unbinding of Ca^{2+} from TnC, detachment of the actin-myosin cross-bridges, and overcoming of the viscoelastic properties of the myocardium. Relaxation includes both passive and active mechanisms, and the multiple indices of relaxation reflect varying aspects of the processes enumerated earlier.

Ventricular chamber stiffness and myocardial stiffness are two indices that reflect the passive components of diastolic function. Chamber stiffness is defined as the change in ventricular pressure for a given change in ventricular volume (dP/dV) from the nadir of the ventricular pressure to the beginning of atrial systole. The reciprocal of chamber stiffness is compliance, dV/dP. LV pressure can be plotted as a function of ventricular volume or some aspect of ventricular dimensional change during the diastolic filling phase. The data can be fitted by linear regression analysis to the following formula:

where P is ventricular pressure, b is a constant, L is a volume or segment measurement, and k_c is the chamber stiffness constant [95] (Fig. 16-22) (Figure Not Available) .

To obtain an accurate assessment of the stiffness constant, it is important to obtain data over a wide range of diastolic ventricular pressures and volumes. [96] Several factors contribute to chamber stiffness, including the passive elastic properties of the myocardium, the extent of myocardial relaxation, viscoelastic forces, coronary turgor, geometric factors such as ventricular shape, and wall thickness. The k_c has units of the reciprocal of either volume, area, or length, depending on which dimension has been measured.

Figure 16-22 (Figure Not Available) Left ventricular chamber stiffness. Chamber stiffness is estimated from LV diastolic pressure versus LV diastolic volume curves. The data at increasing volumes are fitted to a simple exponential equation $P = be^{k_c L}$, where P equals LV diastolic pressure, b is a constant, L is a volume or segment measurement, and k_c represents the modulus for chamber stiffness. The stiffness curve is steeper and the value of k_c greater in the hypertrophic cardiomyopathy (HCM) patient than in the healthy patient. *(From Gaasch et al [95])*

Although chamber stiffness gives an overall synthesis of many factors involved in the global ventricular diastolic properties, myocardial stiffness refers directly to the muscle and connective tissue itself. Myocardial stiffness is defined as the ratio of myocardial stress to myocardial strain. Stress is defined as the force per unit cross-sectional area, whereas strain is the deformation of a material produced by a force. A plot of myocardial stress versus strain yields a curvilinear relationship, where the slope of any tangent to the line represents the elastic stiffness k_m . Myocardial stiffness represents the intrinsic molecular properties of the myocardium. Hypertrophy leads to an increase not only in muscle mass but also in extracellular connective tissue and perhaps in the intracellular cytoskeletal components and results in an increase in myocardial stiffness and in k_m . Similarly, following chronic ischemia and infarction, myocardial stiffness increases and k_m is higher. The measurement of myocardial strain is variable, because in some circumstances (e.g., localized ischemia or infarction) strain results from the local deformation caused by a stress placed on that area of tissue. One can therefore understand that because strain varies in particular areas of the ventricle, myocardial elasticity, and, in particular, the modulus of stiffness k_p , can be considerably different in different areas of the ventricle.

Cardiac Reflexes

Before discussing specific reflexes, it is important to understand the various pathways by which cardiac mechanoreceptors elicit their physiologic responses. These receptors, which can be found throughout the atria, ventricles, pericardium, and coronary arteries, are linked via either myelinated or unmyelinated afferent fibers that travel through the vagus to the brain stem or the dorsal root ganglia to the spinal cord. [62] It is presumably the central integration and processing of these various sympathetic and parasympathetic nerve inputs that determine the particular response or reflex elicited on the heart and systemic circulation.

Baroreceptor Reflex

The baroreceptor reflex, also called the carotid sinus reflex, responds to changes in blood pressure via circumferential and longitudinal stretch receptors present in the carotid sinus and aortic arch. Increases in blood pressure stimulate these two receptors, which send impulses along the afferent limbs of the glossopharyngeal nerve (nerve of Hering) and vagus nerve, respectively, to the nucleus solitarius in the medullary cardiovascular center. This center actually comprises two functional areas: a lateral and rostrally located pressor center and a central and caudally located depressor center, in which hypothalamic and limbic system inputs are then integrated. The response is decreased sympathetic activity, which, in turn, decreases contractility, heart rate, and vascular tone, and increased parasympathetic activity, which also decreases heart rate and further depresses contractility. Typically, these receptors begin to respond at pressures in excess of 170 mm Hg; however the set point shifts upward in patients with chronic or poorly controlled hypertension. Meanwhile, decreases in blood pressure have the reverse effect, and these receptors play an important role in the response of the cardiovascular system to acute blood loss and shock. However, at pressures lower than 50 to 60 mm Hg, the baroreceptors lose much of their functional capacity. [97]

Chemoreceptor Reflex

The chemoreceptor reflex responds to changes in pH status and blood oxygen tension at an arterial partial pressure of oxygen (P_{O_2}) of less than 50 mm Hg via receptors in the carotid and aortic bodies. [98] Conditions of acidosis and hypoxia stimulate these receptors, especially those within the carotid body, which also send their impulses along the glossopharyngeal and vagus nerves to the chemosensitive area of the medulla, located bilaterally just beneath its ventral surface. This area responds by stimulating respiratory centers to increase ventilation and also by increasing parasympathetic activity, which produces significant bradycardia and decreased contractility. [99] If hypoxia persists, direct central nervous stimulation will lead to improved ventricular performance independent of parasympathetic activity.

Bainbridge Reflex

The Bainbridge reflex responds to changes in RA or central venous pressure via stretch receptors present within the RA wall and cavoatrial junction. Increases in intravascular volume or right-sided filling pressures stimulate these receptors, which also send their impulses through vagal afferents to inhibit parasympathetic activity and to increase heart rate. [59] The changes in heart rate, however, are dependent on the underlying rate prior to stimulation, and relatively fast heart rates are less sensitive to further increase. In addition, there is also a direct effect of stretching on the SA node, which leads to enhanced automaticity and increased heart rate.

Bezold-Jarisch Reflex

The Bezold-Jarisch reflex responds to noxious ventricular stimuli via chemoreceptors and mechanoreceptors present within the LV wall. The activated receptors send their impulses along unmyelinated vagal afferent type C fibers, which reflexively increase parasympathetic tone, leading to bradycardia, hypotension, and coronary artery vasodilation. [100] Conditions under which ischemic myocardium is then reperfused, such as the aftermath of treatment with nitrates or heparin, thrombolytic therapy following infarction, or coronary bypass grafting, may also elicit this reflex. [101] [102]

Valsalva Maneuver

The Valsalva maneuver occurs with forced expiration against a closed glottis, producing increased intrathoracic pressure, increased central venous pressure, and decreased venous return to the heart. [103] The resulting decrease in cardiac output and blood pressure is then sensed by baroreceptors, which respond by reflexively increasing heart rate via

---

sympathetic stimulation. As the glottis opens and venous return subsequently increases, the heart responds by vigorous contraction, which increases cardiac output and blood pressure, thereby causing baroreceptors to reflexively decrease heart rate via parasympathetic stimulation.

Cushing Reflex

Cushing reflex occurs in response to cerebral ischemia that is secondary to increased intracranial pressure from increased cerebrospinal fluid production, decreased resorption, or a mass effect. The initial reflex is a direct central nervous system sympathetic stimulation leading to increased heart rate, contractility, and blood pressure in an effort to increase cerebral perfusion. This is followed by reflex bradycardia mediated by baroreceptors present within the carotid sinus and aortic arch as a result of the increased peripheral vascular tone.

Oculocardiac Reflex

The oculocardiac reflex responds to pressure on the globe of the eye or traction on the surrounding structures via stretch receptors within the extraocular muscles. Increases in tension on these muscles, especially the medial rectus, activate these receptors, which send their afferent impulses via the short and long ciliary nerves to the ciliary ganglion and, eventually, via the ophthalmic division of the trigeminal nerve, to the gasserian ganglion, which results in increased parasympathetic tone and profound reflex bradycardia. The incidence of this condition ranges from 30 to 90 percent of all ophthalmic surgical cases and can be attenuated by pretreatment with an antimuscarinic agent such as atropine or glycopyrrolate.

CORONARY BLOOD FLOW

Coronary blood flow, like blood flow in other vessels, is dependent on a pressure gradient, principally driven by mean arterial pressure. However, because aortic pressure can vary widely and because the heart beats continuously, the pressure gradient and, hence, coronary blood flow fluctuate depending on the state of contraction. During systole, especially on the left side of the heart, the pressure within the coronary artery secondary to extravascular compression from the squeezing effect of the contracting myocardium virtually eliminates antegrade coronary blood flow. This situation is diagrammed in Figure 16-23 (Figure Not Available) , in which the coronary blood flow goes to zero just prior to ventricular ejection, corresponding to isovolumic contraction and increased extravascular compression. [104] Conversely, coronary blood flow through the left side is maximal during early diastole, corresponding to the period of isovolumic relaxation (see Fig. 16-8 (Figure Not Available) , E to A) and minimal extravascular compression. Coronary blood flow through the right side, however, is maximal during peak systole, because developed pressure and consequently extravascular compression within the RV are considerably less than in the LV, thus allowing for antegrade flow during both systole and diastole. [5]

Figure 16-23 (Figure Not Available) The differences in coronary blood flow through the left and right sides of the heart during systole and diastole occur because of differences in ventricular muscle mass. *(From Berne and Levy [6])*

The difference between resting and maximal coronary blood flow is termed the *coronary flow reserve.* Hence, factors that decrease maximal coronary blood flow (e.g., tachycardia, increased blood viscosity, increased myocardial contractility, and increased ventricular size) also decrease coronary flow reserve. This is important because basal cardiac oxygen consumption is 6 to 10 mL O_2 /mm/100 g, and transcoronary extraction of oxygen is near the limits allowable by the oxyhemoglobin dissociation curve. Thus, unlike the kidney, which can compensate for increased oxygen consumption by increasing oxygen extraction, the heart has little "extraction reserve" and must increase oxygen delivery via increasing coronary blood flow to meet increased metabolic demands.

Under normal circumstances, the myocardial wall pressure is highest near the endocardium and is lowest near the epicardium. Thus, endocardial blood flow is greatly influenced by diastolic ventricular muscle relaxation, which decreases myocardial wall pressure and enhances the pressure gradient. This maximizes perfusion to the inner wall of the ventricle, thus making the endocardium relatively more sensitive to pathologic changes such as hypotension, partial coronary occlusion and ischemia, myocardial hypertrophy, and severe aortic stenosis.

The presence of stenosis tends to cause vasodilation in an effort to maintain coronary blood flow across the lesion.

However, as the extent of stenosis increases to more than 90 percent of the luminal cross-sectional area, the compensatory vasodilatory properties of the artery are exceeded, and the blood flow decreases. Thus, if a coronary artery provides blood flow to two distal branches and one of the branches is tightly occluded by a stenotic lesion, administration of a pharmacologic vasodilator or endogenous release of local mediators may cause preferential vasodilation of the normal vessel, because the stenotic vessel is already maximally dilated. This results in a phenomenon known as *coronary steal,* in which there is a relative increase in blood flow to the area of the heart served by the normal anatomy and a relative decrease in blood flow to the area of the heart served by the stenotic vessel.

Consequently, the coronary arteries, like the carotid and renal arteries, exhibit some degree of autoregulation, which acts to maintain coronary blood flow within tightly controlled limits over a perfusion pressure range of 0 to 140 mm Hg independent of myocardial oxygen demand. [105] [105A] Coronary perfusion pressure is defined as the difference between diastolic aortic pressure and LV end-diastolic pressure. [106] Factors influencing coronary artery autoregulation include neural, metabolic, and humoral inputs, as well as numerous myocardial reflexes, which are the result of parasympathetic and sympathetic innervation of the coronary vessels. [107] Parasympathetic stimulation of muscarinic receptors in coronary arteries produces direct vasodilation, whereas sympathetic stimulation of adrenergic receptors induces coronary dilation secondary to increased metabolic demand. Although unopposed alpha $_1$ -adrenergic stimulation may produce coronary artery spasm, the overall contribution of alpha-adrenergic stimulation on basal coronary tone is relatively small. In fact, the vasodilating properties of beta receptor activation appear to predominate over the alpha-adrenergic effects. [108]

Locally produced metabolites also appear to be important mediators of coronary vascular resistance. One hypothesis is that vasodilatory substances are released by myocytes in proportion to their level of work, thus ensuring an adequate supply of fresh substrate to meet existing metabolic demands. These vasodilatory substances presumably act on opposite mechanisms that generate basal vascular tone. In addition, vascular endothelium also produces vasoregulators that act independently of cardiac metabolism to influence coronary blood flow. [109] Some of the mediators of vascular tone that have been proposed include adenosine, ATP, prostaglandins, nitric oxide, endothelin, oxygen, and K^+ . [110]

Adenosine was first proposed as a physiologic regulator of coronary blood flow approximately 60 years ago. [111] [112] Over the past quarter-century, many data support its role as the most important mediator coupling coronary blood flow with myocardial oxygen consumption. In fact, adenosine release has been postulated to be an indicator of an imbalance between oxygen supply and demand. [113] Production of adenosine in the heart has three sources: one coupled to the cytosolic phosphate potential as a representation of the cellular energy state and the other two independent of it. Within the cardiomyocyte, adenosine is generated by the dephosphorylation of AMP by the enzyme, 5
-nucleotidase. High levels of ATP increase the activity of this enzyme and result in an increase in production of adenosine. [114] [115] [116] Adenosine can then diffuse out of the cell and may cause an increase in coronary blood flow to match metabolic demands. Extracellular adenosine production occurs by the hydrolysis of interstitial AMP and interstitial *S*-adenosylhomocysteine. Adenosine receptors are found in both the smooth muscle and the endothelial cells of the coronary arteries. [117] [118] The exact mechanism of action of adenosine in producing coronary vasodilation is unknown; however, it is postulated that alpha $_2$ -adenosine receptors are coupled to adenylate cyclase and increase levels of cAMP, thereby promoting coronary relaxation. Meanwhile, others have postulated that the alpha $_1$ -adenosine receptors are linked to guanylate cyclase, and they produce coronary vasodilation by a mechanism similar to that of nitric oxide. [119] Prostaglandin E_1 , a potent coronary vasodilator, probably acts through adenosine to achieve its vasomotor activity. [120]

In 1987, a substance that was previously known as endothelium-derived relaxing factor was identified as nitric oxide. Production of this labile substance from vascular endothelium was first noted to be the mechanism by which acetylcholine elicited relaxation of the smooth muscle in blood vessels. Since then, nitric oxide has been the subject of numerous investigations because it is linked to many cellular functions. Nitric oxide activates guanylate cyclase, which, in turn, increases intracellular production of cGMP. Cyclic GMP is known to initiate a cascade of phosphorylation/dephosphorylation reactions, most notably the dephosphorylation of myosin light chains, resulting in smooth muscle relaxation. [121] Arteriolar vascular beds are more sensitive to the relaxant effects of nitric oxide than venous beds. [122] Thus, nitric oxide released from vascular endothelium plays an important role in overall vascular tone.

Endothelin is a vasoconstrictor that was first noted to be released from endothelial cells grown in culture. It is a 21-amino acid peptide containing 2 intrachain disulfide bridges. Endothelin receptors have been found in both cardiac and smooth muscle cells, as well as in endothelial cells. Ironically, binding of endothelin to its receptor

in vascular beds also triggers the production of nitric oxide and prostacyclin, so it appears that endothelin regulates vascular tone by both direct and indirect mechanisms. [123] [124] [125] Endothelin induces vasoconstriction via activation of phosphoinositide-selective phospholipase C. Activation of this enzyme in smooth muscle leads to the breakdown of inositol triphosphate, which causes the release of calcium from intracellular stores and generalized vasoconstriction. Another byproduct of inositol triphosphate turnover, diacylglycerol, stimulates protein kinase C, which phosphorylates numerous intracellular proteins and leads to vasoconstriction. [126]

Oxygen, and more specifically a mixed venous oxygen tension at a P_{O_2} threshold of 32 mm Hg, plays an important role in coronary autoregulation. [127] In fact, arteriolar resistance varies directly with tissue P_{O_2}. [109] The hypothesis is that ATP-sensitive K^+ channels present in vascular smooth muscle open in response to a reduction in ambient tissue oxygen levels. The resultant efflux of K^+ from vascular myocytes produces hyperpolarization of the cell membrane such that Ca^{2+} channels are less likely to open. The slow inward current is therefore reduced, and cytosolic Ca^{2+} levels are decreased, a process that promotes smooth muscle relaxation and an overall decrease in vascular resistance. Sulfonylureas, such as glibenclamide, block the opening of ATP-sensitive K^+ channels and virtually abolish the coronary vasodilation that normally results from hypoxia and ischemia. [128]

INTRODUCTION: LIVER BLOOD FLOW

Gross Anatomy and Vascular Supply

The liver lies in the right upper quadrant of the abdominal cavity and is attached to the diaphragm. It is the largest gland in the human body and weighs approximately 1.5 kg, which represents 2 percent of body weight in adults and almost 5 percent in neonates. The liver is also a vital blood reservoir by virtue of its large vascular capacity. Ordinarily, it contains 25 to 30 mL blood per 100 g tissue, which is 10 to 15 percent of total blood volume, [1] of which approximately 20 percent is in the arterial system, 10 percent is in the capillaries, and 70 percent is in the venous system. [2] In addition to serving as a reservoir, the venous bed plays a major role in fluid homeostasis. Small changes in hepatic venous pressure result in massive fluid transudation into the lymph and leakage into the outer surface of the capsule and into the peritoneal cavity. This fluid contains 80 to 90 percent of the protein concentration of normal plasma protein.

Under normal resting conditions in humans, total hepatic blood flow is 1,200 to 1,400 mL/min (~100 mL/min/100 g), which represents about 25 percent of cardiac output. Blood flow to the four lobes of the liver is derived from two major sources, the portal vein and the hepatic artery (Fig. 17-1) (Figure Not Available) . The hepatic artery is a branch of the celiac axis and accounts for 25 to 30 percent of total hepatic blood flow and 45 to 50 percent of the oxygen supply. The portal vein is a valveless afferent nutrient vessel of the liver that carries blood from the entire capillary system of the stomach, spleen, pancreas, and intestine. The portal vein supplies 70 to 75 percent of total hepatic blood flow but only 50 to 55 percent of the oxygen supply because this blood is partially deoxygenated in the preportal organs and tissues. The sinusoids are the hepatic capillaries formed by the merging of the hepatic arterial and the portal streams (Fig. 17-2) (Figure Not Available) . The sinusoids, which are lined by thin endothelial cells, large Kupffer cells, and fat-storing Ito cells, comprise the principal blood flow conduit in the liver parenchyma. [3] Fenestration of the endothelium facilitates passage of blood constituents into the space of Disse, whereby they gain access to the hepatic parenchymal cells. Blood flows along the sinusoids to the terminal hepatic venule (central vein) of the hepatic veins, which drain the liver and empty into the inferior vena cava. Three major hepatic veins (right, middle, and left) and numerous smaller branches empty into the inferior vena cava on the posterior surface of the liver.

Microcirculation of the Liver

Within the liver, the portal vein and hepatic artery give rise to progressively smaller intrahepatic branches and ultimately form terminal portal venules and hepatic arterioles. These terminal blood vessels supply a small, irregular cluster of parenchymal cells referred to as the *liver acinus.* This liver acinus is the functional microvascular unit of the liver and is formed about a vertical axis consisting of a terminal portal venule, a hepatic arteriole, a bile duct, lymph vessels, and nerves. The terminal portal venule and hepatic arteriole course along with a bile ductule and are jointly referred to as

Figure 17-1 (Figure Not Available) Schematic representation of splanchnic circulation. *(Modified from Gelman, [151] reproduced with permission of S. Karger AG, Basel)*

the *portal axis.* Blood enters the acinus at its center, flows outward, and empties either directly into the sinusoidal capillaries or through a complex peribiliary plexus (supplying the bile ducts), which subsequently drains into the sinusoids.

The parenchymal cells of the liver acinus can be subdivided into three circulatory zones (Fig. 17-3) (Figure Not Available) , based on orientation with regard to the afferent vessels (portal axis). Zone 1 encompasses the hepatocytes close to the portal axis and the origin of the sinusoid. These cells are bathed in blood that is rich in oxygen and nutrients. The cells in zone 3 are situated at the periphery of the acinus and receive blood that has already

exchanged gases and metabolites with cells in zones 1 and 2, zone 2 being the arbitrary intermediary transition zone. This unique microvascular arrangement results in metabolic heterogeneity from zone 1 to zone 3. The cells of zone 1 contain numerous mitochondria and are ideally suited

Figure 17-3 (Figure Not Available) The blood supply of the hepatic structural unit, which occupies adjacent sectors of neighboring hexagonal fields. Zones 1, 2, and 3 represent areas supplied with blood of first, second, and third quality, respectively, with regard to oxygen and nutrients. These zones cluster about the terminal afferent vascular twigs and extend into the periportal field from which these twigs originate. Zones 1
, 2
, and 3
designate corresponding areas in a portion of an adjacent structural unit. In zones 1 and 1
, the afferent vascular twigs empty into the sinusoids. The circles A, B, and C delimit concentric bands of the hepatic parenchyma arranged around a small portal field. PS, portal spaces; THV, terminal hepatic venule. *(From Rappaport et al [153])*

for oxidative metabolism and synthesis of glycogen. Zone 3 cells receive the blood with the lowest oxygen tension and are optimum for anaerobic metabolism. Biotransformation of the majority of drugs, chemicals, and toxins occurs in zone 3, owing to the abundance of smooth endoplasmic reticulum, reduced nicotinamide adenine dinucleotide phosphate, and cytochrome P-450. The cells of zone 3 are the most sensitive to damage from circulatory disturbances (ischemia, hypoxia, and congestion) and to injury by toxic byproducts of biotransformation. Consequently, drug biotransformation is compromised early in the ischemic process.

Measurement of Liver Blood Flow

The techniques for measurement of hepatic blood flow can be broadly divided into three categories: (1) methods based on the clearance of a substance from the circulation, (2) techniques based on indicator dilution methodology, and (3) miscellaneous measurement techniques.

Parenchymal Clearance Techniques

The unique capacity of the liver to remove substances from the circulation makes clearance techniques well suited for measurement of hepatic blood flow. Hepatic clearance is a measure of the overall efficiency of hepatic extraction and depends on blood flow as well as on the intrinsic ability of the liver to eliminate the compound. If a substance is cleared from the circulation exclusively by the liver, the indirect Fick principle can be used to derive total hepatic blood flow. Several substances with a high hepatic extraction ratio (e.g., propranolol, lidocaine, indocyanine green, and colloidal particles) have been used to estimate hepatic blood flow.

In spite of the high expense and limited stability, constant infusion of indocyanine green is regarded as the most reliable method. [4]

Reticuloendothelial Particle Clearance

Radiolabeled colloidal particles such as those of gold 198 are very efficiently phagocytosed by the reticuloendothelial cells in the liver; the area under the initial curve is used as a measure of blood flow, assuming a normally functioning reticuloendothelial system. [5]

Indicator Dilution Techniques

Indicator dilution methods for assessing hepatic blood flow have an advantage over clearance methods in that hepatic function is not a dependent variable. Radiolabeled marker substances, especially iodinated serum albumin, are injected intrasplenically; the flow through the liver is then estimated from indicator dilution curves obtained either by continuous sampling from one hepatic vein or by external gamma-scintillation counting. [6] This technique is valid when the marker substance is not metabolized by the liver and when there is uniform mixing. [6] [7]

Miscellaneous Techniques

Square-wave electromagnetic flow probes provide the most reliable direct method for the measurement of hepatic artery and portal vein blood flow. [8] This method does require invasive techniques for implantation that can perturb the system. However, once implanted, these probes can be left *in situ,* and measurements can then be made in the unanesthetized patient by telemetry.

Regulation of Liver Blood Flow

Intrinsic Regulation

Intrinsic regulation occurs by mechanisms that regulate blood flow independently of the influence of nerves and blood-borne vasoactive compounds. Three major mechanisms are primarily responsible for intrinsic regulation of hepatic blood flow: autoregulation, metabolic control, and the hepatic arterial buffer response.

Autoregulation

Autoregulation is due to the tendency for local blood flow to remain constant in spite of changes in arterial pressure. It is hypothesized that increased arterial perfusion pressure results in hepatic artery vasoconstriction, presumably because of a myogenic response of the arteriolar smooth muscle to stretch imposed by the increased perfusion pressure. Pressure-flow autoregulation in the hepatic arterial system exists to some extent in the metabolically active (postprandial) liver, but probably not in the unstimulated (fasted) liver. [9] [10] However, because surgery is most often performed when the patient is in the fasted state, it is likely that pressure-flow autoregulation does not exist to any great degree during anesthesia and surgery. There is no evidence of autoregulation in the portal venous system; instead of the nonlinear pressure-flow relationship associated with autoregulation, there exists a linear pressure-flow relationship. [11] Arterial or portal venous autoregulation is probably not a principal mechanism for control of hepatic blood flow.

Metabolic Control

Changes in the composition of the portal venous and systemic blood composition affect liver blood flow. These changes include arterial hypoxemia, [12] systemic hypercarbia, [13] and alkalosis. [14] Hepatic arterial blood flow is increased by decreased portal oxygen tension and pH. Postprandial hyperosmolarity increases both hepatic arterial and portal venous blood flow. [15]

Hepatic Arterial Buffer Response

Hepatic arterial buffer response is the phenomenon by which decreases in portal blood flow are associated with increased hepatic arterial blood flow. [16] This reciprocal relationship between the hepatic artery and portal vein tends to

maintain the constancy of the hepatic oxygen supply (which is essential for hepatocyte function) and of the total hepatic blood flow (which is essential for clearance of exogenous and endogenous substances). [16] Thus, when portal venous flow decreases, hepatic arterial resistance decreases and hepatic arterial flow increases, and vice versa. It has been suggested that washout of locally produced adenosine can account for the hepatic arterial buffer response. Other factors--neural, myogenic, and metabolic, as well as the oxygen content or pH of portal venous blood--may also significantly influence the buffer response. [17] In spite of significant increases in hepatic arterial blood flow, this compensatory mechanism is unable to compensate completely for a decrease in portal venous flow.

Extrinsic Regulation

Neural Control

Branches of the vagus, splanchnic, and sometimes phrenic nerves enter the liver mainly in association with the blood vessels and bile ducts. The sympathetic and parasympathetic nerves form an intercommunicating plexus, which terminates on arterioles and venules. Stimulation of the outflow of the sympathetic nervous system (e.g., hypercarbia, pain, hypoxia) reduces liver blood flow and blood volume abruptly, and 80 percent, or approximately 500 mL, of the hepatic blood can be expelled within a matter of seconds. [2] [18] The liver in this way represents a major reservoir of whole blood, which can be rapidly distributed in a precise and controlled manner in response to the activity of its autonomic innervation. Functional vagal innervation does exist in the dog and influences regional distribution within the liver by exerting effects on presinusoidal sphincters, [19] rather than by affecting total liver blood flow.

Humoral Factors

Of the systemic hormones, epinephrine is the most likely to attain vasoactive concentrations physiologically. Both alpha- and beta-adrenergic receptors are present in the hepatic arterial bed, whereas only alpha receptors exist in the portal vasculature. [20] Thus, epinephrine injected directly into the hepatic artery initially induces vasoconstriction via the alpha receptors, followed by vasodilation mediated by the beta receptors; the portal bed only vasoconstricts in response to intraportal epinephrine. Any action of dopamine on the liver circulation is of little physiologic significance, because any vascular effect it possesses alone would be overwhelmed by the concomitant presence of epinephrine, norepinephrine, and sympathetic activation. [20] [21] Glucagon causes a graded and long-lasting hepatic arterial vasodilation and can antagonize the hepatic arterial vasoconstrictor responses to a wide range of physiologic stimuli, including stress-induced sympathoadrenal outflow. [22] Angiotensin II evokes profound vasoconstriction of both hepatic arterial and portal beds, together with a significant reduction in mesenteric outflow, and this translates into a substantial reduction in total liver blood flow. [23] Vasopressin also induces marked splanchnic vasoconstriction; consequently, reduction in venous outflow into the portal system and a reduction in inflow resistance in the portal vasculature occurring after vasopressin administration make this hormone very effective in alleviating portal hypertension. [24]

Effects of Anesthesia on Liver Blood Flow

Apart from the specific effects of individual anesthetics on liver blood flow, ancillary influences, including surgery [25] and the mode of ventilation, need to be considered. During upper abdominal surgery, total hepatic blood flow can be decreased by up to 60 percent by surgery alone; this is considerably more than any alteration produced by anesthetics. When ventilation is controlled, portal venous blood flow decreases because of an increase in splanchnic vascular resistance with hypocarbia. [26] The application of positive endexpiratory pressure decreases hepatic blood flow even further by increasing hepatic venous pressure. [27]

All anesthetics and techniques that decrease cardiac output produce at least proportional decrements in total hepatic blood flow. In addition, some anesthetics have

more specific effects on hepatic blood flow that either mitigate or accentuate these changes. Halothane anesthesia usually decreases hepatic blood flow to a greater extent than other commonly used volatile anesthetics. [28] Isoflurane increases hepatic artery blood flow at both 1 and 2 minimum alveolar concentration (MAC), in contrast to halothane. [29] In 1988, Payen et al [30] reported the demonstration of isofluraneinduced increases in total hepatic blood flow in humans by a pulsed Doppler method.

Regional anesthesia may decrease hepatic blood flow. The extent to which subarachnoid block decreases hepatic blood flow depends on the level of the block; a T4 level of anesthesia results in a 20 percent reduction in liver blood flow, which closely parallels the decrease in systemic blood pressure. [31] The effects of induced hypotension on liver blood flow have also been examined. When the mean arterial blood pressure is decreased by 40 percent with a sodium nitroprusside infusion, there is no net change in liver blood flow, although there is an inversion in the contributions from the portal and hepatic vascular beds. [32] However, when more profound hypotension is induced, ischemic injury may ensue. [33] Although all forms of anesthesia decrease liver blood flow, oxygen requirements by the liver also decrease, so that anoxic metabolism does not routinely occur. [34] [35]

METABOLIC FUNCTION OF THE LIVER

Protein

The liver is the major site of amino acid metabolism, encompassing both the breakdown of amino acids to form substrates for the carbohydrate and fat metabolic pathways and the synthesis of a large number of biologically essential proteins.

Albumin, the major protein in human serum, accounts for 15 percent of the total hepatic protein synthesis. Albumin synthesis ranges from 120 to 300 mg/kg/dL. The higher figure is noted in the neonatal liver, and there is a progressive decline in synthesis rate with age. [36] Factors that regulate albumin

synthesis include dietary availability of amino acids, [37] hormonal balance, and plasma oncotic pressure. [38] Intravascular albumin accounts for about 40 percent of the exchangeable albumin pool, and in this location it exerts its principal function, maintenance of normal oncotic pressure. Various substances bind to albumin in the serum, a feature that makes albumin an important transport vehicle for drugs, hormones, metals, and metabolites. The half-life of albumin is approximately 20 days, so that a decrease in serum albumin is unlikely to occur within a short time of acute liver injury. In patients with ascites and chronic liver disease, the total exchangeable pool of albumin may be normal, but the serum level is often low. [39]

The vitamin K-dependent coagulation factors II, VII, IX, and X are synthesized in the liver, together with factors V, XI, XII, and XIII and fibrinogen, which are not dependent on vitamin K for synthesis. If the fat-soluble vitamin K is deficient, as in obstructive jaundice, or if it is antagonized by one of the coumarin anticoagulants, the coagulation factors are synthesized at the normal rate, but they lack the gamma-carboxylglutamic acid residues, which are attached in a post-translational event under the influence of vitamin K. The half-lives of the coagulation factors are relatively short; thus, abnormalities in coagulation quickly become apparent in acute liver damage. The actual level of clotting factors in the plasma represents a balance between synthesis and catabolism, and because the liver also synthesizes inhibitors of both coagulation and fibrinolysis, a combination of decreased synthesis and increased removal may arise in acute liver disease. Thus, prolongation of prothrombin time resulting from a deficiency of factors II, V, VII, and X is observed in parenchymal liver disease. When used as a liver function test, the prothrombin time has proved of some value in predicting the outcome of patients suffering from acute liver cell failure after hepatotoxin ingestion, [40] as well as that of patients with liver disease who are undergoing surgery. [41]

Ceruloplasmin, the copper-containing alpha-globulin, is synthesized in the liver. The plasma level is increased in biliary cirrhosis, Hodgkin's disease, pregnancy, and myocardial infarction, and as such it is considered an acute-phase reactant protein. [42]

Breakdown of amino acids by transamination and oxidative deamination leads to the formation of keto acids, ammonia, and glutamine within the liver. The Krebs-Henseleit urea cycle converts the ammonia and most of the other nitrogenous excretory products into urea. Both severe acute and chronic liver disease are characterized by a failure to synthesize urea, as a result of which its blood concentration is significantly reduced. There is also an excessive accumulation of ammonia, which in some way contributes to the encephalopathy often noted in hepatic failure. [43]

Carbohydrates

The liver is especially important for maintaining a normal blood glucose level in the circulation, especially after a carbohydrate meal, and also for releasing glucose into the blood stream during a diurnal fast or sustained exercise. [44] The rate of uptake or release of glucose by the liver is proportional to the degree of hypoglycemia or hyperglycemia, and thus the blood glucose concentration determines whether the liver is a glucose-producing or glucose-using organ.

The liver responds to conditioning of carbohydrate deprivation by increasing the rate of glucose production from endogenous sources. Liver glycogen is degraded to provide glucose, which is then released into the blood. Glycogen metabolism within the liver is regulated by two rate-limiting enzymes: (1) glycogen synthase, which synthesizes chains of glucose residues from uridine diphosphate (UDP)-glucose units, and (2) glycogen phosphorylase, which degrades glycogen, one glucose residue at a time, to glucose 1- phosphate. [45] Catecholamines probably stimulate the rate of gluconeogenesis via cyclic adenosine monophosphate (cAMP)-dependent (beta-mimetic) and cAMP-independent (alpha-mimetic) mechanisms. [46] Insulin antagonizes the action of both glucagon and catecholamines on hepatic gluconeogenesis. After glycogen stores in the liver have been exhausted by starvation (~24 h) or prolonged exercise, the only remaining endogenous source of glucose is by gluconeogenesis from lactate, glycerol, and certain amino acid (especially alanine and glutamine) precursors. The actions of glucagon and catecholamines on the gluconeogenic pathway are mediated by an increase in the cAMP concentration and therefore an increase in the activity of cAMP-dependent protein kinase. [47]

Fat

Lipid reaches the liver via the lymph and the blood in the form of chylomicrons, where it is broken down by stepwise degradation to acetylcoenzyme A (acetyl-CoA). This is a key molecule in a number of metabolic processes involving fat in the tricarboxylic acid cycle or the synthesis of triglyceride phospholipid, cholesterol, and lipoproteins. Glucose in excess of that needed to saturate hepatic glycogen stores, as well as other pathways, is converted very efficiently to fatty acids in the liver. The two pathways available for the metabolic disposal of fatty acids in the liver are esterification and oxidation. [48] Glucagon markedly stimulates the rate of fatty acid oxidation in liver, whereas insulin inhibits it. The beta oxidation of fatty acids proceeds to acetyl-CoA in the mitochondria, where the acetyl-CoA is further oxidized in the tricarboxylic acid cycle to carbon dioxide and water or is converted to ketone bodies. However, the liver lacks the enzyme required for oxidation of ketones, which is present in abundance in most other tissues. The amount of ketosis in the fasted state is self-limited, because ketones stimulate insulin secretion from the pancreas, [49] thereby limiting lipolysis in adipose tissue and thus the availability and oxidation of fatty acids in the liver. This fail-safe mechanism is obviously lacking in states of insulin deficiency and can result in diabetic ketoacidosis.

Fatty acids are esterified with glycerol in the liver to form triglycerides, which are then incorporated into lipoproteins, principally very-low-density lipoprotein (VLDL), that are secreted by the liver. The principal factor affecting VLDL production is the amount of free fatty acids reaching the liver. Secretion of VLDL is also stimulated by insulin [50] and estrogens. [51]

Bilirubin

About 300 mg bilirubin is formed daily, mostly from the destruction of senescent erythrocytes. The heme part of the myoglobin molecule is converted to bilirubin and is carried to the liver tightly bound to albumin. Within the liver cell, bilirubin is conjugated with glucuronic acid. Unlike unconjugated bilirubin, the conjugated form is nontoxic, and the pigment is now readily secreted by the liver into the bile and then into the alimentary tract. A small portion of the conjugated bilirubin formed by the hepatic cells returns to the plasma, either directly into the liver sinusoids or indirectly by absorption into the blood from the bile ducts or lymphatics. Appreciable amounts of conjugated bilirubins in plasma reflect defective hepatic secretion, which, in the presence of minor liver damage, may occur without increasing the plasma level of total bilirubins to more than 1 mg/dL. [52]

Effects of Anesthesia on Hepatic Metabolism

In response to fasting and surgical trauma, there is an increase in the circulating concentrations of catabolic hormones such as catecholamines, glucagon, and cortisol and a concomitant decrease in plasma concentrations of the anabolic hormones insulin and testosterone. These endocrine changes result in substrate mobilization and ultimately produce a catabolic state with negative nitrogen balance. Surgical trauma increases protein degradation and urea production and excretion and decreases protein synthesis. [53] The severity of these changes largely depends on the extent of the surgery and on the patient's initial status. [54] Hyperglycemia is ubiquitously associated with surgery, but whether this is due to increased hepatic glycogenolysis is in dispute. Hepatic fat metabolism is only slightly affected by surgery. Inasmuch as anesthetics can influence the release of these stress hormones (e.g., catecholamines, cortisol), hepatic metabolism will also be altered. If the afferent neurogenic impulses from the area of surgical trauma are blocked, these endocrine-metabolic responses can be attenuated, a change that results in improved nitrogen balance. This block can be most effectively accomplished with epidural analgesia, [55] with lesser effects noted with halothane, [56] enflurane, [57] morphine, [58] and either thiopental [59] or fentanyl [60] used to supplement nitrous oxide.

Few studies, most of which have used halothane, have examined the direct effects of anesthetics on intermediary metabolism. Halothane inhibits oxygen consumption of urea synthesis and gluconeogenesis in the isolated perfused liver. [61] Because the major pathways for clearing lactate from the plasma are also inhibited by halothane, there is an increase in lactate concentration above that normally observed after the addition of fructose to the medium of the isolated perfused liver. [62] The 1982 study of Rannels et al [63] revealed that exposure to halothane inhibits the peptide chain initiation step in protein synthesis within 15 minutes, whereas the process of protein secretion is unaffected. In isolated rat hepatocytes, clinically relevant concentrations of either halothane or enflurane (0.5-1.0 mmol/L), inhibited protein synthesis in a dose-dependent manner. [64]

BILE FORMATION

Bile eliminates many endogenous and exogenous substances from the liver while at the same time fulfilling an important function as a digestive fluid. [65] The bile is primarily formed by the hepatocyte (canalicular bile) and is then modified downstream in the ductules, ducts, and gallbladder mucosa by reabsorption and secretion of electrolytes and water. By this process, constituents such as bile salts, cholesterol, and phospholipids become highly concentrated in the gallbladder bile. Narcotics cause spasm in the sphincter of Oddi and an increase in pressure in the common bile duct. [66] This effect can be largely attenuated by halothane and, to a lesser extent, by enflurane, [67] as well as by nitroglycerin, naloxone, atropine, and glucagon. [68]

HEMATOLOGIC FUNCTION

Erythropoietic activity is largely confined to the liver from the 9th to the 24th week of gestation and continues to be an important site for hematopoiesis until approximately 2 months after birth. However, with the development of the bone marrow, recognizable hematopoietic cells completely disappear from the liver and only persist in the setting of congenital hemolytic anemias. Those cells may reappear in response to bone marrow failure or in the presence of myeloproliferative disorders. Heme is synthesized predominantly in the bone marrow and the liver by way of porphyrin metabolites. Patients with acute hepatic porphyrias have a defect in hepatic heme synthesis and may have their illness exacerbated by many anesthetics, including barbiturates, benzodiazepines, ketamine, pentazocine, and halothane. [69]

HUMORAL FUNCTION

The liver plays a vital role in the biotransformation of many hormones; for example, 50 percent of insulin secreted by the pancreas is degraded by the liver in a single passage and does not reach the systemic circulation. [70] Thyroxine (T_4), the major secretory product of the thyroid gland, is actively taken up by the liver, where it is converted to triiodothyronine (T_3) and can also be inactivated. In addition, the liver synthesizes the plasma proteins that bind the thyroid hormones. Thus, the liver can influence the distribution of the thyroid hormones between the intracellular and extracellular compartments. Aldosterone, estrogens, androgens, and antidiuretic hormone are all inactivated by the liver; thus, liver disease results in profound endocrine abnormalities.

IMMUNOLOGIC FUNCTION

The liver is the largest organ in the reticuloendothelial system; as much as 10 percent of its weight is derived from the Kupffer cell mass. Teleologically, the importance of this system relates to its ability to phagocytose antigens absorbed from the gastrointestinal tract, thus acting as a filter for the systemic circulation.

DRUG BIOTRANSFORMATION

Most xenobiotics contain lipophilic functional groups to facilitate penetration of membrane barriers, thereby expediting intestinal absorption. Excretion of these compounds would occur slowly, owing to a high degree of protein binding and renal tubular reabsorption. Thus, a function of drug biotransformation is to render molecules more polar so that the products can be efficiently eliminated. Drug metabolism is primarily a hepatic event, although it also occurs in the kidney and, to a lesser extent, in the intestine, lung, and skin. By converting lipophilic substances to excretable metabolites, hepatic enzymes detoxify drugs by terminating their pharmacologic activity. Unfortunately, reactive intermediates, which themselves are responsible for some toxic effects, may be formed during metabolism.

Enzymatic Reactions

The enzymatic reactions involved in hepatic drug metabolism may be divided into functionalization reactions (phase 1) and conjugation or synthetic reactions (phase 2). Phase 1 reactions often generate reactive species because they introduce carboxyl, epoxide, or hydroxyl groups into the parent compound. In phase 2 reactions, catalyzed by transferase enzymes, the chemical groups generated by phase 1 reactions serve as receptors for polar substances such as acetate, amino acid, sulfate, glucuronic acid, and glutathione. [71] The products of phase 2 reactions are usually less toxic and less biologically active than those of the parent compound. Furthermore, the water solubility of the phase 2 product is enhanced beyond that achieved by phase 1 reactions alone.

Phase 1 Reactions

Oxidation is the most common form of drug biotransformation, accounting for more than 90 percent of all reactions. It is catalyzed by the cytochrome P-450 system and, to a lesser extent, by the mixed-function oxidases. Many of the reductive pathways in the liver are catalyzed by cytochrome P-450. [72]

Phase 2 Reactions

Frequently, the final step in the metabolism of a foreign compound involves conjugation with a water-soluble metabolite. The most common conjugate encountered is the glucuronic acid adduct catalyzed by UDP-glucuronyl transferase, which is localized to the endoplasmic reticulum. Glutathione, a cysteine-containing tripeptide, is conjugated to xenobiotics by its free thiol group. Under adverse conditions (e.g., starvation), the available glutathione substrate may be rapidly depleted, so that potentially toxic compounds accumulate. Administration of cysteamine (mercaptoethylamine) or *N*-acetylcysteine (glutathione precursors) enhances the rate of synthesis of glutathione and is effective in combating the toxicity of certain electrophilic compounds.

Factors Affecting Hepatic Drug Metabolism

Perfusion models of hepatic drug elimination address the important determinants of hepatic drug disposition, such as hepatic blood flow, intrinsic hepatic clearance, and protein binding [73] [74] ; however, these models weight the importance of a specific variable, depending on whether the drug is efficiently or poorly extracted by the liver. Thus, elimination of a drug that has a high extraction ratio is influenced more directly by changes in hepatic blood flow than by changes in intrinsic hepatic clearance or protein binding. Whereas elimination may not be affected by changes in protein binding, changes in protein binding of highly extracted drugs may alter their pharmacologic effect. The disposition of poorly extracted drugs is more sensitive to changes in the intrinsic ability of the liver to eliminate a drug and in binding of the drug to blood constituents than it is to hepatic blood flow. Table 17-1 (Table Not Available) presents a compilation of frequently employed drugs with high and low extraction ratios. [75]

More than 300 compounds, including drugs, insecticides, organic solvents, carcinogens, and other environmental contaminants, are known to stimulate some type of microsomal xenobiotic-metabolizing activity. [76] These enzyme-inducing compounds result in an increase in the cellular amount of RNA coding for the appropriate enzyme in the cell. Clinical effects of enzyme induction only become apparent when the rate-controlling step in detoxification or elimination is affected. However, induction may have major effects in enhancing the metabolism of xenobiotics to toxic intermediates. For example, isoniazid enhances defluorination of enflurane, thereby increasing the risk of fluoride nephrotoxicity. The rate and manner in which an individual substance affects drug metabolism are determined in part by genetic factors, [77] but these factors are rarely apparent unless they result in toxicity.

Delayed development of xenobiotic metabolism in fetal liver, which extends into the newborn period, has a protective role. Polar compounds that would otherwise be formed by xenobiotic metabolic reactions in the liver would accumulate

TABLE 17-1 -- Drugs that Are Efficiently and Poorly Extracted from the Blood by the Liver

(Not Available)

Modified from Williams and Benet [75]

in the fetus because of lack of transfer across the fetoplacental barrier. The cytochrome P-450 content in the liver of newborns is only 28 percent of what is normally present. Phase 2 reaction rates are exceedingly slow, as reflected by the development of neonatal hyperbilirubinemia because of delayed development of bilirubin-UDP-glucuronyltransferase. At the other end of the life cycle, there appear to be decreased metabolic rates for meperidine [78] and amylobarbital. [79] More often, increased plasma half-lives of drugs in geriatric patients are due to changes in drug distribution rather than in metabolism. [80]

Certain factors in the perioperative period are known to decrease hepatic drug-metabolizing activity, including inflammation, [81] fever, [82] and the infusion of nitrogen-free [83] and nitrogen-rich [84] solutions.

Effects of Anesthesia on Drug Metabolism

Ketamine is capable of inducing its own metabolism, a feature that may account for the rapid development of tolerance to this agent. [85] Diazepam has been reported to both increase and decrease its own metabolism. [86]

Anesthetics capable of decreasing hepatic blood flow influence the clearance of perfusion-dependent drugs with high extraction ratios. More important, the volatile anesthetics, especially halothane, inhibit drug biotransformation by direct effects on the cytochrome P-450 and glucuronyltransferase systems. Halothane impairs the metabolism of phenytoin, [87] warfarin, [88] and ketamine. [89] Halothane also decreases the metabolism of enflurane in rats, possibly by competing for the same

drug-metabolizing sites on microsomal enzymes. [90] Fentanyl clearance is also decreased by concomitant halothane administration, possibly by the effect of halothane on hepatic blood flow. [91] Similar findings have been noted with verapamil [92] and propranolol clearance during halothane anesthesia. [93] In isolated rat hepatocytes, both halothane and enflurane were found to inhibit the metabolism of acetaminophen, antipyrine, and sulfanilamide in a dose-dependent manner over a clinically relevant range. [64] However, in a study involving long-term exposure of human patients to trace anesthetic concentrations of halothane, Duvaldestin et al [94] demonstrated a 29 percent increase in antipyrine metabolism, which is highly suggestive of enzyme induction. Subsequent observations suggest that the cytochrome c reductase activity is most likely to be altered by chronic low-level exposure. [95]

EVALUATION OF LIVER FUNCTION

Clinical Evaluation

The clinical evaluation of the liver and biliary tract should include a complete history and physical examination with appropriate laboratory tests to identify subclinical abnormalities and to define the disease process at a higher level of resolution. Particular attention in the history should be devoted to information regarding drug and alcohol intake; exposure to chemicals and/or toxic agents; receipt of injections and transfusions; family history of liver or biliary tract disease; itch, jaundice, abnormal pain, and indigestion; and alteration in stool or urine color. Physical examination should concentrate on establishing the size and texture of the liver and spleen and on detecting jaundice, ascites, collateral portal circulation, spider angiomas, hepatic encephalopathy, and fetor hepaticus.

Laboratory Tests

Hepatic function is extremely complex; therefore, there are a number of different biochemical tests that can be used to evaluate hepatic function. Generally speaking, some tests characterize hepatic function, some characterize liver damage, and some deal with specific markers of hepatic disease (Table 17-2) (Table Not Available) .

Aminotransferases

Elevated plasma levels of intracellular enzymes, such as aspartate aminotransferase (AST) and alanine aminotransferase (ALT), are suggestive of hepatocellular damage. The highest ALT levels are in the liver, whereas AST levels are similar in liver, heart, and skeletal muscles. [96] [97] However, some organs other than liver, for example, heart, skeletal muscle, adipose tissue, brain, and kidney, contain aminotransferases, and this lack of tissue specificity limits the clinical usefulness of these enzymes as indicators of hepatic injury.

TABLE 17-2 -- Blood Tests and the Differential Diagnosis of Hepatic Dysfunction

(Not Available)

From Gelman [68]

Acute liver necrosis is accompanied by markedly elevated AST and ALT with the degree of the elevation reflecting the acuteness and severity of the injury but not necessarily hepatic function or prognosis. Marked elevations of AST and ALT are better indicators of acute injury than in chronic conditions, in which aminotransferase activity may be normal. Liver-specific enzymes, such as ornithine carbamoyl transferase and alcohol dehydrogenase, [96] [97] [98] have been used experimentally but are not yet widely available for clinical application. Although serum AST and ALT levels are valuable in the diagnosis of liver disease, they are best used in conjunction with other enzyme assays (e.g., LDH, CK) and measures of hepatic and renal function (e.g., blood urea, creatinine, ammonia, and bilirubin).

Alkaline Phosphatase

Alkaline phosphatase (AP) is actually a group of as many as 11 isoenzymes that are typically membrane-associated and have been identified in most body tissues. [96] [97] The activity of AP is greatest in the liver, bone, intestine, kidney, and placenta. Measurement of AP is useful in diagnosis of hepatobiliary disease, including acute hepatitis, cholestatic disease, and hepatomas. The activity of AP is markedly elevated by extrahepatobiliary obstruction (e.g., cholelithiasis or gallstones) and, to a lesser extent, by intrahepatic biliary obstruction. Liver disease that results in parenchymal cell necrosis does not typically elevate AP unless there is associated damage to the canaliculi or biliary stasis. Interpretation of serum AP can be complicated by nonhepatic elevations in AP associated with bone disease (e.g., Paget's disease, ricketts, and osteomalacia), rapid bone growth during puberty, and release from the placenta during the third trimester of pregnancy (see Table 17-2) (Table Not Available) .

Serum Albumin and Coagulation Factors

Serum albumin is a fairly good indicator of hepatocyte function, but abnormal distribution, changes in plasma volume, and alterations in albumin degradation may also contribute to hypoalbuminemia in liver disease. Serum albumin concentration is a more useful index of the severity of cellular dysfunction in chronic liver disease, because the plasma half-life is approximately 20 days, and changes in synthesis are detectable only after an appreciable time lag. The half-lives of the liver-derived coagulation factors, unlike that of albumin, are very short, ranging from 4 days for fibrinogen to a few hours for factor VII. Therefore, a decrease in hepatic synthesis of coagulation factors is quickly reflected in decreased plasma concentrations. The best estimate of hepatic function is provided by estimation of prothrombin time. Abnormalities of the prothrombin time indicate impaired hepatic synthesis of some or all of the clotting factors I, II, V, VII, and X. Failure to correct this abnormality readily by administration of vitamin K indicates that severe hepatocellular disease is present and that the impaired absorption of the fat-soluble vitamin from the gastrointestinal tract may be only partially responsible for the clotting abnormality. In acute liver failure, prothrombin time correlates with the degree of encephalopathy. Dye removal tests with Bromsulphalein, indocyanine green, or rose bengal have also been used to test hepatic function. Systemic retention of dye will occur if blood flow, uptake, intracellular binding, metabolic transformation, or biliary excretion is disordered. For quantitative assessment of specific functions of the hepatocyte, more complicated techniques can be employed, including galactose elimination and bile acid disappearance tests.

Serum Bilirubin

The functional status of the excretory apparatus of the liver is best assessed by measuring the bilirubin in the serum, which in the majority of the normal population does not exceed 1 mg/dL. However, as many as 10 percent of otherwise healthy persons have mildly elevated values for serum total bilirubin that are entirely accounted for by an increase in unconjugated bilirubin. These persons may have Gilbert syndrome (benign unconjugated hyperbilirubinemia) and probably represent the lowermost pole of the normal distribution of hepatic bilirubin UDP-glucuronyltransferase in the population. When the serum bilirubin level is higher than 4 mg/dL, this abnormality may be detected clinically as a yellow discoloration of body tissues, which is best appreciated in the sclerae by use of natural light. Conjugated bilirubin in serum indicates dysfunction of either the liver parenchyma or the bile ducts. Even in unconjugated hyperbilirubinemia from acute hemolysis, there may be an increase in the conjugated fraction. An increase in urine bilirubin indicates the presence of conjugated bilirubin in the serum, because unconjugated bilirubin is not excreted by the kidney.

Transport Function

Disturbances in the transport function of the hepatocyte, particularly with regard to the excretion of conjugated bile acids or mechanical obstruction of the biliary tree,

cause increased amounts of AP to enter plasma. Because the placenta, bone, and intestines also contribute to AP activity in the plasma, it is important to identify the tissue of origin when increased concentrations occur. Procedures available to differentiate the sources of the increased enzyme include simultaneous determination of 5
-nucleotidase or leucine aminopeptidase and/or gamma-glutamyl transpeptidase. Even though 5
-nucleotides can also be found in other tissues such as the placenta, bone, and the aorta, the activity of these substances in the serum does not rise during normal pregnancy, during the period of normal bone growth, or in diseases of the bone. In known hepatobiliary diseases, elevations in AP and 5
-nucleotidase tend to parallel each other, and for these reasons estimates of 5
-nucleotidase concentrations in serum are most useful in distinguishing between hepatic and nonhepatic causes of increased AP activity.

Radiologic Techniques

Radiologic techniques for demonstrating the biliary tract include percutaneous and endoscopic cholangiography. Percutaneous

transhepatic cholangiography is especially of value when dilated bile ducts are present. Endoscopic cholangiography is useful in localizing the site of biliary tract disease before surgery. Furthermore, papillotomy via the endoscope can obviate the need for surgical treatment of common bile duct stones. Esophagogastroscopy is a reliable and simple method for detecting submucosal varices in the upper digestive tract. Hepatic venous pressure measurements are useful in defining the level of block in patients with portal hypertension, whereas splenoportography delineates the splenic and portal veins. Radionuclide and ultrasonic scanning are useful for detecting space-occupying lesions of the hepatobiliary system. For evaluation of the immunologic status of the patient with suspected liver disease, the presence of high serum gamma-globulin levels is a strong indicator of significant chronic liver disease.

Antinuclear Antibody

Antinuclear antibody is present in 75 percent of patients with chronic active hepatitis, and the antimitochondrial antibody is present in nearly all patients with primary biliary cirrhosis. Alpha-fetoprotein is a marker of primary liver cell cancer. Infection with the virus of type A or B hepatitis is associated with the appearance of specific antigens and antibodies in serum.

PATHOPHYSIOLOGY OF LIVER DISEASE

Mechanisms of Hepatocellular Injury

Death of hepatic parenchymal cells, or hepatocytes, is common to virtually all hepatic diseases, but the mechanisms responsible for the cell death are poorly understood. Hepatocellular degeneration and mechanisms of cell death and target structures are discussed in detail in the literature. [99] [100] [101]

Cholestatic Injury

Cholestasis is an (intrahepatic) impairment in the secretion of bile or an (extrahepatic) impairment of the flow of bile from the liver to the intestine. Characteristically, substances that are normally secreted into bile, such as bile acids, cholesterol, and bilirubin, are increased in the serum. [67] Enzymes and proteins normally found in bile--AP, gamma-glutamyltranspeptidase, 5
-nucleotidase, leucine aminopeptidase, and immunoglobulin A--are also generally increased in the serum. [102] Bilirubin is probably the most toxic of the bile constituents and interferes with many enzyme systems, including those of respiration and oxidative phosphorylation, with glycogenesis, and with the tricarboxylic acid cycle. Bilirubin also interferes with heme biosynthesis and lipid, amino acid, and protein metabolism. At high concentrations, bilirubin may also interfere with membrane function. [67]

Hypoxia/Ischemia

Hypoxic injury is a consequence of circulatory disorders in which the oxygen supply to the tissue is compromised. Hypoxia is one of the most frequent causes of cellular apoptosis and necrosis in human disease. The effects of hypoxia on the liver have been studied in experimental animals, in which the duration and severity of the oxygen deprivation can be controlled. In these studies, hypoxia has been associated with decreased adenosine triphosphate, which stimulates glycolysis, depletes glycogen stores, and leads to accumulation of lactate and a consequent decrease in intracellular pH. The loss of high-energy phosphates also leads to decreased protein synthesis and interference with the ion pumps responsible for maintaining potassium and sodium homeostasis. The end result is cellular swelling and a loss in plasma membrane integrity, which facilitates release of intracellular hepatic enzymes into plasma.

Although most normal cellular aerobic metabolism results in tetravalent reduction to water, a small percentage of oxygen is univalently or divalently reduced to oxygen and hydrogen peroxide. [103] Endogenous antioxidant enzymatic defenses and expendable soluble or lipophilic scavengers typically maintain intracellular concentrations of oxidants in the nanomolar range. [104] However, hepatic ischemia results in a pathologic condition in which tissue antioxidant defense capabilities can become overwhelmed and essential biochemical processes are impaired. There has been a surge of interest in the effects of ischemia or hypoxemia that has focused on minimizing the hepatic damage associated with preservation and transplantation. The preservation and reperfusion damage are blamed for the primary nonfunction of transplants and the relatively high rate of complications and rejections. [105] There is accumulating evidence that reactive oxygen and nitrogen species play a significant role in postreperfusion injury in transplanted organs. Indirect evidence for oxidants in preservation injury has been provided by the observation that lipid peroxides are elevated in plasma of human patients following liver transplantation and that alpha-tocopherol levels were inversely related to oxidant production. [106] The appearance of an oxidation product of uric acid (allantoin) provides additional indirect evidence for involvement of oxidants following human liver transplantation. [107] [108] Humans lack the enzyme responsible for conversion of uric acid to allantoin. Therefore, detection of allantoin in plasma suggests that its formation was due to reactive oxidants and provides strong evidence for the production of reactive oxygen species during transplantation of the human liver. Electron paramagnetic resonance spin trapping has been utilized to demonstrate that storage of livers in hypothermic preservation solution results in formation of both carbon- and oxygen-centered radical adducts, [109] providing direct evidence for oxidants in perfusion and transplantation. Radical adducts increased three to four times following liver transplantation, a finding indicative of enhanced rates of oxidant formation. Electron paramagnetic resonance evidence of free radical formation has also been observed in Kupffer cells following preservation and transplantation. [110] Reactive nitrogen species also appear to play a role in graft dysfunction following preservation and transplantation because the plasma concentration of nitrogen oxides

increases with allograft rejection [111] and correlates with allograft cellular response in recipients. It has been suggested that excess production of oxidants coupled with depletion of endogenous tissue antioxidants renders the preserved liver susceptible to the reactive oxygen metabolites formed on reperfusion of the preserved liver. [112] [113]

Although reactive oxygen metabolites can arise from a number of sources, the enzyme xanthine oxidase (XO) has frequently been implicated as a significant intracellular source of toxic oxygen radicals. Much of the evidence for involvement of XO in ischemia-reperfusion is based on the protective effects of allopurinol, an XO inhibitor. [112] [114] The significant improvement of the quality of livers preserved in University of Wisconsin solution has been attributed to the inclusion of antioxidants and allopurinol. [114] [115] [116] Although there is considerable evidence that XO is a significant intracellular source of oxidant stress, there is accumulating evidence that it can also exert oxidant stress to remote tissues (e.g., lung and heart) via extracellular routes following release of XO into the circulation. Human liver and intestine contain the greatest specific activity of XDH+XO. [98] Immunolocalization studies have demonstrated that XO is predominantly in hepatocytes, endothelial cells, and Kupffer cells (Parks, unpublished data).

Hepatocellular damage resulting from hepatic ischemia, acute hepatitis, or cholecystitis has been associated with increased concentrations of circulating XO, along with other hepatocellular enzymes. [117] [118] We have provided evidence that human liver releases significant amounts of XO into the systemic circulation on reperfusion. [119] In animal models, we have demonstrated that, following liver transplantation, XO staining was intense in pericentral hepatocytes, intermediate in midzonal regions, and lowest adjacent to portal vein and to a lesser extent in Kupffer cells. The regions of highest XO/AO staining correspond to those regions in which ischemia and hypoxia would be most severe, because oxygen is extracted as blood flows from the portal triads (zone 1) to central vein branches (zone 3). Circulating XO can bind and concentrate on vascular endothelial cell surfaces, [98] [120] [121] [122] and it may involve tissues with low endogenous XO (e.g., heart and lung). The binding of circulating XO to endothelium and the subsequent generation of vascular cell-derived oxygen may react with nitric oxide (NO) to produce peroxy-nitrite ($ONOO^-$) and may result in extrahepatic tissue damage.

Free Radicals and Lipid Peroxidation

Free radicals can also be formed by the oxidation of organic molecules. It is well established that carbon tetrachloride forms the highly reactive trichloromethyl radical. The toxicity of nitrofurantoin, paraquat, and other aromatic compounds may also involve production of free radicals. One of the proposed mechanisms for halothane toxicity involves formation of reactive oxygen species. It is also possible that certain compounds could deplete essential antioxidants and thereby render the hepatocyte susceptible to oxidant stress. Such is the case in the depletion of reduced glutathione by acetaminophen and bromobenzene. [123] [124]

Bacterial, Viral, and Immunologic Injury

Bacterial products such as endotoxin can produce degeneration and subsequent death of hepatocytes. Endotoxins are lipopolysaccharides consisting of a hydrophilic carbohydrate portion, a bacterial strain-specific oxygen chain, a less variable core, and a common lipid A. [99] The lipid portion is responsible for the biologic reactions common to endotoxins and for the binding to high-density lipoproteins in blood and cells. In the liver, binding of endotoxin is greater for Kupffer cells than for the hepatocyte. Although the binding of endotoxin to the hepatocyte may produce some direct toxicity, the stimulation of Kupffer cells to produce eicosanoids and other cytotoxic mediators may lead to cholestasis and to hepatocellular injury. Viruses can also elicit hepatocellular injury, which can be direct or, more likely, indirect through the production of cytokines, resulting in lymphocyte- or macrophage-dependent cytotoxicity. The best examples are the hepatitis viruses and certain herpesviruses. Liver membrane antigens may be the target of cell-mediated injury because antibodies to these antigens are typically found in autoimmune hepatitis and primary biliary cirrhosis. [125] Other potential membrane antigens for cell-mediated cytotoxicity include liver-specific lipoproteins and hepatic lectin, antigens to which hepatitis B and other liver diseases may be directed. [99]

Alcohol

Hepatic dysfunction is the primary manifestation of long-term chronic ethanol consumption, but there are also strong links between alcohol consumption and cardiovascular effects, such as cardiomyopathies, arrhythmias, coronary heart disease, stroke, hypertension, and respiratory distress syndrome. [126] [127] Damage to liver and other tissues associated with chronic ethanol consumption has been attributed to (1) acetaldehyde-associated toxicities, (2) altered metabolism and relative hypoxia at a microvascular level, (3) formation of reactive oxygen and nitrogen species, (4) depletion in antioxidant defenses, and (5) formation of protein adducts with consequent alterations in function and structure.

The major pathway for ethanol metabolism involves alcohol dehydrogenase (ADH), a zinc metalloenzyme, with at least five molecular isoforms. [110] [128] Various tissues contain ADH isozymes; however, extrahepatic metabolism accounts for less than 5 percent of total ethanol metabolism. [128] Once in the liver, ethanol is metabolized by the (1) cytoplasmic ADH pathway, (2) microsomal ethanol oxidizing system in the endoplasmic reticulum, and (3) catalase located in the peroxisomes, [128] to result in formation of acetaldehyde. Acetaldehyde is then oxidized to acetate in hepatic mitochondria, but long-term ethanol consumption diminishes the ability of mitochondria to remove acetaldehyde, thus allowing tissue and plasma levels to increase. [130] Acetaldehyde may form adducts with proteins that impair normal function. [130] Acetaldehyde may also induce chemotactic substances (e.g., leukotriene B_4), which attract cytotoxic neutrophils to the hepatic parenchyma. [131] In addition, acetaldehyde can alter the hepatocellular plasma membrane, [132]

---

increase formation of superoxide, a cytotoxic reactive oxygen species, [133] and directly bind to the antioxidant glutathione, thereby reducing hepatic antioxidant levels. [134]

Ethanol administration has a profound "hypermetabolic" effect on liver that results in a marked increase in hepatic oxygen consumption. The resulting hypoxia, especially around the perivenular region (zone 3) where alcohol dehydrogenase activity is concentrated, could ultimately contribute to liver damage. [110] [128] This "ischemic" component could explain many of the similarities between ethanol-induced and ischemia-induced liver injury. In fact, it is suggested that the increase in nitric oxide (·NO) production associated with ethanol administration may be a compensatory mechanism to counteract ethanol-induced vasoconstriction of the hepatic microcirculation, [135] [136] and it may involve induction of nitric oxide synthase. It is postulated that the hepatic hypoxia is responsible for the release of proinflammatory cytokines, tumor necrosis factor, and interleukins 1 and 6, which are elevated in alcoholic liver disease. [106] [109] The proinflammatory mediators may increase expression of adhesion molecules, decrease leukocyte velocity, increase margination and platelet adherence, and reduce hepatic blood flow. [137] Complement may also be activated, further amplifying the inflammatory process. [138] This inflammatory cascade could be responsible for the pulmonary and cardiac injury associated with hepatoenteric ischemia-reperfusion, [103] [104] [106] and ultimately could result in chronic manifestations.

Chronic ethanol consumption results in a pathologic condition in which oxidant production is increased while essential tissue antioxidant defenses are diminished; consequently, essential biochemical processes become impaired. [139] Chronic ethanol administration may (1) increase $O_2^{\cdot -}$ production by the microsomal ethanol oxidizing system, (2) increase $O_2^{\cdot -}$ production by cytosolic oxidases (aldehyde oxidase, xanthine oxidase), and (3) activate inflammatory cells, such as Kupffer cells. [140] The ethanolinduced increase in oxidant production has been demonstrated indirectly by increased lipid peroxidation [129] [141] and directly by electron spin resonance. [142] Production of ·NO is also increased by chronic ethanol administration and presumably reflects increased iNOS activity in hepatocytes,macrophages (including Kupffer cells), vascular endothelial cells, and vascular smooth muscle. [143] The ·NO can react with $O_2^{\cdot -}$ to form peroxynitrite ($ONOO^-$), which also exhibits toxicity, including oxidation and nitration of lipids and proteins and oxidation of sulfhydryl groups. [144] [145] [146]

Essential tissue and plasma antioxidants are depleted on long-term exposure to ethanol administration, partially because of malnutrition, but also through interaction with oxidants. [139] [147] [147] Oxygen radical-mediated ethanol toxicity may be accentuated by the reduction of glutathione or hepatic alpha-tocopherol levels by long-term ethanol consumption. [129] [148] [149] Furthermore, the gene expression of antioxidant-producing enzymes [150] is modulated by long-term ethanol administration and may influence whether oxidant-induced tissue damage is manifested.

Chronic Liver Diseases

Although the previous discussion focuses on acute hepatocellular injury, almost all the mechanisms discussed can also result in chronic liver dysfunction. In chronic injury, the injury process has been modified by adaptive changes in spite of the continuation of the noxious stimulus. Microsomal, mitochondrial, and even antioxidant enzymes may be induced. Other adaptive changes include lysosome alterations, cellular hypertrophy, fatty acid metamorphosis, changes in transcription and translation, and altered transport and storage function. [99] The failure of adaptive changes to compensate for the injury ultimately leads to fibroplasia, which encircles hepatocytes, and to cirrhosis, which interferes with parenchymal perfusion and leads to loss of hepatic function. Acute and chronic diseases of the liver can be silent (subclinical) or clinically overt. Subclinical disease is usually detected when abnormal biochemical test results are reported during routine screening procedures. Clinically overt disease, regardless of origin, is typically characterized by portal hypertension, jaundice, variceal bleeding, ascites, hepatorenal syndrome, and portosystemic encephalopathy.

Chapter 18 - Renal Physiology

Robert N. Sladen

INTRODUCTION

The kidneys contain approximately 2 ×10^6 nephrons, each of which consists of a glomerulus and a tubule, which empties into a collecting duct. Urine is formed by the combination of glomerular ultrafiltration and tubular reabsorption and secretion. These functional units collectively enable the kidneys to maintain a remarkably stable interior milieu despite large fluctuations in fluid and solute intake. Together they regulate intravascular volume, osmolality, and acid-base and electrolyte balance and excrete end products of metabolism and drugs. The nephron also elaborates hormones that contribute to fluid homeostasis (renin, prostaglandins, kinins), bone metabolism (1,25-dihydroxycholecalciferol) and hematopoiesis (erythropoietin). The function of the nephron is closely integrated with the vascular supply of the kidney (Fig. 18-1) (Figure Not Available) .

The Glomerulus (Renal Corpuscle)

The glomerulus consists of five distinct components: capillary endothelium, glomerular basement membrane, visceral epithelium, parietal epithelium, and mesangium. [1] [2] The afferent arteriole supplies a highly convoluted tuft of capillary loops, which subsequently drains into the efferent arteriole (Fig. 18-2) (Figure Not Available) . The capillary endothelium is fenestrated with pores about 70 to 100 nm in diameter. It lies on the glomerular basement membrane, which consists of a thick lamina densa sandwiched between two thin laminae rarae, externa and interna, with a total cross-section of about 350 nm. The blind epithelial sac of the renal tubule is invaginated around the capillary tuft as the Bowman capsule. The visceral layer, which is applied to the basement membrane, consists of podocytes with filamentous, interdigitating foot processes, which contain actin and abut the basement membrane. The gaps between the foot processes (filtration slits, about 25-60 nm) are bridged by a membrane, or slit diaphragm, whose size and permeability may be altered by contraction of the foot processes. The visceral layer is reflected back at the vascular pole of the glomerulus to form the parietal squamous epithelium of the Bowman capsule. The Bowman space, between the visceral and parietal layers of the capsule, becomes the lumen of the proximal tubule at the urinary pole of the glomerulus, and the parietal endothelium merges with the cuboidal cells of the proximal tubule. The central mesangial cells are specialized pericytes with numerous functions, including structural support, matrix elaboration, and phagocytosis. They contain myofilament-like threads consisting of actin and myosin, which contract in response to a number of vasoactive substances, especially angiotensin II, and restrict blood flow to fewer capillary loops. The mesangial cells thereby regulate the effective surface area for filtration and, as a consequence, glomerular permeability. [3]

Formation of the Glomerular Ultrafiltrate

To cross from the plasma to the tubular fluid, a molecule must pass in succession through the fenestrated capillary endothelium, the glomerular basement membrane, and the epithelial slit diaphragm. The capillary endothelium restricts the passage of cells only, but the basement membrane filters plasma proteins. All three layers contain negatively

Figure 18-1 (Figure Not Available) Anatomic relationships of the nephron and the renal vasculature. The left side of the diagram represents the renal vasculature as distributed through the inner medulla, outer medulla, and cortex. Arteries are drawn as solid lines, veins as hollow tubes. The renal artery divides serially into interlobar arteries (1), arcuate arteries (2), and interlobular arteries (3). The afferent arterioles (5) branch off laterally and provide the capillary tufts of the renal glomeruli in the outer cortex (7a), whose efferent arterioles (6) supply the cortical capillary network (not shown). In the juxtamedullary zone (7b), the efferent arterioles become the vasa recta, which are closely applied to the long loops of Henle (8, 8a, 9). The venous drainage consists of stellate veins (4), interlobular veins (3a), arcuate veins (2a), and interlobar veins (1a). The right side of the diagram represents two nephrons. On the left is the more numerous superficial cortical nephron with a short loop of Henle. On the right is the juxtamedullary nephron with a long loop of Henle, which dives deep into the inner medulla to generate the hyperosmotic interstitium required for tubular urine concentration. G, glomerulus; PT, proximal tubule; DTL, descending thin loop of Henle; ATL, ascending thin loop of Henle; TAL, thick ascending loop; DT, distal tubule; CCD, cortical collecting duct; OMCD, outer medullary collecting duct; IMCD, inner medullary collecting duct. *(From Kriz and Bankir [174])*

charged glycoproteins, which retard the passage of other negatively charged proteins. Thus, the filtration barrier is both size-selective and charge-selective. [2] Molecules with an effective radius of less than 1.8 nm (water, sodium, urea, glucose, inulin) are freely filtered. Molecules larger than 3.6 nm (hemoglobin, albumin) are not filtered. Filtration of molecules between 1.8 and 3.6 nm depends on their electrical charge. Cations are filtered, whereas anions are not. In glomerulonephritis the negatively charged glycoproteins are destroyed, polyanionic proteins are filtered, and proteinuria ensues.

Glomerular ultrafiltration and the formation of tubular fluid depends on the balance of Starling forces regulating fluid flux across the filtration barrier. [2] Glomerular filtration rate (GFR) depends on the permeability of the filtration barrier and the net difference between the hydrostatic forces pushing fluid into the Bowman space and the osmotic forces keeping fluid in the plasma:

where uf = ultrafiltration, gc = glomerular capillary, and bs = Bowman space.

The ultrafiltration coefficient, K_f , reflects capillary permeability and glomerular surface area. The hydrostatic pressure in the glomerular capillary, P_{gc} , is effectively determined by the renal arterial pressure. The plasma oncotic pressure (pi_{gc}) is determined by afferent arteriolar plasma flow. Rapid blood flow washes out osmotically effective molecules and keeps the plasma osmotic pressure low, and vice versa.

Renal Autoregulation

In 1951 the classic dog studies of Shipley and Study [4] demonstrated that the kidney maintains a constant renal blood flow and GFR through an arterial pressure range of 80 to 180 mm Hg (Fig. 18-3) (Figure Not Available) . They also showed that urinary flow rate is not subject to autoregulation. Tubular water reabsorption, which determines urinary flow rate, is closely related to the hydrostatic pressure in the peritubular capillaries. Hypotension, whether induced or inadvertent, results in decreased urinary flow rate, which may be correctable only when the arterial blood pressure is restored toward normal.

The precise mechanism for renal autoregulation has still not been defined. In the vascular tree from the renal artery to the renal vein, most of the pressure decrease occurs in the afferent and efferent arterioles. Renal vascular resistance appears to be mediated by variable resistance of the preglomerular afferent arteriole. As mean arterial pressure decreases, renal vascular resistance decreases and renal blood

Figure 18-2 (Figure Not Available) Photomicrograph of a cast of a glomerulus without Bowman's capsule. At lower left the afferent arteriole (A) originates from an interlobular artery and enters the glomerulus with its many capillary loops. At upper left the efferent arteriole (E) leaves the glomerulus and branches to form the peritubular capillary plexus. Magnification ×300. *(From Tisher and Madsen [1])*

flow (RBF) is maintained. The most plausible explanation is that the arterioles constrict in response to increased arterial pressure and vice versa (i.e., a myogenic response). It is unlikely that the renin-angiotensin system plays a role: as arterial pressure falls, renin release and renal vascular resistance increase, which is the opposite of autoregulation.

It has also been postulated that tubuloglomerular feedback

Figure 18-3 (Figure Not Available) Autoregulation of glomerular filtration rate (GFR) and renal blood flow (RBF), based on the original work of Shipley and Study. [4] GFR and RBF remain constant between renal arterial pressures of 80 and 180 mm Hg. *(From Pitts [175])*

via the juxtaglomerular apparatus may play a role (see below). When arterial pressure increases through the autoregulatory range, it enhances delivery of sodium chloride to the cells of the macula densa, which induces afferent arteriolar constriction and decreased RBF and GFR. [2] The opposite effect occurs when arterial pressure declines. Autoregulation enables the kidney to maintain solute and water regulation independently of wide fluctuations of arterial blood pressure.

Although not to be abolished by most anesthetic agents, autoregulation appears to be impaired in severe sepsis, [5] acute renal failure, [6] and possibly during cardiopulmonary bypass. [7] In these situations, RBF is strikingly reduced during hypotension and is restored by normalization of renal perfusion pressure, even if this is achieved by vasoconstrictor therapy.

The Tubule

The tubule has four distinct segments: the proximal tubule, the loop of Henle, the distal tubule, and the connecting segment. The loop of Henle itself is divided into the pars recta (the straight portion of the proximal tubule), the descending and ascending thin limb segments, and the thick ascending limb. Each distal tubule drains into a collecting duct, which courses through the cortex, outer medulla, and inner medulla before entering the renal pelvis at the papilla (see Fig. 18-1) (Figure Not Available) .

There are two populations of nephrons. Those that occupy the outer and middle renal cortex are far more numerous, receive about 85 percent of the renal blood flow, and have short loops of Henle. Their efferent arterioles drain into a peritubular capillary plexus. Those that occupy the juxtamedullary renal cortex receive about 10 percent of the RBF and have larger glomeruli and long loops of Henle, which dive deeply into the inner medulla. Their efferent arterioles drain into elongated vascular conduits, the vasa recta, which are closely applied to the loops of Henle. Although the vasa recta receive less than 1 percent of the renal blood flow, they play an important role in generating the countercurrent mechanism for medullary hypertonicity and renal concentrating ability (see below).

The Juxtaglomerular Apparatus

The juxtaglomerular apparatus provides a remarkable integration of tubular and glomerular structure and function (Fig. 18-4) (Figure Not Available) . A modified portion of the thick ascending loop, the macula densa, is applied to the glomerulus at the vascular pole between the afferent and efferent arterioles. The cells of the macula densa appear to have a chemoreceptor function, which senses the concentration of sodium chloride (NaCl) in the tubular lumen of the thick ascending loop. The juxtaposed segments of the afferent and efferent arterioles contain modified smooth muscle cells (granular cells), which produce renin. The arterioles are innervated with sympathetic nerve fibers and contain baroreceptors, which respond to intraluminal pressure changes. Renin catalyzes the formation of angiotensin, which modulates efferent and afferent arteriolar tone and GFR. The relationship of the

Figure 18-4 (Figure Not Available) The juxtaglomerular apparatus. *(From Stanton and Koeppen [2])*

juxtaglomerular apparatus to the sympathoadrenal system is discussed later in the section on neurohormonal regulation of renal function.

Tubuloglomerular Feedback

When NaCl delivery to the macula densa is increased, renin-angiotensin elaboration is triggered, and arteriolar constriction ensues, which decreases GFR (tubuloglomerular feedback). The true role of tubuloglomerular feedback is unknown. Some have suggested that it is involved in renal autoregulation, [2] and others have postulated that it may be a compensatory mechanism to prevent polyuria in acute renal failure ("acute renal success"). When the thick ascending loop becomes ischemic, reabsorption of NaCl ceases, the ability of the tubule to concentrate urine is lost and, theoretically, intractable polyuria should result. Thurau and Boylan [8] suggested that the increased delivery of NaCl to the macula densa triggers angiotensin-mediated arteriolar constriction, which decreases GFR, induces oliguria, conserves intravascular volume, and protects the organism from dehydration.

Tubular Reabsorption and Secretion

The tubule has an enormous capacity for reabsorption of water and NaCl. Of the 180 L/d protein-free glomerular ultrafiltrate, 98 to 99 percent of the water and 99 percent of the sodium is reabsorbed. Many other filtered substances are completely reabsorbed, but some, such as glucose, have a maximum rate of tubular reabsorption (tubular maximum). Tubular reabsorption of glucose increases at a rate equal to that of the filtered load, which, if the GFR is constant, is directly proportional to that of plasma glucose. Once plasma glucose exceeds the tubular maximum (375 mg/dL), no further glucose is reabsorbed, and glycosuria results. Thereafter, the amount of glucose excreted in the urine increases in direct proportion to the filtered load.

Many important endogenous and exogenous solutes are secreted into the tubular lumen from the capillary blood. Some also have a tubular maximum for secretion, such as para-amino hippurate (PAH), which is used to calculate renal plasma flow. This is discussed further in the section on renal function tests.

There is a striking relationship between the structure and function of the different segments of the tubule (Fig. 18-5) (Figure Not Available) .

Figure 18-5 (Figure Not Available) Structure-function relationships in the renal tubule. The most metabolically active components of the tubule are the proximal tubule, the thick ascending loop of Henle, and the first part of the distal tubule. Their cells are large, and on the capillary surface (basolateral membrane) there are many invaginations rich in mitochondria. The cells of the proximal tubule have a brush-border on the luminal surface (apical cell membrane), whereas the cells of the descending and thin ascending loops of Henle are flattened with few mitochondria. The second part of the distal tubule and collecting duct are intermediate in nature. The intercalated cells of the distal tubule have many mitochondria, the principal cells few. *(From Stanton and Koeppen [2])*

The most metabolically active components of the tubule are the proximal tubule, the thick ascending loop of Henle, and the first part of the distal tubule. Figure 18-6 (Figure Not Available) illustrates a tubular cell in the thick ascending loop of Henle, which encompasses all the major mechanisms of reabsorption and secretion. The tubular lumen abuts the apical cell membrane, which joins adjacent cells at the right junctions. The remainder of the cell is lined by the basolateral cell membrane, which interfaces with the lateral interstitial spaces on either side and with the peritubular capillary at its base. There are a number of protein-based active transport systems. Of these the most important is the sodium-potassium adenosine triphosphatase (Na-K-ATPase) system, situated in the basolateral membrane, which, in exchange for potassium from inside the tubular cell, pumps sodium out of the tubular cell into the interstitial fluid (and capillary blood) against a concentration and an electrical gradient. The consequent decrease in intracellular sodium concentration in turn facilitates passive reabsorption of sodium from the tubular lumen into the

cell. The transport of virtually all solutes is coupled to that of sodium. Active transport systems that move solutes in the same direction into or out of the cell are called symporter systems, and those that move solutes in opposite directions are called antiporter systems. Whereas solutes are transported by both active and passive mechanisms, water always diffuses passively along an osmotic gradient.

Proximal Tubule

The first part of the proximal tubule reabsorbs about 100 percent of the filtered glucose, lactate, and amino acids as well as some phosphate by coupling with sodiumsymporter systems. [2] Hydrogen ions are extruded into the tubule by a sodium-H^+ antiporter system in exchange for bicarbonate. The absorption of organic anions and bicarbonate in the first part of the proximal tubule results in a relatively high chloride concentration downstream, promoting passive ingress of chloride. This leaves the tubular fluid positively charged relative to blood, further promoting the movement of sodium from the tubular fluid into the cell.

Most NaCl is absorbed transcellularly by a sodium-H^+ and chloride-based antiporter system in the apical cell membrane. Sodium is pumped into the interstitial space by the Na-K-ATPase pump, and chloride is pumped by a potassium-chloride symporter system, and the resulting increase in osmolality draws water across as well. In all, about two-thirds of the filtered water, chloride, and potassium are reabsorbed by the proximal tubule, coupled with and strongly influenced by sodium absorption. [2]

The proximal tubule is also an important site of secretion of many endogenous anions (bile salts, urate), cations (creatinine, dopamine) and drugs (diuretics, penicillin,

Figure 18-6 (Figure Not Available) Mechanisms of tubular secretion and reabsorption. This tubular cell in the thick ascending loop of Henle encompasses the major mechanisms of secretion and reabsorption, one or more of which is used by various segments of the tubule. The most ubiquitous and important transport mechanism is the energy-requiring Na-K-ATPase pump in the basolateral cell membrane (1), which pumps sodium out into the interstitium against its concentration gradient and maintains a low intracellular concentration. This favors inward movement of sodium from the tubular lumen, facilitated by a sodium chloride symporter system on the apical cell membrane (2), which creates enough potential energy to draw in potassium against its concentration gradient and which is the primary inhibitory site of action of loop diuretics. A sodium-H^+ antiporter system on the apical cell membrane (3) aids sodium reabsorption and extrudes H^+, thereby promoting reaction of water with carbon dioxide to form H^+ and bicarbonate ion under the influence of carbonic anhydrase (CA). Bicarbonate diffuses out into the capillary. Sodium reabsorption is thereby coupled to H^+ loss and bicarbonate reabsorption. The transport proteins create a positive charge in the lumen, which drives ions such as sodium, calcium, potassium, and magnesium passively through the tight junctions by paracellular diffusion. The thick ascending loop of Henle is uniquely highly water-impermeable so that luminal osmolality progressively falls to less than 150 mOsm/kg (the "diluting segment"). *(Modified from Stanton and Koeppen [2])*

probenecid, cimetidine). Organic ions compete for protein transport systems. Thus, administration of probenecid impairs tubular secretion of penicillin and prolongs its action. In chronic renal insufficiency there is an accumulation of organic acids that compete with drugs such as furosemide for secretor proteins, thereby conferring the "resistance" to loop diuretics encountered in this condition.

Thick Ascending Loop of Henle

The metabolically active component of the loop of Henle is the thick ascending loop, which reabsorbs about 20 percent of the filtered sodium, chloride, potassium, and bicarbonate. Only the descending loop is permeable to water. In the water-impermeable thick ascending loop, sodium is actively reabsorbed, but water remains. In this so-called diluting segment of the kidney, tubular fluid osmolality decreases to less than 150 mOsm/kg H_2O.

As in the proximal tubule, the Na-K-ATPase pump in the basolateral membrane is the engine that drives the resorptive capacity of the thick ascending loop. [2] Sodium moves from the tubular lumen by passive diffusion along its concentration gradient. A sodium-H^+ antiporter system in the apical cell membrane mediates the net secretion of H^+ and reabsorption of bicarbonate.

An important symporter protein system couples the reabsorption of sodium, chloride, and potassium (the latter against its concentration gradient) across the apical membrane. This system is the major site of action of loop diuretics in their inhibition of NaCl reabsorption in the thick ascending loop of Henle.

Oxygen Balance in the Medullary Thick Ascending Loop

The kidneys receive 20 percent of the total cardiac output but extract relatively little oxygen. The renal arteriovenous oxygen difference [(a-v)O_2] is only 1.5 mL/dL. However, there is a marked discrepancy between the renal cortex and medulla with regard to blood flow, oxygen delivery, and oxygen consumption (Table 18-1) . The medulla receives only 6 percent of the RBF and has an average oxygen tension (P_{O_2}) of 8 mm Hg. Thus, it is possible that severe hypoxia could develop in the medulla despite a relatively adequate total

TABLE 18-1 -- Distribution of Renal Blood Flow Between Cortex and Medulla

	CORTEX	MEDULLA
Percent of renal blood flow	94	6
Blood flow (mL/min/g)	5.0	0.03
P_{O_2} (mm Hg)	50	8
O_2 extraction ratio (V_{O_2}/D_{O_2})	0.18	0.79

O_2 = oxygen; V_{O_2} = oxygen consumption; D_{O_2} = oxygen delivery; P_{O_2} = oxygen tension. The renal medulla receives only a small fraction of the total renal blood flow, and flow rates are extremely slow. As a result, the tissue oxygen tension is extremely low, and the medulla extracts almost 80 percent of the oxygen delivered to it. A very mild reduction in total and cortical renal blood flow may therefore induce ischemia and hypoxia in the renal medulla. *Data from Brezis, Rosen, and Epstein.* [9]

RBF, and the metabolically active medullary thick ascending loop of Henle is particularly vulnerable. [9]

The medullary thick ascending loop is also a potential site for nephrotoxic injury. Intrarenal blood flow is regulated by endogenous vasoactive compounds. In the outer cortex, adenosine induces vasoconstriction. In the juxtamedullary zone, generation of prostaglandins and nitric oxide promote vasodilation. The net effect is to direct as much available blood flow to the medulla as possible. Drugs that inhibit prostaglandin synthesis, such as nonsteroidal antiinflammatory agents, can upset this compensatory mechanism and result in medullary ischemia.

Any stress resulting in activation of the sympathoadrenal system (pain, trauma, hemorrhage, hypoperfusion, sepsis, congestive heart failure) results in renal cortical constriction and potential tubular ischemia. The kidney is relatively devoid of beta $_2$ -receptors so that endogenous or exogenous epinephrine induces vasoconstriction through alpha receptors or angiotensin activation. In hemodynamically mediated renal injury, the initial response to renal hypoperfusion is increased active NaCl absorption in the thick ascending limb. This increases oxygen consumption in the face of decreased oxygen delivery. Subsequent sympathoadrenal responses and renal cortical vasoconstriction may be a compensatory attempt to redistribute blood flow to the medulla. Ultimately, ATP stores become depleted, and active NaCl reabsorption winds down. This increases the NaCl concentration in tubular fluid reaching the macula densa in the distal tubule, resulting in angiotensin release and afferent arteriolar constriction (i.e., tubuloglomerular feedback). Teleologically, the resultant decrease in GFR benefits renal oxygen balance by decreasing solute reabsorption and oxygen consumption in the medullary thick ascending loop and by preserving intravascular volume. [9]

This hypothesis implies that ischemic or nephrotoxic insults to the renal tubules could be alleviated by the administration of loop diuretics or dopaminergic agents. These drugs inhibit active sodium reabsorption in the thick ascending limb, thereby decreasing oxygen consumption and enhancing tubular oxygen balance. [10]

Distal Tubule and Collecting Duct

The proximal segment of the distal tubule is structurally and functionally similar to the thick ascending loop. An apical cell membrane NaCl symporter system is the site of action of thiazide diuretics.

The last part of the distal tubule is composed of two types of cells. Principal cells reabsorb sodium and water and secrete potassium via the Na-K-ATPase pump. Intercalated cells secrete H^+ and reabsorb bicarbonate by an H^+ -ATPase pump in the apical cell membrane.

Regulatory Mechanisms in Salt and Water Reabsorption

Osmotic Equilibrium

The ability of the kidney to concentrate urine is dependent on three factors: (1) the development of a hypertonic medullary interstitium by the countercurrent mechanism and urea recycling, (2) the impermeability to water of the ascending loop of Henle, and (3) the action of antidiuretic hormone (ADH) in increasing water permeability in the last part of the distal tubule and collecting ducts and active NaCl reabsorption in the thick ascending loop of Henle.

The medullary interstitium is rendered hypertonic by the countercurrent multiplier effect of the loop of Henle. The primary mechanism is the separation of solute from water (the single effect) by the combination of NaCl reabsorption and water impermeability in the ascending limb. This results in increased NaCl concentration and osmolality in the medullary interstitium. The descending limb is freely permeable to water, which diffuses into the interstitium along the osmotic gradient, and the tubular fluid becomes progressively hyperosmotic at the bend of the loop.

The vasa recta, which are closely applied to the long loops of Henle of juxtamedullary nephrons, maintain this condition by removing water and adding solute as they pass through the medullary interstitium. A standing osmotic gradient is thereby set up between the cortex (300 mOsm/kg), juxtamedullary zone (600 mOsm/kg), and deep medulla (1,200 mOsm/kg). This process is enhanced by the passive recycling of urea, which diffuses out of the inner medullary collecting duct into the interstitium and thence into the distal loop of Henle. These processes are summarized in Figure 18-7 (Figure Not Available) .

Tubular Concentration and Dilution

Hypovolemia

The tubular response to hypovolemia (contracted extracellular volume) is controlled by a series of vasoconstrictor, salt-retaining neurohormonal systems. Initially, the GFR and filtered load of sodium decrease. Sodium reabsorption in the proximal tubule is increased from about 66 to 80 percent by sympathetic activity and angiotensin II as well as by the decline in peritubular capillary pressure induced by renal vasoconstriction. Sodium delivery to the thick ascending loop of Henle, distal tubule, and collecting duct is decreased as is the relative proportion of extraction, but release of aldosterone and ADH causes avid reabsorption of sodium at these sites. Under the influence of ADH, water is also avidly reabsorbed in the collecting duct so that the urine becomes

---

Figure 18-7 (Figure Not Available) Tubular concentration of urine in the juxtamedullary nephrons, which have long loops of Henle associated with the vasa recta. Dashed arrows represent passive movement of fluid or solutes along concentration or osmolar gradients; solid arrows represent active transport. (1) Tubular fluid enters the distal proximal tubule iso-osmotic with plasma (300 mOsm/kg). In the descending limb of Henle (2), water rapidly diffuses out into the increasingly hypertonic medulla and is removed by the vasa recta so that the tubular fluid becomes hypertonic, owing largely to concentration of sodium chloride (NaCl). Urea diffuses in from the hypertonic interstitium, further increasing tubular fluid osmolality (1,200 mOsm/kg). In the thin ascending loop of Henle (3), NaCl passively diffuses into the interstitium along its concentration gradient, but water is trapped in the water-impermeable tubule, which progressively decreases tubular fluid osmolality. Urea passively diffuses into the tubular fluid (urea recycling). Tubular dilution is accelerated by active reabsorption of NaCl in the thick ascending loop (the diluting segment) and proximal distal tubule (4). The fluid entering the distal tubule is quite hypo-osmotic (100 mOsm/kg). In the collecting segment (5), the osmolality of the tubular fluid returns to that of plasma (300 mOsm/kg), but unlike the contents of the proximal tubule, the solute component consists largely of urea, creatinine, and other excreted compounds. Increased plasma ADH renders the cortical and medullary collecting ducts (6) permeable to water, which passively diffuses into the hypertonic medullary interstitium. Even though some urea diffuses out into the medulla, the maximal osmolality of concentrated urine (7) approaches that of the hypertonic medullary interstitium, about 1,200 mOsm/kg. In the absence of ADH, the collecting ducts remain impermeable to water, and the urine is diluted. *(From Stanton and Koeppen [24])*

highly concentrated (osmolality 600 mOsm/kg) but with virtually no sodium (10 mEq/L).

Diuretic agents abolish the kidney's ability to concentrate urine by washing out the hypertonic medulla. They do this either by an osmotic effect that prevents water reabsorption (mannitol) or by inhibition of active NaCl transport in the thick ascending loop (furosemide) or the first part of the distal tubule (hydrochlorthiazide). An early and important manifestation of acute tubular necrosis is the loss of urinary concentrating ability caused by the breakdown of the energy-requiring Na-K-ATPase pump in the thick ascending loop of Henle.

Hypervolemia

The tubular response to an expanded extracellular volume is controlled by a series of vasodilator, salt-excreting neurohormonal systems. Decreases in sympathetic and angiotensin II activity and the release of atrial natriuretic peptide (ANP) cause renal plasma flow (RPF), GFR, and the filtered sodium load to increase. The same effects, along with an increase in peritubular capillary hydrostatic pressure, cause sodium reabsorption in the proximal tubule to decrease from 67 to 50 percent. The declines in aldosterone and ADH decrease sodium absorption in the thick ascending loop of Henle, distal tubule, and collecting duct, although the absolute sodium load increases as does the relative proportion of sodium absorption at these sites. ANP, together with the absence of ADH, impairs water absorption at the collecting duct so that a dilute urine (osmolality 300 mOsm/kg) with abundant sodium (80 mEq/L) is produced. This urine profile (low osmolality, high urinary sodium) may be seen in hypovolemia if tubular resorptive capacity is depressed by loop diuretics or lost completely, as in acute tubular necrosis.

RENAL FUNCTION TESTS

Renal hemodynamic function is defined by RBF, RPF, intrarenal distribution of flow, filtration fraction, and renal vascular resistance. Glomerular function is defined by GFR. Tubular functions include concentrating ability, water conservation,

and sodium conservation. For practical purposes, however, tests of renal function can be described as those based on clearance techniques (the most commonly used), those that test tubular function, and those that are largely used for clinical and laboratory investigation.

Renal Clearance Techniques

Renal function is most frequently assessed by clearance techniques, [11] which provide an indirect estimate of function based on the Fick principle:

That is, the amount of substance *x* excreted by the kidney equals the amount delivered to the kidney by the renal arterial flow minus the amount returning from the kidney in the renal venous flow. Therefore

The amount of substance *x* delivered to the kidney is the product of the arterial plasma concentration ($P_a x$) and RBF, and the amount returning from the kidney is the product of the venous plasma concentration ($P_v x$) and RBF. The amount of substance *x* excreted is the product of the kidney's urine concentration (U_x) and the urine flow rate in milliliters per minute (V). Note that $U_x \times V$ (urine concentration times flow rate) represents the urinary excretion rate of substance *x*. Therefore,

However, in practice, RBF and venous return are not measured, and the removal of substance *x* by the kidney is expressed by the concept of clearance, which is defined as the virtual volume of plasma cleared of substance *x* per unit time, in milliliters per minute. This allows the urinary excretion rate to be equated to the renal arterial plasma concentration:

By rearrangement, clearance of substance *x* may be calculated:

where U_x is the concentration of substance *x* in the urine in mg/dL, V is the urine flow rate in milliliters per minute, and P_x is the concentration of substance *x* in the plasma, assuming that the substance's concentration is identical in the renal arterial plasma and in an arm vein.

Para-Amino Hippurate Clearance

PAH is an organic anion that is almost completely cleared from the plasma in a single pass through the kidney by means of a combination of glomerular filtration and proximal tubular secretion. Calculated clearance of PAH (C_{PAH}) therefore represents renal plasma flow. To obtain maximal PAH extraction, a steady state with a low plasma PAH level must be achieved by giving an intravenous loading dose followed by an infusion to maintain a plasma PAH concentration of about 2 mg/dL. [11] A carefully timed catheter urine collection is required. Because only 90 percent of the renal plasma flow enters the peritubular capillaries surrounding the proximal tubule, PAH clearance underestimates true renal plasma flow, and it is known as the effective renal plasma flow ($_{E}RPF$).

where U_{PAH} is the concentration of PAH in the urine, and P_{PAH} is its concentration in the plasma. The normal effective renal plasma flow is 660 mL/min/1.73 m^2.

Effective renal blood flow ($_{E}RBF$) may be derived if the hematocrit level (Hct) is known:

There are a number of circumstances in which C_{PAH} provides misleading information about renal plasma flow. If the plasma PAH concentration exceeds the tubular maximum of 12 mg/dL, the excess PAH is returned to the renal vein, the secreted fraction declines, and renal plasma flow is underestimated. [2] About 80 percent of

PAH is cleared by tubular secretion, so if proximal tubule function deteriorates, PAH clearance declines and again underestimates renal plasma flow.

These errors can be overcome if arterial and renal vein PAH levels are accessible. The renal extraction of PAH (E_{PAH}) can be calculated and serves as an indicator of proximal tubule function:

where A_{PAH} is arterial PAH concentration, and V_{PAH} is renal vein PAH concentration. When renal function is normal, renal vein PAH is close to zero, and PAH extraction approaches 1.0. As proximal tubule function declines, the concentration of PAH in the renal vein increases, and PAH extraction progressively decreases below 1.0. True RPF is calculated by dividing PAH clearance by PAH extraction:

PAH clearance may also misrepresent renal plasma flow in the presence of hypovolemia (PAH is sequestered in the kidney) and oliguria. Thus, despite its relative convenience as an experimental tool, PAH clearance may be an unreliable indicator of RBF during the perturbations induced by anesthesia and surgical stress.

Inulin Clearance

Inulin is an inert polyfructose sugar that is completely filtered by the glomerulus and is neither secreted nor reabsorbed by the renal tubules. The volume of plasma cleared of inulin (mL/min) represents the GFR. Inulin clearance is

measured identically to PAH clearance, and an indwelling intravenous cannula and urinary catheter must be in place. After an intravenous loading dose of 30 to 50 mg/kg, a continuous infusion of inulin is given to establish a steady-state plasma concentration of 15 to 20 mg/dL. The bladder is usually flushed with air to eliminate any pooled urine. Then, a very carefully timed urine collection is made, which can be as short as 30 minutes. It is generally accepted that inulin clearance (C_{IN}) provides the most accurate available determination of GFR (i.e., it represents the gold standard):

where U_{IN} is urinary inulin in mg/dL, P_{IN} is plasma inulin in mg/dL, and V is urine flow rate in mL/min. This relationship also implies that the renal excretion of inulin (urinary inulin times urine flow rate) is determined solely by the GFR and the plasma inulin concentration:

Although inulin clearance is the standard measure of GFR in experimental situations, it is seldom used clinically because its accurate measurement is laborious and requires meticulous attention to detail. The inulin assay is timeconsuming, and inulin itself is in short supply because of lack of demand. Inulin meets all the criteria of an ideal filtration marker, but large changes in blood glucose during the test may interfere with its measurement, and its accuracy in reflecting GFR cannot be directly assessed, only inferred. The predicted variability of inulin clearance is 20 percent when measurements are compared at two different times in the same individual and 40 percent when measurements are compared between two individuals. [11]

Normal values for inulin clearance are 110 to 140 mL/min/1.73m^2 (males) and 95 to 125 mL/min/1.37m^2 (females).

Filtration Fraction

The filtration fraction (FF) is the fraction of the RPF that is filtered by the glomerulus:

Normally, GFR is about 125 mL/min, and RPF is about 660 mL/min so that the FF approximates 125/660, or about 0.2. Changes in FF are considered to represent changes in periglomerular arteriolar tone. An increase in FF indicates that GFR is increased relative to RPF. This could be achieved by efferent arteriolar constriction or afferent arteriolar dilation and maintains glomerular filtration pressure in the face of decreased RPF. Conversely, a decrease in FF implies that GFR is decreased relative to RPF by afferent arteriolar constriction or efferent arteriolar dilation.

Creatinine Clearance

Creatinine is the endogenous end product of creatine phosphate metabolism, is normally generated from muscle at a very uniform rate, and is handled by the kidney in a manner similar to that of inulin. Thus, creatinine clearance (C_{CR}) provides a simple, inexpensive bedside estimate of GFR. A single blood sample is drawn at the midpoint of a carefully timed urine collection:

where U_{CR} is the urinary creatinine concentration in mg/dL, P_{CR} is the plasma creatinine concentration in mg/dL, and V is urine flow rate in mL/min.

Bedside use of creatinine clearance has been restricted by the belief that a prolonged (12-24-hour) urine collection is necessary to eliminate error induced by residual urine in the bladder neck after spontaneous voiding, a practice both tedious and cumbersome. The estimated creatinine clearance depends on when the blood sample is drawn, so if the serum creatinine changes rapidly during the time of urine collection, a misleading result may be obtained.

It is not the duration of urine collection that is critical, but rather the fact that its timing is precise. [12] The variability of creatinine clearance with a 1-hour urine collection is no greater than of 24-hour collection if a good urine flow is induced by diuresis, and care is taken to empty the bladder. [13] In catheterized patients with urine flow rates of more than 15 mL/h, creatinine clearance obtained with 2-hour urine collections gives values equivalent to those obtained with 12- to 24-hour collections. [14] [15] Moreover, a 2-hour creatinine clearance enables rapid, repeated estimates of GFR to be obtained. This not only makes it a viable bedside test in critically ill patients but also implies that a changing GFR can be closely tracked by serial estimations of creatinine clearance (Figs. 18-8 (Figure Not Available) , 18-9 , and 18-10) . For example, in trauma patients, a 1-hour creatinine clearance of less than 25 mL/min determined within 6 hours of surgery reliably

Figure 18-8 (Figure Not Available) Creatinine clearance: 2- versus 22-hour values. There is a close and significant correlation in creatinine clearance estimation from a 2-hour and a 22-hour urine

collection. CC02, 2-hour urine collection; CC22, 22-hour urine collection. *(From Sladen, Endo, and Harrison [15])*

Figure 18-9 New-onset acute renal failure. In a patient developing acute renal failure in the intensive care unit, the exponential decline in creatinine clearance is tracked equally well whether a 2-hour (CC02) or a 22-hour (CC22) urine collection is used. However, data from the 2-hour collection are available well before those from the 22-hour collection.

predicted postoperative acute renal failure, despite the absence of oliguria. [16]

There is considerable variation in the normal range of creatinine clearance, as wide as the range of normal values of body size. [13] Tobias et al [12] reported a variation in creatinine clearance between 88 and 148 mL/min and in serum creatinine between 0.9 and 1.5 mg/dL in a single healthy individual over 5 years. There is a diurnal variation in creatinine clearance, with higher values in the afternoon and a variance of up to 25 percent around mean values. [17] It is prudent to obtain short-collection creatinine clearance estimations at the same time each day to minimize diurnal variability. "Normal" creatinine clearance is related to body surface area and weight, so values may fluctuate widely in patients with cachexia or edema.

Figure 18-10 Renal revascularization. Patient with renovascular hypertension and renal insufficiency admitted to the intensive care unit for preoperative monitoring and stabilization. Bilateral renal revascularization was performed, and following return from the operating room there was a substantial decline in renal function. These changes were tracked equally well by creatinine clearance derived from a 2-hour (CC02) and a 22-hour (CC22) collection.

Creatinine clearance has a number of inherent limitations even if collection error is carefully avoided. Creatinine generation rate varies with muscle mass, physical activity, protein intake, and catabolism. The most commonly used serum creatinine assay is the Jaffe reaction, which is based on the red color of the creatinine complex with alkaline picrate. It also measures other normally-occurring chromogens, such as glucose, protein, ketones, and ascorbic acid, which represent about 14 percent of total creatinine when renal function is normal, although substantially less when serum creatinine is elevated. Ketoacidosis, barbiturates, and cephalosporin antibiotics may artifactually increase serum creatinine by as much as 100 percent and falsely decrease measured creatinine clearance. Unlike inulin, about 20 percent of creatinine is secreted by the proximal tubule, so that creatinine clearance overestimates GFR, and the ratio between the clearance of creatinine and inulin is 1.2:1. As the GFR declines, tubular secretion of creatinine increases. When GFR is less than 40 mL/min/1.73m ^{2} , a creatinine/inulin clearance ratio as high as 1.81 to 2.51 may be achieved. [18] [19] [20] In patients with normal renal function, the underestimate of GFR induced by the Jaffe reaction is balanced by the overestimate of GFR induced by tubular creatinine secretion, and creatinine clearance provides a reasonable representation of GFR. However, widely used drugs such as trimethoprim, H_2 -antagonists, and salicylates block tubular secretion of creatinine and may elevate serum creatinine and decrease creatinine clearance. When serum levels of creatinine are very high, it is excreted into the gut and undergoes extrarenal metabolism by intestinal organisms.

For all these reasons, an isolated creatinine clearance estimation may not diagnose lesser degrees of renal dysfunction. Nonetheless, serial estimations of creatinine clearance provide a useful clinical guide to alterations in renal function and prognosis. The variability of creatinine clearance diminishes as GFR declines; in fact, loss of variability is a clue to deteriorating renal function. If the GFR is rapidly declining, the creatinine clearance alerts the physician earlier and more compellingly than the serum creatinine because it reflects creatinine excretion rate (i.e., urine creatinine content times urine flow rate [$U_{CR}V$]). Directional changes between creatinine clearance and inulin clearance show good agreement. [18] At low levels of GFR a creatinine/inulin clearance ratio as high as 2:1 (e.g., 12 versus 6 mL/min) would induce little actual difference in clinical management.

Serum Creatinine

Serum creatinine is a useful marker of stable renal function, but it is unreliable when GFR is rapidly changing. [18] [19] [20] Serum creatinine concentration depends on its volume of distribution (total body water), creatinine generation rate (muscle mass and rate of catabolism), and creatinine excretion rate (GFR). Perioperative fluid administration increases total body water and dilutes serum creatinine, which underestimates renal dysfunction. In a cachectic patient with very low muscle mass, creatinine generation may be so feeble that the serum creatinine remains subnormal even in the face of a markedly decreased GFR. In some patients with a serum creatinine of less than 0.9 mg/dL, creatinine clearance may be less than 25 mL/min. [13] [14] The relationship

Figure 18-11 (Figure Not Available) The relationship between serum creatinine and GFR as measured by creatinine clearance is reciprocal and exponential. Doubling of the serum creatinine corresponds to halving of the GFR. Relatively large declines in GFR from normal are associated with small increases in serum creatinine until GFR decreases below 60 mL/min; further decrements are associated with large increases in serum creatinine. *(From Alfrey and Chan [176])*

between serum creatinine and GFR is inverse and exponential. An increase in serum creatinine from 0.8 to 1.6 mg/dL implies a 50 percent decrease in GFR, and early renal dysfunction may be missed. A much larger increase from 4 to 8 mg/dL also represents a 50 percent decrease in GFR, but by this time renal insufficiency is well established (Fig. 18-11) (Figure Not Available) . After a transient renal insult, such as that caused by suprarenal aortic cross-clamping, serum creatinine may increase for a few days while GFR is actually recovering. [21] In oliguric acute renal failure, serum creatinine is directly proportional to creatinine generation rate. Creatinine clearance is reliably low but is associated with a wide variability of serum creatinine.

Serum Creatinine-Based Nomograms

Cockroft and Gault [22] formulated a nomogram for the rapid estimate of creatinine clearance without urine collection. The nomogram was based on population studies incorporating serum creatinine, age, weight, and gender.

For females, the derived creatinine clearance is multiplied by 0.85.

In these formulas, the body weight that is used may substantially alter the derived creatinine clearance. In obese or edematous patients, the total body weight is much greater than the lean body mass from which creatinine is derived, and creatinine clearance is overestimated. In cachectic patients with depleted lean body mass, creatinine production is so low that serum creatinine is frequently less than 1.0 mg/dL and overestimates the true GFR. Robert et al [23] demonstrated that when the Cockroft and Gault equation incorporates ideal body weight (from a nomogram) and serum creatinine corrected to 1.0 mg/dL if it is less than 1.0 mg/dL, single measurements in hemodynamically stable patients correlate more closely with inulin clearance than either a 30-minute or a 24-hour creatinine clearance.

Serum creatinine-based nomograms are subject to the same limitations as serum creatinine itself in tracking changing renal function. Rapid alterations in GFR are reflected by rapid changes in the creatinine excretion rate, which is incorporated into measured creatinine clearance as $U_{CR}V$. In contrast, serum creatinine itself changes much more slowly and depends on the equilibrium point between creatinine production and excretion. In fact, serum creatinine does not begin to increase above normal levels until the GFR declines below 50 mL/min/1.73m ^{2} , and occasionally it will remain normal even when the GFR dips as low as 20 to 40 mL/min/1.73m ^{2} .

Tubular Function Tests

Tests of renal tubular function can define states of diuresis and antidiuresis and natriuresis and antinatriuresis. Under certain circumstances the tests can distinguish oliguria due to prerenal azotemia, which is reversed by restoration of hemodynamic status to normal, from that due to established acute renal failure, which persists

despite restoration of normal renal blood flow. In the former, tubular conservation mechanisms are enhanced, and in the latter they are lost. However, in nonoliguric renal dysfunction, which accounts for more than 50 percent of cases encountered clinically, the differences in tubular function are less distinct from prerenal azotemia. Diuretic therapy overcomes tubular conserving function. Thus, treatment with loop diuretics, osmotic diuretics, saline loading, or natriuretic vasodilators (low-dose dopamine, fenoldopam, prostaglandin E1, or ANP) may render tubular function tests uninterpretable.

Urinary Concentrating Ability

Concentrating ability is a very sensitive index of tubular function. In prerenal states, urinary osmolar concentration is markedly increased. In acute tubular necrosis, the ability to concentrate urine may be lost 24 to 48 hours before serum creatinine or blood urea nitrogen (BUN) starts to increase.

Urine-to-Plasma Osmolar Ratio

The normal tubular response to dehydration or hypovolemia is to generate a urine-to-plasma osmolar ratio ($U:P_{OSM}$) of 1.5 or greater. Isosthenuria ($U:P_{OSM} = 1.0$) in the presence of oliguria implies loss of tubular function and

established acute renal failure. However, isosthenuria can occur in a prerenal state following diuretic administration.

Free Water Clearance

Free water clearance (C_{H_2O}) attempts to represent the degree of urinary concentration or dilution by distinguishing the clearance of solute from that of free water. The solute or osmolar clearance (C_{OSM}) is calculated by standard methods, using urine osmolality in mOs/kg (U_{OSM}), plasma osmolality in mOs/kg (P_{OSM}), and urine flow in mL/min (V):

Then, the osmolar clearance is subtracted from the urine flow rate to give free water clearance:

If the urine is isosmotic with plasma, the osmolar clearance equals the urine flow rate so that C_{H_2O} is zero. If the urine is dilute (hypo-osmotic), the urine flow rate exceeds osmolar clearance, and the difference is the free water clearance. If the kidney is able to concentrate urine normally (hyperosmotic urine), urine flow rate is less than osmolar clearance, which results in a negative free water clearance (i.e., free water retention), also known as tubular conservation of water (TC_{H_2O}). Conceptually, TC_{H_2O} represents the volume of fluid that would have to be added to the urine to make its osmolality equivalent to that of plasma. [24]

With the onset of acute tubular necrosis and loss of concentrating ability, the urine becomes isosmotic, and C_{H_2O} approaches zero (±0.25 mL/min). However, in distinguishing between prerenal and intrarenal oliguria, C_{H_2O} does not really provide any more information about concentrating ability than $U:P_{OSM}$, and in addition it requires a timed urine collection.

The concept of free water excretion emphasizes that renal regulation of solute and of water balance are independent of each other. The kidney has an enormous range in its ability to handle water. The maximum excretion of water, or positive free water clearance, is 18 L/d, about 10 percent of the GFR. The maximum conservation of water, or negative free water clearance, is 8 L/d. [24]

Water Conservation

Urine-to-Plasma Creatinine Ratio

The urine-to-plasma creatinine ratio ($U:P_{CR}$) represents the proportion of water filtered by the glomerulus that is abstracted by the distal tubule. Normally, about 98 percent of water is abstracted, and urine creatinine is much greater than plasma creatinine. The ratio can increase a hundred-fold in severe prerenal states. When tubular function is lost, the ratio declines to less than 20:1. For example, two patients have a serum creatinine of 2.0 mg/dL. In one, urine creatinine is 100 mg/dL, which implies a prerenal state ($U:P_{CR}$ 50:1). In the other, urine creatinine is 20 mg/dL, which suggests acute tubular necrosis ($U:P_{CR}$ only 10:1). Similar information may be obtained during the performance of an inulin clearance test by calculating the urine-to-plasma inulin ratio.

Sodium Conservation

Urine Sodium

During dehydration or hypovolemia, the tubules intensely reabsorb sodium so that urine sodium (U_{Na}) declines to less than 20 mEq/L. In established acute renal failure, the ability to conserve sodium and protect the intravascular volume is lost, and U_{Na} exceeds 60 to 80 mEq/L. Diuretic therapy overcomes tubular sodium conservation so that a high U_{Na} does not necessarily imply loss of tubular function. However, if U_{Na} remains low in the face of diuretic therapy, an intense prerenal state exists.

Fractional Excretion of Sodium

Fractional excretion of sodium (FE_{Na}) expresses sodium clearance as a percentage of creatinine clearance:

Based on the relationship expressed in Equation 5:

Urine flow rate (V) is identical in the numerator and denominator and it cancels out:

Thus, FE $_{Na}$ may be calculated from a spot sample of blood and urine without requiring a timed urine collection.

During dehydration or hypovolemia, sodium clearance and FE $_{Na}$ are decreased to less than 1 percent of creatinine clearance. When tubular ability to conserve sodium is lost in acute renal failure, FE $_{Na}$ increases to more than 3 percent. However, FE $_{Na}$ increases with normal tubular function after diuretic therapy and during postoperative sodium mobilization. Sequential increases in FE $_{Na}$ associated with declining creatinine clearance indicate more reliably deteriorating renal function than an isolated high FE $_{Na}$.

Investigational Tests of Renal Function

Glomerular Filtration Rate

Radioisotopic Filtration Markers

The use of intravascularly injected radiolabeled compounds to define GFR is potentially simpler and more

precise than the methods discussed above because it involves detection of decay in radiation and avoids the necessity for a timed urine collection. These compounds include sodium iothalamate (I^{125}), diethylenetriaminepenta-acetic acid (DTPA) (Tc^{99m}), and ethylenediaminetetra-acetic acid (EDTA) (Cr^{51}). However, none of these compounds are inherently superior to inulin in their renal handling, the tests require great attention to detail and quality control, and there is the constant risk, albeit low, of radiation exposure. [11]

Total Renal Blood Flow

Flow Probes

Flow measurement by electromagnetic flow probes is based on the creation of a magnetic field around the circumference of the vessel. The field is disrupted by blood flow, and a voltage output proportional to blood velocity is generated. Ultrasonic flow probes use the Doppler technique, in which high-frequency sound is transmitted across the lumen of the vessel. A shift in sound frequency is created by the movement of blood and is proportional to blood velocity.

Flow-probe placement is invasive and requires direct surgical exposure of the renal arteries. Probes must be calibrated in vitro before and after measurements. However, they are generally very accurate.

Thermodilution Estimation of Renal Vein Effluent

Schaer et al [25] used a double-lumen pigtail catheter with a thermistor placed in the renal vein of dogs under direct vision or with fluoroscopy. RBF was calculated by thermodilution with cold saline, which allowed repeated measurements in conscious animals. The effect of the presence of the probe itself on RBF is unknown. A similar technique was used by Haywood et al [26] to measure RBF for the assessment of renal oxygen delivery and consumption during septic shock in pigs.

Contrast Ultrasonography

Aronson et al [27] attempted to measure RBF in vivo using contrast ultrasound. They injected sonicated albumin microspheres into the aorta of anesthetized dogs and then recorded simultaneous ultrasonography images of the kidney and aorta and calculated RBF using a mathematical model. RBF was altered by means of a renal artery occluder or vasoactive drugs (dopamine or fenoldopam), and the results were compared with direct measurements by electromagnetic flow probe. Although the correlation between ultrasonography and flow probe measurements of RBF was reasonable (0.84), there was a large bias (in many cases greater than 200 mL/min) and variance. Ultrasonography tended to overestimate RBF, especially when cardiac output was changing. The authors concluded that this method allows estimation of trends in RBF and may be helpful in the qualitative assessment of regional distribution of blood flow between the renal cortex and medulla.

Intrarenal Blood Flow Distribution

Diffusible Gas Tracers

A great deal of supposition about the intrarenal distribution of RBF within and between the renal cortex and medulla was based on studies using the radioactive gases xenon [133] and krypton [85] . The gases are injected into the renal artery, and radioactivity is counted externally. Renal radioactivity disappears faster the higher the blood flow, and flow is calculated mathematically from washout curves. In 1963 Thorburn et al [28] extrapolated four monoexponential components from these curves, said to represent the outer renal cortex (zone I), juxtamedullary cortex (zone II), medulla (zone III), and perihilar fat (zone IV). Blood flow was greatest in zone I and progressively diminished through zones II to IV.

During the next decade studies, such as those by Hollenberg et al, [29] using this technology suggested that ischemia and stress cause intrarenal redistribution of blood flow from zones I to II. Juxtamedullary nephrons are relatively saltretaining and have loops of Henle that penetrate the hypertonic medulla. Thus, this finding explained the retention of NaCl and edema observed during states of relative renal cortical hypoperfusion. However, the shortcomings of gas tracer techniques have generated skepticism about the validity of these studies. [30] The washout curves have not been matched to any specific anatomic area; xenon [133] itself decreases RBF, and the inert gases may diffuse out into the interstitium, especially in pathologic states.

Radioactive Microspheres

This is a terminal experimental procedure, which consists of injection of radioactive microspheres--radiolabeled polystyrene beads 9 to 50 mum in diameter--into the central circulation. It is presumed that the microspheres are distributed to and within organs proportional to blood flow. The animal is then sacrificed, the organs are removed and dissected, and radioactivity is counted.

Intrarenal localization of the microspheres truly represents regional blood flow. However, it is assumed that the injection does not itself interfere with renal hemodynamics and that all microspheres come to rest in the glomeruli without passing through the kidney or plugging arteries. Inner cortical afferent arterioles run at right angles to interlobular arteries, and microspheres may bypass them because of axial streaming. This error would give an overestimation of outer cortical blood flow.

Figure 18-12 Neurohormonal regulation of renal function. Normally, there is a balance between those systems promoting renal vasoconstriction and sodium retention versus those systems promoting renal vasodilation and sodium excretion. Surgical stress, ischemia, and sepsis tip the balance in favor of vasoconstriction and sodium retention. On the other hand, hypervolemia (or the induction of atrial stretch) tips the balance in favor of vasodilation and sodium excretion.

NEUROHORMONAL REGULATION OF RENAL FUNCTION

The role of the kidney in controlling the interior milieu appears to be modulated by two mutually dependent but opposing neurohormonal systems that maintain blood pressure, intravascular volume, and salt and water homeostasis by a complex set of interactions (Fig. 18-12) . The sympathoadrenal axis, the renin-angiotensin-aldosterone system, and ADH defend against hypotension and hypovolemia by promoting vasoconstriction and salt and water retention. The prostaglandins, bradykinins, and ANPs defend against hypertension and hypervolemia by promoting vasodilation and salt and water excretion (Fig. 18-13) (Figure Not Available) .

Anesthesia does not perturb these systems to any substantial degree. Most recent work suggests that in the intact organism, anesthetics affect renal function by the extrarenal circulatory changes that they induce rather than by their direct actions on the kidney. [31] Surgical or traumatic injury,

Figure 18-13 (Figure Not Available) Neurohormonal renal regulatory systems. RBF, renal blood flow; GFR, glomerular filtration rate; Na, sodium; x, decreased; y, increased. *(Modified from Sladen [177])*

on the other hand, induces profound vasoconstriction and salt and water retention, which may persist for several days. The clinical sequel is postoperative oliguria and edema. Renal vasoconstriction also predisposes the kidney to further perioperative ischemic and nephrotoxic insults. Elucidation of the role of ANP enhances the concept that these changes can be prevented or modified by maintenance of normal or increased intravascular (and thereby atrial) volume.

Systems Promoting Vasoconstriction and Salt Retention

The Sympathoadrenal Axis

Sympathetic effects on the kidney are mediated by circulating epinephrine and neuronal release of norepinephrine. The renal cortex has a dense plexus of autonomic nerve fibers derived from the T12 to L4 spinal segments via the celiac plexus. The primary stimulus to the sympathetic response is a decrease in arterial blood pressure sensed by baroreceptors in the aortic arch, carotid sinus, and afferent arteriole. Afferent fibers travel via the vagus nerve and decrease impulse transmission rate to the mediating centers in the hypothalamus, which results in increased adrenergic nerve activity. The kidney does not have any parasympathetic innervation.

A G-protein coupled phospholipase-C receptor mediates vasoconstrictor responses in vascular smooth muscle and the mesangium. It responds not only to alpha-adrenergic stimulation (epinephrine, norepinephrine) but also to a wide variety of other hormones and peptides, including angiotensin II, vasopressin, endothelin, platelet-activating factor, and leukotrienes. [3] The receptor subunit in the cell membrane is coupled through G_q protein to phospholipase C, which hydrolyzes phosphatidylinositol biphosphate (PIP_2) to inositol triphosphate (IP_3) and diacylglycerol (DAG). DAG activates protein kinase, which opens a calcium channel in the membrane. IP_3 triggers the release of calcium from the sarcoplasmic or endoplasmic reticulum. Both mechanisms result in a rapid increase in intracellular calcium, which binds with calmodulin and thereby activates myosin light-chain kinase, resulting in smooth muscle contraction. The calcium-calmodulin complex simultaneously activates phospholipase A_2, resulting in the production of vasodilator prostaglandins (see below).

Mild alpha-adrenergic stimulation appears to cause preferential efferent arteriolar constriction, which preserves the filtration fraction. Severe alpha-adrenergic stimulation causes predominant afferent arteriolar constriction, and decreases filtration fraction. [32] Thus, the adrenergic response to a moderate decrease in renal perfusion (e.g., general anesthesia) favors the preservation of the GFR. In contrast, the adrenergic response to shock exacerbates the decrease in GFR already induced by renal hypoperfusion.

Adrenergic nerves also supply the proximal tubule, thick ascending limb of Henle, and collecting duct, and their stimulation enhances NaCl reabsorption at these sites. Gas tracer studies suggested that sympathetic activation caused sodium retention by intrarenal redistribution of RBF from the outer cortex to salt-retaining juxtamedullary nephrons, but this was not confirmed by microsphere studies. [29] [30]

There is a close relationship between sympathetic stimulation and activation of the renin-angiotensin system. Adrenergic stimulation releases renin from the juxtaglomerular apparatus, and adrenergically induced vasoconstriction can be blocked by angiotensin-converting enzyme (ACE) inhibitor drugs such as captopril.

The effects of the administration of exogenous adrenergic agents depend on their agonist activity. Drugs with predominantly alpha-adrenergic effects, such as norepinephrine, epinephrine, phenylephrine, and high-dose dopamine (>10 mug/kg/min) exacerbate the endogenous sympathetic responses to hypotension. Drugs with predominantly $beta_1$ - and $beta_2$ -adrenergic activity (dobutamine, isoproterenol) cause marked increases in cardiac output and thus RBF, but it is difficult to ascertain their intrarenal effects. Dopaminergic agonists, such as low-dose dopamine (<3 mug/kg/min), dopexamine, and fenoldopam, selectively increase RBF and may oppose alpha-adrenergic renal vasoconstriction. [25] They induce a quite different response in the kidney and will be discussed separately.

The Renin-AngiotensinAldosterone System

Renin and Angiotensin

As already discussed, the juxtaglomerular apparatus consists of three groups of juxtaposed specialized tissues: modified fenestrated endothelial cells of the afferent arterioles, which produce renin; modified distal tubular cells, which have chemoreceptors (the macula densa); and the mesangial cells of the glomerulus, which have contractile properties (see Fig. 18-4) (Figure Not Available) . Together these provide an important regulating system for blood pressure, salt, and water homeostasis. [33]

Renin release is controlled by several mechanisms. A decrease in renal artery perfusion pressure triggers baroreceptors in the afferent arterioles. Sympathetic nerve stimulation and circulating catecholamines act on beta-adrenergic receptors in the afferent arterioles. The cells of the macula densa of the distal tubule sense increases in chloride concentration in the tubular fluid, which triggers renin release from the afferent arteriole. As discussed previously, this tubuloglomerular feedback appears to play a role in modulating GFR during normal and abnormal renal function through a continuous feedback loop. [8] [24] Thus, renin secretion is stimulated by actual hypovolemia (hemorrhage, diuresis, sodium loss or restriction) or effective hypovolemia (positive pressure ventilation, congestive heart failure, sepsis, or cirrhosis with ascites).

Renin acts on angiotensinogen, a large circulating glycoprotein released from the liver, and cleaves off a decapeptide, angiotensin I. In the kidney and in the lung

angiotensin I is further cleaved by endothelial-based ACE to form an octapeptide, angiotensin II, a potent vasoconstrictor (Fig. 18-14) . Renin is the rate-limiting enzyme in the production of angiotensin II. [34]

Activation of modest amounts of angiotensin II causes renal cortical vasoconstriction, predominantly at the level of the efferent arterioles. This acts to maintain glomerular filtration fraction in the face of mild to moderate decreases in RBF or perfusion pressure. The importance of this protective mechanism is emphasized by the deterioration in GFR

Figure 18-14 Renin-angiotensin system. For explanation, see text. ACE, angiotensin-converting enzyme.

that occurs when ACE inhibitors are administered to patients with hypotension, renal insufficiency, or unilateral renal artery stenosis. [35] [36] Severe stress induces the release of high levels of angiotensin II, which constricts the glomerular mesangial cells and decreases the glomerular filtration fraction. Angiotensin II promotes systemic vasoconstriction at about one-tenth of its renal effect, yet systemic arterial pressure can be markedly decreased by ACE inhibitors such as captopril and enalapril or angiotensin receptor antagonists. The effect of angiotensin II in causing salt and water retention is enhanced by its actions in stimulating aldosterone secretion by the adrenal cortex, ADH secretion by the posterior pituitary, and NaCl reabsorption by the proximal tubule. [33]

Angiotensin II triggers a number of mechanisms that modulate or oppose its own actions. It inhibits renin secretion by a negative feedback mechanism. Blockade of angiotensin formation by ACE inhibitors causes vasodilation but increases plasma renin levels. Angiotensin II activates phospholipase A_2, which triggers the synthesis of intrarenal prostaglandins. Vasodilator prostaglandins modulate the action of angiotensin II and may be responsible for its preferential activity on the efferent arteriole at low plasma levels. [34] Angiotensin-induced vasoconstriction increases atrial pressure and releases ANP, which opposes the reninangiotensin-aldosterone system.

The consequences of ACE inhibition on renal function depend on the patient's volume status, systemic hemodynamics, and baseline renal function and the presence of renovascular stenoses. In the long-term treatment of hypertension and CHF, especially in diabetics, the administration of ACE inhibitors such as captopril, enalapril, or lisinopril decreases renal vascular resistance and appears to benefit renal function. Preliminary data suggest that short-term pretreatment with captopril may prevent a decrease in RBF and GFR and preserves sodium excretion during cardiopulmonary bypass. [37] However, deterioration in renal function and hyperkalemia have been reported with the use of ACE inhibitors in patients with hypotension, renal insufficiency, or unilateral renal artery stenosis, probably related to the block of compensatory angiotensin-mediated efferent arteriolar constriction. [35] [36] It may be prudent to avoid their use in the immediate perioperative period.

Aldosterone

Aldosterone is a steroid hormone secreted by the zona glomerulosa of the adrenal cortex in response to hypokalemia, angiotensin II, and adrenocorticotropic hormone (ACTH). It acts at the thick ascending limb of the loop of Henle, the principal cells of the distal tubule, and the collecting duct to increase active absorption of sodium and passive absorption of water, culminating in an expanded blood volume. Sodium retention in vessel walls appears to enhance their response to vasoconstrictor agents.

In the principal cells, aldosterone induces cytoplasmic transcription of messenger ribonucleic acid (mRNA) to synthesize proteins that form sodium channels in the apical cell membrane and enhance the Na-K ATPase pump in the basolateral cell membrane. [24] Sodium is transported from the tubular fluid into the peritubular capillary, with chloride following along the electrical gradient thus created. This process involves protein synthesis, and there is a delay of about 1 to 2 hours from the secretion of aldosterone to its action on sodium reabsorption. Contrast this to sympathetic activity and angiotensin II, whose effects are immediate.

Antidiuretic Hormone (Arginine Vasopressin)

Antidiuretic hormone (ADH) regulates urinary volume and osmolality and controls diuresis or antidiuresis. It is a nine-amino-acid peptide, 8-arginine-vasopressin (AVP), which is synthesized in the supraoptic and paraventricular nuclei of the anterior hypothalamus. From there it undergoes

Figure 18-15 Synthesis of renal prostaglandins. Phospholipase A_2 is stimulated by ischemia, norepinephrine, and angiotensin II and cleaves arachidonic acid from its bond with membrane phospholipid. Cyclooxygenase acts on arachidonic acid to form evanescent cyclic endoperoxides (PGG_2 and PGH_2). Action of isomerase and prostacyclin synthetase culminate in the formation of vasodilator prostaglandins PGD_2, PGE_2, and PGI_2 (prostacyclin), which oppose the actions of the renin-angiotensin system on the kidney and protect against ischemic stress. Inhibition of cyclooxygenase by nonsteroidal anti-inflammatory drugs predisposes the kidney to damage. Under hypoxic or ischemic conditions, cyclic endoperoxides undergo reduction to the vasoconstrictor PGF_2, which acts on thromboxane receptors. Endotoxin increases the activity of leukocyte lipooxygenase and thromboxane synthetase. Leukotrienes (especially C_4 and D_4) and thromboxane (TXA_2) induce renal vasoconstriction and contribute to the vasomotor nephropathy of sepsis.

neuroaxonal transport to the posterior pituitary gland, where it is stored in granules before it is released into the circulation. [38] AVP acts on specific V_2-receptors in the collecting ducts to induce water reabsorption and a decreased flow of concentrated urine. It also increases NaCl reabsorption in the thick ascending loop of Henle, which maintains the hypertonicity of the medullary interstitium and facilitates movement of water out of the collecting duct along the osmotic gradient. This results in tubular conservation of water, increased urine osmolality, decreased plasma osmolality, and negative free water clearance without significant alteration in solute excretion.

The V_2-receptor on the basolateral cell membrane of the collecting duct responds to AVP via a receptor mechanism analogous to the beta-adrenergic receptor. [24] Through activation of G protein-coupled adenylyl cyclase, ATP is converted to cyclic adenosine monophosphate (cAMP), which activates protein kinase. Protein kinase causes preformed vesicles containing water channels to migrate and fuse with the apical cell membrane, resulting in a dramatic increase in its permeability to water. Water is reabsorbed into the cell and passes through the freely permeable basolateral membrane into the peritubular capillary. This process is rapidly reversed when plasma AVP levels decline: AVP plasma half-life is between 5 and 15 minutes.

Regulation of AVP Secretion

Hypothalamic osmoreceptors are sensitive to increases in serum osmolality of as little as 1 percent above normal. As illustrated in Figure 18-16A (Figure Not Available) , the threshold for AVP secretion (and the sensation of thirst) is between 280 and 290 mOsm/kg; once this is exceeded, the secretion rate has a very steep gain. [39] Even mild dehydration results in antidiuresis, with urine osmolality rapidly increasing as plasma AVP levels rise from 0 to 5 pg/mL (Fig. 18-16B) (Figure Not Available) .

AVP secretion is also stimulated by decreases in intravascular volume (mediated by stretch receptors with vagal afferents in the left atrium and pulmonary veins) and psychic stress (via cortical input). Hypovolemia-induced secretion of AVP overrides osmolar responses and contributes to the perioperative syndrome of inappropriate ADH secretion: fluid retention, hypoosmolality and hyponatremia. [40] The situation is exacerbated by administration of large volumes of hypotonic solutions that decrease serum osmolality.

Systemic arterial hypotension is a very potent trigger for AVP release, mediated by aortic and carotid baroreceptors. Plasma AVP may reach levels ten- to a thousand-fold greater than normal (Fig. 18-16C) (Figure Not Available) . At these concentrations AVP acts as a vasoconstrictor, especially in the outer renal cortex. It does so by stimulating the V_1-receptor, which exists on vascular smooth muscle, glomerular mesangial cells, and the vasa recta and promotes vasoconstriction via the phosphatidylinositol pathway. [38]

Anesthetic agents have little direct effect on AVP secretion, except via the changes that they induce in arterial blood pressure, venous volume, and serum osmolality. Surgical stimulation is a major stimulus to AVP secretion. This stress response, whether mediated by pain or by volume changes, is profound and lasts at least 2 to 3

days after the surgical procedure.

Figure 18-16 (Figure Not Available) Physiologic regulation of arginine vasopressin (AVP). For explanation, see text. *(From Landry [39])*

Patients in septic shock have inappropriately low plasma levels of AVP, about 3 pg/mL compared with patients in congestive heart failure (CHF) (about 22 pg/mL). [41] The mechanism is unknown but appears to reflect an impaired baroreflex secretion of AVP from the hypothalamus. At the same time, septic patients are profoundly sensitive to the vasoconstrictor effects of even low levels of AVP, presumably because of downregulation of the V_1-receptor. A similar phenomenon has been observed in patients with vasodilatory shock (i.e., low systemic vascular resistance [SVR] and hypotension despite increased cardiac index [CI] and norepinephrine infusion) in the postoperative period after placement of a left ventricular assist device. [42] Argenziano et al postulated that AVP deficiency may have been the result of excessive preoperative baroreceptor-mediated release in these patients with end-stage cardiac failure, compounded by downregulation of alpha-adrenergic receptors in CHF and after cardiopulmonary bypass.

Mets et al [43] reported profound refractory vasodilation after heart transplantation in two patients who had previously been on a combination of amiodarone and an ACE inhibitor. Blood pressure improved with infusion of low-dose AVP. The authors suggested that two of the three vasoconstrictor systems that normally maintain blood pressure were impaired: the sympathoadrenal system by amiodarone and the renin-angiotensin system by the ACE inhibitor. However, the endogenous AVP response was also inadequate, and exogenous AVP was therapeutic.

Systems Promoting Vasodilation and Salt Excretion

Prostaglandins

Intrarenal prostaglandins play an important role in endogenous renal protection. [44] [45] [46] [47] Prostaglandins are classified as autocoids because, unlike true hormones, they are produced in minute amounts and have a local, evanescent action. They are also referred to as eicosanoids because their structure is based on a 20-carbon fatty acid (eicosa is 20 in Greek). Vasodilator prostaglandins are important not so much to maintain normal renal function as to preserve it during the ischemic insults of acute trauma and surgery. The synthesis of intrarenal prostaglandins is summarized in Figure 18-15 .

Phospholipase A_2, which resides in the inner lipid layer of the cell membrane, controls prostaglandin production. It is stimulated by ischemia and hypotension and also by norepinephrine, angiotensin II, and AVP. Thus, the factors that induce and mediate the stress response simultaneously activate prostaglandins, which defend the kidney against their actions. Arachidonic acid is converted to PGG_2, the precursor of the vasodilator prostaglandins, by cyclooxygenase, which is inhibited by nonsteroidal anti-inflammatory drugs (NSAIDs) such as aspirin, indomethacin, meclofenamate, and ketorolac.

The important vasodilator renal prostaglandins are PGD_2, PGE_2, and PGI_2 (prostacyclin). They oppose the actions of norepinephrine and angiotensin II, antagonize AVP, and block distal tubule sodium reabsorption. Prostaglandins may be particularly important in decreasing the vasoconstrictor activity of angiotensin II on the afferent arteriole and glomerular mesangial cells. [34] Production of prostaglandins promotes renal vasodilation, maintains intrarenal hemodynamics, and enhances sodium and water excretion. At the same time that they modulate the actions of the reninangiotensin system, prostaglandins stimulate renin secretion so that there is a constant "yin and yang" between the two systems. [48]

Exogenous infusion of synthetic prostaglandins such as PGE_1 prevents ischemia-induced acute renal failure in animals and may have a role in the preservation of the donor kidney in renal transplantation. [49] The renal vasodilator response to mannitol during hypoperfusion appears to be mediated through prostaglandin activation. [50]

The renal protective effect of prostaglandins is illustrated by the fact that NSAIDs cause nephrotoxicity in ischemic

but not in normal kidneys. Cyclooxygenase is reversibly inhibited by NSAIDs for about 8 to 24 hours. A single dose of aspirin causes its irreversible acetylation. In platelets the impact lasts for the lifetime of these cells (7 to 10 days), but the kidney resynthesizes cyclooxygenase within 24 to 48 hours. During conditions of stress, NSAIDs or aspirin compromises prostaglandin-dependent renal function, resulting in decreased RBF and GFR and increased renal vascular resistance. Diuretic-induced sodium excretion is attenuated, and hyperkalemia may occur. Adverse effects of NSAIDs and aspirin have been demonstrated in animal models of hemorrhage, endotoxemia, increased venous pressure, and low cardiac output and in humans with mild underlying renal dysfunction who also have congestive heart failure, ascites, or systemic lupus erythematosus. [51]

Derivatives of arachidonic acid that induce vasoconstriction may be important in pathologic states. Thromboxane (TXA_2) is derived from cyclic endoperoxides by the action of thromboxane synthetase. It induces vasoconstriction and platelet aggregation, and in the kidney it causes mesangial cell contraction. This decreases GFR by diminishing the effective glomerular surface area and filtration constant (K_f). Renal levels of thromboxane are increased in experimental acute renal failure and sepsis. In animal experiments, the administration of a specific thromboxane synthetase inhibitor prevents the deterioration in renal function induced by injection of endotoxin. Another vasoconstrictor prostaglandin, PGF_2, which acts on the thromboxane receptor, is formed when arachidonic acid is oxidized by free radicals liberated by leukostasis during acute inflammation. The leukotrienes, arachidonic acid derivatives formed by lipooxygenase, are also released from endotoxin-activated leukocytes. Like thromboxane, leukotrienes C_4 and D_4 induce mesangial cell contraction and decrease GFR.

Kinins

Kinins act as vasodilators, which enhance the actions of prostaglandins and modulate the renin-angiotensin system. [52] They closely interact with these systems. For example, kinins stimulate phospholipase A_2, and kininase (which controls intrarenal kinin concentration) is blocked by ACE inhibitors. The two important intrarenal kinins, bradykinin and kallidin, appear to decrease renal vasoconstriction induced by adrenergic hormones and angiotensin II.

Atrial Natriuretic Peptide

The potential role of an endogenous natriuretic hormone was postulated for many years before atrial natriuretic peptide (ANP) was identified. For example, in 1972 Gorfinkel et al [53] demonstrated a profound difference in the renal response to different forms of shock induced in dogs. Hypovolemic shock resulted in low atrial pressure and a rapid diminution of RBF to 10 percent of control, whereas in their cardiogenic shock model atrial pressures were elevated and RBF was preserved at 75 percent of control despite low cardiac output. This suggested that atrial distention caused the release of a renal protective hormone. In 1981 de Bold et al [54] confirmed the existence of ANP by demonstrating that an extract of atrial tissues caused natriuresis in rats. In the subsequent decades the important actions of ANP on renal hemodynamics and sodium excretion have been well characterized. [55] An entire series of peptides with a similar precursor has been identified, with a core of 25 to 28 amino acids required for ANP-like activity.

ANP is released from electron-dense granules in atrial myocytes in response to local wall stretch and increased atrial volume. [34] It dilates vascular smooth muscle through guanylate cyclase activation and formation of cyclic guanosine monophosphate (cGMP). In addition, ANP competitively blocks norepinephrine at the phospholipase C-linked receptor and induces a noncompetitive blockade to angiotensin II at the same site. It thereby reverses vascular smooth muscle constriction induced by these compounds. ANP causes a prompt, sustained increase in GFR and glomerular filtration fraction, even when RBF is not increased or when arterial pressure is decreased. This suggests that it causes afferent arteriolar dilation with or without efferent arteriolar constriction. The increased GFR increases the filtered load of sodium, but natriuresis may be due to increased medullary blood flow, which washes out the concentration gradient. [56]

The "yin and yang" of the systems controlling the internal milieu is epitomized by the release of ANP as a result of vasoconstriction and salt retention induced by epinephrine, angiotensin, aldosterone, and AVP which ultimately results in atrial stretch. ANP may have a mutually antagonistic interaction with endothelin, the

endogenous vasoconstrictor peptide produced by vascular endothelium. [34] ANP appears to oppose the renin-angiotensin-aldosterone system on several fronts (Fig. 18-17) . It inhibits renin secretion and decreases angiotensin-stimulated aldosterone release. It also inhibits aldosterone release directly at the zona glomerulosa

Figure 18-17 Interactions between ANP and the renin-angiotensinaldosterone system. Hypotension or hypovolemia triggers release of renin from the afferent arteriole, causing the formation of angiotensin II, which stimulates release of aldosterone from the adrenal cortex. Angiotensin II and aldosterone cause vasoconstriction and sodium retention, ultimately resulting in reexpansion of the intravascular volume; this causes atrial distention, which triggers release of ANP. ANP inhibits release of renin, renin's action on angiotensinogen to form angiotensin II, angiotensininduced vasoconstriction, stimulation of aldosterone secretion by angiotensin II, and the actions of aldosterone on the collecting duct. Thus, the actions of ANP promote vasodilation and sodium excretion. Therapeutic administration of fluids to distend the atrium and release ANP is an important intervention to curtail renal vasoconstriction and sodium retention.

of the adrenal cortex and blocks the salt-retaining action of aldosterone at the distal tubule and collecting duct. It acts directly at the medullary portion of the collecting duct to inhibit NaCl reabsorption via cGMP activation. [24] ANP inhibits AVP secretion from the posterior pituitary and antagonizes its effect on the V_2 -receptor in the collecting duct, thereby promoting diuresis.

The protective role of endogenous ANP is illustrated in a study by Shannon et al, [57] who had noticed that patients undergoing mitral valve replacement appeared to have poorer urine output after cardiac surgery than those undergoing aortic valve replacement or coronary revascularization. They discovered that patients whose postoperative mean left atrial pressure declined by more than 7 mm Hg from preoperative values (which commonly occurs with correction of mitral valve disease) had significantly decreased postoperative urine sodium excretion and flow rate. Furthermore, there was a direct correlation between the quantitative decrease in left atrial pressure with surgery and a postoperative decline in circulating ANP levels (Fig. 18-18) (Figure Not Available) . In other words, patients with mitral valve disease and high left atrial pressure have a constant stimulus to ANP release. Valve replacement or repair results in decreased left atrial pressure, decreased ANP, and declining salt excretion and urine flow rate.

Exogenous administration of ANP decreases systemic blood pressure, probably through venodilation and decreased cardiac preload. It increases GFR, induces natriuresis, and can also reverse renovascular hypertension. Urodilatin, an ANP congener produced by the kidney and excreted in the urine, lacks the systemic vasodilator effects of the parent compound but has similar action on renal function.

There has been considerable interest in the ability of infused ANP to reverse established acute renal failure (ARF) ("renal rescue"). Animal studies of both ischemic [58] [59] and nephrotoxic [60] ARF have demonstrated that ANP infusion improves RBF and GFR, induces natriuresis, and decreases azotemia and renal histologic damage.

In a small uncontrolled human study, Cedidi et al [61] infused urodilatin in eight patients with oliguric ARF after liver transplantation. Blood pressure remained stable, but central venous pressure declined, all patients developed a marked natriuresis within 2 to 4 hours, and in 6 patients hemodialysis was avoided. In a controlled pilot study [62] on 53 patients with established intrinsic ARF, ANP infusion doubled creatinine clearance from 10 to 21 mL/min in 24 hours and decreased the incidence of dialysis from 52 to 23 percent ($P < .05$). This was followed by a large randomized, controlled, multicenter study in which 504 patients were prospectively identified as having oliguric (urine output <400 mL/d) or nonoliguric acute tubular necrosis (ATN). [63] Anaritide, a 25-amino acid synthetic analog of ANP, or placebo was infused for 24 hours. In patients with oliguric ARF, anaritide infusion induced significantly greater dialysis-free survival than in those with placebo, 27 versus 8 percent ($P < .008$). However, in nonoliguric ARF anaritide actually appeared to worsen survival (48% versus 59% with placebo). It is noteworthy that in the nonoliguric patients anaritide induced a decrease in blood pressure and urine flow rate, whereas in the oliguric patients blood pressure was less affected, and urine flow rate increased. This suggests

Figure 18-18 (Figure Not Available) Correlation between left atrial pressure and plasma ANP in a group of patients undergoing cardiac surgery. (A) There is significant correlation (r = 0.8, $P < .001$) between absolute preoperative left atrial pressure and plasma ANP. (B) There is a significant correlation (r = 0.72, $P < .002$) between the postoperative decrease in left atrial pressure and postoperative decrease in plasma ANP, ANF, atrial natriuretic factor, synonymous with ANP. Delta, change. *(From Shannon et al [57])*

that there may be intrinsic pathologic differences between oliguric and nonoliguric ATN. It also emphasizes the importance of maintenance of renal perfusion pressure in ARF, given the loss of renal autoregulation that occurs. [6]

The Dopaminergic System

There are two subtypes of dopaminergic (DA) receptors. [64] At the end-organ, DA_1 -receptors occur not only on the renal and splanchnic vasculature but also on the proximal tubule itself. [65] Stimulation of the DA_1 -receptor causes renal vasodilation, increased RBF and GFR, natriuresis, and diuresis. Neuronal DA_2 -receptors exist on the presynaptic

TABLE 18-2 -- Dopaminergic Agonists and Antagonists

RECEPTOR	AGONIST	ANTAGONIST
DA_1 , DA_2	Dopamine	Haloperidol, chlorpromazine, metoclopromide
DA_1	Fenoldopam	SCH 23390
DA_2	Bromocriptine	Domperidone

DA_1 = dopamine-1 receptor. DA_2 = dopamine-2 receptor. Dopamine is a nonselective dopaminergic agonist; haloperidol, chlorpromazine, and metoclopromide are nonselective dopaminergic antagonists (the clinical importance of this property is not known). Fenoldopam is a selective DA_1 -receptor agonist, which shows promise as a vasodilator agent that preserves renal blood flow. Bromocriptine is a selective DA_2 - receptor agonist used in Parkinson's disease to enhance central dopaminergic activity. SCH 23390 and domperidone are selective DA_1 - and DA_2 -receptor antagonists.

terminal of postganglionic sympathetic nerves. Stimulation inhibits the release of norepinephrine from presynaptic vesicles, a mechanism analogous to stimulation of the presynaptic alpha$_2$ -receptor. Through inhibition of norepinephrine, DA_2 -receptor activation facilitates vasodilation. Dopaminergic agonists and antagonists may be classified on the basis of their selective or nonselective action on DA_1 - and DA_2 - receptors (Table 18-2) .

Dopaminergic receptors form an integral part of the endogenous vasodilator-natriuresis system. Dopamine produced in the kidney acts as a natriuretic hormone by inhibiting tubular Na^+ -K^+ -ATPase activity. It appears to constitutively activate the DA_2 -receptor, which then synergistically enhances the activation of the DA_1 -receptor. [66] It has been suggested that decreased dopaminergic activity contributes to the pathogenesis of idiopathic edema, which manifests as retention of salt and water in the upright position. [67]

Dopamine

Low-dose dopamine (1-3 mug/kg/min) has a nonselective agonist effect on DA_1 - and DA_2 -receptors, causing renal and splanchnic vasodilation. [68] [69] Its action may also involve inhibition of sodium reabsorption by the proximal tubule, resulting in brisk saliuresis. [65] When dopamine was compared with dobutamine in equi-inotropic doses after cardiac surgery, effects on GFR, effective RPF, renal vascular resistance, and FF were similar. However, dopamine caused greater urine flow rate, natriuresis, fractional excretion of sodium, and potassium excretion, suggesting that tubular dopaminergic receptors exist. [70] Dopamine has also been shown to block the renal vasoconstrictor effects of norepinephrine. [25]

Clinically, dopamine is indicated as a diuretic when urine output is low (<0.5 mL/kg/h) despite apparently adequate intravascular volume and cardiac output. Dopamine's effectiveness is limited by its mixed adrenergic activity, with overlapping dose-response curves. From 3 to 10 mug/kg/min beta $_1$ -adrenergic effects predominate but can cause unwanted tachycardia even at lower doses. At doses above 10 mug/kg/min, dopamine has an increasing activity on the alpha $_1$ -adrenergic receptor. In part this is due to its biotransformation to norepinephrine. The net effect is progressive renal vasoconstriction and diminished urine flow rate. Haloperidol, chlorpromazine, and metoclopramide are nonselective dopaminergic antagonists, but there are few data on their clinical inhibition of dopamine action. [71]

There are few data on the perioperative protective effect of low-dose dopamine. Dog studies did not demonstrate any improvement in RBF, GFR, or urine flow rate when low-dose dopamine was infused during thoracic aortic cross-clamping. [72] Dopamine does not significantly increase GFR or RBF in chronic renal insufficiency when the baseline GFR is less than 50 mL/min/1.73M^{-2} . [73] In a retrospective study on patients undergoing orthotopic liver transplantation, prophylactic low-dose dopamine decreased the incidence of dialysis-dependent ARF from 27 to 9.5 percent of patients. [74] In a subsequent controlled prospective study, Swygert et al [75] failed to find that it had any benefit on intraoperative urine flow, postoperative creatinine clearance, ARF, or mortality. Grundmann et al [76] randomized 50 cadaveric kidney graft recipients into two equal groups; one received dopamine 2 mug/kg/min for 4 days. Although the dopamine group had higher urine flow, postoperative creatinine clearance and requirement for dialysis were identical. Moreover, dopamine frequently caused tachycardia.

Dopexamine

Dopexamine is a synthetic analogue of dopamine. It is a potent beta $_2$ -receptor agonist and nonselective dopaminergic agonist, with about one-third of dopamine's effect on the renal vasculature [77] (Table 18-3) . Its effects are predominantly chronotropic, with moderate inotropic effect and intense arterial vasodilation (inodilation). Used in the dose range of 1 to 5 mug/kg/min, it provides left and right ventricular afterload reduction in acute and chronic heart failure while augmenting RBF. [78] Tachycardia is common, but tachyarrhythmias are not. Potential advantages include improved myocardial efficiency through its vasodilator and lusitropic actions (enhanced diastolic relaxation and decreased wall stress) while it promotes renal perfusion. Dopexamine provides the pharmacologic profile of a phosphodiesterase inhibitor such as amrinone, with the rapid onset and offset of action of a catecholamine.

Fenoldopam

Fenoldopam, a benzazepine dopamine analogue, is a selective DA $_1$ -receptor agonist and is devoid of DA$_2$ -, beta-, or alpha-adrenergic activity. When administered between 0.03 to 0.3 mug/kg/min, there is a dose-related increase in renal

TABLE 18-3 -- Dopamine Derivatives

RECEPTOR	DA$_1$	DA$_2$	beta $_1$	beta $_2$	alpha $_1$
Dopamine	+++	++	++	±	+++
Dobutamine	0	0	+++	++	±
Dopexamine	++	+	±	+++	0
Fenoldopam	++++	0	0	0	0

DA$_1$ = dopamine-1 receptor, DA$_2$ = dopamine-2 receptor, beta$_1$ = beta-1 receptor, beta$_2$ = beta-2 receptor, alpha$_1$ = alpha-1 receptor.

blood flow and natriuresis. In vitro, it antagonizes norepinephrine-induced vasoconstriction. It is rapidly metabolized, with a half-life of 10 minutes, and when administered by intravenous infusion has a rapid onset and offset of effect.

Fenoldopam is as effective as sodium nitroprusside in controlling severe hypertension, but unlike nitroprusside it induces significant increases in GFR, urine flow, and saliuresis, without rebound hypertension. [79] [80] [81] In 1998 fenoldopam was approved for the short-term parenteral treatment of severe hypertension. The selective DA$_1$ -receptor agonist activity of fenoldopam suggests that it may confer protection against nephrotoxic or ischemic renal insults without the beta-adrenergic side effects of dopamine. [82] At present this remains a theoretical rather than practical concept.

PERIOPERATIVE ISCHEMIC AND NEPHROTOXIC INJURY

This section will review perioperative agents and events that may disrupt normal renal physiology. If the disruption is severe enough or occurs in susceptible individuals, it may induce ischemic or nephrotoxic renal injury.

Perioperative Events

Anesthetic Agents

The choice of an anesthetic technique to preserve renal function during and after surgery is predicated on the preservation of RBF and perfusion pressure, the suppression of vasoconstrictor, salt-retaining stress responses to surgical stimulation and postoperative pain, and the avoidance or curtailment of nephrotoxic insults. No single anesthetic drug alone meets these criteria.

Regional Anesthesia

Spinal or epidural anesthesia (Ch. 42) that achieves sympathetic blockade of the fourth through tenth thoracic segments is extremely effective in suppressing the sympathoadrenal stress response and release of catecholamines, renin and AVP. During major surgery, RBF and GFR are preserved as long as adequate renal perfusion pressure is maintained. [83] [84] [85] This implies careful titration of the block, especially in elderly patients with cardiovascular disease, and a 25- to 50-percent increase in intraoperative fluid requirement. [86] However, Gamulin et al [87] found that renal sympathetic blockade obtained by epidural anesthesia did not block increases in renal vascular resistance induced by infrarenal aortic cross-clamping nor did it prevent postoperative decreases in creatinine clearance.

General Anesthesia

The overall effect on renal function of anesthetic drugs in common use (Chs. 6 and 34) has been well summarized by Priano. [31] All anesthetic techniques and agents tend to decrease GFR and intraoperative urine flow. Some drugs also decrease RBF, but FF is usually increased, which implies that angiotensin-induced efferent arteriolar constriction limits the decrease in GFR. However, these effects are much less significant than those caused by surgical stress or aortic cross-clamping, and after emergence from anesthesia usually resolve promptly. Any anesthetic technique that induces hypotension will result in decreased urine flow because of altered peritubular capillary hydrostatic gradients, regardless of the maintenance of RBF and GFR by autoregulation (which is usually preserved during anesthesia). Permanent injury seldom results, unless the kidneys are abnormal to begin with or the hypovolemic insult is prolonged and exacerbated by nephrotoxins.

Halothane, enflurane, or isoflurane with nitrous oxide induce mild to moderate reductions in RBF and GFR, primarily due to their effects on the central circulation (myocardial depression, peripheral pooling). [88] [89] These effects can be modified by prior hydration. [90] High-dose opioid techniques using fentanyl or sufentanil do not depress myocardial contractility and have minimal effect on RBF and GFR. They are considerably more effective in suppressing the release of catecholamines, angiotensin II, aldosterone, and AVP during surgery than are volatile agents. However, during cardiopulmonary bypass both AVP and catecholamine levels rise markedly despite high-dose opioid anesthesia. [91] [92] [93] Intravenous agents such as thiopental and diazepam cause minor changes in renal function, about 10 to 15 percent deviation from control. Ketamine increases RBF but decreases urine flow rate, possibly through sympathetic activation; it preserves RBF during hemorrhagic hypovolemia. [94]

Nephrotoxicity of Volatile Anesthetics

The potential nephrotoxicity of volatile anesthetics (Ch. 6) is due to their metabolic production of free fluoride ions, which cause a tubular lesion that results in loss of concentrating ability and polyuric acute renal failure. [95] Toxicity is exacerbated by aminoglycosides or prior renal dysfunction. Peak fluoride levels less than 50 mum/L seldom induce injury, whereas levels >150 mum/L are associated with a high incidence of polyuric acute renal failure. [96] Administration of methoxyflurane at more than 1 minimum alveolar concentration (MAC) for more than 2 hours is capable of generating a peak fluoride level greater than 100 mum/L; for this reason, this anesthetic is no longer used. Enflurane is metabolized more rapidly, and most studies have indicated that peak fluoride levels seldom rise above 25 mum/L. However, the antituberculotic agent isoniazid enhances fluoride production. Only isolated reports of fluoride-induced nephrotoxicity due to enflurane have appeared. [97] [98] Isoflurane produces peak fluoride levels less than 4 m/L, and halothane is not metabolized to fluoride at all. [99]

The potential nephrotoxicity of sevoflurane remains controversial. Although its metabolism generates more fluoride than enflurane, clinically significant fluoride-induced nephrotoxicity has not been detected. Compound A, a vinyl ether formed by degradation of sevoflurane at low flow through carbon dioxide absorbents, is capable of inducing renal injury in rats. Although ARF has not been reported in humans, Eger et al reported evidence of transient renal injury

(albuminuria, tubular enzymuria) in volunteers subjected to 8 hours of 1.25 MAC sevoflurane at 2 L/min gas flow. There were no changes in urinary concentrating ability, serum creatinine, or blood urea nitrogen (BUN).

Eger's findings have been disputed by other laboratories. Bito et al compared 6-hour patient exposure to low- and high-flow sevoflurane and low-flow isoflurane exposure and found no differences in BUN, creatinine, or tubular enzymes for 3 days postoperatively. [100] Kharasch et al [101] had similar results with the use of sevoflurane or isoflurane at 1 L/min in 73 patients undergoing procedures lasting longer than 2 hours, and they concluded that moderate duration of low-flow sevoflurane anesthesia, even with the formation of compound A, is as safe as low-flow isoflurane anesthesia. [101] Ebert et al [102] attempted to duplicate the original 8-hour Eger sevoflurane study in volunteers at two sites with blinded laboratory analyses. [102] Biochemical derangements were minimal and transient, and there were no significant changes in BUN, creatinine, or creatinine clearance. Despite the similarity in experimental design, the mean level of compound A was about 25 percent lower, and the mean arterial pressure about 10% higher than the Eger study and may have accounted for the difference in results.

Subsequently, Eger et al [103] described a dose-response relationship between biochemical markers of glomerular and tubular injury (urinary albumin, alpha-glutathione-Stransferase) and compound A exposure expressed as parts per million-hours (ppm/h). They suggested that the threshold of renal injury is 80 to 168 ppm/h; they observed alteration in biochemical markers with 1.25 MAC sevoflurane at 2 L/min for 4 hours (but not for 2 hours) and none with desflurane.

In summary, clinically significant renal injury with the use of low-flow sevoflurane anesthesia has not been reported in patients, even with moderate preexisting renal dysfunction. The relationship between compound A formation, biochemical injury, and clinically relevant renal dysfunction remains unclear and unproven. Nonetheless it appears prudent to follow current FDA guidelines, which recommend a fresh gas flow of at least 2 L/min to inhibit compound A formation and rebreathing and to

enhance its washout.

Positive Pressure Ventilation

Positive pressure ventilation (Ch. 72) and positive endexpiratory pressure (PEEP) decrease RBF, GFR, sodium excretion, and urine flow rate. [104] [105] The extent of depression of renal function depends on the mean airway pressure. Thus, the impact on the kidney is greater with inverse ratio ventilation than with intermittent mandatory ventilation (IMV) and greater with IMV than spontaneous ventilation with PEEP (continuous positive airway pressure).

These changes are largely mediated by transmission of airway and intrapleural pressures to the intravascular space, leading to decreases in venous return, transmural (i.e., effective) cardiac filling pressures, and cardiac output. Transmission may actually be attenuated in acute lung injury because of poor lung compliance. High levels of mean airway pressure may compress the pulmonary arterial circulation, increase right ventricular afterload, and induce the intraventricular septum to shift into the left ventricle and decrease its filling and cardiac output. [106] Positive pressure ventilation increases inferior vena caval pressure and renal venous pressure and might increase tubular sodium reabsorption by increases in peritubular capillary pressure.

The decrease in cardiac output and systemic arterial pressure results in a carotid and aortic baroreceptor-mediated increase in sympathetic nerve tone to the kidney, with renal vasoconstriction, antidiuresis, and antinatriuresis. Volume receptors in the atria respond to decreased filling by decreased ANP secretion, resulting in increased sympathetic tone, renin activation, and AVP activity.

Salt and water retention during airway pressure therapy was originally thought to be due to an AVP effect, [107] but it is now considered that sympathetic responses are more important and that sodium retention is largely the result of decreased sodium delivery to the tubules. The reninangiotensin-aldosterone system undoubtedly augments the renal responses to positive pressure ventilation. Annat et al [108] found that 15 cm H_2O PEEP depressed cardiac output, RBF, GFR, and urine volume by 20 to 30 percent and was associated with increases in renin and aldosterone but not AVP. The impairment in renal function induced by airway pressure therapy can be prevented or reversed by preserving normal circulatory status, either by hydration or by use of dopamine. [109] [110]

Induced Hypotension

During anesthesia with induced hypotension (Ch. 41) , substantial reduction of GFR and urine flow rate is common. However, when the duration of hypotension is less than 2 hours, no permanent impairment of renal function occurs, even in elderly patients. [111] Vasodilator agents used to induce hypotension differ in their effect on RBF. The ganglionic blocker trimethaphan camsylate abolishes autoregulation and causes the greatest decrease in RBF. [112] Sodium nitroprusside has a lesser impact on renal vascular resistance, but its administration is associated with marked renin-angiotensin activation and catecholamine release (inhibited by propranolol), which results in rebound hypertension if the infusion is suddenly discontinued. [113] Nitroglycerin decreases RBF less than sodium nitroprusside. [114] The selective DA_1 -dopaminergic agonist fenoldopam is capable of providing induced hypotension without any significant decrease in RBF. [115]

Aortic Cross-Clamping

The effects of suprarenal and infrarenal aortic cross-clamping (Ch. 51) on renal function in patients undergoing major vascular surgery were compared by Myers et al. [21] Regardless of the position of the aortic cross-clamp, RBF was decreased to 50 percent of normal during surgical preparation of the aorta, presumably due to direct compression or reflex spasm of the renal arteries. After release of the suprarenal cross-clamp, RBF increased above normal (reflex hyperemia), but GFR remained depressed to one-third of control for up to 2 hours. After 24 hours GFR was still only two-thirds of control. Tubular functions (concentrating ability, sodium and water conservation) were markedly impaired,

but urine flow was maintained. Myers and Moran [116] observed that these changes resembled an attenuated form of acute tubular necrosis. All patients received mannitol pretreatment, which probably limited the tubular insult because oliguria was uncommon and recovery was relatively rapid. However, cross-clamp times longer than 50 minutes were associated with prolonged depression of GFR and transient azotemia.

Infrarenal aortic cross-clamping may also impair RBF and GFR by inducing decreases in cardiac output in response to increased systemic vascular resistance. [117] Atheromatous embolism of the renal arteries may be induced by cross-clamping or manipulation in areas of dense aortic plaque. Partial or complete cortical necrosis may occur, which is usually irreversible.

Renal Protection During Aortic Cross-Clamping

Mannitol has been used for more than 40 years to provide renal protection during aortic cross-clamping. [118] Its protective effects have been clearly demonstrated in animal models of ischemic acute tubular necrosis (ATN), [119] but few prospective controlled human studies exist. Low-dose dopamine is also commonly used during major vascular surgery, but in an animal study of thoracic aortic cross-clamping it did not prevent the impairment and delayed recovery of RBF, GFR, and urine flow observed after cross-clamp release. [72] In a human study of infrarenal cross-clamping, Paul et al [120] compared diuretic therapy with a combination of mannitol and dopamine versus fluid loading with saline to a pulmonary artery occlusion pressure (PAOP) of 12 to 15 mm Hg. Although mannitol and dopamine substantially increased urine flow and sodium excretion during cross-clamping, they were no better than saline on attenuating residual GFR depression after cross-clamp release.

Cardiopulmonary Bypass

Cardiopulmonary bypass (Ch. 49) induces hypotension with nonpulsatile flow, which promotes renal vasoconstriction and decreased RBF. Norepinephrine levels increase progressively during bypass, and the renin-angiotensin system is activated. Acute renal failure has been associated with persistent elevation of plasma renin levels. [121] Thromboxane, released from activated platelets, and vascular elaboration of endothelin could possibly contribute to renal vasoconstriction during extracorporeal circulation. Tubular enzymuria and microalbuminuria, an index of subclinical injury to the nephron, is consistently observed during cardiopulmonary bypass. [122] Despite these observations, the incidence of acute renal failure remains less than 2 percent of all patients. Nonetheless, when it does occur after cardiac surgery, ARF is associated with a forbidding mortality rate--60 to 90 percent.

Renal Protection During Cardiopulmonary Bypass

Pulsatile perfusion during cardiopulmonary bypass does not appear to offer an advantage with respect to RBF or catecholamine release. Although plasma renin activity is suppressed by pulsatile perfusion, microalbuminuria persists, and there is no evidence that outcome is better. [123] Badner et al [124] found no difference in postoperative renal function in a group of patients with normal kidneys undergoing pulsatile or nonpulsatile CPB. Case series that claim that pulsatile CPB confers protection to patients with chronic renal insufficiency undergoing cardiac surgery do exist, but unfortunately they are neither randomized nor prospective. [125] [126]

It has been observed in animal studies of cardiopulmonary bypass that RBF is dependent on renal perfusion pressure, and infusion of dopamine does not increase RBF during low pressure states. [7] This suggests that autoregulation may be impaired during cardiopulmonary bypass. However, Hilberman et al [127] found no relationship between low flow (<50 mL/kg/min) and mean arterial pressure (<50 mm Hg) and postoperative ARF. Instead, the severity of postoperative renal dysfunction and its outcome correlated with the severity of cardiac dysfunction after cardiopulmonary bypass. [128]

Other important risk factors for postoperative renal dysfunction after cardiac surgery include the complexity of surgery (e.g., combined procedures versus simple revascularization) and preoperative renal function. In a prospective review of more than 4,000 cases at the Cleveland Clinic, Higgins et al [129] demonstrated that the risk of renal morbidity and mortality increases exponentially when the preoperative serum creatinine is greater than 1.9 mg/dL.

There is little evidence that the "prophylactic" administration of low-dose dopamine has a protective role during cardiopulmonary bypass in patients with normal [130] or impaired renal function [131] undergoing cardiac surgery. Moreover, dopamine may induce tachycardia even in the low-dose range and is associated with a higher incidence of supraventricular and ventricular arrhythmias. [132]

Nephrotoxic Insults

Drug-Induced Nephrotoxicity

Nephrotoxic injury by drugs (aminoglycosides, cyclosporin A, amphotericin B, cisplatinum, etc.) or contrast dyes seldom occurs unless coexisting risk factors exist. [9] These may be acute (shock, hypovolemia, congestive heart failure) or chronic (advanced age, diabetes, chronic renal insufficiency). The risk of nephrotoxicity increases exponentially with the number of risk factors and nephrotoxic combinations.

Nephrotoxic acute renal failure is usually nonoliguric, with loss of concentrating ability and slowly progressive azotemia. As GFR declines, toxic serum levels of renally excreted drugs exacerbate nephrotoxicity unless drug levels are carefully monitored and dosage repeatedly adjusted. However, the prognosis for recovery is good if these agents are discontinued in time and no coexistent organ failure exists.

Aminoglycosides

Polycationic aminoglycosides (gentamicin, tobramycin, amikacin) are filtered into the proximal tubule, where they bind to the anionic brush-border membrane phospholipids.

Their nephrotoxicity is directly related to their polycationic status; neomycin (six cationic sites) is more destructive than gentamicin (five sites) or streptomycin (three sites). [133] They are absorbed into intracellular lysosomes by endocytosis and thence released into the cytosol. Within the cell they induce defects in lysosomes, plasma membranes, and mitochondria and, in particular, inhibit oxidative phosphorylation and the synthesis of high-energy phosphate compounds such as ATP.

Aminoglycoside-induced nephrotoxicity is directly related to sustained high-trough serum levels, especially when associated with advanced age, preexisting renal disease, renal vasoconstrictive states (sepsis, hypovolemia, liver disease, congestive heart failure), adjuvant drug therapy (loop diuretics, vancomycin, cephalosporins, NSAIDs, cyclosporin A, amphotericin B), and electrolyte disorders (hypokalemia, hypomagnesemia, hypercalcemia, and metabolic acidosis). [134] A vicious cycle may develop because as the GFR declines secondary to nephrotoxicity, aminoglycoside is retained and exacerbates renal injury.

Prevention of aminoglycoside nephrotoxicity depends on maintenance of adequate hydration, avoidance or removal of the risk factors enumerated above, and careful monitoring of serum aminoglycoside levels. A daily 2-hour creatinine clearance can also be helpful in the early detection of aminoglycoside-induced nephrotoxicity and appropriate dose adjustment for GFR. Once-daily administration of aminoglycosides to achieve a high therapeutic level with an adequate trough period for renal recovery may limit the occurrence of nephrotoxicity. [135] Low-dose dopamine increases renal clearance of aminoglycosides, but it is not known whether this protects against tubular injury.

Cyclosporine A

Cyclosporine A is a remarkably potent immunosuppressive agent and, together with steroids and azathioprine, is routinely used to prevent rejection after organ transplantation. Indeed, heart, lung, and liver transplantation increased exponentially after its release in 1981. It causes renal injury in part because it induces sympathetic hyperreactivity, hypertension, and renal vasoconstriction. Its nephrotoxic effects are exacerbated by preexisting renal dysfunction, hypovolemia, and other nephrotoxic insults. Many transplant patients must tolerate a moderately elevated serum creatinine (1.5-2 mg/dL) in order to sustain adequate immunosuppression. A number of alternative immunosuppressive agents (e.g., CellCept) have been developed in an effort to decrease or eliminate cyclosporine requirement.

Radiocontrast Dyes

The nephrotoxicity of dyes probably involves microvascular obstruction by crenated red cells as well as direct tubular toxicity. The risk is markedly increased in diabetic renal insufficiency, hypovolemia, congestive heart failure, and myeloma. [136] [137] Radiocontrast dyes are hypertonic and cause an osmotic diuresis, which induces a false sense of security but exacerbates hypovolemia and renal damage. Azotemia commences 24 to 48 hours after exposure and peaks at 3 to 5 days. Surgery performed during this period greatly increases the risk of perioperative acute renal failure.

Prevention of nephrotoxicity depends on adequate hydration with or without intravenous mannitol during the study and deferral of elective surgical procedures until the effects of the dye have been evaluated and treated. [138] [139] Calcium channel blockers appear to be protective (see below). Nonionic, low-osmolar radiocontrast agents have been developed, but they are quite expensive and appear to offer the best cost-benefit ratio when used in high-risk situations only, e.g., diabetic nephropathy. [135]

Role of Calcium Channel Blockers

Calcium channel blockers prevent ischemic renal injury by a number of mechanisms, including the prevention of reflow-induced vasoconstriction after ischemia, inhibition of angiotensin action in the glomerulus, and decrease in circulating interleukin-2 receptors. [140] They may reduce the accumulation of oxygen-free radicals and reperfusion injury through prevention of intracellular calcium influx and the calcium/calmodulin-dependent conversion of xanthine dehydrogenase to xanthine oxidase.

However, calcium blockers may overcome renal autoregulation and worsen renal function when they induce hypotension. Administration of nifedipine to patients with renal insufficiency has been reported to cause nonoliguric renal failure that improved when the drug was discontinued. [141] In contrast, in hypertensive patients diltiazem and nifedipine promoted natriuresis and increased RBF and GFR. [142]

Calcium channel blockers confer important protection against nephrotoxins such as cyclosporin, cisplatinum, and radiocontrast dyes. [143] [144] [145] [146] [147] In patients undergoing cadaveric renal transplantation, diltiazem was added to the graft preservative solution, infused into the donor for 48 hours, and then given orally. [143] The incidence of transplant acute tubular necrosis (ATN) decreased from 41 to 10 percent, and when ARF did occur, hemodialysis requirement was significantly less. Diltiazem impairs cyclosporin metabolism so that plasma cyclosporin levels are higher, with fewer episodes of early acute rejection, but it protects against cyclosporin nephrotoxicity. [147] Cyclosporin dosage may be reduced by 30 percent to achieve the same drug levels, representing a substantial cost-savings to patients.

Pigment Nephropathy

Pigment nephropathy implies acute renal injury due to the nephrotoxic effect of the heme pigments myoglobin, hemoglobin, and bilirubin.

Rhabdomyolysis and Myoglobinemia

Muscle necrosis (rhabdomyolysis) occurs most commonly with direct trauma involving major crush or thermal injury. However, it also occurs with acute muscle ischemia induced by vascular disease or injury or by prolonged immobilization. Compartment syndromes exacerbate rhabdomyolysis. They are particularly likely to occur with major hemorrhage in an extremity or when vascular insufficiency coexists with tissue edema (e.g., femoral placement of an intra-aortic balloon after vein harvesting). Dramatic increases in metabolic

rate (caused by severe prolonged fever, status epilepticus or myoclonus, or severe exercise with hypokalemia), severe hypophosphatemia, or direct proteolysis (as in

acute pancreatitis) can all precipitate rhabdomyolysis. [148]

Myoglobin, the oxygen-carrying heme pigment of muscle, is released into the blood stream (myoglobinemia) and rapidly excreted by the glomerulus at a plasma threshold of 0.03 mg/dL. Delivery of myoglobin to the proximal tubule is greater in a well-muscled individual with normal GFR than in a cachectic patient with low GFR. At a urine pH less than 5.6, myoglobin is transformed into ferrihematin, which precipitates in the proximal tubule. [149] Renal damage is facilitated by hypovolemia (i.e., low tubular flow) and acidic urine. Because of the associated hypercatabolic state, oligoanuria is associated with acute hyperkalemia, hypocalcemia, anion-gap metabolic acidosis, and rapid azotemia. Serum creatinine and BUN increase very rapidly (1.0-1.5 mg/dL/d and 20-30 mg/dL/d, respectively).

The most important aid to the diagnosis of rhabdomyolysis is a high index of suspicion. The affected muscle may be obviously ischemic or swollen, painful, and edematous. Urine myoglobin often tests positive without reddish urine. The serum is clear because of the low renal threshold for myoglobin excretion, whereas hemoglobinemia is associated with pink serum. Serial total creatinine phosphokinase (CPK) is a helpful guide to the severity of rhabdomyolysis (i.e., CPK-MM release). [150] Renal damage is much more likely when total CPK exceeds 10,000 U/L.

Prevention of acute nephrotoxic tubular necrosis is dependent on the maintenance of high RBF and tubular flow. Urine flow should be kept between 100 to 150 mL/h by osmotic diuresis with intravenous mannitol, 6.25 to 12.5 g every 6 hours, with or without intravenous furosemide, 10 to 20 mg as required. [151] Urine pH should be kept above pH 5.6 with intravenous sodium bicarbonate, 50 mEq intravenously, as required, and/or acetazolamide, 250 mg every 6 hours. However, because there are no prospective data that confirm the beneficial effect of urinary alkalinization, urine pH should not be increased at the expense of causing significant acid-base imbalance. Calcium should be given to treat hyperkalemia only.

Hemolysis and Hemoglobinemia

Acute intravascular hemolysis due to mismatched blood transfusion (ABO incompatibility) represents a direct and devastating renal insult. Renal damage is thought to be predominantly due to red blood cell stroma rather than to free hemoglobin. Management is essentially the same as for rhabdomyolysis.

Jaundice and Bilrubinemia

There is a direct correlation between the degree of preoperative obstructive jaundice and postoperative renal dysfunction. [152] [153] When cholestasis causes the conjugated bilirubin to increase above 8 mg/dL, bile salt excretion effectively ceases, resulting in portal septicemia and renal damage. This situation is analogous to hepatorenal syndrome and sepsis, in which circulating endotoxins induce renal vasoconstriction and damage (vasomotor nephropathy).

Perioperative protection in jaundiced patients may be provided by giving preoperative oral bile salts (e.g., sodium taurocholate) or intravenous mannitol. In a prospective, randomized study on patients with obstructive jaundice undergoing surgery, Plusa and Clark [154] found no difference in renal outcome between these two regimens. However, mannitol provokes a brisk osmotic diuresis, and it is important to replace urinary losses appropriately. Diuresis-induced hypovolemia negates the protective effect of mannitol. [155] Parks et al [153] reported a prevalence of postoperative oliguria of less than 20 percent of jaundiced patients who received 3 L intravenous crystalloid preoperatively and who were given furosemide with or without low-dose dopamine intraoperatively.

Sepsis

Sepsis is the most common cause of new onset ARF in the postoperative period. [156] Renal function may deteriorate progressively without defined episodes of hypotension. In addition, sepsis predisposes the kidney to further ischemic and nephrotoxic insults; for example, from concomitant aminoglycoside usage. [157] [158] ARF itself and hemodialysis perpetuate sepsis by activating leukocytes. Sepsis may induce renal damage by hypotension and vasomotor nephropathy and through the direct and indirect effects of endotoxin.

There is a reasonable amount of evidence to suggest that renal autoregulation may be impaired in sepsis and that RBF and GFR decline *pari passu* with systemic vascular resistance and mean arterial pressure. Hypotension in turn sets off a cascade of neurohormonal responses (sympathoadrenal activity; renin-angiotensin, vasopressin, and thromboxane activation) that result in decreased RBF, GFR, sodium excretion, and urine flow. The severity of renal dysfunction appears to be directly related to the severity of sepsis and the degree of plasma renin activation. [159]

Renal dysfunction in sepsis is characterized as a vasomotor nephropathy, which implies renal vasoconstriction in the face of increased total cardiac index. Renal vasoconstriction, mesangial cell contraction, decreased ultrafiltration coefficient, and decreased GFR are induced by endotoxin and by compounds activated in sepsis. [160] These include endothelin and eicosanoids, such as thromboxane, prostaglandin F_2, and the leukotrienes C4 and D4. Prostaglandin F_2, which mimics the action of thromboxane, is formed during leukostasis when arachidonic acid is oxidized by free oxygen radicals.

Endotoxin causes leukocyte arachidonic acid to undergo lipooxygenation to form leukotrienes; it also impairs their biliary elimination. In addition, experimental infusion of lipopolysaccharide (endotoxin) directly decreases RBF, GFR, and tubular concentrating ability and increases urinary loss of tubular enzymes. It causes sequestration of leukocytes in peritubular capillaries, induces endothelial lesions by releasing neutrophil-derived elastase (enhanced by reperfusion injury), and potentiates renal ischemia such that brief hemodynamic instability causes rapid loss of renal function. It also potentiates nephrotoxicity. The changes caused by endotoxin are mimicked by the cytokine, tumor necrosis factor-alpha.

It has been estimated that about 10 to 26 percent of septic patients receiving aminoglycoside antibiotics (gentamicin, tobramycin and amikacin) will develop nephrotoxic renal insufficiency. [161] Aminoglycosides are filtered into the proximal tubule, bind to the anionic brush-border membrane phospholipids, become absorbed by endocytosis into intracellular lysosomes, and are released into cytosol. There, they damage lysosomes and membranes, inhibit mitochondrial oxidative phosphorylation, and deplete tubular ATP.

Aminoglycoside nephrotoxicity is enhanced by the interaction of fever, renal vasoconstriction, hypovolemia, and endotoxin. It is also exacerbated by toxic drug levels, prolonged therapy, concomitant drug toxicity (NSAIDs, cyclosporine A, amphotericin B), and electrolyte disorders such as hypercalcemia, hypomagnesemia, hypokalemia, and metabolic acidosis. In the presence of these risk factors, alternative non-nephrotoxic antibiotics should be considered to cover gram-negative infections, including penicillins (ticarcillin), cephalosporins (ceftazidime), carbapenems (imipenem), or monobactams (aztreonam).

Renal Protection in Septic Shock

Supranormal Oxygen Delivery

Over the last decade there has been considerable interest in the concept of supranormal oxygen delivery to the tissues to overcome the defect that exists in oxygen utilization by septic tissues. This approach utilizes inotropic support and blood transfusion to drive global oxygen delivery (DO_2) to one of three end points: (1) DO_2 reaches levels consistently found in survivors, i.e., 600 mL/min/m^2; (2) global oxygen consumption (VO_2) no longer increases with increasing DO_2 (consumption independence); or (3) blood lactate levels start to decline. However, renal DO_2 and VO_2 differ markedly from systemic indices. Renal VO_2 is largely determined by tubular metabolic function, which is regulated by fluid and electrolyte changes. In a volume-loaded septic porcine model, inotropic support with dobutamine increased systemic DO_2 and VO_2 but did not increase renal DO_2 and VO_2. [26] Furthermore, decreased global renal DO_2 does not appear to cause tubular damage, possibly because tubular work and VO_2 are decreased when GFR declines. [162]

Dopaminergic Agents

Low-dose dopamine (1-3 mug/kg/min) is frequently administered to septic patients in the belief that it confers renal protection through renal vasodilation or perhaps by inhibition of the Na^+-K^+-ATPase pump and decrease in renal tubular VO_2.

It is also administered in combination with more potent pressors (dobutamine, epinephrine, and norepinephrine) in sepsis in the hope of enhancing hepatic, renal, and mesenteric perfusion. There are some animal data to support this practice. In a nonseptic dog study in which RBF was measured by thermodilution, the addition of low-dose dopamine to a norepinephrine infusion of 0.2-1.6 mug/kg/min increased RBF by 40 to 50 percent. [25] However, a subsequent study demonstrated that, although low-dose dopamine increased RBF when added to an epinephrine infusion in healthy sheep, this benefit could not be found in an intraperitoneal sepsis model. [163] Other studies have shown that low-dose dopamine can increase hepatic DO_2, possibly at the expense of splanchnic oxygenation.

In patients with sepsis syndrome (signs of sepsis without hypotension), low-dose dopamine infusion doubled urine flow rate and increased creatinine clearance by 60 percent without any change in systemic hemodynamics. [164] However, the renal response to dopamine decreased significantly after 48 hours of dopamine infusion, possibly due to downregulation of the renal dopaminergic receptors or diuresis-induced contraction of the intravascular volume. In patients with established septic shock who required catecholamines for blood pressure support, low-dose dopamine did not alter systemic hemodynamics or renal function.

The potential role of dopexamine in septic shock remains speculative. Most studies have examined its role in splanchnic and hepatic perfusion rather than in renal protection. In animal models of sepsis, it has been shown to have beneficial effects on splanchnic and hepatic DO_2, but its $beta_2$-adrenergic activity in causing tachycardia and hypotension may limit dopexamine's application in clinical sepsis. Smithies et al [165] administered dopexamine to patients with sepsis syndrome, acute respiratory failure, and at least one other organ system failure. Cardiac index increased and gastric intramucosal pH (an index of splanchnic perfusion) improved significantly.

Norepinephrine

In patients with septic shock, profound hypotension, and oliguria, vasopressor therapy with norepinephrine may actually improve renal function by enhancing renal perfusion pressure. Desjars et al [5] evaluated a group of septic patients who remained oliguric despite volume resuscitation and the use of dopamine up to doses of 15 mug/kg/min. The addition of norepinephrine and reduction of dopamine to a low-dose level resulted in an improvement in mean arterial pressure from 50 to 70 mm Hg, a tripling of urine flow, and a doubling of creatinine clearance. Norepinephrine increased the systemic vascular resistance (SVR) with little change in cardiac index or DO_2. Subsequent studies have confirmed that the use of norepinephrine to keep mean arterial pressure greater than 60 mm Hg results in improved cardiac function (increase in stroke volume and decrease in heart rate) and GFR without deleterious effects on cardiac index (CI), oxygen extraction, or VO_2. [166] These findings strongly support the concept that renal autoregulation is impaired in sepsis and that maintenance of adequate renal perfusion pressure is an important component of renal protection.

Vasopressin (AVP)

Landry et al [41] observed unusual sensitivity to the vasoconstrictor effects of infused AVP in patients with septic shock with profound hypotension despite catecholamine infusion. Plasma AVP levels were remarkably low (3.1 ± 1.0 pg/mL) and significantly lower than in a cohort of patients in cardiogenic shock also receiving catecholamines (22.7 ± 2.2 pg/mL, $P < .001$). Infusion of AVP at doses of 2.4 U/h, less

than one-tenth of those used in the treatment of bleeding esophageal varices, resulted in a dramatic increase in systolic blood pressure from 92 ± 4 to 146 ± 4 mm Hg (mean ± SEM, $P < .001$), and catecholamine infusions were able to be discontinued. In an associated report [167] the authors observed that urine flow increased concomitantly in three of five patients, from an average of 30 mL/h to 110 mL/h.

The inappropriately low plasma AVP in septic shock may be attributed to sustained baroreceptor-mediated AVP release as a response to hypotension. It is possible that upregulation of the V_1-receptor could quickly develop and explain the enhanced sensitivity to the vasoconstrictor effects of infused AVP. The beneficial effect of AVP on renal function could in part be due to enhanced renal perfusion pressure in the face of abnormal autoregulation (see above) and also due to the fact that AVP appears to preferentially constrict the efferent arteriole, thereby improving filtration fraction and GFR. [168]

Anti-Inflammatory Agents

Cumming et al [169] demonstrated a marked renal protective effect of a selective thromboxane synthetase inhibitor (U63557A) in laparotomy on a volume-loaded sheep peritonitis model. Administration of the selective inhibitor either before or 30 minutes after surgery prevented deterioration in creatinine clearance, urinary sodium excretion, and urine flow rate. Beneficial effects have also been observed with aprotonin, perhaps through its anti-inflammatory action. [170] In contrast, nonselective cyclooxygenase inhibition by NSAIDs worsens renal function in sepsis by decreasing the synthesis of the renal vasodilator prostacyclin. [47]

The use of pharmacologic doses of methylprednisolone in septic shock was discredited by two large multicenter studies showing no beneficial effect on outcome. [171] [172] Moreover, patients who received steroids had significant increases in BUN but not in serum creatinine, suggesting a prerenal state induced by increased protein catabolism. [173] Other potentially adverse effects of high-dose steroids include impaired mitochondrial function, impaired leukocyte function, and inhibition of phospholipase A_2, resulting in decreased synthesis of intrarenal vasodilator prostaglandins.

Chapter 19 - Cerebral Physiology and the Effects of Anesthetics and Techniques

John C. Drummond
Piyush M. Patel

INTRODUCTION

This chapter reviews the effects of anesthetic agents and techniques on cerebral physiology, and, in particular, their effects on cerebral blood flow (CBF) and metabolism (Table 19-1) . The final section presents a brief discussion of pathophysiologic states including cerebral ischemia and of cerebral protection. The chapter gives greatest emphasis to information that is of immediate relevance to the rationale for the anesthetic and intensive care management of patients with intracranial disease. Chapter 52 presents the clinical management of these patients in detail. Neurologic monitoring, including the effects of anesthetic agents on the electroencephalogram (EEG) and evoked responses, is reviewed in Chapter 35 .

REGULATION OF CEREBRAL BLOOD FLOW

Anesthetic agents cause dose-related and reversible alterations in many aspects of cerebral physiology including CBF, cerebral metabolic rate (CMR) and electrophysiologic function (EEG, evoked responses). The changes in CBF and CMR can be of clinical importance in patients with neurosurgical diseases. Certain anesthetic agents and techniques have the potential to affect the diseased brain and the conduct of the neurosurgical procedure adversely. However, in certain instances, the effects of general anesthesia on CBF and CMR can be manipulated to improve both the operative course and the clinical outcome of patients with neurologic disorders.

The adult human brain weighs approximately 1,350 g and therefore represents about 2 percent of total body weight. However, it receives 12 to 15 percent of cardiac output. This high flow rate is a reflection of the brain's high metabolic rate. At rest, the brain consumes O_2 at an average rate of approximately 3.5 mL of O_2 per 100 g of brain tissue per minute. Whole-brain O_2 consumption (13.5 × 3.5 = 47 mL/min) represents about 20 percent of total-body O_2 utilization. Normal values for CBF, CMR, and other physiologic variables are provided in Table 19-2 .

Approximately 60 percent of the brain's energy consumption [1] is used to support electrophysiologic function. The depolarization-repolarization activity that occurs and that is reflected in the EEG requires energy expenditure for the maintenance and restoration of ionic gradients and for the synthesis, transport, and reuptake of neurotransmitters. The remainder of the energy consumed by the brain is involved in cellular homeostatic activities. Local CBF (l-CBF) and local CMR (l-CMR) within the brain are very heterogeneous, and both are approximately four times greater in gray matter than in white matter. The cell population of the brain is also heterogeneous in its O_2 requirements. Glial cells make up about half of the brain's volume and require less energy than neurons. Besides providing a physically supportive latticework for the brain, the glial cells are important in the reuptake

TABLE 19-1 -- Abbreviations

BBB	Blood-brain barrier
CBF	Cerebral blood flow
CBFV	Cerebral blood flow velocity
CBV	Cerebral blood volume
CMR	Cerebral metabolic rate
CMRg	Cerebral metabolic rate for glucose
$CMRO_2$	Cerebral metabolic rate for oxygen
CNS	Central nervous system
CPP	Cerebral perfusion pressure
CSF	Cerebrospinal fluid
CSFP	Cerebrospinal fluid pressure
CVR	Cerebral vascular resistance
EEG	Electroencephalogram
ICP	Intracranial pressure
l-CBF	Local cerebral blood flow
l-CMR	Local cerebral metabolic rate
LLA	Lower limit of autoregulation
MAP	Mean arterial pressure
MCA	Middle cerebral artery
NO	Nitric oxide
N_2O	Nitrous oxide
PET	Positron emission tomography
r-CBF	Regional cerebral blood flow
TCD	Transcranial Doppler

of neurotransmitters and in the delivery and removal of metabolic substrates and wastes.

The brain's substantial demand for substrate must be met by adequate delivery of O_2 and glucose. However, the space constraints imposed by the noncompliant cranium and meninges require that blood flow not be excessive. Not surprisingly, there are elaborate mechanisms for the regulation of CBF. These mechanisms, which include chemical, myogenic, and neurogenic factors, are listed in Table 19-3 . The precise mechanisms of these effects are for the most part not well understood. However, a substantial volume of research indicates that modulation of the arginine-nitric oxide (NO)-cyclic guanosine monophosphate (cGMP) system [2] [3] is central to the changes in cerebral vascular tone caused by several processes including hypercarbia, [4] [5] increased CMR, [6] [7] volatile agents, [8] [9] [10] and neurogenic mechanisms. [11] [12] [13]

Chemical Regulation

Several factors cause changes in the cerebral biochemical environment that result in adjustments of CBF. These include changes in CMR, arterial CO_2 tension (Pa

$_{CO_2}$) and arterial O_2 tension (Pa $_{O_2}$).

TABLE 19-2 -- Normal Cerebral Physiologic Values

Cerebral blood flow	
Global	45-55 mL/100 g/min
Cortical (mostly gray matter)	75-80 mL/100 g/min
Subcortical (mostly white matter)	20 mL/100 g/min
Cerebral metabolic rate for oxygen	3-3.5 mL/100 g/min
Cerebral vascular resistance	1.5-2.1 mmHg · 100 g · min/mL
Cerebral venous oxygen tension	32-44 mm Hg
Cerebral venous oxygen saturation	55-70%
Intracranial pressure (supine)	8-12 mm Hg

TABLE 19-3 -- Factors Influencing Cerebral Blood Flow [a]

FACTOR	COMMENT
Chemical/Metabolic/Humoral	
Cerebral metabolic rate	The cerebral metabolic rate influence assumes intact flow-metabolism coupling, the mechanism of which is not fully understood

Cerebral Metabolic Rate

Increased neuronal activity results in increased local brain metabolism, and this increase in CMR is associated with a well-matched, proportional change in CBF. [14] [15] Regional CBF and CMR measurements performed during maneuvers designed to activate specific brain regions provide evidence of the strict local "coupling" of CMR and CBF. [16] [17] [18] [19] Although it is clear that local metabolic factors play a major role in these adjustments in CBF, and whereas there is evidence that NO of neuronal origin contributes to the vasodilation that occurs, [6] [7] the complete mechanism of flowmetabolism coupling remains undefined. [20] CMR is influenced by several phenomena in the neurosurgical environment, including the functional state of the nervous system, anesthetic agents, and temperature.

Functional State.

CMR decreases during sleep and increases during sensory stimulation, mental tasks, or arousal of any cause. During epileptoid activity, CMR increases may be extreme, whereas CMR may be substantially reduced in coma.

Anesthetics.

The effect of individual anesthetics on CMR is presented in greater detail later in this chapter. In general, anesthetic agents suppress CMR, with ketamine and nitrous oxide (N_2O) the notable exceptions. It appears that the component of CMR on which they act is that associated with electrophysiologic function. [21] With several agents, including barbiturates, [21] isoflurane, [22] and etomidate [23] (and probably propofol, sevoflurane and desflurane), increasing plasma concentrations cause progressive suppression of EEG activity and a concomitant reduction in CMR. However, increasing the plasma level beyond that required first to achieve suppression of the EEG results in no further depression

Figure 19-1 The interdependency [21] of cerebral electrophysiologic function and cerebral metabolic rate for oxygen (CMRO $_2$). Administration of various anesthetic agents [21] [22] [23] including barbiturates results in a dose-related reduction in $CMRO_2$ and cerebral blood flow (CBF). The maximum reduction occurs with the dose that results in electrocerebral silence. At this point, energy utilization associated with electrophysiologic activity has been reduced to zero, but energy utilization for cellular homeostasis persists unchanged. Additional barbiturate administration causes no further decrease in CBF or $CMRO_2$. EEG, electroencephalogram.

of CMR. The component of CMR required for the maintenance of cellular integrity, the "housekeeping" component, is apparently unaltered by intravenous anesthetics (Fig. 19-1) .

The $CMRO_2$ values observed when complete suppression of the EEG is achieved with different anesthetic agents are very similar. The inference that

anesthetic-induced EEG suppression represents a single physiologic state no matter what agent is employed follows easily. However, there is evidence to the contrary. When barbiturates are administered to the point of EEG suppression, a uniform depression of CBF and CMR occurs throughout the brain. When suppression occurs during isoflurane administration, the relative reductions in CMR and CBF are greater in the neocortex than in other portions of the cerebrum. [24] [25] [26] Electrophysiologic responsiveness also varies. Cortical somatosensory evoked responses to median nerve stimulation can be recorded readily at doses of thiopental far in excess of those required to cause complete suppression of the EEG, [27] but they are difficult to elicit at concentrations of isoflurane associated with a burst-suppression pattern, such as 1.5 minimum alveolar concentration (MAC) [28] (Fig. 19-2) . In addition, the EEG characteristics of the burst-suppression states that occur just before complete suppression differ among anesthetic agents. [29] These differences may be of some relevance to discussions of differences in the "protective" potential of agents that can produce EEG suppression because it is apparent that burst suppression does not represent a uniform physiologic state, irrespective of the agent used to produce it.

Temperature.

The effects of hypothermia on both normal and ischemic brain have been reviewed in detail. [1] [30] [31] CMR decreases by 6 to 7 percent per Celsius degree of temperature reduction. [1] As is the case with some anesthetic agents, hypothermia can also cause complete suppression of the EEG (at 20°C). However, in contrast to anesthetic agents, temperature reduction beyond that at which EEG suppression first occurs *does* produce a further decrease in CMR (Fig. 19-3) . This occurs because, whereas anesthetic agents reduce only the component of CMR associated with neuronal function, hypothermia decreases the rate of energy utilization associated with both electrophysiologic function and the basal component associated with the maintenance of cellular integrity. These decreases were once assumed to be proportional. However, it has been demonstrated that mild hypothermia preferentially suppresses the basal component of CMR. [32] [33] $CMRO_2$ at 18°C is less than 10 percent of normothermic control values, and this probably accounts for the brain's tolerance for moderate periods of circulatory arrest at these and lower temperatures.

Figure 19-2 Cortical somatosensory evoked responses to median nerve stimulation in human patients before induction and during anesthesia with thiopental and isoflurane nitrous oxide (N_2O). In spite of an equivalent or greater degree of cerebral metabolic rate (CMR) reduction with thiopental, cortical evoked responses are better preserved [27] than during anesthesia with isoflurane. [28] This finding suggests that the electroencephalographic (EEG) suppression achieved with different anesthetic agents should not be assumed to be equivalent electrophysiologic states. The cumulative thiopental doses and expired concentrations of isoflurane and N_2O are indicated.

Figure 19-3 The effect of temperature reduction on the cerebral metabolic rate for oxygen ($CMRO_2$). Hypothermia reduces both the components of cerebral metabolic activity identified in Figure 19-1 : that associated with neuronal electrophysiologic activity ("function") and that associated with the maintenance of cellular homeostasis ("integrity"). This is in contrast to anesthetic agents, which alter only the function component. *(Data from Michenfelder [1])*

Hyperthermia has an opposite influence on cerebral physiology. Between 37 and 42°C, CBF and CMR increase. However, at temperatures higher than 42°C a dramatic reduction in cerebral O_2 consumption occurs, an indication of a threshold for a toxic effect of hyperthermia that may occur as a result of protein (enzyme) degradation.

Partial Pressure of Carbon Dioxide

CBF varies directly with Pa co_2 (Fig. 19-4) . The effect is greatest within the range of physiologic Pa co_2 variation. CBF changes 1 to 2 mL/100 g/min for each 1 mm Hg of change in Pa co_2 around normal Pa co_2 values. [34] This response is attenuated below a Pa co_2 of 25 mm Hg. [34] Under normal circumstances, CBF sensitivity to changes in Pa co_2 (DeltaCBF/DeltaPa co_2) appears to be positively correlated with resting levels of CBF. [35] Accordingly, anesthetic agents that alter resting CBF cause changes in the CO_2 response of the cerebral circulation. However, CO_2 responsiveness has been observed in normal brain during anesthesia with all the numerous anesthetic agents that have been studied.

The changes in CBF caused by Pa co_2 are apparently dependent on pH alterations in the extracellular fluid of the brain. [36] NO, in particular NO of neuronal origin, is an important, although not exclusive, mediator of CO_2 -induced vasodilatation. [4] [5] [37] [38] [39] In particular, in primates, the available data indicate that NO's relevance may be limited to the cerebral cortex. [5] The changes in extracellular fluid (ECF) pH and CBF occur rapidly after Pa co_2 adjustments because CO_2 diffuses freely across the cerebrovascular endothelium. Note that in contrast to *respiratory* acidosis, acute systemic *metabolic* acidosis has little immediate effect on CBF because the blood-brain barrier (BBB) excludes the hydrogen ion from the perivascular space. Although the CBF changes in response to Pa co_2 alteration occur rapidly, they are not sustained. In spite of the maintenance of an elevated arterial pH, CBF returns to normal over 6 to 8 hours [40] [41] [42] because cerebrospinal fluid (CSF) pH gradually normalizes as a result of the extrusion of bicarbonate. As a result, the patient who has sustained periods of hyperventilation or hypoventilation deserves special consideration. Acute normalization of Pa co_2 results in a significant CSF acidosis (after hypocapnia) or alkalosis (after hypercapnia). The former results in increased CBF with a concomitant intracranial pressure (ICP) increase that will depend on the prevailing intracranial compliance. The latter conveys the theoretic risk of ischemia.

Partial Pressure of Oxygen

Changes in Pa o_2 from 60 to more than 300 mm Hg have little influence on CBF. When the Pa o_2 is less than 60 mm Hg, CBF increases rapidly (see Fig. 19-4) . The mechanisms mediating the cerebral vasodilation during hypoxia are not fully understood, but they may include neurogenic effects initiated by peripheral and/or neuraxial chemoreceptors as well as local humoral influences. At high Pa o_2 values, CBF decreases modestly. [43] At 1 atm O_2 , CBF is reduced by 12 percent. [44]

Figure 19-4 Changes in cerebral blood flow (CBF) caused by independent alterations in arterial pressures of carbon dioxide and oxygen (Pa co_2 and Pa o_2) and mean arterial pressure (MAP).

Myogenic Regulation (Autoregulation)

Autoregulation refers to the capacity of the cerebral circulation to adjust its resistance in order to maintain CBF constant over a wide range of mean arterial pressure (MAP). In normal human subjects, the limits of autoregulation occur at MAPs of approximately 70 and 150 mm Hg (Fig. 19-5) . The lower limit of autoregulation (LLA) has been widely quoted as an MAP of 50 mm Hg. Although this number may be correct for some animal species, the available data argue that the LLA is considerably higher in humans. [45] Note that the units used on the X axis of "autoregulation curves" influence the correct inflection points of the curve. When the X axis is MAP, the normal average LLA is not less than 70 mm Hg (with considerable interindividual variation). [46] [47] [48] [49] [50] However, cerebral perfusion pressure (CPP) is the ideal independent variable. However, because ICP is usually not measured in healthy subjects, CPP (MAP - ICP) is rarely available. Assuming a normal ICP in a supine subject of 10 to 15 mm Hg, an LLA of 70 expressed as MAP corresponds to an LLA of 55 to 60 mm Hg expressed as CPP.

Above and below the autoregulatory plateau, CBF is pressure dependent (pressure passive) and varies linearly with CPP. Autoregulation is influenced by various pathologic processes and, in addition, by the time course over which CPP changes occur. Even within the range over which autoregulation normally occurs, a rapid change in arterial pressure will result in a transient (3 to 4 minutes) alteration of CBF. [51]

The precise mechanism by which autoregulation is accomplished is not known. NO may participate in the vasodilation

Figure 19-5 Schematic representation of the effect of increasing concentrations of a typical volatile anesthetic agent on cerebral blood flow (CBF) autoregulation. Both the upper and lower thresholds are shifted to the left. MAP, mean arterial pressure.

associated with hypotension in some species, [52] [53] but not, according to a single study, in primates. [54]

Neurogenic Regulation

There is considerable evidence of extensive innervation of the cerebral vasculature. [55] The density of innervation declines with vessel size, and the greatest neurogenic influence appears to be exerted on larger cerebral arteries. [56] This innervation includes cholinergic (parasympathetic [57] and nonparasympathetic [58] [59] [60]), adrenergic (sympathetic [61] and nonsympathetic [62]), serotonergic, [63] [64] and vasoactive intestinal peptide-ergic (VIPergic) [65] systems of extra-axial and intra-axial origin. It is certain that in animals there is an extracranial sympathetic influence via the superior cervical ganglion [61] [66] [67] [68] [69] and parasympathetic innervation via the sphenopalatine ganglion. [57] The intra-axial pathways are less well defined, although there is considerable evidence of innervation arising from several nuclei in animals including the locus caeruleus, [62] the fastigial nucleus [60] the dorsal raphe nucleus [64] and the basal magnocellular nucleus of Mey-nert. [58] [59] Evidence of the functional significance of neurogenic influences has been derived from studies of CBF autoregulation [66] [68] [70] [71] [72] and ischemic injury. [73] [74] Hemorrhagic shock, a state of high sympathetic tone, results in a lower CBF at a given MAP than occurs when hypotension is produced with sympatholytic drugs. This is presumably because, during shock, a sympathetically mediated vasoconstrictive effect shifts the lower end of the "autoregulatory" plateau (see Fig. 19-4) to the right. It is not clear what the relative contributions of humoral and neural mechanisms are to this phenomenon; however, there is certainly a neurogenic component in some species because sympathetic denervation increases CBF during hemorrhagic shock in baboons [70] and rabbits [66] and in head injury in piglets. [75] Activation of cerebral sympathetic innervation also shifts the upper limit of autoregulation to the right and offers some protection against hypertensive breakthrough of the BBB. [71] [72] Experimental interventions that alter these neurogenic control pathways have also been shown to influence outcome after standardized ischemic insults, [73] [74] presumably via influences on vascular tone and therefore CBF. The nature and influence of such pathways in humans are not known, and at present there are no clinical interventions intended to manipulate them that are relevant to the neurosurgical patient. [76]

Viscosity Effects

Blood viscosity can influence CBF. Hematocrit is the single most important determinant of blood viscosity. [77] In healthy subjects, hematocrit variation within the normal range (33-45%) probably results in only trivial alteration of CBF. Beyond this range, changes are more substantial. [77] [78] In anemia, cerebral vascular resistance is reduced and CBF increases. However, this may result not only from reduction in viscosity, but also in response to reduced O_2 -carrying capacity of blood. [79] The effect of viscosity reduction on CBF is more obvious in the setting of focal cerebral ischemia when vasodilation in response to impaired O_2 delivery is probably

already maximal. In this setting, viscosity reduction accomplished by hemodilution results in increases in CBF in the ischemic territory. [80] [81] [82] [83] The best available information suggests that, in the setting of focal cerebral ischemia, a hematocrit of 30 to 34 percent will result in optimal O_2 delivery. [84] [85]

Vasoactive Agents

Many agents with intrinsic vascular effects are employed in contemporary anesthetic practice. These include both anesthetic agents and numerous vasoactive drugs used specifically for hemodynamic manipulation. This section deals with the latter. The actions of anesthetics are discussed in a later section.

Systemic Vasodilators

Most of the drugs used to induce hypotension (including sodium nitroprusside, nitroglycerin, hydralazine, adenosine, calcium channel blockers) also cause cerebral vasodilation. As a result, CBF either increases or is maintained at prehypotensive levels. In addition, CBF is maintained to lower MAP when hypotension is induced with a cerebral vasodilator than with either hemorrhage or a noncerebral vasodilator, such as the ganglionic blocker trimethaphan. [86] Agents that vasodilate the cerebral circulation simultaneously cause increases in cerebral blood volume (CBV) with the potential to increase ICP. The ICP effects of these agents are empirically less dramatic when hypotension is induced slowly. [87] This probably reflects the more effective interplay of compensatory mechanisms (CSF and venous blood shifts) when changes occur more slowly.

Catecholamine Agonists/Antagonists

Numerous drugs with agonist and antagonist activity at catecholamine receptors (alpha $_1$, alpha$_2$, beta, and dopamine) are in common use (Ch 14) . The data regarding the effects of these agents on cerebral physiology contain numerous apparent inconsistencies. In part, these arise because of differences among species, [69] because of differences in the receptor populations on different vessels (e.g., intraparenchymal versus extraparenchymal) within a given species, [69] and because of model differences (e.g., *in vivo* versus *in vitro*). However, other variables have probably contributed. These include the magnitude of the systemic blood pressure changes that occurred as a result of administration of the agent of interest, the status of the autoregulation mechanism (as determined by the anesthetic agents employed and/or damage inherent to the preparation), the status of the BBB, and, in *in vitro* studies, the status of the endothelium. Readers who intend to review this literature should also appreciate that the effects of pressors are reported by various authors in terms of effects on either CBF or CVR. An increase in CVR is occasionally presented as prima facie evidence that the agent in question is a cerebral vasoconstrictor. However, the normal autoregulatory response to a rising MAP entails cerebral vasoconstriction (an increase in CVR) in order to maintain a constant CBF. Accordingly, an increase in CVR may indicate that the agent has a direct effect on the cerebral vasculature, but alternatively, it may indicate the absence of a direct effect and preservation of autoregulation. It is probably most practical to think in terms of changes in CBF rather than changes in CVR because CBF is the variable that is most important to the clinician. The information given later in the discussion and in Table 19-4 emphasizes data obtained in investigations of pressor agents in intact preparations and gives greatest weight to results obtained in humans and higher primates.

alpha$_1$ -Agonists

A frequently encountered clinical concern is that the administration of agents with alpha $_1$ -agonist effects (phenyl-ephrine, norepinephrine) will lead to a reduction of CBF. Data derived from studies in both humans and nonhuman primates do not support this belief. Olesen [88] measured CBF

TABLE 19-4 -- Best Estimates of the Influence of Pure Catecholamine Receptor Agonists and Specific Pressor Substances on Cerebral Blood Flow and Cerebral Metabolic Rate[a]

[a] Where species differences occurred, data from primates were given preference. See text for complete discussion.

in human patients during intracarotid or intravenous infusion of norepinephrine. Intracarotid infusion in doses that raised peripheral MAP from 95 to 117 mm Hg and intravenous infusion that raised MAP from 95 to 142 mm Hg resulted in no change in CBF. King et al [89] administered sufficient norepinephrine to increase average MAP from 91 to 117 mm Hg and observed a reduction in global CBF from 61 to 56 mL/100 g/min, that is, a very small change. Rogers et al [90] saw no reduction of CBF during administration of phenylephrine to patients receiving cardiopulmonary bypass. Intracarotid infusion of norepinephrine in phencyclidine-anesthetized baboons in a dose sufficient to increase MAP by 10 percent had no effect on CBF. [91] alpha$_1$ -Agonists also do not appear to cause cerebral vasoconstriction in rats. [92] [93] [94] [95] The notion that they reduce CBF may be the product of species differences. In both dogs and goats, norepinephrine infusion at rates resulting in a moderate increase in MAP *is* associated with a reduction in CBF that can be blocked by alpha $_1$ -antagonists. [96] [97] [98] [99] Nonetheless, the concern that CBF will be reduced in patients appears unfounded.

CBF increases have been attributed to norepinephrine. These could occur if autoregulation were defective or its limit exceeded. In some instances, the increases may be the result of BBB abnormalities. There are data to suggest that beta-mimetic agents (norepinephrine has some beta-activity) cause activation of cerebral metabolism, [100] with a parallel "coupled" increase in CBF, and this effect is likely to be most apparent when they can gain greater access to the brain parenchyma via a defective BBB [91] [93] [101] (see the epinephrine section later). In summary, it seems likely that circulating alpha $_1$ -agonists will have little direct influence on CBF in humans, with the exception that norepinephrine may cause vasodilation when the BBB is defective.

beta-Agonists

The available data suggest that beta-receptor agonists, in low doses, have little direct effect on the cerebral vasculature, but in larger doses and in association with physiologic stress, they can cause an increase in CMR with an accompanying increase in CBF. [102] An investigation in rabbits by Sercombe et al, [103] who administered isoproterenol with and without selective and nonselective beta-antagonists indicates that the beta $_1$ -receptor is probably the mediator of these effects. The effects are probably enhanced by increased permeability of the BBB (see later). Olesen [88] observed no change in CBF in unanesthetized human volunteers in response to an intra-carotid infusion of approximately 6 mug/min of epinephrine, a dose that caused no change in MAP. However, when King et al [89] administered a larger dose of epinephrine, 37 mug/min intravenously (a dose sufficient to increase MAP from 91 to 109 mm Hg), CBF and CMRO $_2$ rose by 22 and 24 percent, respectively. A similar pattern was observed in rats by Berntman et al, [93] who found that 2 mug/kg/min of epinephrine had no effect on CBF and CMR, whereas 8 mug/kg/min caused increases in both.

There is evidence that a BBB defect enhances the effect of beta-agonists. [91] [101] [104] MacKenzie et al [91] observed no effect of intracarotid norepinephrine (which has some beta-effect) on CBF and CMR in normal baboons. However, when these researchers disrupted the BBB by the intracarotid injection of hypertonic urea, norepinephrine caused increases in CBF and CMR. Artru et al [101] demonstrated that epinephrine caused CMRO$_2$ elevation in dogs but only when BBB permeability to Evans blue was present. Note that in neither of these studies were CBF/CMR changes observed without BBB abnormality. In addition, in the previously described investigation of Berntman et al, [93] CBF and CMR increased, and, although the BBB was not known to be abnormal, MAP was transiently very high (180 mm Hg), and such transient changes can open the BBB. [105] These observations beg the interpretation that beta-agonist increase CBF and CMR *only* when the BBB is injured. However, in the aforementioned clinical study of King et al, [89] MAP was apparently not excessively high, and CBF/CMR increases nonetheless occurred. Accordingly, it does not appear that BBB injury is a necessary condition in humans for the occurrence of beta-mediated increases in CBF and CMR, although such a defect probably exaggerates the phenomenon.

beta-Blockers

beta-Blockers have been reported variously to reduce or to have no effect on CBF and/or CMR. In investigations in several species, including baboons, propranolol has been reported to prevent or to attenuate CBF and CMR effects attributed to beta-agonists. [93] [99] [106] In two investigations in humans, propranolol, 5 mg intravenously, [107] and labetalol, 0.75 mg/kg intravenously [108] had no effect on CBF and CBFV, respectively. Dubois et al [109] observed modest reductions in CBF when labetalol was administered to patients undergoing craniotomy who became hypertensive during emergence from anesthesia. Esmolol has been reported to shorten seizures induced by electroconvulsive therapy, a finding suggesting that it does cross the normal BBB. [110] Esmolol was reported in abstract form to have no effect on CBF and CMR as long as CPP was maintained. [111] Catecholamine levels at the time of beta-blocker administration and/or the status of the BBB may influence the effect of these agents. The database with respect to these possibilities is incomplete. However, the data suggest that beta-blockers are unlikely to have adverse effects on patients with intracranial disorders, other than effects secondary to changes in perfusion pressure.

Dopamine

Dopamine is widely employed in the treatment of hemodynamic dysfunction. In addition, it is commonly used to augment the function of the normal cardiovascular system when MAP elevation is desired as an adjunct to the treatment of focal cerebral ischemia, especially in the setting of vasospasm. Nonetheless, its effects on CBF and CMR have not been defined with certainty. Taken together, the available data [94] [97] [112] [113] [114] [115] suggest that the predominant effect of dopamine in the normal cerebral vasculature is probably vasodilation with minimal CMR change. There is a possibility of a vasoconstrictive effect at high doses. However, vasoconstriction was not evident in rhesus monkeys given doses up to 100 mug/kg/min. In that same investigation, the same doses of dobutamine were associated with CBF and CMR increases of 20 to 30 percent. [115]

alpha$_2$ -Agonists

There is considerable interest in alpha $_2$ -agonists because of their apparent analgesic and sedative effects. This class includes dexmedetomidine and clonidine, with the latter a much less specific and less potent alpha $_2$ -agonist. It appears likely that their predominant effect is reduction of CBF with no effect on CMRO $_2$. [116] [117] [118] [119] [120] The mechanism of the CBF effect is not clear. Dexmedetomidine has been shown to cause constriction of isolated cerebral vessels, [121] a finding suggesting the presence of postsynaptic alpha $_2$ -receptors causing vasoconstriction. [122] It is also possible that alpha $_2$ -agonists act at a central site, such as the locus caeruleus, [62] to cause neurogenically mediated vasoconstriction.

Age

Aging (Chs. 59 and 61) , from childhood to late adulthood, is associated with progressive reduction of CBF and CMRO $_2$. [123] [124] This change may reflect the progressive neuronal loss that occurs with age.

/das/book/view/29494766/875/203.html

EFFECTS OF ANESTHETIC AGENTS ON CEREBRAL BLOOD FLOW AND CEREBRAL METABOLIC RATE

This section deals with the effect of anesthetic agents on CBF and CMR. It includes limited mention of influences on autoregulation, CO_2 responsiveness, and CBV. Discussions of effects on CSF dynamics, the BBB, and epileptogenesis appear later in this chapter.

In neuroanesthesia, considerable emphasis is placed on the manner in which anesthetic agents and techniques influence CBF. The rationale is 2-fold. First, the delivery of energy substrates is dependent on CBF, and, in the setting of ischemia, modest alterations in CBF can substantially influence neuronal outcome. Second, the control and manipulation of CBF are central to the management of ICP because, as CBF varies in response to vasoconstrictor-vasodilator influences, such as Pa CO_2 and volatile anesthetics, CBV varies linearly with it, albeit with some variation among anesthetic agents in the CBF/CBV ratio. [125] In normal brain, CBV is approximately 5 mL/100 g of brain, [126] and over a Pa CO_2 range of approximately 20 to 80 mm Hg, CBV changes by about 0.049 mL/100 g for each 1 mm Hg change in Pa CO_2 . [127] [128] In an adult brain weighing about 1,400 g, this can amount to a 20-mL change in total CBV for a Pa CO_2 range of 25 to 55 mm Hg.

Whereas CBV and CBF usually vary in parallel, there are exceptions. CBV increases during cerebral ischemia, [129] [130] and CBV may vary independently of CBF when MAP is the manipulated variable. Autoregulation normally serves to prevent MAP-related increases in CBV. In fact, as the cerebral circulation constricts to maintain a constant CBF in the face of a rising MAP, CBV actually decreases. [131] When autoregulation is impaired, or its upper limit (150 mm Hg) is exceeded, CBF and CBV then increase in parallel as arterial pressure rises (see Fig. 19-4) . A declining MAP results in a progressive increase in CBV as the cerebral circulation dilates to maintain constant flow, and exaggerated increases in CBV occur as MAP falls below the lower limit of autoregulation. [131] This increase in CBV in the face of falling MAP is almost certainly the principal reason for ICP increases attributed to narcotics (see the later discussion of sufentanil and alfentanil). In healthy subjects, the initial increases in CBV do not result in significant ICP elevation because there is latitude for compensatory adjustments by other intracranial compartments (e.g., translocation of venous blood and CSF to extracerebral vessels and the spinal CSF space, respectively). When intracranial compliance * is reduced, a CBV increase can cause herniation or may reduce CPP sufficiently to cause ischemia.

There have been several investigations of the effects of anesthetic agents on CBV in normal brain. [133] [134] [135] In general, the observed effects confirm a parallel relationship between CBF and CBV. However, the relationship is not consistently one to one, [125] [136] and CBF-independent influences on CBV may occur. It is also an unexplored possibility that anesthetic agents may influence the venous side of the cerebral circulation. Although the intracranial veins are a largely passive compartment, there is evidence, in some species, of some active control of venous caliber by either neurogenic or humoral mechanisms. [67] [69] [137] At present, there is no evidence that these direct effects have clinical significance. Nonetheless, the importance of blood volume on the venous side of the cerebral circulation should not be overlooked. Passive engorgement of these vessels as a result of the head-down posture, compression of the jugular venous system, or high intrathoracic pressure can have dramatic effects on ICP (see Fig. 52-4) .

Intravenous Anesthetic Agents

The general pattern of the effect of intravenous anesthetic agents is one of parallel alterations in CMR and CBF. Most intravenous agents cause a reduction of both. Ketamine, which causes an increase in CMR and CBF, is the exception. The effects of selected intravenous anesthetic agents on human CBF are compared in Figure 19-6 .

It is probable that intravenous agent-induced changes in CBF are largely the result of effects on CMR with parallel (coupled) changes in CBF. If this were the entire explanation, the CBF/CMR ratio would be the same for all agents. It is not. It is therefore likely that there are also direct effects on cerebral vascular smooth muscle (e.g., vasoconstriction, vasodilation, alteration of autoregulatory function) that make contributions to the net effect. For instance, although barbiturates are generally thought of as cerebral vasoconstrictors, some barbiturates actually cause relaxation of cerebral vascular smooth muscle in isolated vessel preparations. [138] [139] [140] However, *in vivo,* a substantial reduction in CMR occurs, and the net effect at the point of EEG suppression

* Note a well-entrenched misuse of terminology. [132] The "compliance" curve that is commonly drawn to describe the intracranial pressure-volume relationship (see Fig. 52-2) actually depicts the relationship DeltaP/DeltaV (elastance) and not DeltaV/DeltaP (compliance). What is here referred to as "reduced compliance" is more correctly described as "increased elastance." Not all disciplines, including most notably neurosurgery, have adopted the revised terminology. The authors have therefore left the misuse uncorrected here.

is vasoconstriction and a substantial decrease in CBF. [21] It appears that, in general, autoregulation and CO_2 responsiveness are preserved during administration of intravenous anesthetic agents.

Barbiturates

A dose-dependent reduction in CBF and CMR occurs with barbiturates. With the onset of anesthesia, CBF and $CMRO_2$ are reduced by about 30 percent. [141] [142] When large doses of thiopental cause complete EEG suppression, CBF and CMR are reduced by about 50 percent. [21] [143] [144] Further increases in the dose of barbiturate have no additional effect on CMR. [21] [145] These observations suggest that the major effect of nontoxic doses of depressant anesthetics is a reduction in the component of cerebral metabolism that is linked to brain function (e.g., neurophysiologic activity), with only minimal effects on the second component, that related to cellular homeostasis (see Fig. 19-1) .

Tolerance to the CBF/CMR effects of barbiturates may develop quickly. [146] [147] In patients with severe head injury in whom "barbiturate coma" was maintained for 72 hours, the thiamylal blood concentration required to maintain EEG burst suppression was observed to be increased by the end of the first 24 hours and continued to increase over the next 48 hours. [148] During deep pentobarbital anesthesia, autoregulation is maintained to arterial pressures as low as 60 mm Hg. [149] CO_2 responsiveness also persists. [150]

Propofol

The effects of propofol (2,6-di-isopropylphenol) on CBF and CMR appear to be quite similar to those of the barbiturates. Three investigations in humans have revealed substantial reductions in both CBF and CMR after propofol administration. [151] [152] Stephan et al [152] administered propofol by bolus plus infusion (2 mL/kg and 0.2 mL/kg/min, respectively) and observed average CBF and CMR decreases of 51 and 36 percent, respectively. Alkire et al [153] assessed cerebral glucose metabolism in volunteers using positron emission tomography (PET) before and during infusion of propofol to the point of unresponsiveness. Whole-brain metabolic rate decreased by 48 to 58 percent, with limited regional heterogeneity observed. Ravussin et al [154] measured lumbar CSF pressure during induction of anesthesia by slow bolus administration of propofol (1.5 mL/kg over 30 s) in patients scheduled for craniotomy. These investigators observed maximal average reductions in lumbar

CSF pressure and in CPP of 32 and 10 percent, respectively.

Both CO_2 responsiveness and autoregulation appear to be preserved during the administration of propofol in humans. [155] [156] Seizures and opisthotonos have been reported to occur after propofol anesthesia. [157] [158] [159] [160] [161] However, systematic studies in both humans [162] [163] [164] and animals, [165] [166] although identifying the occurrence of occasional dystonic and choreiform [162] movements, have failed to confirm the notion that propofol is proconvulsant. In fact, propofol appears to be anticonvulsant in animals (mice). [165] [166] Furthermore, seizures from electroconvulsive therapy were shorter after induction of anesthesia with propofol than with methohexital, [167] a finding that is more consistent with an anticonvulsant effect. In addition, propofol sedation has been widely employed during "awake" resections of seizure foci and other intracranial lesions. [163] [164] [168] Although pronounced high-amplitude beta-frequency activity in the EEG has been observed, [169] there has not been an unexpected incidence of seizures.

Etomidate

The effects of etomidate on CBF and CMR are also superficially similar to those of barbiturates. Roughly parallel reductions in CBF and CMR occur in humans, [170] [171] and they are in general accompanied by progressive suppression of the EEG. [172] The CBF/CMR changes are substantial. Renou et al [170] gave approximately 0.2 mg/kg of etomidate to adults and observed mean reductions in CBF and CMR of 34 and 45 percent, respectively. In dogs, as is the case with barbiturates, no further reduction of CMR occurs when additional drug is administered beyond a dose sufficient to produce EEG suppression. [23] This latter phenomenon has not been demonstrated in humans. However, Bingham et al [173] observed that etomidate lowered ICP when administered to severely head-injured patients in whom EEG activity was well preserved but was ineffective when there was substantial antecedent EEG suppression. Canine data reviewed by Milde et al [23] suggested that, although the global CMR suppression attainable with etomidate is substantial, it is slightly less profound than that achieved with isoflurane and barbiturates. This finding is consistent with the observations of Davis et al [174] that, unlike barbiturates, which cause CMR suppression throughout the brain, the CMR suppression caused by etomidate is regionally variable and occurs predominantly in forebrain structures.

Etomidate has been shown to be effective in reducing ICP without causing reduction of CPP in patients with intracranial tumors [175] and in head-injured patients. [176] However, concerns regarding the occurrence of adrenocortical suppression and renal injury caused by the propylene glycol vehicle [177] probably preclude more than episodic use.

Reactivity to CO_2 is preserved in humans during etomidate administration. [170] [171] Autoregulation has not been evaluated. Myoclonus and epileptogenesis are discussed in a later section.

Narcotics

There are inconsistencies in the available information, but it is likely that narcotics have relatively little effect on CBF and CMR in the normal, unstimulated nervous system. [178] When changes occur, the general pattern is one of modest reductions in both CBF and CMR. The inconsistencies in the literature probably arise largely because, in many studies, the "control" state entailed paralysis and nominal sedation, often with N_2O alone. In these studies, in which substantial reductions of CBF and CMR were frequently observed, the effect of the narcotic was probably a combination of the inherent effect of the agent plus a substantial component resulting from reduction of arousal. Comparable effects related to reduction of arousal may occur and may be

important clinically. However, they should be viewed as nonspecific effects of sedation and/or pain control rather than as specific properties of narcotics. The following discussion emphasizes investigations in which control measurements were unlikely to have been markedly influenced by arousal phenomena.

Morphine.

When morphine (
1 mg/kg) was administered as the sole agent in human patients, Moyer et al [179] observed no effect on global CBF and a 41 percent decrease in $CMRO_2$. The latter is a substantial reduction, and the absence of a simultaneous CBF adjustment is surprising. There have been no other such investigations of morphine alone in humans. Jobes et al [180] gave morphine (1 and 3 mg/kg) with 70 percent N_2O to patients and observed no significant change in CBF or CMR. The N_2O that was used could be expected to have caused a tendency toward increases in CBF and CMR. The relative absence of *net* changes in these variables from the awake control measurements suggests a small to moderate depressive effect of morphine on CBF and CMR at this large dose. Takeshita et al [181] gave morphine, 3 mg/kg, to dogs sedated with 70 percent N_2O (
0.6 MAC). These researchers observed reductions of global CBF and $CMRO_2$ of approximately 60 and 17 percent, respectively. These data cannot be completely reconciled, and the data of Jobes et al [180] are probably relevant to the most common clinical situations. However, morphine can cause substantial histamine release in individual patients. Histamine is a cerebral vasodilator that causes an increase in CBV and a CBF effect that varies depending on the systemic blood pressure response. Autoregulation was observed to be intact between MAP of 60 and 120 mm Hg in human volunteers anesthetized with morphine, 2 mg/kg and 70 percent N_2O. [182]

Fentanyl.

Limited human data are available. Vernhiet et al [183] measured CBF and $CMRO_2$ before and during anesthesia with 12 to 30 (mean, 16) mug/kg of fentanyl with 50 percent N_2O to patients about to undergo cerebral angiography. Atropine and pancuronium were the only other agents administered. Neither CBF nor $CMRO_2$ changed significantly from awake control values in this group of six subjects. However, one of the patients (an epileptic patient with a normal computed tomography [CT] scan) had dramatic and unexplained increases in both CBF and $CMRO_2$. For the remaining five patients, CBF and $CMRO_2$ decreased by 21 and 26 percent, respectively ($P < .05$). The data for fentanyl and N_2O presented in Figure 19-6 are derived from these five patients who received an average of 17 mug/kg of fentanyl. Murkin et al [184] measured CBF before and after induction of anesthesia with high-dose fentanyl, 100 mug/kg, and diazepam, 0.4 mg/kg. CBF fell by 25 percent, although part of this effect may well have been the result of the benzodiazepine (see later) rather than of the fentanyl. Firestone et al, [185] using PET, observed a heterogeneous CBF response to 1.5 mug/kg of fentanyl in healthy volunteers. Increases occurred in frontal, temporal, and cerebellar areas simultaneous with decreases in discrete areas associated with pain-related processing. [185] There are additional data derived from animal experiments. McPherson et al [186] administered fentanyl (25 mug/kg) to pentobarbital-anesthetized dogs and observed no effect on CBF and

Figure 19-6 Changes in cerebral blood flow (CBF) and cerebral metabolic rate for oxygen ($CMRO_2$) caused by intravenous anesthetic agents. The data are derived from human investigations and are presented as a percentage of change from unanesthetized control values. See text for details. No data for the $CMRO_2$ effects of midazolam in humans are available. The data were derived from references [143] [152] [170] [180] [183] [197] [221] [223] and [240]. n.s., not statistically significant.

CMR. CO_2 responsiveness and autoregulation were unaffected, and the hyperemic CBF response to hypoxia also remained intact. Several investigations in lightly anesthetized animals [187] [188] [189] demonstrated much larger fentanyl-induced reductions in CBF and/or CMR than those observed in humans. These data taken together suggest that fentanyl causes a moderate global reduction in CBF and CMR in the normal quiescent brain and, like morphine, causes larger reductions when administered during arousal.

Alfentanil: CBF Effects.

McPherson et al [190] administered alfentanil, 320 mug/kg, to pentobarbital-anesthetized dogs. These researchers observed no changes in CBF, CMR, CO_2 responsiveness, autoregulation, or the CBF response to hypoxia. There have been no studies of the CMR effects of alfentanil in humans. Schregel et al [191] administered 25 to 50 mug/kg of alfentanil to patients receiving 60 percent N_2O after induction of anesthesia with thiopental. CBF velocity (CBFV) decreased transiently. A Doppler measure of middle cerebral artery (MCA) diameter was simultaneously unchanged, a finding suggesting that the CBFV reduction was indicative

of a CBF decrease. Mayberg et al [192] also observed no change in CBFV in response to 25 to 50 mug/kg of alfentanil given to patients during maintenance of anesthesia with isoflurane and N_2O.

Sufentanil: CBF Effects.

Although some laboratory investigations have revealed apparent sufentanil-induced increases in CBF and CMR, [193] most investigations in both animals [194] [195] [196] and humans have indicated that sufentanil

causes, depending on dose, either no change or reductions in CBF and CMR. Stephan et al [197] measured CBF and $CMRO_2$ in patients before and after induction of anesthesia with 10 mug/kg of sufentanil. These investigators observed a 29 percent reduction of CBF and a 22 percent reduction in $CMRO_2$. Murkin et al, [198] in a study involving the same dose of sufentanil and a similar design, made essentially identical observations. Mayer et al [199] gave 0.5 mug/kg of sufentanil to volunteers and observed no change in CBF. Weinstabl et al [200] observed reductions in CBFV when 1.0 and 2.0 mug/kg of sufentanil were given to patients in the intensive care unit (ICU) who had increased ICP. Neither Weinstabl et al [200] nor Mayer et al, [199] who administered sufentanil to healthy volunteers, observed changes in CBFV after 0.5 mug/kg of sufentanil.

Sufentanil: ICP Effects.

The data from the foregoing studies led to the anticipation of no change or a reduction in ICP as a result of administration of either sufentanil or alfentanil. With respect to sufentanil, the bulk of the data derived in animals [193] [195] [196] [201] and in humans [200] [202] [203] [204] [205] have revealed no change in ICP following its administration. However, in some investigations in humans, sufentanil was associated with modest increases in neuraxis pressure. [206] [207] [208] Subsequent investigations appear to indicate that the ICP increases associated with sufentanil are at least in large part the consequence of a normal autoregulatory response to the sudden MAP reduction that can occur as a consequence of sufentanil administration. [209] The message for the clinician should probably be that sufentanil (and, for that matter, fentanyl as well [204]) are best administered in a manner that does not produce a sudden reduction of MAP. MAP reduction clearly reduces CPP and may increase ICP, each of which, in sufficient extreme, may be deleterious. However, it should be noted that the ICP increases attributed to sufentanil have been small. Furthermore, four investigations [210] [211] [212] [213] that compared conditions in the surgical field, including pressure under brain retractors, [210] identified no adverse influences attributable to sufentanil. Accordingly, sufentanil need not be viewed as in any way contraindicated, although it should be used with attention to its effect on MAP.

Alfentanil: ICP Effects.

Although there are fewer data for this drug, the general pattern is similar, and the conclusions should be the same as for sufentanil (preceding paragraph). [206] [214] [215] [216] [217] Alfentanil was included with fentanyl and sufentanil in two of the investigations of conditions in the surgical field mentioned in connection with sufentanil. [210] [211] No adverse effects were noted.

Remifentanil.

Investigations of moderate doses of remifentanil in humans have revealed minimal effects that are very similar to those of the other synthetic narcotics (with the exception of its substantially shorter duration of action). In patients undergoing craniotomy for supratento-rial space-occupying lesions, 1 mug/kg of remifentanil caused no change in ICP. [218] In a second investigation in patients undergoing craniotomy, approximately 0.35 mug/kg/min of remifentanil resulted in CBF values comparable to those observed with moderately deep anesthesia with either isoflurane/N_2O or fentanyl/N_2O, [219] and CO_2 responsiveness was preserved. [219] Greater doses of remifentanil may have more substantial effects. CBFV in the MCA decreased 30 percent in response to 5 mug/kg, followed by 3 mug/kg/min of remifentanil at a constant MAP in patients being anesthetized for bypass surgery. [220] Quantitatively similar observations were made after a large dose of sufentanil in patients undergoing cardiac anesthesia (see earlier). [197]

Benzodiazepines

Benzodiazepines cause parallel reductions in CBF and CMR in humans and monkeys. CBF and $CMRO_2$ decreased by 25 percent when 15 mg of diazepam was given to head-injured patients. [221] Lorazepam given to monkeys in doses sufficient to cause sedation reduced CBF by 24 percent and $CMRO_2$ by 21 percent. [222] The effects of midazolam on CBF (but not CMR) have also been studied in humans. Forster et al [223] [224] observed a 30 to 34 percent reduction in CBF after administration of 0.15 mg/kg of midazolam to awake healthy human volunteers. Veselis et al, [225] using PET, observed a global CBF reduction of 12 percent after a similar dose and noted that the decreases occurred preferentially in the brain regions associated with arousal attention and memory. CO_2 responsiveness was preserved. [226]

The foregoing studies indicate that benzodiazepines should cause moderate reduction of CBF in humans and suggest that the effect may be metabolically coupled. The extent of the maximal CBF and CMR reductions produced by benzodiazepines is probably intermediate between the decreases caused by narcotics (modest) and barbiturates (substantial). [21] [227] [228] It appears that benzodiazepines should be safe to administer to patients with intracranial hypertension provided respiratory depression and an associated increase in Pa CO_2 do not occur.

Flumazenil

Flumazenil is a highly specific, competitive benzodiazepine receptor antagonist. It had no effect on CBF when administered to unanesthetized human volunteers. [224] In two investigations in dogs with normal intracranial compliance, [227] [229] flumazenil resulted in reversal of the CBF-, CMR-, and ICP-lowering effects of midazolam. Whereas Knudsen et al [230] observed no change in either CBF or CMR when patients were aroused from flumazenil midazolam anesthesia at the conclusion of craniotomy for brain tumor resection, Chiolero et al [231] reported severe increases in ICP when flumazenil was given to midazolam-sedated head-injured patients in whom ICP was poorly controlled prior to administration of flumazenil. These latter observations are consistent with two animal investigations. In the investigation of Fleischer et al, [227] mentioned earlier, flumazenil not only reversed the CBF and CMR effects of midazolam, but also caused a substantial, although short-lived, overshoot above premidazolam levels in both CBF (by 44-56%) and ICP (by 180-217%). CMR did not rise higher than control levels, a finding indicating that the CBF increase was not metabolically coupled. A similar increase in CBF after flumazenil reversal of midazolam has also been observed in cats. [232] The CBF overshoot effect is unexplained, but it may

be a neurogenically mediated arousal phenomenon. [233] Flumazenil should probably be avoided or used very cautiously to reverse benzodiazepine sedation in patients with impaired intracranial compliance.

Droperidol

There have been no human investigations of the CBF and CMR effects of droperidol in isolation. However, the available information from animal investigations and drug combination administration in humans [189] [234] [235] [236] [237] taken together suggests that droperidol is not a cerebral vasodilator and probably has little effect on CBF and CMR in humans. The occasional ICP increases that have been observed [235] probably reflect a normal autoregulation-mediated vasodilation in response to an abrupt fall in MAP.

Ketamine

Among the intravenous agents, ketamine is unique in its ability to cause increases in both CBF and CMR. [238] [239] [240] [241] [242] Animal studies indicate that the changes

in CMR are regionally variable. In rats, substantial increases occur in limbic system structures simultaneous with modest changes or small decreases in cortical structures. [239] [243] Depth-electrode studies of ketamine-induced convulsive phenomena suggest that similar preferential activation of thalamic and limbic structures also occurs in humans. [244] The CMR increases that have been repeatedly demonstrated in animals, [239] [243] [245] however, have not been verified in humans. In the only investigation of CMR effects in humans, Takeshita et al [240] observed a 62 percent increase in CBF and no change in CMR, and the explanation for this discrepancy is unclear.

The anticipated ICP correlate of the CBF increase has been confirmed to occur in humans. [246] [247] However, anesthetic agents (diazepam, midazolam, isoflurane/N_2O) have been shown to blunt or to eliminate the ICP or CBF increases associated with ketamine. [242] [246] [248] [249] In fact, decreases in ICP have been reported in response to relatively large doses of ketamine (1.5-5 mg/kg) administered to propofol-sedated head-injured patients. [250] Autoregulation during ketamine administration has not been directly tested. CO_2 responsiveness is preserved. [247] Accordingly, although ketamine is probably best avoided as the sole anesthetic agent in patients with impaired intracranial compliance, it may be reasonable to use it cautiously in patients who are simultaneously receiving the other agents mentioned earlier.

Lidocaine

Lidocaine produces a dose-related reduction of $CMRO_2$ in experimental animals. [251] In dogs, 3 mg/kg lowered $CMRO_2$ by 10 percent, and 15 mg/kg reduced it by 27 percent. When very large doses (160 mg/kg) were given to dogs receiving cardiopulmonary bypass, the reduction in $CMRO_2$ was apparently greater than that seen with high-dose barbiturates. [145] This may arise because the membrane-stabilizing effect of lidocaine also reduces the energy requirement for the maintenance of membrane integrity. In unanesthetized human volunteers, Lam et al [252] observed CBF and CMR reductions of 24 and 20 percent, respectively, after administration of 5 mg/kg of lidocaine over 30 minutes, followed by infusion of 45 mug/kg/min.

Bedford et al [253] compared the effectiveness of bolus doses of thiopental sodium, 3 mg/kg, and lidocaine, 1.5 mg/kg, in controlling the acute increase in ICP that occurred following application of a pin head holder or skin incision in patients undergoing craniotomy. The two regimens were equally effective in causing ICP reduction. However, the MAP decrease was greater with thiopental. Accordingly, a bolus dose of lidocaine is a reasonable adjunct to the prevention or treatment of acute ICP elevation, and it has been recommended for use in the prevention of ICP increases associated with endotracheal suctioning. [254] Note that large doses of lidocaine can produce seizures in humans and in some experimental animals. [255] Lidocaine-induced seizures have not been reported in anesthetized humans. Nonetheless, it seems appropriate to restrict lidocaine doses to amounts that achieve serum levels less than the seizure threshold (>5-10 mug/mL) in awake humans. [256] Viegas et al [257] reported peak serum concentrations of 6.6 to 8.5 mug/mL after a 2-mg/kg bolus of lidocaine. Bolus doses of 1.5 to 2.0 mg/kg therefore seem appropriate.

Inhaled Anesthetics

Volatile Anesthetics

The pattern of volatile agent effects on cerebral physiology is a striking departure from that observed with the intravenous agents, which cause generally parallel changes in CMR and CBF. All the volatile agents produce a dose-related reduction in CMR while simultaneously causing no change or an increase in CBF. [22] [258] [259] [260] [261] [262] As a consequence of this pattern, it has been said that volatile agents cause "uncoupling" of flow and metabolism. However, there is considerable evidence that coupling (CBF adjustments paralleling changes in CMR) persists during volatile agent anesthesia. [259] [263] [264] [265] [266] [267] Accordingly, it is probably more accurate to say that the CBF/CMR ratio is altered (increased) by volatile anesthetics. This alteration is dose related, and under steady-state conditions, there is a positive correlation between MAC multiples and the $CBF/CMRO_2$ ratio. [34] [260] [268] [269] In other words, higher MAC levels cause greater "luxury" perfusion.

The important clinical consequences of volatile agent administration are derived from the increases in CBF and CBV, and consequently ICP, that can occur. Of the commonly employed volatile agents, the order of vasodilating potency is approximately halothane >> enflurane > isoflurane = sevoflurane = desflurane. [26] [262] [267] [270] [271] [272] [273]

CBF Effects.

Because volatile anesthetics modify autoregulation, their effects on CBF and ICP should only be compared when arterial pressure is supported to a common level. In humans, when MAP is maintained at 80 mm Hg, equipotent (1.1 MAC) levels of halothane, enflurane, and isoflurane caused CBF increases of 191, 37, and 18 percent, respectively (Fig. 19-7) . [270] A similar potency scale was observed in a study that compared the degree of brain surface

Figure 19-7 Estimated changes in cerebral blood flow (CBF) and cerebral metabolic rate for oxygen ($CMRO_2$) caused by volatile agents. The CBF data for halothane, enflurane, and isoflurane were obtained during 1.1 MAC anesthesia (with blood pressure support) in human patients, [270] expressed as a percentage of change from awake control values. The $CMRO_2$ data for halothane, enflurane, and isoflurane were obtained in the cat [260] [277] and are expressed as a percentage of change from nitrous oxide (N_2O)-sedated control values. The data for sevoflurane were obtained during 1.1 MAC anesthesia in the rabbit and are expressed as a percentage of change from a morphine/N_2O-anesthetized control state. [262]

protrusion through a craniectomy in cats. [274] The combined results of other studies in humans, most using transcranial Doppler (TCD), indicate that the effects of isoflurane, desflurane (Fig. 19-8) , and sevoflurane are very similar, [267] [273] [275] with relatively little change in CBF (versus baseline determinations in the awake state) at 1.0 MAC concentrations. However, because of variations in blood pressure among study groups and among investigations, a strictly quantitative comparison is not possible. Note that there is some discrepancy among studies in the literature as to the magnitude of the effects of the volatile agents on CBF. Much of this may occur as a result of the interaction of regionally selective CBF methods with the heterogeneity within the cerebrum of the CBF effects of volatile agents. See the discussion on distribution of CBF/CMR changes later.

The effect of volatile anesthetics on CBF is probably the sum of several influences. These include a tendency toward CBF reduction caused by a depression of CMR and a CBF-increasing effect due to vasodilation caused by a substantial direct effect on vascular smooth muscle. [264] As noted previously, NO may be involved in both processes. [7] [8] [9] [10] [20] [276] The effect on smooth muscle apparently predominates, and the net effect of the volatile anesthetics is an increase in global CBF. The suppression of CMR caused by equi-MAC concentrations of the volatile agents differs (isoflurane, enflurane, desflurane, sevoflurane > halothane) (see Figs. 19-7 and 19-8) , and it seems likely that this is the basis of the difference in the magnitude of the CBF increases they cause (halothane > enflurane, isoflurane, desflurane, and sevoflurane).

CMR Effects.

All the volatile agents cause reductions in CMR. The degree of $CMRO_2$ reduction that occurs at a given MAC level is less with halothane than with the other four agents (see Fig. 19-7) . Sevoflurane's effect on CMR is very similar to that of isoflurane [262] (see Fig. 19-7) . The available information, derived in separate investigations in dogs, suggests that desflurane causes slightly less suppression of $CMRO_2$ than does isoflurane, especially at concentrations higher than 1.0 MAC. [22] [261] No direct comparisons of the $CMRO_2$ effects of all of the volatile agents have been

Figure 19-8 A comparison of the effects of desflurane and isoflurane on cerebral blood flow (CBF) (mL/100 g/min) and cerebral metabolic rate for oxygen ($CMRO_2$) (mL/100 g/min). The CBF data were obtained by Ornstein et al [272] in patients anesthetized with the volatile agent in air/oxygen. The $CMRO_2$ data were derived in separate investigations of desflurane by Lutz et al [261] and of isoflurane by Newberg et al [22] performed in the same laboratory using the same canine model.

performed in humans. The administration of 1.0 MAC of each agent to N_2O-sedated cats resulted in approximate $CMRO_2$ reductions of 25 percent with halothane and 50 percent with isoflurane and enflurane. [260] [277] The $CMRO_2$ reduction is dose related. With isoflurane (and almost certainly desflurane and sevoflurane as well), maximal reduction is attained simultaneously with the occurrence of EEG suppression. [22] [261] This occurs at clinically relevant concentrations, that is, 1.5 to 2.0 MAC in humans. [267] [278] In dogs, additional isoflurane up to 6.0 percent end-tidal results in no further CMR reduction and no indication of metabolic toxicity. [22] Halothane presents a contrast to this pattern. Halothane concentrations in excess of 4.0 MAC are required to achieve EEG isoelectricity in dogs, and additional halothane causes further reduction of $CMRO_2$ in concert with alterations in energy charge. The latter changes, which are reversible, suggest interference with oxidative phos-phorylation. [258] These data indicate that, unlike isoflurane, halothane can produce reversible toxicity when administered in very high concentrations.

There is some alinearity in the CBF and CMR dose-response relationships for volatile anesthetics. The initial appearance of an EEG pattern associated with the onset of anesthesia with halothane, enflurane, and isoflurane is accompanied by a precipitous decline in $CMRO_2$. [141] Thereafter, $CMRO_2$ declines in a slower dose-dependent manner. Other studies during anesthetic induction with halothane found marked increases in CBF prior to any alteration in CMR. [142] This finding suggests that the direct effect of a volatile agent on smooth muscle may develop more rapidly than influences related to depression of CMR.

Distribution of CBF/CMR Changes.

The regional distribution in anesthetic-induced changes in CBF and CMR differs markedly with halothane and isoflurane. Halothane produces relatively homogeneous changes throughout the brain. CBF is globally increased, and CMR is globally depressed. The changes caused by isoflurane are more heterogeneous. CBF increases are greater in subcortical areas and hindbrain structures than in the neocortex [25] [26] [279] (Fig. 19-9) (Figure Not Available) . For CMR, the converse is true, with greater reduction in the neocortex than in the subcortex. [24] Desflurane and sevoflurane have not been submitted to similar local CBF (l-CBF) studies. However, given their various similarities, including the similarity of their effects on the EEG (suggesting similar cortical CMR and CBF effects), the interim assumption of similar heterogeneity of CBF distribution seems reasonable. These distribution differences may explain certain apparent contradictions in reported CBF effects in the existing literature for isoflurane. Methods that assess the entire cerebrum and can measure true global CBF (microspheres, PET, autoradiography) will reveal greater increases in CBF than those that emphasize the cortical compartment (radioactive xenon techniques, TCD, venous outflow). For instance, Eintrei et al [271] reported no increase in CBF when isoflurane was administered to patients undergoing craniotomy, yet Adams et al, [280] Grosslight et al, [281] and Campkin et al [282] reported that administration of isoflurane to normocapnic subjects with intracranial disease can result in increases in CSF pressure. The CBF methodology used by Eintrei et al [271] measured cortical flow exclusively, and accordingly, these results of the three investigations are again consistent with a pattern of minimal vasodilation in the cortex and greater increases in CBF in the remainder of the brain.

Cerebral Vasodilation by Volatile Agents: Clinical Implications.

The data presented thus far, in sum, indicate that although isoflurane and, probably, desflurane and sevoflurane may have little cerebral vasodilating effect in cortex, they nonetheless probably cause net cerebral vasodilation in a dose-dependent fashion. Are isoflurane and desflurane and sevoflurane therefore contraindicated in the face of abnormal intracranial compliance? No. Note that the instances of CSF pressure (CSFP)/ICP increases in response to the administration of isoflurane observed in the studies of Adams et al [280] and Campkin et al [282] were usually readily prevented or reversed by the induction of hypocapnia. This indicates that, particularly in the sub-MAC concentrations typical of balanced anesthesia, the use of these drugs is reasonable when there is proper attention to the other important determinants of ICP, in particular CO_2 tension. One report does, however, describe the occurrence of apparent isoflurane-induced increases of ICP in the setting of large cerebral tumors in spite of the induction of hypocapnia. [281] Accordingly, there should be discretion in the setting of large mass lesions, unstable ICP, or sufficient derangement of cerebral physiology that CO_2 responsiveness and flow-metabolism coupling may be impaired in some or all of the brain. When these situations occur (the somnolent, vomiting patient with papilledema, a large mass, and compressed basal cisterns) the clinician may be well advised

Figure 19-9 (Figure Not Available) Regional differences in the cerebral blood flow (CBF) effects of isoflurane (ISO) and halothane (HAL). [25] The figure is a schematic representation of CBF in a coronal autoradiographic image of rat brain. The key indicates the approximate CBF (mL/100 g/min). In the cortex, CBF is less during anesthesia with isoflurane than with halothane. In the subcortex, CBF is similar during anesthesia with the two agents in some structures, and in others it is greater with isoflurane. The average hemispheric CBF with the two agents is very similar. Similar CBF distribution differences occur in humans, although the mean global CBF is greater for halothane than for isoflurane. [26] Amg, amygdala; CPu, caudate-putamen; Ctx, cortex; Hip, hippocampus; Thl, thalamus. *(From Hansen et al [25])*

to use a predominantly intravenous technique until such time as the cranium and dura are open and the effect of the anesthetic technique can be directly assessed. These events are relatively rare in elective neurosurgery.

Situations in which there has been substantial antecedent lowering of CMR by drug administration or disease processes should also justify caution in the use of volatile agents. If a volatile agent has a substantial direct vasodilating effect on the cerebral vasculature that is normally offset by an opposing metabolically mediated vasoconstricting influence, it may be surmised that, when near maximal reduction of CMR has occurred, introduction or an increase in the volatile agent will have a predominantly vasodilating effect. [264] [283] There are data to support this prediction. Murphy et al [270] observed no increase in CBF (versus awake control measurements) during anesthesia with 0.6 and 1.1 MAC isoflurane (with blood pressure support) but at 1.6 MAC, CBF had increased by 100 percent. Maekawa et al [24] measured CBF and l-CMR for glucose (l-CMRg) in rats both awake and during anesthesia with increasing concentrations of isoflurane; 1 MAC isoflurane resulted in an average CMRg decrease in five cortical areas of 54 percent of the awake control value and no change in average CBF. An additional 1.0 MAC (i.e., a total of 2.0 MAC) caused a further CMRg reduction of only 20 percent of the control value, and CBF simultaneously increased by 70 percent (Fig. 19-10) . These data together suggest that isoflurane is a significant cerebral vasodilator when administered in concentrations at and higher than those associated with near maximal CMR suppression or, perhaps, when administered when the component of CMR that is associated with electrophysiologic function is already suppressed by other drugs [264] [283] or pathologic processes.

The net vasodilating effect of equi-MAC concentrations of isoflurane, desflurane, and sevoflurane is less in humans than that of halothane, and the former drugs are probably

Figure 19-10 The relationship between changes in local cerebral metabolic rate for glucose (l-CMRg) and local cerebral blood flow (l-CBF) in the motor-sensory cortex in rats during isoflurane anesthesia. The majority of the CMR suppression caused by isoflurane has occurred by 1.0 MAC, and in this concentration range, CBF is not increased. Thereafter, additional isoflurane causes little further CMR reduction, and cerebral vasodilation occurs. These data (±SD), from Maekawa et al, [24] suggest the importance of metabolic coupling in determining the CBF effects of isoflurane. MAP, mean arterial pressure.

therefore preferable if a volatile agent is to be used in the setting of impaired intracranial compliance. That is not to say that halothane is contraindicated in these circumstances. It has been clearly demonstrated that, when hypocapnia is established prior to the introduction of halothane, the increases in ICP that could otherwise occur in a normocapnic patient with poor intracranial compliance can be prevented or greatly attenuated. [284] Nonetheless, most clinicians prefer isoflurane, desflurane, or sevoflurane because the margin for error is probably wider than with halothane. In addition, it has been demonstrated that avoidance of major ICP elevation can be accomplished by the induction of hypocapnia *simultaneously* with the introduction of isoflurane, [280] whereas CO_2 reduction should be instituted *before* exposure to halothane [284] if ICP increases are to be prevented in a patient population at risk.

Time Dependence of CBF Effects.

The effect of volatile anesthetic agents on CBF has been shown to be time dependent in animal investigations. After an initial increase, CBF falls substantially, reaching a steady state near prevolatile agent levels between 2½ and 5 hours after exposure. [40] [279] [285] The mechanism of this effect is not understood, and the phenomenon was not evident in humans studied during 3- or 6-hour exposures to halothane, isoflurane, desflurane, or sevoflurane. [267] [286]

CO_2 Responsiveness and Autoregulation.

CO_2 responsiveness is well maintained during anesthesia with all the volatile anesthetic agents. [34] [272] [287] [288] [289] By contrast, autoregulation of CBF in response to rising arterial pressure is impaired. This impairment appears to be most apparent with the agents that cause the greatest cerebral vasodilation, [260] [270] and it is dose related [290] [291] (see Fig. 19-5) . Sevoflurane may cause less impairment of autoregulation than other volatile agents. Two studies surprisingly reported no change in CBFV in response to phenylephrine-induced MAP increases during anesthesia with 1.2 to 1.5 MAC sevoflurane. [289] [292] The autoregulatory response to rising pressure is, however, rarely of significance in clinical neuroanesthesia. If anything, it is the CBF response to falling pressure that is important and, as with all vasodilators, CBF is preserved to lower MAP during administration of volatile agents, with no evidence of differences among the various agents. Direct comparisons of CBF with isoflurane, desflurane, and sevoflurane during hypotension are not available.

Epileptogenesis.

Enflurane is potentially epileptogenic in the clinical setting. Of particular relevance to neuroanesthesia is the observation that hypocapnia potentiates seizure-type discharges during enflurane anesthesia. [293] A 50 percent decrease in $CMRO_2$ was noted in human volunteers anesthetized with 3 percent enflurane, but with the onset of seizure activity, $CMRO_2$ returned to normal, [294] indicating the preservation of flow-metabolism coupling. Note that there is no evidence that this type of EEG activity is deleterious when O_2 delivery is maintained during the event. However, because seizure activity can elevate brain metabolism by as much as 400 percent, the use of enflurane, especially in high doses and with hypocapnia, should probably be avoided in patients predisposed to seizures and/or with occlusive cerebrovascular disease.

The EEG-activating property of enflurane has been used intraoperatively to activate and to identify seizure foci that are to be surgically resected, and in this situation, spike activity not present preoperatively has been observed to persist after surgery. [295] There have also been two reports of seizures in the immediate postoperative period following enflurane anesthesia in both predisposed [296] and nonpredisposed individuals. [297] There have been no apparent permanent sequelae from these events, and, in fact, this association is not rigorously proven. At worst, such occurrences are extremely uncommon.

Isoflurane can cause EEG spiking and myoclonus, but, in the experimental setting, it has not been associated with the frank epileptoid activity induced by enflurane. The clinical experience with isoflurane is very large, and unexplained "seizure-like activity" has been reported in only two patients. One occurrence was intraoperative, [298] and the other was immediately postoperative. [299] It therefore appears that epileptogenesis is not a clinical concern with isoflurane. In fact, isoflurane has been successfully employed to control EEG seizure activity in refractory status epilepticus. [300]

Seizures have been reported to occur during induction of anesthesia with high concentrations of sevoflurane in children, including children without a recognized seizure diathesis. [301] [302] Seizure induction in response to intense peripheral stimulation has also been demonstrated in cats receiving 5 percent sevoflurane. [303] No events in response to maintenance concentrations have been reported.

Brain Glucose Concentration.

Kofke et al [304] compared the brain concentrations of glucose and several other intermediary metabolites during administration of halothane, enflurane, and isoflurane in rats. Brain glucose was greater with isoflurane than with halothane and enflurane, but there were no differences in any of the other markers. Plasma glucose concentration was also increased in the isoflurane group and the plasma/brain glucose ratio did not differ among the three agents. There have been no evaluations of brain glucose concentration in humans; however, an increased plasma glucose concentration (versus halothane) has been reported to occur during isoflurane anesthesia. [305] The concern is that increased glucose availability has been shown in both clinical and experimental circumstances to worsen outcome following an episode of cerebral ischemia. However, the clinical significance of this effect of isoflurane is completely unknown, and, at present, the issue should be viewed as a matter of laboratory interest only.

Nitrous Oxide

The available data indicate unequivocally that N_2O can cause increases in CBF, CMR, and ICP. At least some of the CBF and CMR increases may be the result of a sympatho-adrenal-stimulating effect of N_2O. [306] The magnitude of the effect varies considerably according to the presence or absence of other anesthetic agents (Fig. 19-11) . When N_2O is administered alone, very substantial increases in CBF and ICP can occur. In sharp contrast, when N_2O is administered in combination with intravenous agents, including barbiturates, benzodiazepines, narcotics, and propofol, its cerebral vasodilating effect is attenuated or even completely inhibited.

Figure 19-11 Mean percentage increases in cerebral blood flow velocity (CBFV) in the middle cerebral artery of normocapnic subjects exposed to 60 percent nitrous oxide (N_2O) after control recording in three conditions: awake [311] ; 1.1 MAC isoflurane [324] ; and propofol, 150 mug/kg/min. [317]

The addition of N_2O to an established anesthetic with a volatile agent results in moderate CBF increases.

N_2O Administered Alone.

The most dramatic reported increases in ICP or CBF in humans [307] [308] and experimental animals [306] [309] [310] have occurred when N_2O was administered alone or with minimal background anesthesia. For instance, Henriksen et al [307] recorded ICP before and during spontaneous breathing of 66 percent N_2O by patients with intracranial tumors. Mean ICP rose from 13 to 40 mm Hg. The CBF increases observed in humans are more modest than those observed in animals, but they are still substantial. [311] Whether these substantial increases represent the effects of N_2O per se or whether they reflect the nonspecific effects of a "second-stage" arousal phenomenon is not known.

N_2O Administered with Intravenous Agents.

When N_2O is administered in conjunction with certain intravenous anesthetic agents, its CBF effect may be considerably reduced. Phirman and Shapiro [312] observed that a reproducible increase in ICP that had occurred in response to 70 percent N_2O administration to a comatose patient was prevented by prior administration of a combination of thiopental and diazepam in spite of no change in baseline ICP. In an investigation of patients with intracranial tumors and poor intracranial compliance (mean preinduction ICP, 27 mm Hg), [313] 50 percent N_2O introduced during barbiturate anesthesia and after the induction of hypocapnia had a negligible effect on ICP. Jung et al [314] compared lumbar CSFP in patients with brain tumors during administration of 0.7 percent isoflurane or 70 percent N_2O after induction of anesthesia with a barbiturate. Lumbar CSFP was modestly but significantly greater with N_2O. That the increase was less dramatic than those cited earlier for N_2O alone may reflect

the presence of residual barbiturate. Benzodiazepines administered alone have been shown to blunt the CBF response to N_2O in both animals and humans. [315] [316] Narcotics appear to have a similar effect. Jobes et al [180] reported that anesthesia with 1 mg/kg of morphine plus 70 percent N_2O resulted in no change in CBF from awake control values. Because of the very minor effect of morphine on CBF, these data suggest that N_2O did not cause substantial cerebral vasodilation. In a study using TCD, Eng et al [317] observed no change in CBFV when N_2O was introduced in patients anesthetized with propofol.

N_2O Administered with Volatile Anesthetics.

In the majority of the investigations, including several in humans, in which N_2O has been added to an anesthetic of 1.0 MAC or greater, substantial CBF increases have been recorded. [268] [318] [319] [320] [321] [322] [323] [324] [325] Algotsson et al [326] examined the effect of an approximately equi-MAC substitution of N_2O for isoflurane. They compared CBF in patients anesthetized with 1.5 MAC isoflurane and 0.75 MAC isoflurane with 65 percent N_2O. They observed a 43 percent greater CBF with the latter, a finding again consistent with a substantial vasodilating effect by N_2O in the presence of a volatile agent. Similar observations were made by Lam et al [324] and by Strebel et al. [325] Several investigations confirm that CBF will be less with 1.0 MAC of isoflurane than with a 1.0 MAC combination achieved with 50 to 65 percent N_2O and isoflurane. [324] [326] [327] The results of three investigations, including one in humans, indicate that this vasodilating effect of N_2O may be positively correlated with inhaled agent concentration, [320] [321] [325] and they suggest that, in general, the CBF increase caused by N_2O is exaggerated at higher concentrations of both halothane and isoflurane.

N_2O Effects on CMR.

There is not uniform agreement on the effect of N_2O on CMR. Parallel changes in CBF and CMR, [306] [309] CBF increases without alteration of CMR [323] [328] [329] and CMR alteration occurring without changes in CBF [330] have all been reported. This is doubtless the product of differences in species, methods, depth of background anesthesia, and interactions with simultaneously administered agents. There are few data derived from humans. Wollman et al [330] reported that 70 percent N_2O caused a 15 percent reduction in $CMRO_2$ in human volunteers. However, both premedication and induction of anesthesia were accomplished with barbiturates, and the control group was nonconcurrent. Algotsson et al, [326] mentioned earlier, reported no difference in $CMRO_2$ between the two anesthetic conditions studied (1.5 MAC isoflurane versus 0.75 MAC isoflurane/65% N_2O, see previous paragraph) and concluded that N_2O had no effect on CMR. [326] However, given the recognized depressive effect of isoflurane on CMR, the absence of net change in CMR can be interpreted as indicative of an N_2O-mediated CMR increase. From animal experimentation, it appears likely that, at least in some circumstances, N_2O causes increases in CMR. The "cleanest" investigation is that of Pelligrino et al, [309] who measured cortical CBF and CMR in awake goats that received N_2O without premedication or other supplements. After 60 minutes of N_2O inhalation, cortical $CMRO_2$ was increased to 170 percent of control, and global CBF was increased to 143 percent of control. The goats showed no evidence of an excitement stage. They became lethargic and experienced a fall in plasma epinephrine levels suggesting the absence of stress. The CBF response to CO_2 is preserved during administration of N_2O. [321] [323] [330]

Clinical Implications.

In spite of the evident inconsistencies, the data indicate that the vasodilatory action of N_2O can be clinically significant in neurosurgical patients with reduced intracranial compliance. [307] However, it appears that N_2O-induced cerebral vasodilation can be considerably blunted by the simultaneous administration of intravenous agents, although not all agents have been evaluated, and the dose-response relationships are not well defined. N_2O has been widely used in neurosurgery, and banishing it is inconsistent with accumulated experience. Nonetheless, when ICP is persistently elevated or the surgical field is persistently "tight," N_2O should be viewed as a potential contributing factor. In addition, the ability of N_2O to enter a closed gas space rapidly should be recalled, and this drug should be avoided or omitted when a closed intracranial gas space may exist.

Muscle Relaxants

Nondepolarizing Relaxants

The only recognized effect of nondepolarizing relaxants (Ch. 12) on the cerebral vasculature occurs via the release of histamine. Histamine can result in a reduction in CPP because of the simultaneous increase in ICP (caused by cerebral vasodilation) and decrease in MAP. [331] It is not entirely clear, when the BBB is intact, whether histamine directly causes cerebral vasodilation or whether it is a secondary (autoregulatory) response to a reduction in MAP. *d*-Tubocurarine is the most potent histamine releaser among available muscle relaxants. Metocurine, atracurium, and mivacurium also release histamine in lesser quantities. [332] [333] This effect is likely to be clinically inconsequential, [334] unless these agents are administered in the large doses necessary to achieve intubating conditions rapidly. Of this group of drugs, cisatracurium has the weakest histamine-releasing effect. No evidence of histamine release was seen after administration of 0.15 mg/kg (three times the ED_{95} for twitch depression) of cisatracurium in neurosurgical ICU patients. [335]

Vecuronium, in relatively large doses 0.1 to 0.14 mg/kg, had no significant effect on cerebral physiology in patients with brain tumors. [336] [337] Pipecuronium and rocuronium have not been studied, but they should similarly be without direct effect, and no adverse events have been reported.

The indirect actions of muscle relaxants may also have effects on cerebral physiology. Pancuronium given as a large bolus dose can cause an abrupt increase in arterial pressure. This could elevate ICP in the circumstances of impaired intracranial compliance and defective autoregulation; however, no significant clinical event has ever been reported. Muscle relaxation may reduce ICP because coughing and straining are prevented, and this results in a lowering of central venous pressure with a concomitant reduction in cerebral venous outflow impedance. [338]

A metabolite of atracurium, laudanosine, may be epileptogenic. However, whereas large doses of atracurium caused

an EEG arousal pattern in dogs, CBF, CMR, and ICP were unaltered. [339] In cats, the seizure threshold for lidocaine-induced seizures was not different during paralysis with atracurium, vecuronium, or pancuronium. [340] In rabbits, laudanosine administration did not increase the severity of the epileptoid activity caused by direct application of a cephalosporin to the cortical surface. [341] It appears highly unlikely that epileptogenesis will occur in humans with atracurium. [342] [343]

In summary, vecuronium, pipecuronium, rocuronium, atracurium, mivacurium, cisatracurium, metocurine, and pancuronium (if acute MAP increase is prevented with pancuronium) are all reasonable agents for use in the patient with or at risk of intracranial hypertension. Doses of metocurine, atracurium, and mivacurium should be limited to ranges not associated with hypotension. Curare (for the diehards) is best administered slowly and in small divided doses to avoid substantial histamine release.

Succinylcholine

Succinylcholine can produce an increase of ICP in lightly anesthetized human patients. Minton et al [344] studied patients with intracranial tumors. Their subjects received morphine, 0.1 mg/kg 1 hour prior to induction of anesthesia with thiopental, 6 mg/kg. The patients were ventilated by mask with 70 percent N_2O to maintain normocapnia, and then they received succinylcholine, 1 mg/kg. ICP increased from 15 ± 1 (SE) to a maximum of 20 ± 2 mm Hg after 1 to 3 minutes and returned to baseline in 8 to 10 minutes. The effect appears to be the result of cerebral activation (as evidenced by EEG changes and CBF increases) caused by afferent activity from the muscle spindle apparatus. [345] [346] [347] Note, however, that there is a poor correlation between the occurrence of visible muscle fasciculations and an increase in ICP. As could be expected with what appears to be an arousal phenomenon, deep anesthesia has been observed to prevent succinylcholine-induced ICP increases in the dog. [345] In humans, the ICP increase is also blocked by paralysis with vecuronium [344] and by "defasciculation" with metocurine, 0.03 mg/kg. [348] The efficacy of other defasciculating agents has not been examined in humans. However, defasciculation with pancuronium did not prevent ICP increases in the dog. [346]

Although succinylcholine *can* produce ICP increases, it need not be viewed as contraindicated when its use for rapid attainment of paralysis is otherwise seen as appropriate. Kovarik et al [349] observed no ICP change after administration of succinylcholine, 1 mg/kg, to nonparalyzed, ventilated neurosurgical ICU patients, six of ten of whom had sustained head injury. Their observations are very relevant because it is in precisely this population of patients that the issue of the use of succinylcholine arises most frequently. Given that the ICP effects of succinylcholine may be an arousal phenomenon caused by increased afferent traffic from muscle spindles, [347] it is not unreasonable that disease processes that substantially blunt the level of consciousness may similarly blunt this response. As with many agents, the concern should be not whether it is used but how it is used. If succinylcholine is administered with proper attention to the control of CO_2 tension, blood pressure,

and depth of anesthesia, and following defasciculation, preferably with metocurine pending additional information, little hazard should attend its use.

/das/book/view/29494766/875/204.html

OTHER EFFECTS OF ANESTHETICS ON CEREBRAL PHYSIOLOGY

Cerebrospinal Fluid Dynamics

There is approximately 150 mL of CSF in the adult human, half within the cranium and half in the spinal CSF space. The CSF, which is formed in the choroid plexuses and, to a lesser extent, by transependymal diffusion from the brain's interstitium into the ventricular system, is replaced about three times per day. [350] It functions both as a cushion for the central nervous system (CNS) and as an excretory pathway. Anesthetics have been shown to influence both the rate of formation and the rate of reabsorption of CSF. Table 19-5 provides nonquantitative information on the direction of the influences of common anesthetic agents. All the information has been derived from animals, [351] [352] [353] [354] [355] [356] [357] and these processes have not been examined in humans. They may be of relevance when a prolonged closed cranium procedure is to be performed in a patient with poor intracranial compliance. The most deleterious potential combination of effects in the setting of poor intracranial compliance is one of increased CSF production and decreased reabsorption. In the dog, this pattern occurs with enflurane, and this is perhaps another reason (in addition to the potential for epileptogenesis in the presence of cerebral injury and hypocapnia) for omission of enflurane in this circumstance.

The time course of these effects on CSF dynamics is slow. In clinical situations in which the CSF space is to be opened (most craniotomies) or in which a ventriculostomy is in

TABLE 19-5 -- Effects of Anesthetic Agents on the Rate of Cerebrospinal Fluid Secretion and Absorption [a]

[b] Hypocapnia only.

place, these effects are probably of relatively little clinical importance. The exception may occur with desflurane. Muzzi et al [358] measured lumbar CSF pressure (L-CSFP) during approximately 1 hour of 1.0 MAC anesthesia with isoflurane or desflurane in patients with supratentorial tumors. Anesthesia was induced with thiopental; the patients were paralyzed with vecuronium; hypocapnia (Pa CO_2 24-28 mm Hg) was maintained. After introduction of the volatile agent, L-CSFP were initially similar in the two groups. However, over the ensuing 50 minutes, L-CSFP rose progressively in the desflurane group. At the time of dural incision, L-CSFP in the two groups were as follows: isoflurane, 8 ± 2 (SD), and desflurane, 18 ± 6 mm Hg. This difference is neither as trivial nor as transient as many that have been trumpeted as significant in other studies of anesthetic agents in neurosurgery. Subsequently, an investigation revealed that desflurane causes increased CSF formation under conditions of increased ICP and hypocapnia. [357] The clinical results of Muzzi et al are nonetheless surprising because, in a study of similar design by the same investigators, [359] there were no differences in L-CSFP in groups that received either 0.5 MAC isoflurane/50 percent N_2O or 0.5 MAC desflurane/50 percent N_2O. Furthermore, two subsequent studies involving patients without large intracranial lesions [360] [361] revealed either no or trivial differences in the effects of isoflurane and desflurane on L-CSFP. In particular, because of methodologic weaknesses in the 1.0 MAC study of Muzzi et al (nonconcurrent experimental groups, nonblinded investigators [362]), clarifying investigation is necessary. In the meantime, it seems prudent to await a larger experience in situations in which desflurane is administered in patients undergoing ICP monitoring or with an open cranium (to permit observation of conditions in the surgical field) before undertaking prolonged closed cranium use of desflurane in patients with impaired intracranial compliance.

Blood-Brain Barrier

In the majority of the body's capillary beds, there are fenestrations approximately 65 A in diameter between endothelial cells. In the brain, with the exception of the choroid plexus, the pituitary, and the area postrema, tight junctions reduce this pore size to approximately 8 As. As a result, large molecules and most ions are prevented from entering the brain's interstitium. There is little evidence that anesthetic agents alter the function of this "blood-brain barrier" in most circumstances. However, it has been repeatedly demonstrated that acute hypertension can breach the barrier, [363] [364] [365] and certain anesthetics facilitate this phenomenon. [366] Forster et al [105] observed that Evans blue extravasation into rabbit brain was greater when acute hypertension occurred during anesthesia with halothane than with thiopental. It is probable that the effect is the nonspecific result of cerebral vasodilation, [367] rather than a specific effect of halothane. These results were obtained in the setting of extreme, abrupt hypertension in animals with an initially normal BBB. There is also evidence that anesthetics may influence the leakiness of an abnormal BBB at normotension. Smith and Marque [368] submitted dogs to 5 hours of anesthesia following a freeze lesion (which causes an opening of the BBB). Cerebral water accumulation at 24 hours was less in animals anesthetized with pentobarbital or fentanyl/droperidol/N_2O than with halothane, enflurane, or isoflurane. To our knowledge, no peer-reviewed investigation has attempted a comparison of anesthetic effects on BBB function during anesthesia in normotensive human patients.

Epileptogenesis

An extensive review of the convulsant and anticonvulsant effects of anesthetic agents and adjuvants is available. [369] [370] Several commonly employed anesthetic agents have some epileptogenic potential, particularly in predisposed individuals. A concern is that seizure activity may go unrecognized in an anesthetized and paralyzed patient and may result in neuronal injury if substrate demand (CMR) exceeds supply for a prolonged period. [371] A second concern is that the epileptogenic effect will persist in the postanesthesia period, when seizures may occur in less well-controlled circumstances than exist in the operating room. In practice, it appears that spontaneous seizures during or following anesthesia have been extremely rare events. Nonetheless, in patients with processes that may predispose them to seizures, it seems prudent to avoid the use of potentially epileptogenic agents in situations where there are reasonable alternatives.

Enflurane and Sevoflurane

The epileptogenic properties of these drugs are discussed earlier in the section on volatile anesthetics.

Methohexital

Myoclonic activity is sometimes observed with methohexital, and this agent has been used to activate seizure foci during cortical mapping. [372] [373] One clinical report [374] describes the occurrence of seizures in two pediatric patients following induction doses of methohexital administered rectally in one and intramuscularly in the other. Both these patients had temporal lobe lesions and had had previous seizures. It appears that it is specifically patients with seizures of temporal lobe origin, typically of the psychomotor variety, that are at risk of seizure activation by methohexital. [374] [375] It may be noteworthy that recurrent spontaneous seizures after methohexital anesthesia for electroconvulsive therapy have never been reported.

Ketamine

Ketamine can elicit seizures in patients with an epileptic diathesis. [376] Depth-electrode recordings in epileptic patients revealed the occurrence of isolated subcortical seizure activity originating in limbic and thalamic areas during ketamine anesthesia and demonstrated that this subcortical activation may not be reflected in surface EEG recordings. [244] The occurrence of seizures following ketamine anesthesia in neurologically normal subjects has also been reported on

only two occasions, [377] [378] and in one of those instances, seizure thresholds may have been lowered by aminophylline.

Etomidate

Etomidate frequently produces myoclonus that is not associated with epileptiform activity in the EEG. [379] A single instance of severe, sustained myoclonus immediately following anesthesia with etomidate by infusion has been reported. [380] Etomidate has also been shown to precipitate generalized epileptic EEG activity in epileptic patients, [381] and its use in this population should probably be avoided. However, it can be used electively, in low doses, to activate seizure foci for the purposes of intraoperative EEG localization. [382] In the authors' experience (unpublished), selective activation of a quiescent focus can be achieved with 0.1 mg/kg. Larger doses are more likely to lead to generalized activation.

Etomidate has also been noted to be associated with longer seizures in response to electroconvulsive therapy than occur after methohexital or propofol. Remarkably, etomidate, in the dose range of 0.15 to 0.3 mg/kg, does not cause dose-related electroconvulsive therapy seizure inhibition, as is readily demonstrated with the other two agents. [383] The preceding information notwithstanding, there are no convincing reports to indicate epileptogenesis in healthy subjects, and etomidate's use need not be restricted on this basis. In fact, it has been used to control refractory status epilepticus. [384]

Narcotics

Seizures and/or limbic system hypermetabolism can be elicited readily with narcotics in some animal species. [194] [385] [386] [387] [388] Although a CBF increase in deep brain structures associated with pain processing has been observed in human volunteers, [185] humans do not have a clinically apparent correlate of the hypermetabolism effect seen in animals. Several anecdotal reports, unaccompanied by EEG recordings, report that grand mal convulsions have occurred in patients who received both high [389] and low doses of fentanyl. [390] [391] However, systematic investigations of EEG changes during administration of relatively large doses of fentanyl, sufentanil, and alfentanil in humans have *not* documented neuroexcitatory activity, [392] [393] [394] and the "seizures" may been an exaggerated rigidity phenomenon. The exception is the observation that alfentanil, 50 mug/kg, can augment temporal lobe spike activity in patients with temporal lobe epilepsy. [395] Note that untreated rigidity may itself also have important CNS consequences. ICP elevation was observed when alfentanilinduced rigidity occurred in rats during controlled ventilation. [338] The effect probably arose because the associated increase in CVP caused cerebral venous congestion. In the absence of ventilatory support, both hypercapnia and hypoxemia may also occur.

Atracurium

See the discussion of the atracurium metabolite, laudanosine, in the earlier section on nondepolarizing muscle relaxants. All of the advantages of atracurium can be obtained from cisatracurium, which does not release nearly as much laudanosine (Ch. 12) .

CEREBRAL PHYSIOLOGY IN PATHOLOGIC STATES

Cerebral Ischemia

Introduction/Pathophysiology

The brain has a high rate of energy utilization and a very limited energy storage capacity. It is therefore extremely vulnerable in the event of interruption of substrate (O_2 , glucose) supply. Reviews of the pathophysiology of ischemic neuronal injury are available. [396] [397] [398] [399] [400] Only a simplified overview is presented here. Calcium is probably central to this complex process. [400] Calcium is present in the cytosol of normal neurons, where it performs important functions, such as second messenger, coenzyme. Calcium gains access to the cytosol in several ways (Fig. 19-12 A). It enters via both neurotransmitter-gated and voltage-dependent channels. Calcium is also released from intracellular storage sites in the endoplasmic reticulum through the actions of second messengers such as inositol triphosphate (IP3) that have been generated by the action of various neurotransmitters at cell-surface receptors. Calcium's normal concentration range is tightly regulated by energy-consuming processes that extrude it from the cell, resequester it in the mitochondria or endoplasmic reticulum, and inactivate the factors that liberate calcium from storage sites.

In the event of cerebral ischemia, there are two simultaneous impacts on these processes. There is excess release into the synaptic cleft of the neurotransmitters that activate the various calcium influx processes (see Fig. 19-12 A), and there is a failure of the supply of adenosine triphosphate (ATP) that is necessary to clear the calcium from the cytosol (Fig. 19-12 B). Among calcium's normal intracellular functions is the activation of various lipases, nucleases, and proteases. The sustained activation of these and other enzymes by elevated cytosolic calcium during ischemia has many consequences, including direct structural damage, the liberation of fatty acids from membranes, and the initiation of gene transcription. In addition, electron-hungry free radicals that are generated during the reperfusion process contribute to the further degradation of membrane lipids and other structural elements. Among the liberated free fatty acids is arachidonic acid, which is the substrate for the generation, by the action of cyclooxygenase and lipoxy-genase, of various prostaglandins and leukotrienes. These "eicosanoids" have numerous effects including vasoconstriction, vasodilation, alteration of membrane permeability, and leukotaxis, all of which can contribute to the evolution of the ischemic neuronal insult. In particular, the recruited white blood cells that initially adhere to damaged endothelium and subsequently enter brain parenchyma may make a substantial contribution to the progression of injury after ischemia. Some of the gene transcription initiated by ischemia inevitably contributes to restorative processes. However, in some circumstances that are not yet well defined, the transcription leads on to apoptosis (genetically mediated cell death).

Figure 19-12 (A) Neuronal calcium (Ca^{2+}) homeostasis. Cytosolic Ca^{2+} concentration is tightly regulated. Increases result from three primary mechanisms: depolarization of neurons opens voltage-dependent Ca^{2+} channels; ligand-gated channels, e.g., the *N*-methyl- D-aspartate (NMDA) subtype of the glutamate (Glu) receptor, open when activated by their specific neurotransmitter agonists; and, neurotransmitters that may also activate surface receptors leading to generation of inositol triphosphate (IP3), which, in turn, increases Ca^{2+} release from the endoplasmic reticulum (ER) and mitochondria. Ca^{2+} is removed from the cytosol by two adenosine triphosphate (ATP)-driven processes, a Ca^{2+} -ATPase pump and resequestration within the ER/mitochondria, and by a Ca^{2+} -sodium (Na^{+}) exchanger. (B) During ischemia, ATP depletion leads to neuronal depolarization and the subsequent release of supranormal quantities of neurotransmitters, especially glutamate. Excessive stimulation of ligand-gated channels and the simultaneous opening of voltage-dependent Ca^{2+} channels permits rapid entry of Ca^{2+} into neurons. Stimulation of metabotropic glutamate receptors generates IP3, causing release of Ca^{2+} from ER/mitochondria. Activation of the AMPA-gated subset of glutamate receptors also permits excessive entry of Na^{+} . The energy requiring Ca^{2+} extrusion/resequestration processes is inhibited by the lack of ATP, and high intracellular Na^{+} levels may result in the reversal of the Na^{+} -Ca^{2+} exchanger. Excessive free Ca^{2+} results in activation of numerous enzymes: protease activation causes breakdown of the cytoskeleton of the neuron; lipases damage plasma membrane lipids and release arachidonic acid (AA), which is metabolized by cyclooxygenases and lipooxygenases to yield free radicals (FR) and other mediators of cell injury; activation of nitric oxide synthase (NOS) leads to release of NO and, in turn, the generation of peroxynitrite, a highly reactive free radical; and, activated endonucleases damage DNA, rendering the neuron susceptible to apoptosis. Certain protein kinases are also activated, and some of these lead to synthesis of transcription factors that initiate gene transcription and protein synthesis. Some of these new proteins contribute to restorative functions, but others may initiate biochemical processes that culminate in cell suicide, or apoptosis. G, G protein; PLC, phospholipase C; Pi, inorganic phosphate; ADP, adenosine diphosphate; AMPA, alpha-amino-3-hydroxy-5-methyl-4-isoxazopropionic acid.

Lactate formation is an additional element of the pathophysiologic process. Lactic acid is formed as a result of the anaerobic glycolysis that takes place after the failure of the supply of O_2 . The associated pH decline contributes to the deterioration of the intracellular environment. An increased preischemic serum glucose concentration may accelerate this process by providing additional substrate for anaerobic glycolysis. [401] [402] [403] [404]

NO, [2] [3] [405] which has emerged as a probable mediator of CBF changes in many normal physiologic states (see preceding sections), is also of relevance to the pathophysiology of ischemia. NO is, in fact, a weak free radical, [405] [406] which, in turn, leads to the generation of a more reactive species (peroxynitrite) and is a "killer substance" used by macrophages. [2] In cerebral ischemia, NO is probably both friend and foe. [407] It is likely that during a period of focal ischemia, the vasodilating effect of NO (probably constitutively elaborated NO of endothelial origin) serves to augment collateral CBF. [408] However, in the postischemic phase, NO (probably inducible NO of neuronal origin) appears to contribute to neuronal injury. [408]

Much has been made of the difference between complete cerebral ischemia, as occurs during cardiac arrest, and incomplete cerebral ischemia, as may occur during occlusion of a major cerebral vessel or severe hypotension. However, from the clinician's vantage, the important difference is that the residual blood flow during incomplete ischemia may result in enough O_2 delivery to allow for some generation of ATP and thereby to prevent the catastrophic irreversible membrane failure that occurs within minutes during normothermic complete cerebral ischemia. This difference in the rate of failure of energy supply [409] [410] (Fig. 19-13) can result in a much greater apparent tolerance for focal or incomplete ischemia than for complete global ischemia, such as cardiac arrest. The difference is a matter of severity, rather than of the actual initial pathophysiology of the insult, with the exception that limited residual perfusion may potentially be detrimental in the event of hyperglycemia. There is also a theoretic concern that low levels of residual flow will provide sufficient O_2 delivery to permit the formation of O_2 radicals. However, the observation that focal

ischemia is better tolerated than complete global ischemia argues against major importance.

Critical CBF Levels and the Ischemic Penumbra Concept

In the face of a declining O_2 supply, neuronal function deteriorates progressively, rather than in an all-or-none fashion (Fig. 19-14) . There is a substantial reserve at less than normal CBF levels (>50 mL/100 g/min). It is not until CBF has fallen to approximately 22 mL/100 g/min that EEG evidence of ischemia begins to appear. At a CBF level of approximately 15 mL/100 g/min, the cortical EEG is isoelectric. However, only when CBF is reduced to about 6 mL/100 g/min are indications of potentially irreversible membrane failure (elevated extracellular potassium [411] and loss of the direct cortical response [412]) rapidly evident. As CBF decreases in the flow range between 15 and 6 mL/100 g/min, a progressive deterioration of energy supply occurs, leading eventually, with a time course that may encompass hours, [413] [414] rather than minutes, to membrane failure and neuronal death. The brain regions falling within this CBF range (6-15 mL/100 g/min) are

Figure 19-13 A comparison of the rates of failure of energy supply (adenosine triphosphate [ATP]) in complete global ischemia (produced by decapitation in dogs [410]) and in incomplete focal ischemia (middle cerebral artery [MCA] occlusion in monkeys [409]). In the presence of residual cerebral blood flow (CBF), energy supply failure is substantially delayed.

referred to as the "ischemic penumbra"--a region within which the neuronal dysfunction is temporarily reversible but within which neuronal death will occur if flow is not restored. [411] [415] It is the ischemic penumbra phenomenon that accounts for instances, such as in carotid endarterectomy, in which neurologic recovery occurs when the EEG was "flat" for periods longer than those normally associated with neurologic injury. The studies defining this progression have been performed principally in the cerebral cortex of baboons [411] [416] and monkeys, [413] and the actual CBF levels at which the various decrements in function occur may vary with both anesthetic [417] [418] and species. However, in humans anesthetized with halothane and N_2O, the CBF threshold for the initial EEG change [419] is similar to that observed in the animal investigations.

Brain Protection

As outlined earlier, cerebral ischemic injury involves a process whereby energy supply falls short of energy demand, wherein the intracellular environment deteriorates (increased calcium, decreased pH), membrane damage occurs, and secondary processes (eicosanoids, free radicals, white cells, apoptosis) that aggravate the injury are initiated. The numerous brain-protection strategies that have been studied in both the laboratory and the clinic can be classified according to the phase of this sequence that each addresses. They are listed in Table 19-6 . Brain-protection regimens are logically most effective when instituted prior to the onset of ischemia. However, it is reasonable to anticipate some efficacy of certain therapies initiated after the beginning of the insult because many of the insult processes are ongoing in the ischemic and reperfusion phases. The literature dealing with cerebral protection/resuscitation is enormous and cannot be thoroughly reviewed here. Reviews of brain protection are available. [397] [398] [399] [400] Of the many promising protection/resuscitation strategies, only a limited number (discussed later) have reached the stage of human application. Some are relevant to both complete global ischemia (e.g., cardiac arrest) and incomplete focal ischemia (e.g., thromboembolism, vessel occlusion), as mentioned later.

Figure 19-14 The relationships among cerebral perfusion, cerebral blood flow (CBF), the electroencephalogram (EEG), and the functional status/viability of neurons. Note that in the approximate CBF range of 6 to 12 mL/kg/min, the energy supply is insufficient to support electrophysiologic activity (i.e., EEG flat), but it can prevent complete membrane failure and neuronal death for extended periods (see Fig. 19-13) . These areas are referred to as the ischemic penumbra. [411] The data are derived from studies in the cerebral cortex of barbiturate anesthetized baboons [411] [416] and unanesthetized monkeys. [413] The CBF and mean arterial pressure (MAP) thresh-olds may vary with anesthetic agent and with species. [417]

TABLE 19-6 -- Ischemic Neuronal Injury: Pathophysiologic Sequence and Related Protection Strategies

INSULT MECHANISM	PROTECTION STRATEGY	THERAPY EXAMPLE[a]
Failure of energy supply	Decrease energy demand (cerebral metabolic rate)	Hypothermia*
		Barbiturates*
		Other anesthetics
	Increase energy supply (cerebral blood flow)	Induced hypertension*
		Hemodilution*
		Mannitol [528]
		Thrombolysis [529]
	Prevent supranormal energy demand	Seizure prophylaxis and control*
Increased cytosolic Ca^{2+}	Prevent neurotransmitter release	Hypothermia [421] [530]
		Adenosine agonists [531]
		$alpha_2$ -Agonists [532]
		Riluzole [533]
		Lubeluzole* [491]
	Oppose excitatory effects	gamma-Aminobutyric acid agonists [534]
	Block neurotransmitter receptor	Dopamine antagonists [535]
		Glutamate (AMPA) antagonists [536]
		Glutamate (NMDA) antagonists [537]
		Glycine antagonists [538]
		Serotonin antagonists [539]
	Block second messenger (inositol triphosphate) formation	Phospholipase C inhibitors [540]
	Block Ca^{2+} entry into neuron	Ca^{2+} channel blockers*
		Noncompetitive glutamate antagonists [541]
		Potassium channel activator [542]
	Block Ca^{2+} activated processes	Calpain inhibitors [543]
		Protein kinase C inhibitors [544]
Intracellular acidosis	Avoid hyperglycemia	Omit glucose solutions*
		Insulin to normalize plasma glucose [545]
Membrane damage	Inhibit free radical formation	Iron chelators (e.g., deferoxamine [546])
		Xanthine oxidase inhibitors (e.g., allopurinol [546])
	Inhibit nitric oxide	Nitric oxide synthase inhibitors [547]

	Scavenge free radicals	Superoxide dismutase [548]
		Catalase [549]
		Dimethylthiourea [550]
	Act as antioxidants	Aminosteroids [490]
		Vitamin E [551]
	Stabilize membranes	Gangliosides [552]
Fatty acid metabolite-mediated damage	Inhibit formation of prostaglandins and leukotrienes thromboxane synthetase [555]	Inhibitors of lipoxygenase [553] and cyclo-oxygenase [554]
Vascular injury/occlusion	Act as anticoagulants	Heparinoids [556]
	Inhibit platelets	Platelet-activating factor inhibitors [557]
	Inhibit white cell adhesion	Antibody to ICAM (intercellular adhesion molecule) [558]
	Act as thrombolytics	Tissue-plasminogen activators [529]
Apoptosis	Inhibit protein synthesis	Cycloheximide [559]
	Inhibit caspase	z-VAD.FMK [560]

AMPA, alpha-amino-3-hydroxy-5-methyl-4-isoxazopropionic acid; NMDA, *N*-methyl- D-aspartate

[a] Note that although each of the "therapy examples" has shown efficacy in at least one laboratory investigation, only those designated with an asterisk have been proven or are accepted as clinically applicable. For items not discussed in the text, a single reference is provided.

Others are of greater relevance only in focal ischemia, wherein energy supply failure may be more gradual and wherein there is potential for manipulation of collateral CBF.

Considerations Relevant to Both Complete and Incomplete Ischemia

Temperature.

Hypothermia is firmly and justifiably established as the principal cerebral protective technique for circulatory arrest procedures. It unequivocally enhances cerebral tolerance for episodes of ischemia. For deep hypothermia, this effect has been presumed to be largely a function of reduction of CMR. Although pharmacologic agents, such as barbiturates, reduce only that component of CMR associated with electrophysiologic "work" (about 60% of the $CMRO_2$ in the awake state), hypothermia causes a reduction of both electrophysiologic energy consumption and the energy utilization related to maintenance of cellular integrity, and mild hypothermia may preferentially suppress the latter. [32] [33] There has been a surge of interest in *mild* hypothermia as a cerebral protective technique. Laboratory studies have demonstrated that mild degrees of hypothermia (2-4°C) during an episode of ischemia can confer substantial protection, as measured histologically. [30] [420] [421] [422] [423] [424] [425] In addition, there is also evidence from animal studies that hypothermia

initiated in the immediate postischemic period confers protective benefits. [426] [427] [428] [429] [430]

These observations regarding mild hypothermia have cast doubt on the notion that CMR suppression is the sole mediator of the cerebral protective effects of hypothermia. This arises because the amount of CMR suppression associated with protective degrees of hypothermia is in some instances less than that associated with pharmacologic interventions that have been less clearly protective. Microdialysis investigations in the setting of cerebral ischemia have revealed that hypothermia has a very striking inhibitory effect on the release of various neurotransmitters [421] (recall the pathophysiologic cascade discussion earlier), and it may well be that the protective effects of hypothermia are far more dependent on influences on several steps in the biochemistry of ischemia (Table 19-7) than on suppression of CMR. [431] On the strength of the animal investigations cited earlier, mild hypothermia (32-34°C) is being used in some centers in anticipation of possible focal ischemic events, such as aneurysm surgery. There are, however, no data derived in humans to confirm the efficacy of the practice. There have also been several small, single-institution trials of mild hypothermia in head injury [432] [433] [434] [435] (conducted with the rationale that ischemia contributes to the pathophysiology of head injury [436] [437]). The results have been sufficiently favorable that a large, multicenter trial is being conducted.

Hyperthermia has been shown to be deleterious to outcome from standardized ischemic events. [422] [438] [439] [440] Hyperthermia before, during, and after ischemic events should be prevented or treated.

Glucose.

The withholding of glucose-containing solutions in situations in which cerebral ischemia may occur is now an established practice. The practice is based on numerous demonstrations in animal models of brain and spinal cord ischemia that elevation of plasma glucose concentrations prior to episodes of either complete or incomplete ischemia results in an aggravation of neurologic injury. [401] [402] [403] [441] [442] [443] [444] However, it should be noted that most investigations have involved adult animals, and there is less certainty as to the adverse effects of hyperglycemia in immature subjects, such as neonates. [445] Furthermore, it should be noted that only some, [446] [447] and not all, [448] [449] [450] [451] [452] of the investigations in humans have provided confirmation of an independent effect of serum glucose on neurologic outcome. A recurrent theme in the discussion of these studies is

TABLE 19-7 -- Possible Mechanisms of Cerebral Protection by Mild Hypothermia [a]

Reduction of cerebral metabolic rate
Decreased release of excitatory neurotransmitters
Inhibition of activation of protein kinase C (early)
Preservation of late postischemic enzyme function
Protein kinase C
Calcium-calmodulin kinase II
Ubiquitin
Reduction of free radical formation
Inhibition of DNA transcription
Inhibition of apoptosis
Inhibition of proinflammatory cytokines

[a] See published reviews for further details. [30] [561]

that glucose elevation may be the *result* of the stress associated with a severe insult, either ischemic or traumatic, rather than its *cause.* In addition, the inevitable

questions of whether and how quickly immediate pre-risk treatment with insulin of an elevated plasma glucose level reduces risk to normoglycemic levels have not been examined thoroughly. It is these authors' opinion that short-term insulin administration (with its attendant risk of hypoglycemia) in patients with modest glucose elevation, such as 175 to 250 mg/dL, is not yet justified.

Seizures and pH.

Although normalization of systemic pH, prevention and treatment of seizures, which dramatically increase CMR, and control of ICP and CPP are all mundane and lacking in the appeal of the pharmacologic silver bullet, they are important elements of brain protection and resuscitation.

Considerations Relevant to Focal (Incomplete) Ischemia

Protection by Anesthetic Agents.

Before discussing individual agents, it should be noted that a general theme that can be extracted from the literature on this topic, in particular for anesthesia with volatile agents, is that anesthesia per se is protective. It appears that, for undefined reasons, reducing the level of systemic stress associated with a standardized experimental insult results in an improved outcome. [453] [454] In reviewing the literature, readers should be conscious of the possibility that the protective benefit ascribed to an intervention with an anesthetic agent may, in fact, be the product of exaggeration of the injury in a high-stress control state, such as N_2O "sedation."

Barbiturates.

There have been numerous demonstrations of the protective efficacy of barbiturates in focal cerebral ischemia in animals [455] [456] [457] [458] [459] [460] [461] and a single demonstration of effectiveness in humans. [462] The effect has been attributed principally to suppression of CMR. However, CBF redistribution effects and free radical scavenging [463] have been suggested to contribute to this effect, and there is evidence that CMR suppression is not the sole mechanism. [464] [465] [466] Suppression of CMR could logically be expected to benefit brain regions in which O_2 delivery was inadequate to meet normal demands but was sufficient to allow energy consumption by some ongoing electrophysiologic activity, that is, in which the EEG was abnormal but not flat. Such regions are likely to be limited in size in the setting of focal ischemia, yet several animal investigations suggest a very substantial protective effect. [455] [457] [458] [459] Review of these experiments reveals that the methods used to monitor and maintain temperature, although accepted at the time, were below the standards that have evolved from more recent understanding of the effects of both deliberate [420] [424] and inadvertent [427] hypothermia. Unrecognized cerebral hypothermia may well have been a factor in some of the cited investigations, and it is possible therefore that the protective efficacy of barbiturates may have been overestimated. Although more recent publications involving suitable temperature-control methods do, in fact, indicate a protective effect

by barbiturates, [466] [467] [468] the magnitude of that effect was modest by comparison with the results of earlier studies. Barbiturate-induced EEG suppression in an already anesthetized patient may still be logical therapy when it can be applied before or early in the course of a period of temporary focal ischemia, such as temporary occlusion during aneurysm surgery. However, the judgment to institute such therapy should be made after consideration of the risk of the occlusive event, of the patient's cardiovascular status, and of the physicians' willingness to accept the possible prolongation of arousal and with an objective view of the likely magnitude of the protective effect. Numerous investigations in animals and humans have failed to demonstrate any protective effect of barbiturates in the setting of global cerebral ischemia, such as in cardiac arrest. [469] [470]

Because CMR suppression has been the presumed mechanism of effect, barbiturates have traditionally been administered to produce maximal reduction of CMR, which is near complete when EEG burst suppression has been achieved. However, data presented by Warner et al [466] demonstrated that the same protective benefit (expressed as reduction of infarct volume) could be achieved with one-third of the burst-suppression dose. This finding raises a clinically important issue. The various barbiturates (e.g., thiopental, thiamylal, methohexital, pentobarbital) have similar effects on CMR and have generally been assumed to have equal protective efficacy. However, if the mechanism of protection is a pharmacologic effect other than CMR reduction, is it reasonable to assume equivalence among the barbiturates? Probably not. In the opinion of the authors of this chapter, rational use of barbiturates for clinical cerebral protection requires further laboratory investigations. These analyses should entail concurrent comparisons, including dose-response evaluations, for thiopental, methohexital, and pentobarbital.

Isoflurane/Volatile Anesthetics.

Isoflurane is also a potent suppressant of CMR in cerebral cortex, and EEG evidence suggestive of a protective effect in hu- mans has been reported. [417] However, the available laboratory data have not provided consistent confirmation of a protective effect of isoflurane relative to other anesthetics. [424] [439] [454] [461] [467] [468] [471] [472] [473] [474] [475] The available literature suggests that adequate anesthesia per se may have a protective effect [453] [454] versus the awake state, but it does not confirm any advantage of isoflurane over any other volatile agent.

Propofol.

EEG suppression can also be achieved with clinically feasible doses of propofol. Anecdotal information suggests that the drug is being used to provide "protection" during both aneurysm surgery [476] and carotid endarterectomy. However, a search for experimental data using models of focal cerebral ischemia with histologic end points (infarct size) revealed only two relevant investigations. Ridenour et al [477] performed 2 hours of MCA occlusion followed by a 3-day survival period with subsequent determination of infarct volume in rats anesthetized either with 0.5 MAC halothane or propofol in sufficient concentration to produce burst suppression. There was no difference in infarct volume. Young et al [478] compared histologic injury 4 hours after a 2-hour period of temporary MCA occlusion in rats anesthetized with either propofol or isoflurane in burst-suppression inducing doses. There was less injury in the propofol-treated group, but CPP was neither measured nor controlled, thus leaving the conclusion suspect. Accordingly, it is difficult to assert that propofol has proven cerebral protective effects.

Etomidate.

Etomidate was proposed as early as 1988 as a potential protective agent in the setting of aneurysm surgery. [479] It, too, produces CMR suppression to an extent equivalent to that of barbiturates, and, like the barbiturates, etomidate is an agonist at the (inhibitory) gamma-aminobutyric acid ($GABA_A$) receptor. At that time, there were no investigations of etomidate using histologic end points. Subsequently, in a model of temporary forebrain ischemia, a very small protective effect, relative to anesthesia with 1.1 MAC halothane or isoflurane or thiopental, was demonstrated in the hippocampus, but no protective effects were seen in other brain regions including cortex, reticular nucleus of thalamus, and striatum. [480] [481] In a later investigation using a model of temporary MCA occlusion, [468] the volume of injury was not reduced by etomidate relative to a 1.2 MAC-anesthetized halothane control group. In fact, the volume of injury with etomidate was significantly larger than in the control group. Data [482] support the suspicion that this aggravation of injury by etomidate may be related to direct binding of NO as a consequence of etomidate-induced hemolysis, [483] combined with a direct inhibition of the NO synthase enzyme by etomidate, an imidazole. [484] This aggravation of injury may be a phenomenon peculiar to rats. Nonetheless, there is no scientific support for the current use [485] of etomidate for "cerebral protection."

Calcium Channel Blockers.

It is now an established clinical practice to administer nimodipine orally (the intravenous preparation is not approved for clinical use in North America) for 21 days beginning as soon as possible after subarachnoid hemorrhage. [486] However, it has not yet become a standard practice to administer nimodipine or any other calcium channel blocker routinely after neurologic stroke occurring in the operating room or in any other environment. In spite of favorable results in small trials, [487] [488] not all investigations in stroke victims have confirmed the benefits of nimodipine. [489] Those that did reveal beneficial effects saw them only in limited post hoc patient subsets, that is, patients in whom therapy was initiated quickly. [487] [488] An ongoing clinical trial of very early nimodipine use in stroke (VENUS) should provide clarification.

Other Agents.

In spite of the multitude of studies that have revealed "protective" effects in animals, the number of additional pharmacologic agents that have actually been proven effective in attenuating ischemic injury by large, prospective, randomized double-blind clinical trials is remarkably small. These include tirilazad [490] (an antioxidant of the 21-aminosteroid type) in the setting of subarachnoid hemorrhage and lubeluzole [491] (a sodium channel blocker) in clinical stroke.

Manipulation of CBF.

Measures designed to augment CBF (an important determinant of energy supply) are also important. In the ischemic penumbra described earlier, small improvements in CBF have the potential to prolong neuronal survival substantially. The maintenance of a high-normal

CPP can augment collateral CBF [92] and has been shown to result in improvement of various neurophysiologic parameters including neurologic function. [492] [493] [494] Note, however, that this practice carries the inadequately explored risks of increased edema and hemorrhagic infarction if used as support during more than brief periods of ischemia, particularly when several hours have elapsed since the onset of ischemia.

Carbon Dioxide Tension.

Normocapnia should be maintained. Hypercapnia has the potential to cause an intracerebral steal and may worsen intracellular pH. Hypocapnia, in spite of some support for the occurrence of a favorable so-called Robin Hood or inverse steal, [495] [496] has not generally proven effective in either laboratory or clinical settings. [497] [498] [499] [500] [501] Pending further information, normocapnia remains the standard practice.

Intravascular Volume/Hematocrit Manipulation.

Al- though hemodilution has not proven effective in studies of human stroke, both laboratory and clinical data support the practice, and it is an established part of the management of the ischemia associated with vasospasm. However, the data do not currently justify routine hemodilution (a hematocrit of 30-35% is the theoretic optimum) in patients in whom focal ischemia may occur in the operating room. [502] On the other hand, the potentially deleterious effects of hemoconcentration should help to suppress further the out-of-date notion that neurosurgical patients should be "run dry." An elevated hematocrit, because of viscosity effects, reduces CBF. [77] It is the authors' unsubstantiated opinion that in anticipation of a procedure wherein incomplete ischemia may occur, such as carotid endarterectomy, a hematocrit in excess of 55 percent should be lowered by preoperative phlebotomy.

Deferring Elective Procedures After Stroke.

The risks of extension of cerebral infarction in the event of subsequent anesthesia and surgery have not been studied systematically. In patients who have suffered a stroke, CBF undergoes marked changes. Areas of both high and low CBF occur, and stabilization of CBF and CMR is apparent after about 2 weeks. [503] Loss of normal vasomotor responses (CO_2 responsiveness, autoregulation) in the early postinsult period is very common, [504] [505] [506] and changes persist beyond 2 weeks in a small percentage of stroke victims. [505] [506] BBB abnormalities, as reflected by accumulation of CT contrast or brain scan isotopes, are still present 4 weeks after insult, [507] and the histologic resolution of large infarcts is not complete for several months. The available information does not allow a definite statement on how long elective procedures should be deferred. A 6-week delay should give some assurance of the likely recovery of autoregulation, CO_2 responsiveness, and BBB integrity. However, the size and location of the infarction should be weighed. A small infarction in silent cortex may give wider latitudes than a large lesion that has resulted in paresis that is still resolv-ing. Pending other information, it seems reasonable to defer elective surgery for at least 6 weeks after a cerebral vascular accident and preferably for 6 weeks from the point at which a stable postinsult neurologic state has been achieved.

Considerations Relevant to Complete Global Ischemia (Cardiac Arrest)

Maintenance of adequate perfusion pressures following cardiac arrest is of considerable importance (Ch. 75) . Hypotension developing after resuscitation from cardiac arrest may aggravate microcirculatory and vasospastic processes occurring at this time and may increase brain damage. A late phase of intracranial hypertension may occur and is due to the development of extensive cerebral edema, probably both vasogenic and cytotoxic in origin, associated with brain necrosis. Attempts to control this type of intracranial hypertension with osmotherapy usually fail. ICP monitoring is not generally employed because the patients who develop these delayed ICP increases have sustained massive tissue damage.

Both barbiturates and calcium channel blockers have been administered after cardiac arrest. The former are ineffective. [469] [470] [508] The calcium channel blocker nimodipine improved neurologic outcome when administered after complete global ischemia in a primate model, [509] but it was ineffective following complete global ischemia in the cat [510] [511] and the dog. [512] In a small cohort (51 patients) of cardiac arrest victims, nimodipine was shown to improve CBF but not neurologic outcome. [513] In a second trial in approximately 150 cardiac arrest victims, no overall benefit in neurologic outcome was observed. [514] However, a subset of patients in whom initiation of advanced life support was delayed for more than 10 minutes demonstrated improved survival. This single study cannot serve as a justification for the administration after cardiac arrest of nimodipine, especially in the face of the unequivocally negative results of the multicenter lidoflazine cardiac arrest study. [515] Once again, the important therapeutic objectives are maintenance of normocarbia and normotension, normalization of systemic pH, avoidance of hyperthermia, and prevention and treatment of seizures.

Chronic Arterial Hypertension

A recurrent concern is that of acceptable levels of blood pressure reduction in chronically hypertensive patients (Ch. 25) . Firm guidelines have not been established. However, from the vantage of cerebral well-being, limiting elective MAP reduction to 30 to 35 percent of resting mean levels seems appropriate for both hypertensive and normotensive patients. It is reasonable that the same guidelines may apply in both populations because, in chronic hypertension, both the upper limit of autoregulation and the LLA are shifted to the right with apparently little distortion. [46]

The rationale for a limit of 30 to 35 percent is as follows. It has been demonstrated that MAP reductions of 50 percent in nonanesthetized patients, both normotensive and hypertensive, commonly produce reversible symptoms of cerebral hypoperfusion. [46] [516] [517] Although even greater reductions are probably tolerated provided

plateau. It has been demonstrated that a MAP reduction of 25 percent brings both normotensive and hypertensive patients to the LLA. [46] Because MAP reduction exceeds 25 percent of baseline, CBF values are below normal, albeit, in subjects free of occlusive vascular disease, above the threshold for neurophysiologic dysfunction or injury (see Fig. 19-14) . However, physiologic reserve is being encroached on, leaving little margin for error or for other causes of impaired cerebral O_2 delivery (low hematocrit, unrecognized cerebrovascular disease).

It has been demonstrated in animals that treatment of chronic hypertension can restore the LLA to normal. [518] [519] A similar phenomenon has been observed in humans by Strandgaard, [46] although restoration was incomplete and had failed to occur after as much as 12 months of treatment in some subjects. It is an unexplored possibility that the extent of restoration of the LLA with antihypertensive therapy depends on the agent. Some drugs may restore the LLA more effectively than others. In particular, angiotensin-converting enzyme inhibitors have been shown to decrease the LLA acutely in both normotensive and hypertensive subjects. [47] [520]

Intracranial Hypertension

The control of intracranial hypertension is discussed in detail in Chapter 52 .

Brain Tumors

There are few data regarding the physiology of intracranial tumors. Arbit et al [521] measured CBF in cerebral tumors using laser-Doppler technology. In general, they found that tumors had a lower CBF than normal brain. Autoregulation was occasionally apparent, and CO_2 responsiveness was usually present. The investigation of Schregel et al, [522] who measured MCA velocity and vessel area in tumor patients, also revealed that CO_2 responsiveness was occasionally abnormal and that, ipsilateral to the tumor, hyperventilation was sometimes associated with paradoxic increases in MCA flow velocity. There is often considerable edema in association with intracranial tumors. Bedford et al [523] showed that the radiologic extent of the edema (which presumably represents the extent of abnormal vessel leakiness) correlated with the severity of the ICP elevation that occurred in association with intubation-related hypertension. Empirically, the edema associated with tumors is improved by steroids, [524] and it has been shown in patients with intracranial tumors [525] that, over a time course as short as 6 hours, BBB function is improved by administration of dexamethasone (Ch. 52) .

Coma and Epilepsy

Coma, regardless of its cause, is associated with reductions in brain metabolism. In the case of lesions occurring in the reticular activating system, the reduction in CMR probably represents a normal physiologic adjustment to reduced functional activity. During generalized seizure activity, CMR and CBF may increase dramatically. [371] The intensive motor and brain activity accompanying generalized seizures leads to the development of systemic and cerebral acidosis, often accompanied by a reduction in arterial oxygenation, an increase in Pa_{CO_2}, and peripheral lactic acidosis. If generalized seizure activity continues unabated, arterial hypotension ensues. With muscular relaxation and measures ensuring adequate oxygenation and ventilation, the systemic acidosis and hypotension can be avoided, and the severity of cerebral acidosis can be diminished. During relatively brief episodes of continuous seizures, the brain seems able to meet the high metabolic demands. [371] However, even with effective ventilation and maintenance of perfusion pressure, when seizures continue for a prolonged period, they can lead to the development of irreversible neuronal damage. [526] Therapy aimed at interrupting the seizure and restoring a normal balance between cerebral metabolic demand and CBF is indicated. Barbiturates, benzodiazepines, and other potent anticonvulsants are appropriate. Adequate ventilation, oxygenation, and maintenance of blood pressure are important adjunctive measures. Muscle relaxants must be viewed as purely symptomatic therapy, because they do not alter the abnormal cerebral electrical activity.

The potentially injurious nature of seizures justifies attention to prevention. Practices vary. However, patients who have sustained a severe head injury or subarachnoid hemorrhage and any patient in whom a substantial cortical incision is planned are at risk, and prophylactic anticonvulsants should be considered.

ACKNOWLEDGMENT

The authors gratefully acknowledge the contribution of Harvey M. Shapiro to the development of this chapter.

INTRODUCTION

The physiology of neuromuscular transmission could be analyzed and understood at the most simple level by using the classic model of nerve signaling to muscle via the acetylcholine receptor. Yet recent research has provided more detailed information on these processes, which, within the classic scheme, can modify neurotransmission or response to drugs, or both. One example of this would be the role of qualitative or quantitative changes in acetylcholine receptors modifying neurotransmission and response to drugs. [1] In myasthenia gravis, for example, the decrease in acetylcholine receptors results in decreased efficiency of neurotransmission (and therefore muscle weakness) and altered sensitivity to neuromuscular relaxants. [1] [2] At still another level is the evidence that muscle relaxants act in ways that are not encompassed by the classic scheme of unitary site of action: The observation that muscle relaxants can have prejunctional effects, [3] or that some nondepolarizers can also have agonist-like stimulatory actions on the receptor, [4] has provided new insights into some previously unexplained observations. Although this multifaceted action-response scheme makes the physiology and pharmacology of neurotransmission more complex, these added insights also bring experimentally derived knowledge much closer to clinical observations.

Crucial to the seminal concepts that have developed relative to neurotransmitter, acetylcholine, and its receptor systems have been the introduction of powerful and contemporary techniques in molecular biology, immunology, and electrophysiology. These have augmented the more traditional pharmacologic, protein chemical, and cytologic approaches. [5] Additionally, recent research has elucidated the manner in which the nerve ending regulates not only the synthesis and release of transmitter but also trophic factors, both of which control muscle function, and how these processes are influenced by exogenous and endogenous substances. [1] [6] [7] [8] Research continues into how receptors are synthesized and anchored at the end plate, the role of the nerve terminal in the maturation process, and the synthesis and control of acetylcholinesterase, the enzyme that breaks down acetylcholine. The reader is referred to several recent reviews that provide detailed insights into these areas. [7] [8] [9] [10]

NEUROMUSCULAR TRANSMISSION

Overview

Neuromuscular transmission occurs by a fairly simple and straightforward mechanism. The nerve synthesizes acetylcholine and stores it in small, uniformly sized packages called *vesicles.* Stimulation of the nerve causes these vesicles to migrate to the surface of the nerve, rupture, and discharge acetylcholine into the cleft separating nerve from muscle. Acetylcholine receptors in the end plate of the muscle

respond by opening its channels for influx of sodium ions into the muscle to depolarize the muscle. The end plate potential thus created is continued along the muscle membrane by the opening of the sodium channels present throughout the muscle membrane, initiating a contraction. [11] The acetylcholine immediately detaches from the receptor and is destroyed by acetylcholinesterase enzyme, which also is in the cleft. Drugs, notably depolarizing relaxants or carbachol, can also act on these receptors to mimic the effect of acetylcholine and cause depolarization of the end plate. These drugs are, therefore, called *agonists* of the receptor, since to a greater or lesser extent, at least initially, they stimulate the receptor. Nondepolarizing relaxants also act on the receptors, but they prevent acetylcholine from binding to the receptor and so prevent depolarization by agonists. Since these nondepolarizers prevent the action of agonists (e.g., acetylcholine, succinylcholine), the nondepolarizers are also referred to as *antagonists* of the acetylcholine receptor. Other compounds, frequently called *reversal agents* (e.g., neostigmine), inhibit acetylcholinesterase enzyme and therefore impair the hydrolysis of acetylcholine. The increased accumulation of undegraded acetylcholine can effectively compete with nondepolarizing relaxants, displacing the latter from the receptor (law of mass action), antagonizing the effects of nondepolarizers.

Morphology

The neuromuscular junction is specialized, both on the nerve side and on the muscle side, to transmit and receive chemical messages. [2] [3] [4] [5] [6] [7] Each motoneuron runs without interruption from the ventral horn of the spinal cord to the neuromuscular junction as a large myelinated axon. As it approaches the muscle, it branches repeatedly to contact many muscle cells and to gather them into a functional group known as a motor unit. The architecture of the nerve terminal is quite different from that of the rest of the axon. As the terminal reaches the muscle fiber, it loses its myelin to form a spray of terminal branches against the muscle surface and is covered by Schwann cells. [7] [9] This arrangement conforms to the architecture on the synaptic area of muscle membrane (Fig. 20-1). The nerve is separated from the surface of the muscle by an approximate 20 nm gap, *the junctional cleft.* The nerve and muscle are held in tight alignment by protein filaments, which span the cleft between nerve and end plate. The muscle surface is heavily corrugated, with deep invaginations of the junctional cleft--the primary and secondary clefts--between the folds in the muscle membrane; thus, the end plate's total surface area is very large. The shoulders of the folds are densely populated with acetylcholine receptors, about 5 million of them in each

Figure 20-1 Adult neuromuscular junction with the three cells that constitute the synapse: the motor neuron (nerve terminal), muscle fiber, and Schwann cell. The motor neuron from the ventral horn of the spinal cord innervates the muscle. Each fiber receives only one synapse. The motor nerve loses its myelin to terminate on the muscle fiber. The nerve terminal covered by a Schwann cell has vesicles clustered about the membrane thickenings, which are the active zones, toward its synaptic side, and mitochondria and microtubules toward its other side. A synaptic gutter, made up of a primary and many secondary clefts, separates the nerve from the muscle. The muscle surface is corrugated, and dense areas on the shoulders of each fold contain acetylcholine receptors. The sodium channels are present at the clefts and throughout muscle membrane.

junction. These receptors are sparse in the depths between the folds. Instead, these deep areas contain sodium channels.

The trophic function of the nerve is most vital for the development and maintenance of adequate neuromuscular function. Before birth, each muscle cell commonly has contacts with several nerves and thus has several neuromuscular junctions. At birth, all but one of the nerves retract and a single end plate remains. Once formed, however, the nerve-muscle contact, especially the end plate, is durable. Even if the original nerve dies, the one replacing it innervates exactly the same region of the muscle. The nerve endings on fast muscles are larger and more complicated than those on slow muscles. The reason for this is unclear. These differences in the nerve endings on the muscle surfaces may play a role in the differences in the response to muscle relaxants of fast and slow muscles.

Since all the muscle cells in a unit are excited by a single neuron, stimulation of the nerve either electrically or via an action potential originating from the ventral horn, or by any agonist, including depolarizing relaxants (e.g., succinylcholine), causes all muscle cells in the motor unit to contract synchronously. The synchronous contraction of the cells in a motor unit is fasciculation and often is vigorous enough to be observed through the skin. Although most adult human muscles have only one neuromuscular junction per cell, an important exception is some of the cells in the extraocular muscles. The extraocular muscles are "tonic" muscles, and, unlike other mammalian striated muscles, they are multiply innervated, with several neuromuscular junctions strung along the surface of each muscle cell. These muscles contract and relax slowly, rather than quickly as other striated muscles do; indeed, they can maintain a steady contraction, or contracture, whose strength is proportional to the stimulus received. Physiologically, this apparently is a specialization that holds the eye steadily in position. These muscles are important to an anesthetist because depolarizing relaxants affect them differently than they do most skeletal muscles. Instead of causing a brief contraction followed by paralysis, the drugs cause long-lasting contracture response, which pulls the eye against the orbit and contributes to a rise in the pressure of the intraocular fluid. [12]

The *perijunctional zone* is the area of muscle between and around the receptive area, and it is critical to the function of the neuromuscular junction. The perijunctional zone contains a mixture of the receptors, which include a smaller density of acetylcholine receptors and high-density sodium channels. The admixture enhances the capacity of the perijunctional zone to respond to the depolarization (end plate potential) produced by acetylcholine receptors and to transduce it into the wave of depolarization that travels along the muscle to initiate muscle contraction. The density of sodium channels in the perijunctional area is richer than in more distal parts of the muscle membrane. [13] The perijunctional zone is close enough to the nerve ending to be influenced by transmitter released from it. Moreover, special variants (isoforms) of receptors (see Biology of Prejunctional and Postjunctional Nicotinic Receptors) and sodium channels can appear in this area at different stages of life and in response to abnormal decreases in nerve activity. Congenital abnormalities in the acetylcholine receptor or the sodium channels (mutations) are also known. [11] [14] These variabilities seem to contribute to the differences in response to relaxants that are seen in patients of differing pathologic conditions and ages. [1] [15] These qualitative differences may also play a role in altered muscle function (see Myopathy of Critical Illness).

Quantal Theory

The contents of the ending are not homogeneous. As diagrammatically illustrated in Figure 20-1 , the vesicles are congregated in the portion toward the junctional

surface, whereas the microtubules, mitochondria, and other support structures are located toward the opposite side. The vesicles containing the transmitter are ordered in repeating clusters alongside small, thickened, electron-dense patches of membrane referred to as an *active zone.* This thickened area is a cross-section of a band running across the width of the synaptic surface of the nerve ending, believed to be the structure to which vesicles attach before they rupture into the junctional cleft. High-resolution scanning electron micrographs reveal small protein particles arranged alongside the active zone, between vesicles. These are believed to be special channels, the voltage calcium channels, that allow calcium to enter the nerve and cause the release of vesicles. [16]

When one observes the electrophysiologic activity of a skeletal muscle, small, spontaneous, depolarizing potentials at neuromuscular junctions can be seen. These potentials have only one-one hundredth the amplitude of the evoked end plate potential produced when the motor nerve is stimulated. Except for amplitude, these potentials resemble the end plate potential in time course and in the manner in which they are affected by drugs. Therefore, these small amplitude potentials are called miniature end plate potentials (MEPP). Statistical analysis led to the conclusion that they are unitary responses; that is, there is a minimum size for the MEPP, and the sizes of all MEPPs are either equal to or multiples of this minimum size. Because MEPPs are too big to be produced by a single molecule of acetylcholine, it was deduced that they are produced by uniformly sized packages, or quanta, of transmitter released from the nerve (in the absence of stimulation). The stimulus-evoked end plate potential is the additive depolarization produced by the synchronous discharge of quanta from several hundred vesicles. The action potential that is propagated to the nerve ending allows the entry of calcium in the nerve through voltage-gated calcium channels, and this causes vesicles to migrate to the active zone, fuse with the neural membrane, and discharge their acetylcholine into the junctional cleft. [16] [17] Since the release sites are located immediately opposite the receptors on the postjunctional surface, little transmitter is wasted, and the response of the muscle is coupled very directly with the signal from the nerve. The amount of acetylcholine released by each nerve impulse is large, at least 200 quanta of about 5,000 molecules each, and the number of acetylcholine receptors activated by the transmitter released by a nerve impulse also is large, about 500,000. The ions (mostly Na^+ and some Ca^{2+}) that flow through the channels of the activated receptors cause a maximum depolarization of the end plate, which in turn causes an end plate potential that is greater than the threshold for

stimulation of the muscle. This is a very vigorous system. The signal is carried by more molecules of transmitter than are needed, and these evoke a response that is greater than needed. At the same time, only a small fraction of the available vesicles and receptors/channels are used to send each signal. Consequently, transmission has a substantial margin of safety, and at the same time the system has substantial capacity in reserve.

THE NEUROMUSCULAR JUNCTION

Motor Nerve Endings

The axon of the motor nerve carries not only electrical signals from the spinal cord to the muscles but also all the biochemical apparatus needed to transform the electrical signal into a chemical one. All the ion channels, enzymes, other proteins, macromolecules, and membrane components needed by the nerve ending to synthesize, store, and release acetylcholine and other trophic factors are made in the cell body and are transmitted to the nerve ending by axonal transport (Fig. 20-2) . [7] [9] The simple molecules choline and acetate are obtained from the environment of the nerve ending, the former by a special system that transports it from the extracellular fluid to the cytoplasm and the latter in the form of acetylcoenzyme A from mitochondria. The enzyme choline acetyltransferase brings about the reaction of choline and acetate to form acetylcholine, which is stored in cytoplasm until it is transported into vesicles, which are more into position for release. During a nerve action potential, sodium flows across the membrane and the resulting depolarizing voltage opens calcium channels, which allow entry of the calcium ion into the nerve and cause the release of acetylcholine.

A nerve action potential is the normal activator that releases transmitter, acetylcholine. The number of quanta released by a stimulated nerve is greatly influenced by the concentration of ionized calcium in the extracellular fluid. If calcium is not present, depolarization of the nerve, even by electrical stimulation, will not produce release of transmitter. Doubling the extracellular calcium results in a 16-fold increase in the quantal content of an end plate potential. The calcium *current* persists until the membrane potential is returned to normal by outward fluxes of potassium from inside the nerve cell. Thus, the calcium current can be prolonged by potassium channel blockers (e.g., 4-aminopyridine, and tetraethylammonium), which slow or prevent potassium efflux out the nerve. The increase in quantal content produced in this way can reach astounding proportions. [18] An effect of increasing the calcium in the nerve ending is also seen clinically as the so-called *post-tetanic potentiation,* which occurs after a nerve of a patient paralyzed with a nondepolarizing relaxant is stimulated at high, tetanic frequencies. Calcium enters the nerve with every stimulus, but it cannot be excreted as quickly as the nerve is stimulated and so accumulates during the tetanic period. Since the nerve ending contains more than the normal amount of calcium for some time after the tetanus, a stimulus applied to the nerve during this time causes the release of more than the normal amount of acetylcholine. The abnormally large amount of acetylcholine antagonizes the relaxant

Figure 20-2 The working of a chemical synapse, the motor nerve ending, including some of the apparatus for transmitter synthesis. acetylCoA, acetyl coenzyme A; Ach, acetylcholine; CAT, choline acetyltransferase. Large intracellular structures are mitochondria. Acetylcholine, synthesized from choline and acetylcoenzyme A, is transported into coated vesicles, which are moved to release sites. A presynaptic action potential, which triggers calcium influx through specialized proteins (Ca^{2+} channels), causes the vesicles to fuse with the membrane and discharge transmitter. Membrane from the vesicle is retracted from the nerve membrane and recycled. The transmitter is inactivated by diffusion, catabolism, or reuptake.

and causes the characteristic increase in the size of the twitch.

Calcium enters the nerve via specialized proteins called *calcium channels.*[8] Of the several types of calcium channels, two seem to be important for transmitter release, the P channels and the slower L channels. The P channels, probably the type responsible for the normal release of transmitter, are found only in nerve terminals. [8] [19] In motor nerve endings they are located immediately adjacent to the active zones (see Fig. 20-2) . They are voltage-dependent (i.e., they are opened and closed by the changes in membrane voltage caused by the nerve action potential). Alterations in calcium entry into nerve ending can also alter release of transmitter. Eaton-Lambert myasthenic syndrome is an acquired autoimmune disease in which antibodies are directed against the voltage-gated calcium channel at nerve endings. [20] In this syndrome, the decreased function of the calcium channel causes decreased release of transmitter, resulting in inadequate depolarization and therefore muscle weakness. Patients with myasthenic syndrome exhibit increased sensitivity to depolarizing and nondepolarizing relaxants. [1]

Tiny concentrations of bivalent inorganic cations (e.g., magnesium, cadmium, manganese) can also block calcium entry through P channels and profoundly impair neuromuscular transmission. This is the mechanism for muscle weakness in the mother and fetus when magnesium sulfate is administered to treat preeclampsia. The P channels, however, are *not* affected by calcium entry-blocking drugs, such as verapamil, diltiazem, and nifedipine. These drugs have profound effects on the slower L channels present in the cardiovascular system. As a result, the L-type calcium channel blockers at *therapeutic* doses have no significant effect on the normal release of acetylcholine or on the strength of normal neuromuscular transmission. There have been a few reports, however, that calcium entry-blocking drugs may increase the block of neuromuscular transmission induced by nondepolarizing relaxants. The effect is small, and not all investigators have been able to observe it. The explanation may lie in the fact that nerve endings also contain L-type calcium channels.

There seem to be two pools of vesicles that release acetylcholine, a readily releasable store and a reserve store, sometimes called VP2 and VP1, respectively. [7] [21] The vesicles in the former are a bit smaller and are limited to an area very close to the nerve membrane, where they probably are bound to the active zones. These vesicles are the ones that ordinarily release transmitter. The release seems to occur when calcium ion enters the nerve via the P channels lined up on the sides of the active zones. [21] This calcium needs to move only a very short distance (i.e., a few atomic radii), to encounter a vesicle and to activate a protein, *synaptophysin,* in the vesicle wall. [22] The activated protein seems to react with the nerve membrane to form a pore, through which the vesicle discharges its acetylcholine into the junctional cleft.

The majority of the vesicles in the nerve ending are the larger "reserve" vesicles. These are firmly tethered to the *cytoskeleton* by proteins, the *synapsins.* From their position on the cytoskeleton, they may be moved to the readily releasable store to replace worn-out vesicles or to participate in transmission when the nerve is called upon to work especially hard (e.g., when it is stimulated at very high frequencies or for a very long time). Under such strenuous circumstances, calcium may penetrate more deeply than normal into the nerve or may enter via L channels to activate calcium-dependent enzymes, which cause breakage of the synapsin links that hold the vesicles to the cytoskeleton, thereby allowing the vesicles to be moved to the release sites. Repeated stimulation requires the nerve ending to replenish its stores of vesicles filled with transmitter, a process known as *mobilization.* The term commonly is applied to the aggregate of all steps involved in maintaining the nerve ending's capacity to release transmitter--everything from the acquisition of choline and the synthesis of acetate to the movement of filled vesicles to the release sites. The uptake of choline as well as the activity of choline acetyltransferase, the enzyme that synthesizes acetylcholine, probably are the a rate-limiting steps. [7] [8] [9] [16] [17] [18] [19]

Acetylcholinesterase

The acetylcholine released from the nerve diffuses across the junctional cleft and reacts with specialized receptor proteins in the end plate to initiate muscle contraction. Transmitter molecules that do not react immediately with a receptor or that are released after binding to the receptor are destroyed almost instantly by the acetylcholinesterase in the junctional cleft. Acetylcholinesterase is an asymmetric protein made in the muscle, under the end plate. It is secreted from the muscle but remains attached to it via thin stalks of collagen fastened to the basement membrane. [7] [10] Most of the molecules of acetylcholine released from the nerve initially

pass between the enzymes to reach the postjunctional receptors, but as they are released from the receptors, they invariably encounter acetylcholinesterase and are destroyed. Under normal circumstances, a molecule of acetylcholine reacts with only one receptor before it is hydrolyzed. Acetylcholine is a potent messenger, but its actions are very short-lived because it is destroyed in less than 1 millisecond after it is released.

Postjunctional Receptors

The similarity of the acetylcholine receptors among many species and the abundance of acetylcholine receptors from the *Torpedo* electric fish have greatly facilitated research in this area. The availability of the messenger ribonucleic acids (mRNAs) of humans and other species and of deoxyribonucleic acids (DNAs) has allowed the study of the receptor in artificial systems such as oocytes from frogs and mammalian cells that do not express the receptor (e.g., COS or fibroblast cells). It is also possible, by molecular techniques, to mutate receptors to simulate pathologic states and then study receptor function in these artificial systems. By using these and related techniques, a great deal has been learned about the synthesis, composition, and biologic function and the mechanisms that underlie physiologic and pharmacologic responses in the acetylcholine receptors. [4] [23] [24] [25] It is now evident that two isoforms of postjunctional receptors exist, a junctional or mature and an extrajunctional or immature receptor. [1] [7] (See Biology of Prejunctional and Postjunctional Nicotinic Receptors). The differences between receptor subtypes, however, can be neglected in a general discussion of the role of receptors in neuromuscular transmission.

Figure 20-3 Sketch of acetylcholine receptor channels (right) and tracings of cell patch records of receptor channel openings (left). The mature, or junctional, receptor consists of two alpha-subunits and one each of beta-, epsilon-, and delta- subunits. The immature, extrajunctional or fetal form consists of two alpha-subunits and one each of beta, gamma, and delta. The subunits are arranged around the central cation channel. The immature isoform containing the gamma-subunit shows long open times and low amplitude channel curents. The mature isoform containing the epsilon-subunit shows shorter open times and high amplitude channel currents. Substitution of the epsilon-subunit for the gamma-subunit gives rise to the fast-gated, high conductance channel type.

The acetylcholine receptors are synthesized in muscle cells and are anchored to the end plate membrane by a special protein known as the 43-Kd protein. The receptors, formed of five subunit proteins, are arranged like the staves of a barrel into a cylindrical receptor with a central pore for ion channeling. The key features are sketched in Fig. 20-3 . The receptor protein is about 250,000 d molecular weight. Each receptor has five subunits, which are designated alpha, beta, delta, and epsilon or gamma; there are two subunits of alpha and one of each of the others. [1] [7] Each of the subunits consists of approximately 400 to 500 amino acids. The receptor protein complex passes entirely through the membrane and protrudes both beyond the extracellular surface of the membrane and also into the cytoplasm. The binding site for acetylcholine is on each of the alpha-subunits, and these are the sites of competition between the receptor agonists and antagonists. Both agonists and antagonists are attracted to the binding site and either may occupy the site, which is located near cysteine residues (unique to the alpha-chain) at amino acid positions 192-193 of the alpha-subunit. [26] Radiolabeled alpha-bungarotoxin from the cobra is used to quantitate the receptor that binds to heptapeptide region 189-199 of the alpha-subunit. [27]

Progress in electrophysiologic techniques have moved *pari passu* with advances in molecular approaches to study the receptor. Patch clamping is a technique in which a glass micropipette is used to probe the membrane surface until a single functional receptor is encompassed. The tip of the pipette is pressed into the lipid of the membrane, and the electronic apparatus is arranged to keep the membrane potential clamped (fixed) and to measure the current that flows through the channel of the receptor. The solution in the pipette can contain acetylcholine, tubocurarine, another drug, or a mixture of drugs. By application of these drugs to the receptor via the micropipette, electrical changes could be monitored.

Figure 20-4 illustrates the results of the classical depolarizing action of acetylcholine on end plate receptors. Normally, the pore of the channel is closed by the approximation of the cylinders (subunits). When **both** alpha-subunit sites are occupied by an agonist, the protein molecule undergoes a conformation change that forms a channel in the center through which ions can flow along a concentration gradient (see Fig. 20-4). When the channel is open, there is a flow of sodium and calcium from the outside of the cell to the inside, and of potassium from the inside to the outside. The channel in the tube is large enough to accommodate many cations and electrically neutral molecules, but it excludes anions (e.g., chloride). The current carried by the ions depolarizes the adjacent membrane. The net current is depolarizing and creates the end plate potential that stimulates the muscle to contract. In this instance, downward-going (depolarizing) rectangular pulses (see Fig. 20-3) can be recorded by the electrophysiologic technique described previously.

The pulse stops when the channel closes and one or both agonist molecules detach from the receptor. The current that passes through each open channel is minuscule, only a few picoamperes (about 10^4 ions per millisecond). However, each burst of acetylcholine from the nerve normally opens about 500,000 channels simultaneously, and the total current is more than adequate to produce depolarization of the end plate and contraction of muscle. Thus, the opening of a channel causes the conversion of chemical signals from a

Figure 20-4 The actions of acetylcholine or curare on end plate receptors. (A) The ion channel is inactive and does not open in the absence of acetylcholine. (B) Even the binding of one acetylcholine **(** **)** to one of two binding sites does not open the channel. (C) When acetylcholine binds to recognition sites of *both* alpha-subunits simultaneously ( ), it triggers a conformation change that opens the channel and allows ions to flow across the membrane. (D) The action of antagonists (e.g., curare, bold square). Acetylcholine is in competition with tubocurarine for the receptor's recognition site but may also react with acetylcholinesterase. Inhibiting the enzyme increases the lifetime of acetylcholine and the probability that it will react with a receptor. When one of the two binding (recognition) sites is occupied by curare, the receptor will not open, even if the other binding site is occupied by acetylcholine.

nerve to current flows to end plate potentials, leading to muscle contraction. We are used to thinking of the end plate potential as a graded event, which may be reduced in magnitude or extended in time by drugs, but in reality the end plate potential is the summation of many all-or-nothing events occurring simultaneously at a myriad of individual ion channels. It is these tiny events that are affected by drugs.

Receptors that do not have two molecules of agonists bound, remain closed. Both alpha-subunits must be occupied simultaneously by agonist; if only one of them is occupied, the channel remains closed (see Fig. 20-4) . This is the basis for the prevention of depolarization by antagonists. Drugs such as tubocurarine act by binding to either, or both, alpha-subunits and in so doing preventing acetylcholine from binding and opening the channel. This interaction between agonists and antagonists is competitive, and the outcome--transmission or block--depends on the relative concentrations and binding characteristics of the drugs involved (see Drug Effects on Postjunctional Receptors).

Individual channels are also capable of a wide variety of conformations. [28] [29] Most simply, they may open or stay closed, thus affecting total current flow across the membrane. However, they can do more. They may open for a longer or shorter time than normal, open or close more gradually than usual, open briefly and repeatedly (chatter), or pass fewer or more ions per opening than they usually do. Also, their function is influenced by drugs, changes in the fluidity of the membrane, temperature, the electrolyte balance in the milieu, and other physical and chemical factors. [30] Thus, receptor-channels are dynamic structures that are capable of a wide variety of interactions with drugs and of entering a wide variety of current-passing states. All these influences on channel activity ultimately are reflected in the strength or weakness of neuromuscular transmission and the contraction of a muscle.

DRUG EFFECTS ON POSTJUNCTIONAL RECEPTORS

Classical Actions of Nondepolarizing Muscle Relaxants

Neurotransmission occurs when the action potential releases acetylcholine and binds to the receptor. All nondepolarizing relaxants impair or block neurotransmission by competitively preventing the binding of acetylcholine to its receptor. The final outcome (block or transmission) is dependent on the relative concentrations of the chemicals and their comparative affinities for the receptor. Figure 20-4 shows a system exposed to acetylcholine and tubocurarine. One receptor has attracted two acetylcholine molecules and opened its channel where current will flow to depolarize that segment of membrane. Another has attracted one tubocurarine molecule; its channel will not open, and no current will flow, even if one acetylcholine molecule binds to the other site. The third receptor has acetylcholine on one alpha-subunit and nothing on the other. What will happen depends on which of the molecules binds. If acetylcholine binds, the channel will open and the membrane will be depolarized; if tubocurarine binds, the channel will stay closed and the membrane will not be depolarized. At other times, one or two tubocurarine molecules may attach to the receptor, in which case the receptor is not available to agonists; no current flow is recorded. In the presence of moderate concentrations

of tubocurarine, the amount flowing through the entire end plate at any instant is reduced from normal, which results in a smaller end plate potential and, if carried far enough, a blockade of transmission.

Normally, acetylcholinesterase enzyme destroys acetylcholine and removes it from the competition for a receptor, so that tubocurarine has a better chance of inhibiting transmission. If, however, an inhibitor such as neostigmine is added, the cholinesterase cannot destroy acetylcholine. The concentration of agonist in the cleft remains high, and this high concentration shifts the competition between acetylcholine and tubocurarine in favor of the former, thus improving the chance of two acetylcholine molecules binding to a receptor even though tubocurarine is still in the environment. This is the mechanism by which cholinesterase inhibitors overcome the neuromuscular paralysis produced by nondepolarizing relaxants. It must be noted, however, that the channel opens only when acetylcholine attaches to both the recognition sites. A single molecule of antagonist, however, is adequate to prevent the depolarization of that receptor. This modifies the competition by biasing it strongly in favor of the antagonist. Mathematically, if the concentration of tubocurarine is doubled, the concentration of acetylcholine must be increased 4-fold if acetylcholine is to remain competitive. This means that paralysis produced by high concentrations of antagonist is more difficult to reverse than those produced by low concentrations. Following large doses of nondepolarizing relaxants, reversal drugs may be ineffective until the concentration of the relaxant in the perijunctional area decreases to a lower level by either redistribution or elimination of the drug.

Classical Action of Depolarizing Muscle Relaxants

Depolarizing relaxants, at least initially, simulate the effect of acetylcholine and therefore can be considered agonists despite the fact that they block neurotransmission after initial stimulation. Structurally, succinylcholine is actually two molecules of acetylcholine bound together. It is, therefore, not surprising that it can mimic the effects of acetylcholine. Succinylcholine or decamethonium can bind to the receptor, open the channel, pass current, and depolarize the end plate. These agonists, similar to acetylcholine, attach only briefly; so each opening of a channel is of very short duration, 1 millisecond or less. The response to acetylcholine, however, is over in milliseconds because of its rapid degradation by acetylcholinesterase, and the end plate resets to its resting state long before another nerve impulse arrives. In contrast, the depolarizing relaxants characteristically have a biphasic action on muscle--an initial contraction, followed by relaxation lasting minutes to hours. The depolarizing relaxants, since they are not susceptible to hydrolysis by acetylcholinesterase, are not eliminated from the junctional cleft until after they are eliminated from the plasma. The time required to clear the drug from the body is the principal determinant of how long the drug effect lasts. Whole body clearance of the relaxant is very slow, as compared with the acetylcholine, even when the plasma cholinesterase is normal. Since relaxant molecules are not cleared from the cleft quickly, they react repeatedly with receptors, attaching to one almost immediately after separating from another, thereby repeatedly depolarizing the end plate and opening channels.

The quick shift from excitation of muscle contraction to blockade of transmission by depolarizing relaxants occurs even though--indeed because--the end plate is continuously depolarized. This comes about because of the juxtaposition at the edge of the end plate on the muscle membrane--a different kind of ion channel, the sodium channel that does not respond to chemicals but opens when they are exposed to a transmembrane voltage change. The sodium channel is also a cylindrical transmembrane protein, through which sodium ions can flow through. Two parts of its structure act as gates that allow or stop the flow of sodium ions. [31] Both gates must be open if sodium is to flow through the channel; the closing of either cuts off the flow. Because these two gates act sequentially, a sodium channel has three functional conformation states and can move progressively from one state to another (counterclockwise in Fig. 20-5) .

When the sodium channel is in its resting state, the lower gate (called the time-dependent or inactivation gate) is open, but the upper gate (the voltage-dependent gate) is closed, and sodium ions cannot pass. When the molecule is subject to a sudden change in voltage by depolarization of the adjacent membrane, the top gate opens and, since the bottom (time-dependent) gate is still open, sodium flows through the channel. The voltage-dependent gate stays open as long as the molecule is subject to a depolarizing influence from the membrane around it; it will not close until the depolarization disappears. However, shortly after the voltage-dependent gate opens, the bottom gate closes and again cuts off the flow of ions. It cannot open again until the voltage-dependent gate closes. When the depolarization of the end plate stops, the voltage-dependent gate closes, the

Figure 20-5 Sketch of sodium channel. The bars represent parts of the molecule that act as gates. The upper one is voltage dependent; the lower one is time dependent. The top drawing represents the resting state. Once activated by a voltage change, the molecule and its gates progress as illustrated but only in the counterclockwise direction (see text for details).

time-dependent one opens, and the sodium channel returns to its resting state. This whole process is short-lived when depolarization occurs with acetylcholine. The initial response of a depolarizing muscle relaxant resembles that of acetylcholine, but since the relaxant is not hydrolyzed rapidly, depolarization of the end plate is not brief.

The depolarization of the end plate by the relaxant initially causes the voltage gate in adjacent sodium channels to open, causing a wave of depolarization to sweep along the muscle, causing muscle contraction. Shortly after the voltage-dependent gate opens, the time-dependent inactivation gate closes. Since the relaxant is not removed from the cleft, the end plate continues to be depolarized. Since the sodium channels immediately adjacent to the end plate are influenced by the depolarization of the end plate, their voltage-dependent gates stay open and consequently their inactivation gates stay closed. Since sodium cannot flow through a channel that has a closed inactivation gate, the perijunctional muscle membrane does not depolarize. When the flow of ions though the sodium channels in the perijunctional zone stops because the inactivation gates have closed, the channels downstream (beyond the perijunctional zone) are freed of depolarizing influence. In effect, the perijunctional zone becomes a buffer that shields the rest of the muscle from events at the end plate. Consequently, the muscle membrane is separated into three zones: the end plate, which is depolarized by succinylcholine; the perijunctional muscle membrane, in which the sodium channels are frozen in an inactivated state; and the rest of the muscle membrane, in which the sodium channels are in the resting state. Since a burst of acetylcholine from the nerve cannot overcome the inactivated sodium channels in the perijunctional zone, neuromuscular transmission is blocked. This phenomenon is also called *accommodation.* During accommodation, when the synapse is inexcitable via the nerve (transmitter), direct electrical stimulation of muscle will cause muscle contraction, since the sodium channels beyond the junctional area are in the resting excitable state.

The extraocular muscles contain tonic muscle, which is multiply innervated and chemically excitable along most of its surface. Accommodation does not occur, and these muscles can undergo a sustained contracture in the presence of succinylcholine. The tension so developed forces the eye against the orbit and accounts for part of the rise in intraocular pressure produced by depolarizing relaxants. There is also evidence that the extraocular muscles contain a special type of receptor that does not become desensitized (see subsequent discussion) in the continued presence of acetylcholine or other agonists. [32]

Nonclassical and/or Noncompetitive Actions of Neuromuscular Drugs

Several drugs can interfere with the receptor, directly or via its lipid environment, to change transmission. These drugs react with the neuromuscular receptor to change its function and to impair transmission, but do not act via the acetylcholine binding site. These reactions cause druginduced changes in the dynamics of the receptor so that instead of opening and closing sharply, the modified channels are sluggish. They open more slowly and stay open longer or they close slowly and in several steps, or both. These effects on channels cause corresponding changes in the flow of ions and distortions of the end plate potential. The clinical effect depends on the molecular events. For example, procaine, ketamine, inhaled anesthetics, or other drugs that dissolve in the membrane lipid may change the opening or closing characteristics of the channel. [33] [34] If the channel is prevented from opening, transmission is weakened. If, on the other hand, the channel is prevented from or slowed in closing, transmission may be enhanced. They do not fit the classic model and the impaired neuromuscular function is not antagonized by increasing perijunctional acetylcholine concentrations with cholinesterase inhibitors. Such drugs can be involved in two clinically important reactions, receptor *desensitization* and *channel blockade.* The former occurs in the receptor molecule, while the latter occurs in the ion channel.

Desensitization Block

The acetylcholine receptor, because of its flexibility and the fluidity of the lipid around it, is capable of existing in a number of conformational states. [30] [33] [34] [35] The resting receptor is free of agonist, so its channel is closed. The second state is when two molecules of agonists are bound to the alpha-subunit of the receptor, and the receptor has undergone the conformation change that opens the channel and allows ions to flow. These reactions are the bases of normal neuromuscular transmission. Some receptors that bind to agonists, however, do not undergo the conformation change to open the channel. Receptors in these states are termed *desensitized* (i.e., they are not sensitive to the channel-opening actions of agonists). They bind agonists, indeed, with exceptional avidity, but the binding does not result in the opening of the channel. The mechanisms by which desensitization occurs are not known. The receptor macromolecule, 1,000 times larger by weight than most drugs or gases, provides many places at which the smaller molecules may act. The interface between lipid and receptor protein provides additional potential sites of reaction. Several different conformations of the protein are known, and because acetylcholine cannot cause the ion channel to open in any of them, they all are included in the functional term *desensitization.* Some evidence suggests that desensitization is accompanied by phosphorylation of a tyrosine unit in the receptor protein. [36]

Although agonists (e.g., succinylcholine) induce desensitization, the receptors are in a constant state of transition between resting and desensitized states whether or not agonists are present. Agonists do promote the transition to a desensitized state or, because they bind very tightly to desensitized receptors, trap a receptor in a desensitized state. Antagonists also bind tightly to desensitized receptors and can trap molecules in these states. This action of antagonists is not competitive with that of acetylcholine; in fact, it may be augmented by acetylcholine if the latter promotes the change to a desensitized state. Desensitization can lead to significant misinterpretations of data. Superficially, the preparation seems to be normal, but its responsiveness to agonists or antagonists is altered. One variety occurs very rapidly, within a few milliseconds after application of an agonist. This may explain the increased sensitivity to nondepolarizers

after prior administration of succinylcholine. There also is the phenomenon caused by prolonged administration of depolarizing relaxants and known as phase II block (see under Phase II Block). This frequently is referred to as a desensitization blockade but should not be, because desensitization of receptors is only one of many phenomena that contribute to the process.

Many other drugs used by anesthetists also promote the shift of receptors from a normal state to a desensitized state. [33] [34] [35] These drugs, some of which are listed in Table 20-1 , can weaken neuromuscular transmission by reducing the margin of safety that normally exists at the neuromuscular junction, or they can cause an apparent increase in the capacity of nondepolarizing agents to block transmission. These actions are independent of the classic effects based on competitive inhibition of acetylcholine. The presence of desensitized receptors means that fewer receptor-channels than usual are available to carry transmembrane current. Therefore, the production of desensitized receptors decreases

the efficacy of neuromuscular transmission. If many receptors are desensitized, insufficient normal ones are left to depolarize the motor end plate, and neuromuscular transmission will not occur. Even if only some receptors are desensitized, neuromuscular transmission will be impaired, and the system will be more susceptible to block by conventional antagonists such as tubocurarine or pancuronium.

Channel Block

Local anesthetics and calcium entry blockers block the flow of sodium or calcium through their respective channels. Thus, the term *channel-blocking drugs.* Similarly, a block to the flow of ions can occur at the acetylcholine receptor with concentrations of drugs used clinically and may contribute to some of the phenomena and drug interactions seen at the receptor. Two major types, closed channel and open channel block, can occur. [37] [38] In closed channel block, certain drugs can occupy the mouth of the channel and by their presence prevent physiologic ions from passing through the channel to depolarize the end plate. The process can take place even when the channel is not open. In open channel block, a drug molecule enters a channel that has been opened by reaction with acetylcholine but does not necessarily penetrate all the way through. Open channel blockade is use-dependent, which means that molecules can enter the channel only when it is open. In both open and closed channel block, the normal flow of ions through receptor is impaired, resulting in prevention depolarization of the end plate and a weaker or blocked neuromuscular transmission. However, since the action is not at the acetylcholine recognition site, it is not a competitive antagonism of acetylcholine and is not relieved by anticholinesterases that increase concentrations of acetylcholine. Indeed, increasing the concentration of acetylcholine may cause the channels to open more often and thereby become more susceptible to blockade by usedependent compounds. In this regard, there is evidence that neostigmine and related cholinesterase inhibitors themselves can act as channel-blocking drugs. [37] [38]

Channel blockade is believed to play a role in some of the antibiotics, cocaine, quinidine, piperocaine, tricyclic antidepressants, naltrexone, naloxone, and histrionicotoxininduced alterations in neuromuscular function. Muscle relaxants, in contrast, can bind to the acetylcholine recognition site of the receptor and also occupy the channel. Pancuronium preferentially binds to the recognition site. Gallamine seems to act equally at the two sites. Tubocurarine is in between: At low doses, those that produce minimal blockage of transmission clinically, the drug is essentially a pure antagonist at the recognition site; at larger doses, it also enters and blocks channels. Decamethonium and succinylcholine as agonists can open channels and as slender molecules also enter and block them. In fact, decamethonium and some other long, thin molecules can penetrate all the way through the open channel and enter the muscle cytoplasm. Whether prolonged administration of nondepolarizers, as in the intensive care situation, can result in entry of the relaxant, occupation of the channel, and finally entry of drug into the cytosol is unknown. This effect may partially explain the muscle weakness associated with relaxant therapy in the intensive care unit.

Phase II Block

Phase II block is a complex phenomenon that occurs slowly at junctions continuously exposed to depolarizing agents. The junction is depolarized by the initial application of a depolarizing relaxant, but then the membrane potential gradually recovers toward normal, even though the junction is still exposed to drug. Neuromuscular transmission usually remains blocked throughout the exposure. Several things seem to be involved. The repeated opening of channels allows a continuous efflux of potassium and influx of sodium, and the resulting abnormal electrolyte balance distorts the function of the junctional membrane. Calcium entering the muscle via the opened channels can cause disruption of receptors and sub-end plate elements themselves. On the other hand, the activity of a sodium-potassium adenosine triphosphatase pump in the membrane increases with increasing intracellular sodium and, by pumping sodium out of the cell and potassium into it, works to restore the ionic balance and membrane potential toward normal. As long as the depolarizing drug is present, the receptor channels remain open and ion flux through them remains high. [39]

Factors influencing the development phase II block include the duration of exposure to the drug, the particular drug used and its concentration, and even the type of muscle (i.e., fast or slow). Interactions with anesthetics and other agents also affect the process. All of these drugs may also have prejunctional effects on the rate and amount of transmitter release and mobilization. With so many variables involved in the interference with neuromuscular transmission, phase II block is a complex and ever-changing phenomenon. Thus, the reversal response of a phase II block produced by a depolarizing muscle relaxant to administration of cholinesterase inhibitors is difficult to predict. It is, therefore, best that reversal by cholinesterase inhibitors is not attempted, although the response to tetanus or train-of-four stimulation resembles that produced by nondepolarizers.

BIOLOGY OF PREJUNCTIONAL AND POSTJUNCTIONAL NICOTINIC RECEPTORS

Immature/Extrajunctional Versus Mature/Junctional Isoforms

As already indicated, there are two isoforms (variants) of the postjunctional acetylcholine receptors. The acetylcholine receptor isoform present in the innervated, adult neuromuscular junction is referred to as the adult, mature, or junctional receptor. When there is decreased activity in muscle, as seen in the fetus before innervation, following lower or upper motor neuron injury, after burns or sepsis, or after other events that cause increased muscle protein catabolism, another isoform is expressed. [40] To contrast with the mature, junctional receptors, the other isoform is referred to as the immature, extrajunctional, or fetal form of acetylcholine receptor. (Indirect evidence suggests that this immature isoform is not seen in muscle protein catabolism and wasting occurring with malnutrition.) [41] The differences in the protein structure of the isoforms cause significant qualitative variations among the responses of individual patients to relaxants and seem to be responsible for some of the anomalous results that are observed when administering relaxants to particular individuals. These qualitative differences in the isoforms can also cause variations in function of muscle. [14]

The structural composition and other characteristics differ between the two isoforms. [1] [7] [40] At the molecular level, both types of receptors consists of five subunits (see Fig. 20-3) . The mature junctional receptor is a pentamer of two alpha-subunits and one each of the beta-, delta-, and epsilon-subunits. The immature receptor consists of two alpha, and each of beta, delta and gamma-subunits. That is, in the immature receptor the gamma-subunit is present instead of the epsilon-subunit. The gamma- and epsilon-subunits differ from each other very little in amino acid homology, but the differences are great enough to affect the physiology and pharmacology of the receptor and its ion channel. Although the names junctional and extrajunctional imply that each is located in the junctional and extrajunctional areas, this is not strictly correct. Junctional receptors are always confined to the end plate (perijunctional) region of the muscle membrane. The immature, or extrajunctional, receptor may be expressed anywhere in the muscle membrane. Despite the name *extrajunctional,* they are not excluded from the end plate. During development and in certain pathologic states, the junctional and extrajunctional receptors can coexist in the perijunctional area of the muscle membrane (Fig. 20-6) .

Quite in contrast to other cells, muscle cells are unusual in that they have many, usually hundreds of, nuclei per cell. Each of these nuclei has the genes to make both types of receptors. Multiple factors, including electrical activity, growth factor signaling, and presence or absence of innervation, control the expression of the two types of receptor isoforms. [6] [7] [8] [42] This is most clearly seen in the developing embryo, as the neuromuscular junction is formed. Before they are innervated, the muscle cells of a fetus synthesize only the immature receptors, hence the term fetal isoform of receptor. The synthesis is directed by nearly all the nuclei in the cell, and the receptors are expressed throughout the membrane of the muscle cell (see Fig. 20-6) . As the fetus develops and the muscles become innervated, muscle cells begin to synthesize mature isoform of receptors, which are inserted exclusively into the developing (future) end plate area. The nerve releases several growth factors that influence the synthetic apparatus of the nearby nuclei. First, nerve-supplied factors induce the subsynaptic nuclei to increase synthesis of the acetylcholine receptors. Next the nerve-induced electrical activity results in repression of receptors in the extrajunctional area. Finally, the nervederived factors cause the clustering of the receptors in the subsynaptic area. [5] [7] [42] The innervation process progresses somewhat slowly during fetal life and infancy. [15] With time, the immature receptors diminish in concentration and disappear from the peripheral part of the muscle. A child is usually about 2 years old before nerve-muscle contacts are mature. Thus, in the active, adult, normal, innervated muscle, only the nuclei under and very near the end plate direct the synthesis of receptor; only the genes for expressing the mature receptors are active. The nuclei beyond the junctional area are not active and therefore no receptors are expressed anywhere in the muscle cells beyond the perijunctional area.

Figure 20-6 Distribution of acetylcholine receptors in developing adult, mature, and denervated muscle. (A and B) In the early fetal stage, mononucleated myoblasts, derived from the mesoderm, fuse to form multinucleated myotubes. The gamma-subunit containing immature acetylcholine receptors are scattered throughout the muscle membrane. (C) As the nerve makes contact with muscle, clustering of the receptors occurs at the synapse associated with some loss of extra synaptic receptors. (D) Maturation of the junction is said to occur when epsilon-subunit-containing receptors replace the gamma-subunit-containing receptors. Note that even mature muscle is multinucleated, but is devoid of extrasynaptic nuclei. (E) Denervation or some other pathologic states (burns, sepsis) leads to reexpression of the gamma-subunit receptor, at both the junctional and the extrajunctional areas. The latter changes are potentially reversible.

Proteins implicated in the linking of the mature receptors to the cytoskeleton include urotrophin, alpha- and beta-dystroglycan, and rapsyn. Several lines of evidence indicate that the clustering, expression, and stabilization of the mature receptors is triggered by at least three growth factors, agrin, acetylcholine receptor inducing activity, and calcitonin-gene related peptide. [6] [7] [42] Agrin is also released from the muscle, but muscle-derived agrin does not seem to be as important in the clustering and maturation of the receptor. The synapsins are made in the nerve and seem to play a role in the maturation of vesicular arrangement. All of these growth factors interact with distinct membrane and cytosolic receptor proteins causing phosphorylation, activation of nuclear (gene) transcriptional systems. These in turn control qualitative and quantitative changes at the junction. Once begun, the process is very stable; that is, these nuclei in the junctional area continue to express mature receptors.

The extrajunctional receptors can reappear soon after upper and lower motor denervation and in certain pathologic states (burns, immobilization, loss of electrical activity). The appearance of the immature receptors can be prevented by stimulating a denervated muscle with an external electrical stimulus. It has been suggested that the calcium that enters the muscle during activity is important to the suppression process. In the pathologic states just enumerated, if the process is severe and prolonged, extrajunctional receptors are inserted all over the surface of the muscle, including the perijunctional area. The junctional nuclei also continue to make mature receptors. The end plates thus will consist now of both mature and immature receptors. The synthesis of immature receptors is initiated within hours of inactivity, but it takes several days for the whole muscle membrane to be fully quoted with receptors. This upregulation of receptors has implications for the use of both depolarizing and nondepolarizing relaxants.

The changes in subunit composition (gamma versus epsilon) in the receptor confer certain changes in electrophysiologic (functional), pharmacologic, and metabolic characteristics. [1] [7] The mature receptors are metabolically stable, with half-life approximating 2 weeks, whereas the immature receptor has a metabolic half-life of less than 24 hours. Immature receptors have a smaller single-channel conductance and a 2- to 10-fold longer mean channel open time than mature receptors (see Fig. 20-3) . The changes in subunit composition may also alter the sensitivity or affinity, or both, of the receptor for specific ligands. Depolarizing or agonist drugs such as succinylcholine and acetylcholine depolarize immature receptors more easily, resulting in cation fluxes; one-tenth to one-hundredth doses, necessary for mature receptors, can effect depolarization. Potency of nondepolarizers is also reduced, demonstrated as resistance to nondepolarizers documented in burns, denervation, and immobilization. [1] This resistance may be related to decreased affinity of the receptor to nondepolarizers and to the upregulation of receptors. Indeed, recent data suggest that some nondepolarizers may also cause a partial agonist response in immature receptors, explaining the decreased potency. [4] The altered sensitivities for cholinergic ligands may also result from changes in composition of the lipid membrane surrounding the receptor that is known to occur with

some pathologic states. [30]

The sensitivity to muscle relaxants may occur in only certain parts of the body or certain muscles if only some muscles are affected by the diminution of nerve activity (e.g., after a stroke). The sensitivity to relaxants can begin to change between 24 and 72 hours after an injury or hospitalization. The most serious side effect with the use of succinylcholine in the presence of upregulated receptors in one or more muscle is hyperkalemia. [1] In these subjects, the receptors can be scattered over a large surface of the muscle. As indicated previously, the immature receptors are especially sensitive to succinylcholine. The channels opened by the agonist allow potassium to escape from the muscle and enter the blood. If a large part of the muscle surface consists of upregulated (immature) receptor-channels, each of which stays open for a longer time, the amount of potassium that moves from muscle to blood can be very large. The resulting hyperkalemia can cause dangerous disturbances in cardiac rhythm, including ventricular fibrillation. Moreover, it is difficult to prevent the hyperkalemia by the prior administration of nondepolarizers because extrajunctional receptors are not very sensitive to block by nondepolarizing relaxants. Larger than normal doses of nondepolarizers may attenuate the increase in blood potassium but will not completely prevent it.

Myopathy of Critical Illness

Critical illness (also see Chs. 12 and 72) such as sepsis, trauma, and burns induce functional and pharmacologic aberrations at the skeletal muscle, similar to that seen with upper or lower motor neuron injuries. As indicated previously, the aberrant *pharmacologic* responses consist of a hyperkalemic response to succinylcholine and resistance to nondepolarizers. The important *functional* change is muscle weakness resulting in hypoventilation, dependence on respirators, and decreased mobilization. [43] [44] The pathognomic biochemical feature in all of these conditions is the upregulation of acetylcholine receptors with expression of immature (gamma-subunit) isoform of receptors. [40]

The immature, as compared with the mature, isoform has different electrophysiologic characteristics, including prolonged open-channel time. In some clinical conditions, the presence of a prolonged open-channel time (due to congenital mutations in the receptor) is associated with muscle weakness. [14] [45] In the pathologic state of burns, sepsis, and trauma, in which muscle weakness is a concomitant finding, the expression of the immature isoform at the perijunctional membrane may have a role in muscle weakness. Additionally, the expression of the immature isoform may decrease the number of mature isoforms, a situation akin to myasthenia gravis, in which the mature receptor number at the junction is decreased. Furthermore, in mice, deletion of the mature epsilon-subunit-containing receptors causes muscle weakness despite the expression of immature receptors at the postjunctional membrane. [46] In all of these conditions in which the immature isoform is expressed, signaling via receptor tyrosine kinases or via growth factors seems to be impaired. [47] [48] Additional compounding effects related to deficient growth factor signaling include apoptosis in muscle with loss of contractile elements. Apoptosis, occurring in cardiac muscle, contributes significantly to myocardial dysfunction. [49] The loss of muscle mass, due to apoptosis, may compound the skeletal muscle weakness related to immature receptor expression. [50] Signaling via receptor kinases and its effects on acetylcholine expression and apoptosis seem to be an intense area of research by many groups. Correction of the altered signaling mechanism may therefore reverse the expression of the immature to mature isoform, attenuate the apoptosis in muscle, and correct the muscle weakness associated with critical illness.

Prejunctional Receptors

Compared with the postjunctional area, the prejunctional nerve ending is less well understood. Many drugs, with an abundance of potential targets for drug action, can affect the capacity of the nerve terminal to carry out its functions. The trophic function to maintain the nerve-muscle contact involves release and replenishment of acetylcholine together with trophic factors that require signaling through many receptors, of which the prejunctional nicotinic receptor is just one. Prejunctional or nerve terminal-associated cholinergic receptors have been demonstrated pharmacologically, but their form and functions are not well understood. Previously, it was observed that succinylcholine produces fasciculations and that these are prevented by nondepolarizing relaxants. Since a fasciculation is, by definition, the simultaneous contraction of the multitude of muscle cells in a single motor unit and since only the nerve can synchronize all the muscles in its motor unit, it was apparent that succinylcholine must also act on nerve endings. Also, since nondepolarizing relaxants prevent fasciculation, it was concluded that they acted on the same prejunctional receptor. Since then it has been shown many times that very small doses of cholinergic agonists (e.g., succinylcholine) and antagonists (e.g., curare) affect nicotinic receptors on the nerve ending, the former by depolarizing the ending and sometimes inducing

repetitive firing of the nerve, and the latter by preventing the action of agonists. [3]

Another clue to differences was the finding that although both pre- and postjunctional nicotinic receptors bind alpha- bungarotoxin, prejunctional binding was reversible whereas postjunctional binding was not. Additional clues were found in the many demonstrations of quantitative differences in the reaction of pre- and postjunctional nicotinic receptors to cholinergic agonists and antagonists. [51] For instance, it was known that tubocurarine and hexamethonium bind very poorly to the recognition sites of ganglionic nicotinic cholinoceptors and were not competitive antagonists of acetylcholine at this site. Instead, they blocked the opened channels of these receptors and owed their ability to block ganglionic transmission to this property. The functional characteristics of the receptor channels may also be different. For example, the depolarization of motor nerve endings initiated by administration of acetylcholine can be prevented by tetrodotoxin, a specific blocker of sodium flux with no effect on the end plate.

Specific information on the molecular organization of the neuronal nicotinic receptors on motoneuron terminal is lacking, but work on other parts of the nervous system (e.g., the brain and ganglia) indicate that they are structurally quite different from those found on the postjunctional muscle membrane. [52] [53] Some of the subunit composition is similar, but other subunits do not resemble that of the postjunctional receptor. At least ten different gene products (alpha $_2$ to alpha$_8$ and beta$_2$ to beta$_4$) are thought to contribute nicotinic receptors expressed in neurons. Most strikingly, nervous tissue does not contain genes for gamma-, delta- or epsilon-receptor subunits; it contains only the genes for alpha- and beta-subunits. Furthermore, the alpha- and beta-subunit genes in nerve and muscle are not exactly the same; they are variants. Muscle contains only one gene for each subunit, which are now termed alpha $_1$ and alpha$_1$ -subunit. By contrast, nervous tissue contains neither of these but rather contains a number of related genes termed alpha $_2$ through alpha$_8$. To emphasize the distinction between neural and muscle nicotinic receptors, the former are termed Nn and the latter Nm. With so many different subunits available, there are many possible combinations, and it is not known which combinations are found in motor nerves. Their physiologic roles have also not been completely characterized.

The nicotinic receptor in the nerve ending of the neuromuscular junction may serve the function of regulator of transmitter release, as shown in other parts of the nervous system. The nicotinic receptor on the junctional surface of the nerve senses transmitter in the cleft and, by a positive feedback system, causes the release of more transmitter. In other parts of the nervous system, this positive feedback is complemented by a negative one, which senses when the concentration of transmitter in the synaptic cleft has increased appropriately and shuts down the release system. Indirect evidence suggests that these receptors are muscarinic cholinergic receptors. Convincing data that motor nerve endings contain muscarinic receptors or a negative feedback system are not yet available for the motor neuron. The nerve ending is also known to bear several other receptors (e.g., opioid, adrenergic, dopamine, purine, and adenosine receptors, and receptors for endogenous hormones, neuropeptides, and a variety of proteins). The physiologic roles of these or of the effects of anesthetics on them are unknown.

The motor nerves take up choline, synthesize acetylcholine, store it in vesicles, and move the vesicles into position to be released by a nerve action potential, a series of processes known collectively as *mobilization.* Muscle relaxants to a greater or lesser extent, however, seem to influence this mobilization process. Tubocurarine and related muscle relaxants have a profound effect in decreasing the nerve's capacity to prepare more acetylcholine for release. Tubocurarine has no direct effect on the release process for acetylcholine; the amount of transmitter released is controlled by the availability of releasable acetylcholine and the amount of calcium that enters the nerve. Although it has frequently been observed that nondepolarizing relaxants do not diminish the transmitter released by a single nerve impulse or the first in a high-frequency train of impulses, they sharply decrease the release triggered by subsequent nerve pulses in the train. The most common manifestation of this is the so-called *tetanic fade* commonly seen after a nondepolarizing relaxant is administered. This effect is thought to be due to inhibition of the process that replenishes releasable acetylcholine. [3]

/das/book/view/29494766/875/214.html

ANTAGONISM OF NEUROMUSCULAR BLOCK

Mechanism of Antagonism

The nondepolarizing relaxants block (also see Ch. 12) neuromuscular transmission predominantly by competitive antagonism of acetylcholine at the postjunctional receptor. Therefore, the most straightforward way to overcome their effects is to increase the competitive position of acetylcholine. Two factors are important, the first of which is the concentration of acetylcholine. Increasing the number of molecules of acetylcholine in the junctional cleft changes the agonist/antagonist ratio and increases the probability that agonist molecules will occupy the recognition sites of the receptor. It also increases the probability that an unoccupied receptor will become occupied. It should be recalled that normally only about 500,000 of the 5 million available receptors are activated by a single nerve impulse, and so a large number of receptors are in "reserve" and could be occupied by an agonist. The second factor important to the competitive position of acetylcholine is the length of time acetylcholine is in the cleft. Acetylcholine must wait for the antagonist to dissociate spontaneously before it can compete for the freed site. The nondepolarizing relaxants bind to the receptor for slightly less than 1 millisecond, which is longer than the normal lifetime of acetylcholine. To put it another way, the destruction of acetylcholine normally takes place so quickly that most of it is destroyed before any significant number of antagonist molecules have dissociated from the receptor. Prolonging the time during which acetylcholine is in the junction allows time for the available acetylcholine to bind to receptor, when the antagonist dissociates from the receptors.

Classes of Drugs Used

Two classes of drugs, potassium channel-blocking drugs and acetylcholinesterase inhibitors, are used clinically to reverse

non-depolarizer-induced paralysis. The best known of the potassium blocking drugs is 4-aminopyridine. Its actions are predominantly prejunctional; it impedes the efflux of potassium from the nerve ending. Since the efflux of potassium is the event that normally ends the action potential of the nerve ending, this action prolongs the depolarization of the nerve. Because the flux of calcium into the nerve continues for as long as the depolarization lasts, drugs of this class indirectly increase the flux of calcium into the nerve ending. Therefore, the nerve releases more acetylcholine and for a longer time than usual, conditions described previously, which are effective in antagonizing nondepolarizing relaxants. Because they act prejunctionally, these drugs can antagonize a block produced by certain antibiotics that act on the nerve ending, notably the polymyxins. Although 4-aminopyridine and drugs like it can be used clinically, their use is severely restricted because they are not specific. They affect the release of transmitters by all nerve endings, including motor nerves, autonomic nerves, and central nervous system components. Accordingly, their use is accompanied by a variety of undesirable effects, and in practice they are used only in special circumstances. A most serious side effect of potassium channel blockers is seizures.

The more commonly used antagonists of neuromuscular block (e.g., neostigmine, pyridostigmine, and edrophonium) all inhibit acetylcholinesterase by mechanisms that are similar but not identical. [54] Neostigmine and pyridostigmine are attracted by an electrostatic interaction between the positively charged nitrogen in the molecules and the negatively charged catalytic site of the enzyme. This produces a carbamylated enzyme, which is not capable of further action (i.e., the catalytic site is blocked and the enzyme is inhibited). Edrophonium has neither an ester nor a carbamate group, but is attracted and bound to the catalytic site of the enzyme by the electrostatic attraction between the positively charged nitrogen in the drug and the negatively charged acetylcholinesterase site of the enzyme. Edrophoniuim also seems to have prejunctional effects, enhancing the release of acetylcholine from the nerve terminal. This effect is, therefore, useful when deep neuromuscular block needs reversal. Of the three commonly used anticholinesterases, edrophonium shows by far the greatest selectivity between acetylcholinesterase and butyrylcholinesterase, the serum esterase that hydrolyzes succinylcholine and mivacurium. It greatly favors the former enzyme and therefore would seem to be the most desirable agent to reverse mivacurium. However, assuming that the patient has normal serum esterase, pharmacokinetic factors are the principal determinants of the duration of blockade, and the activity of serum esterase or the lack of it plays only a minor role in the recovery. Therefore, there is little reason to prefer one or another reversal drug on these grounds.

The cholinesterase inhibitors do not only act preferentially at the neuromuscular junction but also act at other synapses that use the same transmitter, including muscarinic receptors. Thus, it is desirable to administer an atropine-like drug along with the cholinesterase inhibitor to counter the effects of the acetylcholine that accumulates in the muscarinic synapses of the gut, bronchi, and cardiovascular system. These three anticholinesterase inhibitors do not affect synapses in the central nervous system because all are quaternary ammonium ions, which do not easily penetrate the blood-brain barrier. Therefore, a quaternary ammonium derivative of atropine, such as glycopyrrolate, which does diffuse through the blood-brain barrier, frequently is used to limit the anticholinergic effects to the periphery. Other cholinesterase inhibitors, notably physostigmine and tacrine, are not quaternary ammonium compounds, and they have profound effects in the central nervous system. These may be antagonized by atropine but not by its quaternary ammonium analogue derivatives. Unlike the other cholinesterase inhibitors, physostigmine and tacrine are also potent inhibitors of the enzyme phosphodiesterase, which plays an important role in the regulation of transmitter release at many synapses in the central nervous system. This action may be related to the reported efficacy of these two in the treatment of Alzheimer's dementia.

Cholinesterase inhibitors also have actions at the postjunctional membrane, independent of its effects on the enzyme. Several of these compounds contain methyl groups on a positively charged nitrogen, and they can act as agonists on the receptor channels, initiating ion flow and enhancing neuromuscular transmission. It was noted long ago that neostigmine, physostigmine, and certain organophosphates can increase the frequency of MEPPs and increase the quantal content of end plate potentials, but the importance of the increased transmitter release to reversal of neuromuscular blockade is not known. Also, continuous exposure to the carbamate- or organophosphate-containing inhibitors causes degeneration of pre- and postjunctional structures, apparently because these structures accumulate toxic amounts of calcium. The neural actions of these drugs are prevented by calcium channel blockers such as verapamil. All the drugs of this class also act in or on receptors to influence the kinetics of the open-close cycle and to block the ion channel. [37] [38] The clinical significance of the drugs on reversal of nondepolarizers is not known.

SUMMARY

The neuromuscular junction provides a rich array of receptors and substrates for drug action. Several drugs used clinically have multiple sites of action. The muscle relaxants are not exceptions to the rule that most drugs have more than one site or mechanism of action. The major actions seem to occur by the mechanisms and at the sites described for decades, namely, agonistic and antagonistic actions at postjunctional receptors for depolarizing and nondepolarizing relaxants, respectively. This description of neuromuscular drug action is a simplistic one. Neuromuscular transmission is impeded by nondepolarizers because they prevent access of acetylcholine to its recognition site on the postjunctional receptor. If the concentration of nondepolarizer is increased, another, noncompetitive action, namely block of the ion channel, is superimposed. The paralysis is also potentiated by the prejunctional actions of the relaxant preventing the release of acetylcholine. The latter can be documented as fade that occurs with increased frequency of stimulation. Therefore, a more accurate description of the relaxant effects recognizes that the neuromuscular junction is a complex system and a dynamic one, in which the phenomena produced by drugs are composites of actions that vary with drug, dose, activity in the junction and muscle,

---

time after administration, the presence of anesthetics or other drugs, and the age and condition of the patient. Inhibition of the postjunctional acetylcholinesterase by anticholinesterases increases concentration of acetylcholine, which can compete and displace the nondepolarizerreversing paralysis. These anticholinesterases also have other effects, including those on nerve terminals and on the receptor, by an allosteric mechanism.

Depolarizing compounds initially react with the acetylcholine recognition site and, like the transmitter, open ion channels and depolarize the end plate membrane. Unlike the transmitter, they are not subject to hydrolysis by acetylcholinesterase and so remain in the junction. Soon after administration of the drug, some receptors are desensitized and, although occupied by an agonist, do not open to allow current to flow to depolarize the area. If the depolarizing relaxant is applied in high concentration and allowed to remain at the junction for a long time, other effects occur. These include entry of the drug into the channel to obstruct it or to pass through it into the cytoplasm. Depolarizing relaxants also have effects on prejunctional structures, and the combination of pre- and postjunctional effects plus secondary ones on muscle and nerve homeostasis results in the complicated phenomenon known as phase II blockade.

Intense research in the area of neuromuscular transmission continues at a rapid pace. The newer observations on receptors, ion channels, membranes, and prejunctional functions reveal a much broader range of sites and mechanisms of action for both agonists and antagonists and thereby allow a more complete understanding. In recognizing these sites and mechanisms we begin to bring our theoretical knowledge closer to explaining the phenomena observed when these drugs are administered to living humans. Most of the recent work seems to be focused on the postjunctional membrane and the control of acetylcholine receptor expression in normal and diseased states. The presence or absence of the mature and immature isoform seem to complicate matters further. In certain pathologic states (e.g., sepsis, burns, immobilization, and chronic use of relaxants), upregulation of acetylcholine receptors occurs, usually with expression of the immature isoform. The altered functional and pharmacologic characteristics of these receptors results in increased sensitivity with hyperkalemia to succinylcholine and resistance to nondepolarizers. An area of increasing attention is the control of the expression of mature versus immature receptors and the role of the immature isoform of the receptor in the muscle weakness associated with the critical illnesses enumerated previously. The immature isoform expression is probably related to aberrant growth factor signaling, which may also cause apoptosis in muscle. Loss of muscle mass due to apoptosis may contribute to the muscle weakness of critical illness. In the future, it may be possible to manipulate the signaling mechanism to alter the expression of the receptor isoforms, attenuate apoptosis, and possibly improve muscle functions. Alternately, these could be achieved by gene therapy.

Chapter 21 - Research Design and Statistics in Anesthesia

Dennis M. Fisher

INTRODUCTION

The process by which new information is acquired in anesthesia and in most medical specialties has changed. Traditionally, many issues of interest to anesthesiologists could be examined by descriptive, noncomparative studies such as one describing the physiologic effects of a new anesthetic. Although such studies provided valuable information to guide the clinician in the use of new anesthetics or devices, they often did not focus on comparisons with other drugs or techniques. In addition, outcomes research (which I define as the influence of an anesthetic practice on such outcomes as patient survival, satisfaction, or morbidity) was quite rare. In recent years and decades, the focus has changed so that the emphasis of many investigations is on a comparison among techniques. In addition, outcome studies examining such important issues as cardiovascular morbidity and mortality after surgery are now common. In this changing context of research, this chapter, formerly entitled "Statistics in Anesthesia," has been revised to examine a broader set of issues. In particular, a new section provides an overview of issues related to the design and conduct of research studies. This new material is not designed to be a comprehensive primer to guide researchers in research design. Rather, its intent is to provide an introduction to which "users" can refer, to assist in their critical assessment of published or unpublished materials. My assumption is that the critical reader of the medical literature will be better equipped to judge the quality of medical research if issues regarding research design and analysis are better understood. Although laboratory-based research now appears with greater frequency in the anesthesia literature than in past years, my efforts focus on clinically relevant research. In order to follow the logical approach that research design precedes analysis, the new section on research design precedes the section on analysis. However, the discussion of research design often requires some understanding of statistical techniques. Therefore, the reader may need to move between the two sections.

Mention of the word *statistics* evokes in many members of the medical community two responses: first, a recognition of its necessity for research, and second, distaste. This distaste results from a number of sources--the limited (and often incomprehensible) teaching provided in many courses, the inconsistent terminology used by different investigators, the frequency with which statistics is used to mislead rather than to clarify, and finally, a wariness of mathematics. Those who are not knowledgeable about the language and techniques of statistics may believe that journal editors ensure the appropriateness and accuracy of statistical techniques used in their publications. Unfortunately, this may not be true: several reviews have demonstrated a high incidence of statistical errors in reputable journals. [1] [2] In response to these criticisms, one journal, *Circulation Research,* adopted

the policy that articles accepted for publication must undergo review by a statistician. [3] This policy has not been widely accepted, probably because of potential delays in the editorial process and the additional costs of using a statistical advisor. However, one major anesthesia journal, *Anesthesiology,* added a statistical consultant to its editorial board.

In recent decades, emphasis on statistical analysis in research studies has increased. Readers tend to believe that any conclusion accompanied by the statement " $P < .05$" is true; conversely, all observations not supported by that statement are believed to be untrue. This emphasis on statistical significance has encouraged investigators to focus their analyses on statistical testing rather than on actually examining individual data points. When data have been collected, the investigator might call on one of several resources such as a hand-held calculator, a computer, or even a statistician (many of whom lack expertise in the statistical concerns relating to medicine). The raw data are entered, along with instructions on which test is desired, and the investigator is rewarded with a number of statistical results. For example, when data are analyzed by linear regression, the output from a computer program might state " $P < .001$." If the investigator does not understand terms such as *within-groups variance, residual mean square,* or *standard error of the estimate,* the statement " $P < .001$" suggests that the data show a strong statistical association. As examined later, for linear regression, the validity of the association is better supported by other statistical statements. However, the uninitiated researcher is usually pleased with the probability associated with this *P* value and may not devote additional time to interpreting or understanding the results. Of greater importance, he or she may not realize that these results do not ensure that a statistical difference exists, that the correct statistical test was employed, or even that the study was performed in a manner that permits any conclusions to be drawn. [4] Gaining a thorough knowledge of statistical techniques requires much time and energy. However, most statistical techniques used in medical research are simple. Emerson and Colditz [5] reviewed the statistical tests employed in original articles published in the *New England Journal of Medicine* from 1978 to 1979. These investigators found that seven statistical techniques (descriptive tests, *t*-tests, contingency tables, nonparametric tests, epidemiologic statistics, Pearson correlation, and simple linear regression) made up 82 percent of all the tests used in these studies. A compilation of the statistical tests used in manuscripts in *Pediatrics*[6] demonstrates similar findings, as does a review [7] of the two major U.S. anesthesia journals, *Anesthesiology* and *Anesthesia and Analgesia.*

This chapter introduces the reader to the principles governing these simple statistical tests. After the new section on research methodology and study design, descriptive statistics (how to examine and describe data) and the concept of probability are discussed. These concepts are then used to examine the principles of inferential statistics (i.e., using statistics to draw conclusions). For each statistical test, the mathematic derivation of that test and examples are provided.

The statistical techniques appropriate for most medical research have changed little in recent years. However, the techniques actually used by investigators have changed, a result of several factors. First, many investigators have learned the utility of nonparametric approaches. Second, particularly in anesthesia, investigators have become aware of the power of such techniques as repeated-measures analysis of variance (described later). Finally, the increasing number of outcome studies in anesthesia has required introduction of some epidemiologic methods previously rarely used in the anesthesia literature. In response, this chapter includes sections on power analysis (prospective determination of sample size), the Fisher exact test, nonlinear regression techniques (including logistic regression), and relative risks. With these additions, the investigator is offered an exposure to techniques useful for most statistical analyses.

RESEARCH METHODOLOGY AND STUDY DESIGN

On occasion, an investigation begins without a welldesigned plan regarding the design of the study and the sta-tistical analysis. After the study is under way or completed and the investigators have accumulated a large mass of data, they begin to contemplate its analysis. Unfortunately, in many instances, data are collected in an inappropriate manner, or the study was not designed to permit the question of interest to be answered. This chapter is not designed to address the many issues related to study design; instead, the reader is referred to other sources such as a recent monograph, *Medical Uses of Statistics,*[8] published by the *New England Journal of Medicine.* Unfortunately, much research effort has been wasted by not considering issues of study design or the type of statistical analysis prior to beginning the study.

Research interests in the anesthesia community have changed in recent years. Earlier research efforts focused on issues such as the physiologic effects of anesthetic techniques or pharmacologic agents. These studies were typically performed on small numbers of subjects, and statistical analysis was often descriptive or consisted of simple tests such as analysis of variance. As anesthetic and surgical techniques improved such that perioperative risk is now minimal, and as society has begun to question the cost-benefit ratio of medical therapy, the focus of medical research has shifted toward questions related to this cost-benefit ratio. Other medical specialties adopted these approaches a decade ago. For example, internists examined issues such as the cost-benefit ratio of a newer, expensive antibiotic or the efficacy of single versus multiple doses of antibiotics. In recent years, members of the anesthesia community, led by pioneers such as Dennis Mangano, have asked similar questions about anesthesia care.

One problem inherent to outcomes research in anesthesia results from our tremendous success in providing medical care without adverse outcomes. Consider a trial examining efficacy of a new antibiotic to treat a resistant infection. If the traditional therapy failed in 40 percent of patients, and we expected the new treatment to fail in fewer than 20 percent of patients (and its exorbitant cost could be justified only if its success rate attained this level or better), a power analysis reveals that a sample size of 128 patients (64 in each group) would be sufficient to "ensure" success of a clinical trial (Table 21-1) . One can readily imagine the drug's manufacturer sponsoring two or more clinical trials with this number of patients.

TABLE 21-1 -- Sample Sizes Needed to Detect a 50 Percent Decrease in the Incidence of an Adverse Event with a *P* Value of 5 Percent and 80 Percent Power

INCIDENCE IN CONTROL GROUP (%)	NUMBER PER GROUP (*n*)
40	64
10	342
1	3681

In contrast, the expected outcome of anesthesia and surgery is "success," and the expected "failure" rate, be it death, heart failure, or some other severe adverse outcome, is small. If the expected death rate after cardiac surgery were 1 percent, and we wanted to demonstrate that an intervention improved this to 0.5 percent (this is probably an unreasonable increment in successful outcome when one considers the multifactorial nature of severe adverse events during anesthesia), a sample size of 7,362 patients (3,681 in each group) would be necessary. This leads to an obvious problem. Who is willing to pay for one or more trials of this magnitude?

Selecting an Outcome or Surrogate Outcome

A clinically based profession such as anesthesia generates many questions of interest. For example, clinicians want to know whether a new antiemetic improves the patient's course relative to postoperative nausea and vomiting (PONV) or whether a drug given during cardiopulmonary bypass improves the perioperative course of patients undergoing coronary artery bypass grafting. Although these are but two of many questions important to clinical anesthesia, I use them as examples of statistical analyses.

The incidence of PONV in control (typically, placebo) groups ranges from 20 to 70 percent, and treatment with various drugs may decrease this incidence by 20 percent. In contrast, the incidence of perioperative myocardial infarction (MI) in control groups is much lower, probably 1 to 5 percent. This difference in the incidence of the adverse events in the control group has tremendous implications for study design. If the investigator expects that the "treatment" (i.e., the drug or monitoring device or any intervention that distinguishes a group from the control group) will improve outcome 2-fold, an expected incidence of vomiting of 50 percent in a control group might decrease to 25 percent with treatment; similarly, an incidence of MI may decrease from 1 percent in the control group to 0.5 percent with treatment. The sample size sufficient to demonstrate statistical significance differs between these two outcomes and might be prohibitive for the MI end point (see Table 21-1) but not for the PONV end point. Rather than discarding the MI issue as untestable, the investigator might choose to study a surrogate outcome measure instead. For MI, a surrogate outcome might be the incidence of electrocardiographic (ECG) changes consistent with ischemia. In certain instances, a surrogate marker may be desirable, not because it occurs more frequently, but because it can be measured more readily. For example, costs of medical care are often difficult to assess, but charges can be quantified more easily.

An ideal surrogate marker is one that is easy to measure and is sufficiently common to permit the study to be performed with a reasonable sample size. A second consideration is that changes in the incidence of surrogate measures must reflect changes in the incidence of the true measure. If it were known that under a variety of circumstances, 20 percent of patients who show ECG signs of ischemia develop MI, it might be reasonable to study the incidence of ECG changes rather than that of MI. However, if one anesthetic technique led to a frequent occurrence of ECG changes but not to MI, whereas another technique led to the same frequent occurrence of ECG signs and frequent MI, studies involving the surrogate outcome should not be extrapolated to predict the incidence of the true outcome.
