There are various ways in which to assess an individual's level of sleepiness. These include behavioral indicators, subjective

measures, and physiologic measures. Behavioral indicators of sleepiness include yawning, ptosis, decreased social interaction, and microsleep events. Many of these behaviors are difficult to quantify. Subjective measures include various types of numeric or visual analogue scales that attempt to measure how sleepy the individual *feels.* These methods are used frequently in studies of sleepiness because they are very easy to implement. Subjective feelings of fatigue and sleepiness are often underestimated by individuals in comparison with their level of physiologic sleepiness. Both behavioral and subjective sleepiness can be masked by a stimulating environment, even though the individual remains physiologically sleepy. When environmental stimuli wane, physiologic sleepiness manifests itself as an overwhelming need to fall asleep. A person who is physiologically alert does not experience sleepiness as environmental stimuli decreases. For example, without physiologic sleepiness, an individual becomes bored during a boring lecture, but does not fall asleep.

Physiologic (objective) measures of sleepiness have been used extensively in sleep research and sleep medicine. Carskadon and Dement and colleagues [193] [194] [195] developed the Multiple Sleep Latency Test (MSLT), which is now thought of as the standard method for quantifying daytime sleepiness. The MSLT tests the propensity of an individual to fall asleep in a sleep-inducing environment (dark, temperature-controlled room, minimal noise, comfortable bed). Once again, the level of daytime sleepiness reflects acute and cumulative sleep loss, circadian disruption, and fatigue and correlates with performance. The MSLT is performed in a standard sleep laboratory setting and consists of five opportunities to fall asleep every 2 hours over the course of the day, usually from 10 AM to 6 PM. To determine precisely when sleep onset occurs, the EEG (central positions), EOG (outer canthi), and submental EMG are measured. These variables are scored according to standardized and accepted criteria. [194] Sleep latency is measured from the beginning of the test (lights out) until sleep onset. A *short* sleep latency (i.e., falling asleep quickly) is a sign of *increased* sleepiness, and a *long* sleep latency (i.e., falling asleep slowly) is a sign of *decreased* sleepiness. For research purposes, sleep is not allowed to accrue during the test; therefore, if the subject falls asleep, he or she is awakened after 1.5 minutes of continuous sleep. If the subject does not fall asleep within 20 minutes, the test is terminated. The MSLT score is the average of the five sleep latencies measured over the course of the day. A normal MSLT score is greater than 10 minutes, whereas a pathologic score is less than or equal to 5 minutes. The pathologic level corresponds to the daytime sleepiness typically seen in patients with narcolepsy, sleep apnea, or in healthy individuals deprived of sleep for 24 hours.

Sleep Deprivation and Fatigue in Medical Personnel

Human error represents a significant risk to hospitalized patients, [196] [197] and it has been estimated to play a role in more than 70 percent of anesthesia mishaps. [148] This is similar to the error rate seen in cognitively similar work environments such as aviation. [152] Clearly, the physiologic capabilities and limitations of the human operator in complex work environments remain central to safe and productive performance. The 24-hour demands of medical care parallel the physiologic challenges present in other operational domains, yet minimal data are available to quantify the fatigue-related risk to performance and alertness in medical personnel.

Providing quality health care requires physicians to attend to life-critical details such as the monitoring of changing vital signs, administering the correct type and dose of medications, and in general, making crucial decisions to achieve optimal patient care. Physicians, like other workers, are affected by all the physiologic, psychologic, and behavioral demands that characterize work environments requiring continuous, around-the-clock operation. However, whereas much of the health-care system (e.g., nursing) relies on multiple work shifts to cover the 24-hour day, physicians more typically work long duty periods and frequently experience sleep loss, circadian disruption, and fatigue. Even minimal levels of sleep loss, for example, obtaining as little as 2 hours less sleep than an individual requires, can lead to lapses in performance, increased physiologic sleepiness during the daytime (including microsleeps), and altered moods. This level of degraded performance and alertness almost certainly contributes to medical error and health-care mishaps.

Resident physicians, in particular, work long, grueling hours, often for years at a time. On-call duty periods commonly last 24 to 36 hours, occasionally even longer, and some resident groups work 100 to 120 hours per week. [198] These schedule demands cannot help but lead to acute and chronic sleep loss, circadian disruption, and fatigue with subsequent adverse effects on performance, alertness, and mood. Therefore, individuals who administer life-sustaining care are *at risk* for making

fatigue-related mistakes and causing costly medical errors.

A case of an intraoperative death occurring when the anesthesiologist was described by witnesses as being asleep received considerable media attention (*Dateline NBC,* prime-time news magazine, October, 1995). [199] The patient apparently suffered from an episode of malignant hyperthermia. If the witnesses' statements are correct, the anesthesiologist's sleep state may have had a profound impact on his suboptimal response to this crisis.

How Long Are the Work Hours of Anesthesiologists?

Berry and Hall [200] reported on the work hours of residents in seven anesthesiology programs. They found that the programs surveyed were within current guidelines of the Accreditation Council for Graduate Medical Education (ACGME) for overall resident work hours. The ACGME Special Requirements for Residency Training in Anesthesiology further state that, "while the actual number of hours worked by residents may vary, residents should have sufficient off-duty time to avoid undue fatigue and stress. Residents should be allowed to spend, on average, at least 1 full day out of 7 away from the hospital, and participate in on-call duty in the hospital no more frequently than on average every third night." These guidelines also call for an 80-hour work week that comprises the total duty time of the house officer in the hospital (including sleep during on-call periods).

In this survey, residents within clinical anesthesia years 1 to 3 spent an average of 64 to 66 hours per week in the hospital. This survey did not address the sleep habits of the survey respondents, thus making it impossible to assess the impact that these work hours had on the subjects' sleep cycle, complaints of fatigue, alteration in mood, or impairment of performance.

In a survey of California anesthesiologists (residents, faculty, and private practitioners), Gaba et al [157] reported that respondents worked an average of 52±16 hours per week and were on call approximately 5 nights and 2 weekend days per month. Those surveyed slept an average of approximately 7 hours when not on call and 5 hours when they were on call. Gravenstein et al [201] reported on the work hours of different categories of anesthesia caregivers. In their survey, professional hours in the typical work week were 56 hours for an anesthesiologist, 48 hours for a CRNA, and nearly 70 hours for a resident. From the surveys described earlier, the average work week for anesthetists as a whole ranges from 50 to 70 hours.

Residents, who receive a fixed salary, are unlikely to want to work after a 24-hour on-duty period. Most anesthesia residency programs provide for residents to be relieved from clinical work after such an on-call period. This is clearly not the case for many anesthesiologists in practice, who often receive compensation on a fee-for-service basis. In their survey of California anesthesiologists, Gaba et al [157] found that 41 percent of respondents were expected at least "sometimes" (21% "often" or "always") to "do cases the day after being awake most of the night on call." The majority of all survey respondents reported feeling fatigued at work, and that this had increased in recent years. Approximately 20 percent of anesthesiologists in this survey felt a significant amount of production pressure to work while fatigued. [157]

Do Anesthesiologists Perceive Fatigue as a Problem?

The survey by Gaba et al [157] also revealed that more than 50 percent of respondents believed that they had made an error in clinical management that *they* thought was related to fatigue. In another survey of anesthesiologists and CRNAs, the majority (61%) of respondents recalled having made an error in the administration of anesthesia that they attributed to fatigue. [201] Data from these surveys reveal that issues of sleepiness and fatigue *are* perceived by anesthesia practitioners as being important causative factors in reducing anesthesia-related patient safety.

Sleep and Performance

Previous studies addressed the effects of sleep deprivation and fatigue on physician performance and well-being. Major reviews of this literature identified little consensus. [202] [203] Some of the published studies showed sleep deprivation to have negative effects on physician performance, whereas other studies showed no statistically significant effects. There are several methodologic flaws in the existing literature: (1) the degree of acute sleep deprivation of subjects was poorly defined, and no assessment of chronic fatigue was made; typically, studies relied on only the previous night's sleep as a level of "fatigue," and subjects could well have been chronically fatigued during baseline (control) trials, which could mask the degree of impairment resulting from the acute fatigue of being on call; (2) measuring actual clinical performance is difficult and was not attempted; most studies had to rely on simple cognitive tasks that probed only short-term memory, immediate recall, and simple reaction time; the validity of using such simple tests to probe complex performance has been challenged because these simple tests do not assess the higher-level cognitive functions most critical to skilled medical care [71] ; (3) most of the performance tests were of very short duration (3-5 minutes); studies have shown that, if sufficiently motivated, even fatigued subjects can perform well on short-duration tasks; and (4) practice effects were not adequately accounted for; if subjects have not learned a particular performance test sufficiently to achieve maximum performance, subsequent trials will almost certainly show performance improvement because of further learning of the task.

Some studies requiring subjects to perform sustained vigilance tasks of long duration have, in fact, shown a performance impairment in fatigued physicians. [74] [204] [205] Tasks of this type that require sustained attention to detail are highly relevant to the anesthetist's tasks, and they are the most sensitive to sleep loss and fatigue.

Evaluation of Physiologic Sleepiness in Anesthesia Residents

Howard et al [206] evaluated physiologic daytime sleepiness (using the MSLT as described earlier) of anesthesia residents in three different conditions. The conditions studied were (1) "baseline" (daytime shift, no on-call duty period in previous 48 hours); (2) "post-call" (immediately after a 24-hour work and in-house on-call period); and (3) "sleep satiated." The sleep-satiated condition requires further explanation. Residents were told to maximize sleep, and they were allowed to arrive for work at 10 AM (3 hours later than normal) for 4 consecutive days prior to testing. They were not on call during this time. The sleep-satiated condition was studied to provide a true control state of maximal rest and optimum alertness. Studies of adolescents have demonstrated that sleep extension improves daytime alertness. [181]

In this study, the anesthesia residents had an MSLT score of 5.9±2.7 minutes in the "baseline" condition and 6.1±4.7 minutes in the "post-call" condition, both scores revealing nearly pathologic levels of daytime sleepiness seen in patients with narcolepsy or sleep apnea. The "baseline" group slept an average of 6.6±0.98 hours per night, whereas the "post-call" group reported an average of 6.2±0.64 hours of sleep during their night on call. Ironically, although the on-call periods were during rotations that often have very busy call nights, only a few subjects were, in fact, awake most of the night. In the "sleep-satiated" condition, when subjects were allowed to extend their sleep to an average of over 9 hours per night, the MSLT score was in the normal range (13±5.1 minutes).

Figure 80-9 shows MSLT profiles for anesthesia residents studied in these three conditions. The two lower curves demonstrate physiologic sleepiness that is in the pathologic

Figure 80-9 Average sleep latency profiles for residents in different work conditions. Both the baseline and post-call groups show a low sleep latency and no decrease in the afternoon. The sleep-satiated group shows a normal sleep latency, with a characteristic circadian lull. Error bars represent the standard error of the mean.

range (<5-minute sleep latency). These individuals were less alert and were prone to falling asleep at this level of physiologic sleepiness. These results clearly demonstrate that medical personnel who have not been on call *cannot* be assumed to be "rested" when compared with "fatigued" post-call residents. These data also support that, under normal working conditions, the resident physicians studied were physiologically sleepy to near pathologic levels. This finding documents a previously unknown level of chronic sleep deprivation in this population. Importantly, these data cast substantial doubt on previous studies of the performance of medical personnel that have relied on the assumption that individuals working under "normal" conditions are truly rested. However, preliminary data from this study on the performance of these residents on a 10-minute task of visual reaction time (psychomotor vigilance task [PVT]) show no clear significant reduction in performance

in the post-call state or of an increase in performance in the sleep-satiated state. Ironically, although the on-call residents in this study were expected (by the nature of their call duties) to lose considerable sleep, their average on-call sleep in the study was higher than expected. Those who did lose considerable sleep were too few to permit statistical analysis.

Geer et al [207] studied performance of residents on the same PVT reaction time test, before and after a 24-hour on-call period. Results of their study showed that residents obtained less sleep while on call (3.2 versus 7.6 hours) and had self-reported sleepiness ratings that were significantly higher after being on call. Post-call data from the vigilance task revealed that the fastest 10 percent of response times (a measure of peak performance) was slower and the number of lapses was greater, when compared with the subjects' own performance before the on-call period.

Building on this study, the same group evaluated both residents and faculty members before and after a 24-hour call period. [208] Performance on the PVT was significantly worse (slower mean and fastest reaction times and more and longer lapses) after call for residents, but not for faculty members. Although residents reported more sleep than faculty before being on call, the residents lost more sleep on call than did faculty members (resident mean sleep loss, 4.8 hours; faculty mean sleep loss, 2.1 hours).

Thus, even using standard laboratory tests of reaction times (which have been shown by sleep researchers to be sensitive to sleep loss), performance tests of anesthesiologists after an on-call period show conflicting results. Furthermore, how the laboratory test correlates with more complex anesthestic performance remains an unanswered question. Geer et al [209] measured the performance of residents before and after being on call by constructing several clinical management scores based on the subjects' handling of different critical incidents using a "screen-based" anesthesia simulator (the ASC). Overall, there was no significant difference in the clinical management scores of residents between the pre-call and post-call conditions. However, these were short (20-minute) simulations, and the screen-based simulator is far from the reality of actual OR work.

Lichtor et al [210] used a realistic anesthesia simulator as well as standard psychomotor tests to study the effects of fatigue on medical personnel. In one study, these investigators found that "fatigued" individuals had impaired performance on a coordination task and a vision test (Maddox Wing) similar to the impairment seen when under the influence of a low dose of alcohol (0.5 g/kg). "Performance" in the realistic simulator was not significantly impaired after a 24- to 36-hour on-call period. However, the details of this experiment have never been published, and the assessment of clinical performance depends heavily on the duration and intensity of the simulation, as well as on the complexity of the behaviors to be measured.

Weinger et al [211] at UCSD conducted task analyses of residents performing matched-difficulty general anesthesia cases during the daytime and at night. Residents reported higher workloads during nighttime cases (although cases were matched for difficulty), and the task analyses showed lower task efficiency at night. However, reaction time to the red light secondary task (see the earlier section on secondary tasks) was no different at night than during the day.

Howard et al (VA-Stanford) is conducting a complex assessment of the occurrence of microsleeps and of multiple measures of performance (including PVT, multiple types of secondary task probes, and response to clinical events) in highly rested versus highly fatigued anesthesia residents conducting long (4-hour) anesthetic regimens using a realistic patient simulator.

Evaluation of Subjective Sleepiness

Howard et al [212] also investigated the degree of discrepancy between the residents' subjective sleepiness (how sleepy they *felt*) and their physiologic sleepiness (how easily they fell asleep). Subjective sleepiness was measured using a validated numeric scale (Stanford Sleepiness Scale [213] [214]), whereas physiologic sleepiness was measured using the MSLT as described earlier. Subjects' self-reported sleepiness immediately prior to each sleep opportunity during the MSLT did not, in general, correlate with their MSLT score. As in previous studies, subjective sleepiness correlated better with physiologic sleepiness when subjects were extremely alert or extremely sleepy.

Furthermore, we also found that subjects demonstrated little ability to determine whether they had actually fallen asleep during the MSLT sleep opportunities. For example, in 51 percent of trials in which the EEG/EOG measurements showed that the subject had fallen asleep, the subjects thought they had remained awake throughout. The same data can also be expressed as follows: in 68 percent of trials in which subjects thought that they had remained awake, they were wrong. These results support the contention that medical personnel *are* physiologically vulnerable to degraded alertness *yet are unable to perceive this decrement.* Thus, an anesthetist could in fact fall asleep during a case, awaken, and be totally unaware of the lapse in vigilance.

Countermeasures

Studies such as the ones described previously are just beginning to establish the true picture of sleepiness and fatigue in medical personnel. From our knowledge of the performance of fatigued individuals in other domains, we know that professionals become increasingly vulnerable to the degrading effects of sleepiness as the sleep debt accumulates. It may be very difficult to determine a causal relationship between anesthetist fatigue and patient outcome. However, it is clear that if the anesthetist is not awake, he or she cannot possibly be aware. Such a lapse in vigilance is unacceptable. Furthermore, the anesthetist cannot prevent sleep by willpower alone, because it is a fundamental physiologic drive. Demands for clinical services must be balanced against the potential for reduced vigilance and error by seriously fatigued practitioners, anesthetists, and surgeons alike. Because fatigue is such a widespread and insidious problem, it is important to determine ways to counteract its effects. *Countermeasures* are methods that institutions or practitioners can use to minimize the negative effects of sleepiness and fatigue on performance. Countermeasures include the following:

1. Education.
2. Sleep hygiene.
3. Rest breaks at work.
4. Strategic napping.
5. Medications.
6. Light therapy.

Education

The first step in addressing sleepiness and fatigue of medical personnel is to educate health-care professionals and the administrators of health-care institutions about the impact of sleep issues on work performance, mood, job satisfaction, and health. Education is a relatively simple and inexpensive countermeasure that can be implemented immediately. Educational programs covering sleep deprivation, circadian disruption and fatigue, and countermeasures have been enthusiastically adopted by an increasing fraction of the aviation community. [215] [216] Similar programs should be developed for the health-care community. Education alone is sufficient for some individuals and institutions to change their work and sleep habits or their organizational and scheduling procedures. However, it is likely that education will not be sufficient to address this issue fully.

Sleep Hygiene

Sleep hygiene is defined as the conditions and practices that promote sufficient quantity and quality of sleep for each individual. Good sleep hygiene includes the following: regularity of bedtime and wake-up time; sufficient time for sustained and individually adequate sleep; restriction of alcohol, caffeine, and nicotine prior to bedtime; and employment of exercise, nutrition, and environmental factors so that they enhance rather than disturb sleep. [217] A regular sleep schedule is an important part of optimal sleep hygiene, but it is often not possible for medical personnel, given the requirement to cover clinical needs on a 24-hour basis. Medical personnel should make greater efforts to maintain as constant a sleep schedule as possible and to maximize sleep opportunities prior to and after periods of reduced sleep.

Social drug use can have profound effects on sleep. Physicians often use caffeine to help stay awake during on-call periods. Caffeine produces an increase in awakenings and decreases the total nocturnal sleep time. These effects can last as long as 12 hours after ingestion. Individuals who ingest large amounts of caffeine and who have nocturnal sleep disturbances should limit or cease their caffeine intake. Nicotine is a stimulant that produces effects similar to those of caffeine. Alcohol

is often used successfully to initiate sleep, but its effect on sleep architecture after sleep onset can be devastating. After ingestion of alcohol, frequent awakenings from sleep occur that can be associated with increased sympathetic nervous system activity, often manifested by headache, sweating, and tachycardia. Clearly, use of these substances should be restricted near bedtime.

Physicians often lack good nutritional habits, especially during long duty periods. Meals may be skipped or ingested quickly whenever there is adequate time. If one is hungry prior to bedtime, it is best to avoid eating or drinking heavily because this, too, can disturb sleep.

The effects of age can make optimum sleep hygiene difficult to achieve. The number of awakenings per night rises after the age of 45 years, corresponding to decreased sleep efficiency (time in bed versus total sleep time) and increased sleep fragmentation. The ability to initiate sleep at any time during a 24-hour day is diminished after the age of 25 years, and "sleeping in" to make up for lost sleep is more difficult as individuals grow older. Sleep-related disorders such as breathing disruptions (obstructive sleep apnea) and periodic limb movements also become more common with age.

The sleep setting should ideally be a dark, quiet room devoid of interruptions such as pets, telephones, pagers, and children. Sleeping surface and environmental temperature should be comfortable. Psychologic stressors increase baseline physiologic arousal and can impair the quality and quantity of sleep. For example, reviewing the previous day's events or attempting to plan tomorrow's activities while trying to fall asleep is not conducive to sleep. An effort should be made to separate the work of the day with a period of relaxation prior to attempting to initiate sleep.

Rest Breaks at Work

Other industries have openly recognized the reality of vigilance decrements resulting from fatigue and sleepiness. The health-care system has not. Rest breaks and rotation of task duties are mandatory for air traffic controllers and are part of naval ship command procedures as an attempt to prevent potential lapses in vigilance. Short breaks have been shown to increase productivity and job satisfaction, and they probably also help to alleviate boredom. [218] In anesthesia training programs, residents are often given rest breaks during the daytime, but this is often not the case with private practitioners. Private practice anesthesia typically does not provide the mechanisms for rest breaks or task duty rotation, in part because of fiscal concerns. An "extra" anesthetist would be necessary to provide for these opportunities on a regular basis.

The optimal timing and length of breaks are unknown, but a periodic relief from duty should be taken when possible. Cooper et al [219] [220] studied the effects of intraoperative exchange of anesthesia personnel. Although in some cases the process of relieving OR personnel caused a problem, it more frequently was associated with the discovery of a preexisting problem. The positive effect of relief of personnel probably depends on the quality of the handover briefing conducted by the anesthetists.

If anesthetists are unable to obtain a break during long work periods, there are measures that they can take to remain alert. They can engage other OR personnel in conversation (although this, too, can be distracting), thereby increasing the level of stimulation in the environment. Walking around or standing up are both techniques that decrease subjective but not physiologic sleepiness. If the anesthetist is having microsleep events, which may be noticed by other personnel rather than by the anesthetist, fatigue is already very severe, and complete sleep is imminent. In such a situation, the practitioner must secure additional assistance in surveillance of the patient and, if necessary, obtain relief to allow him or her to sleep. The patient should not pay the price for the anesthetist's bravado.

Strategic Napping

If adequate sleep during the night cannot be obtained, naps can be utilized to decrease sleepiness and to improve performance. Based on circadian physiology, there are two times during the 24-hour day that are optimal for naps. These are the periods when the body is already physiologically prepared for sleep, corresponding to the two circadian lulls (approximately 2 PM to 6 PM and 2 AM to 6 AM). Napping at times when circadian rhythms are instructing wakefulness is not easily accomplished and can be counterproductive. [221] [222]

The optimal nap length for most individuals is around 45 to 60 minutes, because this acutely improves alertness and allows for improved performance, but it minimizes the possibility of *sleep inertia* on awakening. Sleep inertia corresponds to the period of reduced ability to function optimally immediately on awakening. This phenomenon usually occurs when individuals are awakened out of SWS and is manifested by grogginess and impaired performance lasting as long as 15 to 30 minutes after awakening. Sleep inertia can also occur after being awakened from normal sleep and is most common during the early morning circadian trough (2-6 AM). Depending on the preexisting level of sleepiness, individuals who take naps longer than 40 minutes are at a greater risk for sleep inertia on awakening. Sleep inertia can be important to health-care professionals who may be awakened out of deep sleep to provide emergency care to patients (e.g., emergency cesarean section or emergency intubation). If urgent work can be anticipated, the sleeping individual should be awakened in time (at least 15 minutes) to minimize the fogginess and performance decrement associated with sleep inertia. If sleep inertia is unavoidable, it would be wise for the affected person to ask for help until the grogginess dissipates.

Napping may alter regular nocturnal sleep. Depending on the timing and length of the nap, sleep initiation and maintenance may be more difficult. Increased sleep latency and decreased total sleep time are commonly seen in people who have taken long (2-hour) naps during the day.

Therefore, the decision whether to nap is complex. Data from NASA studies of flight crews (described earlier) demonstrate that, on the whole, napping is a useful countermeasure to fatigue and sleep deprivation. [191] However, no single recommendation can be made for the use of naps in any work environment, and there are as yet no data on the use of naps in the health-care domain.

Further complicating the appropriate use of napping by medical professionals is the finding that physicians have had an individual and cultural tendency to ignore or to minimize the effect of fatigue and sleep deprivation. The culture of medicine views work breaks and naps as signs of weakness. The military has addressed similar attitudes with the concept of "power napping." Troops are strongly encouraged to take naps of 10 minutes to 1 hour when the situation permits, in order to increase their strength and performance. [177] This approach appropriately presents the idea of napping in a positive light as a sign of wisdom and strength, rather than one of cowardice and frailty.

Medications

A few studies have evaluated the effects of sedative-hypnotics for promotion of sleep during nonduty hours of nonmedical personnel (e.g., to assist in daytime sleep after a night shift). [184] Many questions remain unanswered regarding the quality of sleep obtained after using hypnotics, the severity of hangover effects, and the potential risks of abuse. Melatonin, which is a hormone secreted from the pineal gland, may have promise as a nonaddictive daytime sleepinducing agent, but the results of existing studies are controversial.

Stimulants may have a role in the maintenance of alertness during periods of extreme sleepiness. Caffeine is frequently used in this manner. Amphetamines have been used to increase alertness in extreme situations in the military, but their use is contraindicated for normal (even high-risk) civilian work situations because of the many concerns regarding their use. Some of these concerns involve issues such as perceptual distortions, the intensity of poststimulant recovery sleep, medical side effects of use, and the potential

for addiction and abuse. The use of sedatives and potent stimulants to manipulate sleep is *not* considered an appropriate option for anesthetists.

Light Therapy

Properly timed cycles of bright light and darkness have been used in certain circumstances to facilitate adaptation to shift work. Exposure to bright light

(>7,000-12,000 lux) and darkness at the appropriate points in the circadian cycle has been shown to be able to reset the circadian pacemaker by 12 hours over 2 to 3 days. [223] This is an important finding that demonstrates the ability to make significant changes in the circadian system relatively quickly. However, this resetting of the circadian timekeeper is *critically* dependent on the timing, intensity, and duration of the exposures to light and to "total" darkness. Being off by only an hour can prevent the desired effect. Adhering to such time-critical schedules for this treatment is probably impractical for anesthetists, given the many work-related and social factors that affect their activities. Research on light treatment continues and may eventually result in more practical treatment regimens.

Regulations Concerning Work Hours

The work hours of personnel in nearly every other high-risk industry, including aviation, trucking, railroads, shipping, and nuclear power, are regulated by legislation or by rules of statutory regulatory agencies. [224] Although the duty limits are of similar magnitude in all these industries, the most comprehensive regulations are for air transport pilots operating under Part 121 of the FAA Regulations, which affects aircraft with more than 30 seats or greater than 7,500 payload-pound capacity. Currently, these include daily, weekly, and monthly limits on flight duty hours (time operating the aircraft). [225] [226] Limits on total duty (time at work with or without operation of the aircraft) have been proposed, [226] because total duty time for a pilot may be double that qualifying as flight duty per se. The current limits are worded in a complicated fashion. For example, the daily limit is expressed as no more than "8 hours between required rest periods," the required rest being (approximately) 10 consecutive hours of rest per 24-hour period. [225] The weekly limit is 30 flight duty hours, and the monthly limit is 100 flight hours. New recommendations for limits on pilot work hours are 10 hours per day of flight duty (more in multiperson crews and when crew members are allowed opportunities to sleep in the aircraft), 14 hours of total duty per day, and at least 36 continuous hours off duty per 7-day period. [226] Anesthesiologists and other medical professionals frequently violate these limits by a wide margin. In fact, nearly every on-call day for an anesthesiologist violates these limits. In 1989, the Libby Zion case in New York City brought the issue of resident fatigue to national attention. Although the details of the case are complicated, the patient's death was believed to be due to suboptimal medical care in the middle of the night, and many concluded that resident fatigue played a major role. [227] The degree to which resident fatigue was the proximate cause is open to debate, but regulatory changes dealing with house staff supervision and resident work hours did follow in New York State. Other jurisdictions have considered similar rules. These changes cap resident work hours for continuous duty (24 hours) as well as for duty hours averaged over time (80 h/wk, averaged over a 4-week period). It is not clear whether working conditions now allowed under the average weekly cap are significantly better than those previously in force, although it does seem likely for the house officers who were previously at the highest end of the spectrum (120 h/wk). These reforms were very costly to implement, and it is not clear that the regulations are being followed. Of note, even the 80-hour work week still allows for chronic sleep deprivation to ensue. It is still legal for a resident to work more hours in 1 to 2 weeks than an airline pilot can legally work in a month.

Aging

Every person understands that his or her abilities cannot be maintained indefinitely as he or she ages. On average, performance on laboratory tests of discrete sensory-motor and cognitive skills can be shown to decrease with increasing age. [228] However, there are large differences among individuals. Again, except at extreme points of performance failure (e.g., severe impairment of vision or hearing), the contribution of isolated changes in physiologic or cognitive performance is difficult to relate to real work situations. [229] [230] For one thing, the work environment is often rich with redundant cues involving multiple sensory modalities. For another, technologic compensation may be possible, as with the use of hearing aids or glasses. Finally, along with possible physiologic changes of age typically comes greater experience with a variety of situations. For many individuals, the lessons learned from experience more than offset the modest degree of physiologic impairment they face as they grow older. This compensation has, in fact, been documented for skilled typists, chess players, and bridge players. [231] Middle-aged individuals can utilize their experience to solve everyday problems better than young individuals, but for the elderly (on average), compensation by experience is no longer sufficient to offset cognitive slowing. [229] Age takes a toll on short-term (or "working") memory, [232] [233] [234] and there is evidence that aged workers are more sensitive to the interruptions of attention that are so prevalent in dynamic environments. [235] However, few of these deficits have been documented in complex work settings, largely because it is so difficult to measure performance in these domains. The issue of the aging anesthesiologist has raised considerable controversy among anesthesiologists. [236] [237] [238]

What do other industries do about this issue? There is an FAA regulation in the United States (colloquially known as the "Age 60 Rule") that bans pilots older than 60 years of age from flying under Part 121 of the FAA regulations, described earlier. This rule may soon be extended to pilots of commuter aircraft (<30 seats) regulated under Part 135, as part of an overall thrust to increase safety in commuter air transport. There are no such regulations for business or general aviation pilots operating under other regulations. The Age 60 Rule has been in force since 1959, the rationale being that "increased speeds and passenger loads of commercial airliners placed greater demands on pilots with respect

to their physical fitness and piloting skills." [239] Some may argue that the increasingly challenging nature of anesthesia practice also places greater demands on anesthetists than ever before.

The Age 60 Rule has been the topic of much debate, and the U.S. Congress mandated a review of the rule in 1979, resulting in several studies by a variety of investigators and agencies. [239] [240] [241] [242] [243] [244] The conclusions of these studies are in part contradictory. However, the most recent analysis of available data indicates no increase in accidents per hours flown as pilots approach their 60th year and only a slight hint that class III medical certificate pilots (i.e., "private pilots") have an increased accident rate when they are older than 63 years of age. [239] However, the issue is very complex, and the regulators are extremely conservative. FAA regulations do require air transport pilots (encompassing all Part 121 pilots) to pass "class I" medical examinations every 6 months. However, the medical examination process appears to be largely aimed at identifying individuals with chronic medical conditions that put them at risk for sudden incapacitation (such as significant coronary heart disease). Pilot incapacitation during high-workload phases of flight has been shown in simulator testing [245] to lead to a significant rate of crashes, even when there is a second pilot at the controls. These physical examinations should weed out pilots with severe cognitive or sensory-motor deficiencies, but they are not designed to assess subtle aspects of performance change resulting from age. Of course, there are no requirements for medical examination or certification of anesthesiologists.

It is likely that age alone does not independently cause a significant performance decrement, but age correlates with other factors that are likely to affect performance. The concern about aging professionals revolves more around the loss of knowledge and skill as one gets farther from initial training, rather than the loss of fundamental mental capacities. Thus, the originally well-trained practitioner who keeps abreast of the changing standard of care, and who exercises emergency skills frequently, is less likely to be affected by advancing age than is the marginal practitioner whose knowledge and skills were frozen immediately after completion of training and who practices in a low-complexity environment. The FAA regulations deal with this issue for air transport pilots by requiring frequent (every 6 months) evaluations of performance by FAA-certified check pilots. These evaluations are performed both during actual flights and in realistic simulators, and they, in essence, check fitness for duty regardless of age. There is currently no similar program in anesthesia to assess the competency of practitioners at any age, except for initial board certification, which is voluntary. Periodic recertification will be required by the American Board of Anesthesiology after the year 2000, but it is not mandatory to be Board-certified to practice anesthesia, and the recertification examinations are not likely to be as intense, as thorough, or as frequent as those performed by air transport pilots.

Illness and Drug Use

Every anesthetist is vulnerable to transient illnesses, which in some cases probably reduce performance ability. All personnel are vulnerable to chronic medical conditions, which could directly or indirectly affect their fitness and performance capabilities. The culture of the caring professions often leads individuals to continue to work with illnesses that would cause other professionals to stay at home or to seek medical advice. The performance-shaping effects of the illness can be exacerbated by the use of either over-the-counter or prescribed medications. The degree to which illness and medications affect anesthetist performance is unknown.

A serious problem for anesthetists is that of drug abuse (Ch. 84) . [246] [247] [248] [249] [250] [251] It is estimated that up to 8 percent of physicians should be classified as alcoholics. In an anonymous survey of anesthesia personnel from one institution, 75 percent of respondents reported drinking alcohol on a regular basis. [252] They reported drinking an average of 1.6 drinks per day on 2.7 days per week. Just less than 10 percent of subjects reported having been hung over while conducting anesthesia, and 40 percent reported having given anesthesia within 12 hours of alcohol consumption; 84 percent stated that alcohol use never adversely affected their clinical performance.

The degree to which small doses of alcohol or hangovers affect performance on complex, real-world tasks is uncertain. Some studies of general aviation or navy pilots [182] [244] [253] [254] suggested that hangover effects can degrade performance even when more than 8 hours have elapsed since alcohol consumption and there is no

detectable blood alcohol level. However, although statistically significant, the performance changes seen in these studies may not have been functionally significant. These studies [244] [253] [254] also suggested an interaction among age, workload, and hangover in causing performance decrements. However, the "aged" cohort was defined as 31 years of age or older and was compared with a cohort of young pilots in their early 20s. Extrapolating these results to the anesthesia domain is difficult.

Nonetheless, the natural history of serious abuse of alcohol, cocaine, sedatives, or narcotics by anesthetists is such that cognitive performance will at some point be seriously compromised. However, addiction specialists frequently report that job performance is one of the last areas of life to become impaired. [250] For this reason, the period of time in which the addicted anesthetist's performance in the OR is significantly impaired is a relatively small fraction of the total time during which drugs are abused. Although this in no way excuses the practice of conducting anesthesia while under the influence of drugs, it may account for the fact that reports of addicted anesthesiologists are, unfortunately, common, whereas reports of overt patient risk or harm resulting from an addicted physician's errors are unusual.

Anesthesiology has been at the forefront of dealing with impaired medical personnel. The management of those discovered with drug impairment is fairly standardized, [246] [248] but the question whether to return these individuals to anesthesia practice is increasingly controversial, even when they return under carefully monitored reentry protocols. [251] The main risk appears to be to the addict's own safety, although questions about patient safety can never be eliminated.

Ultimately, the responsibility rests with the anesthetist to ensure that his or her own performance level is sufficient for the work at hand. Pilots utilize a mnemonic checklist to review the effects of potential performance-shaping factors

TABLE 80-3 -- Examples of Hazardous Attitudes and Their Antidotes

(Not Available)

Modified from Federal Aviation Administation [256]

and are instructed not to fly if they are impaired for any reason. The difficulty in anesthesiology (and to some degree in aviation) is that the real-world organization and incentives of many practice settings do not provide mechanisms for personnel to excuse themselves if they are temporarily impaired. Ironically, there may now be better means to identify and support the practitioner with a serious addiction than there are for the more common occurrences of profound sleep deprivation or impairment by a transient or chronic illness.

Hazardous Attitudes

Attitudes are an important component of ability, which can affect performance as strongly as physiologic performance-shaping factors. [255] Psychologists studying judgment in aviators have identified five attitude types as being particularly hazardous, and they have developed specific antidote thoughts for each hazardous attitude. [256] These attitudes as related to anesthesia are shown in Table 80-3 (Table Not Available) . The aviation psychologists instruct pilots physically to verbalize the antidote thought whenever they find themselves thinking in a hazardous way.

The invulnerable and macho attitudes are particularly hazardous for anesthetists. They are compounded by production pressures to do more cases in less time with fewer cancellations and with less opportunity for preoperative evaluation. The feeling that a catastrophe "cannot happen to me" and that perfect performance can always be called on to avert a disaster can lead to cavalier behavior and poor planning. It can alter thresholds for believing that abnormal data represent a problem, thereby leading to the fixation error of "everything's OK." In 1984, Cooper et al [148] wrote about their studies of critical incidents in anesthesia:

> Perhaps the most insidious hazard of anesthesia is its relative
> safety. The individual anesthetist rarely, on average, will be responsible for
> a serious iatrogenic complication. It is our impression from the process of
> collecting incidents, that most seemingly minor errors are not taken seriously
> and that risk management depends almost solely on the anesthetist's
> ability to react instinctively and flawlessly every time a problem arises.

Expert human performance is the anesthetist's most powerful tool to safeguard the patient. Planning to avoid catastrophe is likely to be more successful than battling to avert it, however.

SIMULATORS

The preceding discussion of human performance in anesthesia rests heavily on data acquired using computer-based simulators in anesthesia. Anesthesia simulation is an emerging field. In this section, the history of the development of anesthesia simulation is presented, as well as the current status of the field.

Simulation refers to the artificial replication of sufficient elements of a real-world domain to achieve a stated goal. The goals can include understanding the domain better, training personnel to deal with the domain, or testing the capacity of personnel to work in the domain. The fidelity of a simulation refers to how closely it replicates the domain and is determined by the number of elements that are replicated and the error between each element and the real world. The fidelity required depends on the stated goals. Some goals can be achieved with minimal fidelity, whereas others require very high fidelity.

Simulation has probably been a part of human activity since prehistoric times. The rehearsal of hunting activities and of warfare was a likely occasion for simulating the behavior of prey or enemy warriors. Technologic simulation probably dates back to the dawn of technology itself. Good and Gravenstein [257] point to the Roman quintain as a technologic device that crudely simulated the behavior of an opponent during sword fighting. If the swordsman did not duck at the appropriate time after striking a blow, he would be hit by a component of the quintain. In modern times, preparation for warfare has been an equally powerful spur to the development of simulation technologies especially for aviation, shipping, and the operation of armored vehicles. These technologies have been adopted by their civilian counterparts, but they have reached their most extensive use in commercial aviation.

Aviation Simulation History

Although some aircraft simulators were built between 1910 and 1927, none of them could provide the proper feel of the aircraft because they could not dynamically reproduce its behavior. [258] In 1930, Edwin Link filed a patent for a pneumatically driven aircraft simulator. The "Link Trainer" was a standard for flight training before World War II, but

TABLE 80-4 -- Use of Simulators in Complex Work Environments

(Not Available)

From Singleton [259]

the war accelerated its use and the further development of flight simulators. In the 1950s, electronic controls replaced pneumatic ones through analogue, digital, and hybrid computers. The aircraft simulator achieved its modern form in the late 1960s, but it has been continuously refined. Aviation simulators are so realistic now that pilots with experience flying one airliner are routinely certified to fly totally new or different aircraft having never flown the actual aircraft without passengers on board. Similar stories of the development of simulators can be told for a number of other industries.

Uses of Simulators

Although simulators were originally used to provide basic instruction in the operation of aircraft controls, [258] the variety of uses of simulators in general has expanded greatly in the last 30 years. Singleton [259] outlined the possible uses of simulators in all types of complex work situations (Table 80-4) (Table Not Available) .

Thus, simulation can be seen as a powerful generic tool for dealing with human performance issues (training, testing, and research), for investigating human-machine interactions, and for the design and validation of equipment. As delineated later in this chapter, each of these uses is potentially relevant to anesthesiology.

Classification of Patient Simulators

There is no accepted classification scheme for patient simulators for use in anesthesia. Any classification involves some overlaps and gray areas. The following classification and definitions are used in this chapter. In addition to simulators, there are also computer-assisted instruction programs and computer-based training devices. Although the training devices may replicate certain portions of the anesthesia domain, they do not attempt to replicate the bulk of the work environment. Some individuals consider the screen-only simulator as a training device and not as a simulator. Computer-assisted instruction programs and training devices are not reviewed in this chapter. A patient "simulator" is a system that presents the clinical work environment (e.g., operating room, PACU, ICU) in one of the following ways:

1. In actual physical reality, defined as a realistic simulator or a hands-on simulator.
2. On a computer screen only, defined as a screen-only simulator or microsimulator.
3. Using virtual reality, defined as a virtual reality simulator.

Virtual reality refers to a set of techniques in which one interacts with a synthetic ("virtual") environment that exists solely in the computer. [260] In the typical conception of virtual reality, the representation of the synthetic environment is fed fairly directly to the eyes and ears through goggles or visors and headphones (i.e., there is no "screen"). The actions of the user in the environment are translated directly from typical physical activities, *not* through manipulating a special pointing device. There is a continuum of realizations of this ideal, involving compromises on these input/output modalities. At one end of the continuum, which I call a "complete virtual reality simulation," the participant is immersed in a virtual world that fully replicates at least three sensory inputs--vision, hearing, and touch (more technically known as a haptic/kinesthetic system) [260] --and allows complete physical interaction with the world. At the other extreme of the continuum is a screen-based simulator, which generates a limited virtual world, but it restricts its output to a screen display and provides interaction with the virtual world only through a pointing device. The screen-based simulator provides an interface to the human sensory system that is very far from physical reality, whereas a complete virtual reality simulation may be, in its most advanced form, nearly indistinguishable from the real world. A "partial" virtual reality simulator would replicate fewer senses (or less complete replication) and/or could restrict physical interaction with the world. Finally, one can imagine hybrids of realistic simulators and virtual reality simulators in which the virtual reality representation is overlaid onto a real physical environment.

A complete virtual reality patient simulator would be very complicated because it requires the following:

1. A complete computer model of the patient, the environment, and the *function* of every object in the environment that could be utilized (e.g., monitoring devices, carts).
2. A means of tracking visual, audio, and touch fields of the user to determine what is to be displayed and to identify what physical actions are being performed.

3. Appropriate display hardware for every sensory modality and appropriate input hardware for each action pathway (e.g., touch, speech).
4. Hardware to compute all the models, to conduct the tracking, and to produce all the outputs to the display hardware *in real time.*

Virtual reality is a rapidly developing field. There is intense interest in virtual reality in a number of domains, particularly the military and entertainment. Although the potential of this approach is very exciting, practical virtual reality simulators are currently quite limited in capability or extremely expensive to produce, or in many cases, they are both limited and expensive.

Components of a Patient Simulator

An anesthesia patient simulator system contains several components (Fig. 80-10) . A set of outputs make up a representation

Figure 80-10 A schematic diagram of the generic architecture of patient simulator systems. The simulator generates a representation of the patient and the work environment using appropriate interface hardware and/or display technologies. The representation is perceived by the anesthesiologist, whose actions are then input to the simulator through physical actions or input devices. The behavior of the simulated patient is determined through sets of interlinked physiologic models and control logic that are manipulated by the instructor or operator through a workstation that allows selection of different patients, abnormal events, and other features of the simulation.

of the patient, the OR environment, and diagnostic and therapeutic equipment. For screen-only simulators, this representation is generated graphically on the computer screen. For realistic simulators, the representation is generated on actual clinical equipment and on a patient mannequin in an actual OR-like setting. The clinical equipment and the mannequin are stimulated or actuated by interface hardware. Realistic simulators often use physical stimulation of clinical equipment in addition to electronic stimulation. For example, the mannequin can actually be ventilated with any desired mix of inspired gases. Carbon dioxide and other gases can be introduced by the simulator into the mannequin's lungs physically to provide the desired elements of gas exchange. A real respiratory gas analyzer can thus be used to measure the inspired and expired gases.

The simulator must have control logic by which changes in the simulated patient's condition can be generated, to be sent to the appropriate output of the representation. Originally, the control logic was embedded in the software as a fixed sequence of events, or it required continuous inputs from the instructor working from a script. Newer simulators incorporate a more sophisticated technique using mathematical differential equation models of a patient's physiology and pharmacology to provide the bulk of the control logic. These models can be tailored to represent different patients with different pathophysiologic abnormalities. However, not all states or changes in a patient can be modeled using differential equations. For example, ventricular fibrillation is a totally different state of heart rhythm that does evolve continuously from normal rhythms. No model can predict *exactly* when a patient will suffer a myocardial infarction or when an ischemic heart will begin to fibrillate. A model can only predict those factors that increase the likelihood of such events. Thus, most simulators incorporate other modeling techniques in addition to the basic physiologic and pharmacologic mathematical equations, including finite-state models, instructor initiation of abnormal events, and even manual modulation of modeled parameters. In finite-state models, different underlying clinical states are defined, each of which has appropriate entry conditions as well as transition conditions to other states. When an entry or transition condition is met, a new state becomes active, which may directly trigger new observable phenomena (e.g., ventricular fibrillation) or may alter constants in the mathematical models that then evolve in time. [261] [262] [263]

The control logic of realistic simulators is manipulated via an *instructor/operator' s station (IOS)* that allows the instructor to create specific patients, select and implement abnormal events and faults, and monitor the progress of the simulation session. There may also be a remote-control hand-held IOS in addition to the main IOS. The IOS typically provides logs of physiologic changes and the anesthesiologist's response and may provide graphics to support the analysis of a simulation run. Some screen-based simulators provide advice and tutorials linked to the management of simulated events. With realistic simulators, detailed records of the simulation and the actions taken may also be made using video and audio recording of the anesthesiologist working in the simulator.

Sim One: An Anesthesia Simulator Before Its Time

The potential of simulators for training anesthetists was recognized 30 years ago. In the late 1960s, an electromechanical

TABLE 80-5 -- Clinical Features Supported by Sim One[a]

Spontaneous ventilation as well as ability to be ventilated by external bag or ventilator
Palpable pulses with appropriate pulse amplitude
Bucking
Pupillary dilation and constriction
Laryngospasm
Regurgitation of gastric contents
Frowning
Variable jaw tension
Fasciculation
Force-sensitive teeth
Force-sensitive lower lips
Abdominal distention (esophageal intubation)

[a] Sim One, product of the Sierra Engineering Company, Sierra Madre, Calif.

realistic anesthesia simulator was developed (Sim One). [264] [265] Sim One was produced by the Sierra Engineering Company based on specifications from physicians and medical educators from the University of Southern California. [264] [265] The goal was to construct a simulated patient for learning the skill of endotracheal intubation, along with the induction of anesthesia. The system consisted of a patient mannequin comprising the head, neck, thorax, upper abdomen, and arms. The mannequin and the table on which it was permanently mounted contained electromechanical and pneumatic actuators for a variety of clinical features (Table 80-5) . Appropriately for the late 1960s (but not for today), Sim One provided outputs only for clinical cues such as heart sounds and peripheral pulses; it did not provide outputs to any electronic monitors.

Sim One could electronically sense a variety of clinical actions. Placement of the mask on the mannequin's face was sensed by tiny reed relays embedded in the plastic flesh of the face. A special magnetic endotracheal tube was constructed with iron molded into the plastic. Its position could be determined by magnetic sensors. Sim One could automatically recognize the identity and amount injected of four drugs: thiopental, succinylcholine, methoxamine, and ephedrine. This system depended on each drug's being administered using a specific size of needle, and thus it could not be expanded to identify a larger number of drugs. A standard anesthesia machine was specially instrumented to report gas flow rates (but not the concentration) of volatile anesthetic.

A computer program provided the control logic. For example, the program responded to drugs based on the dose-time-effect curves for those drugs. However, there was no true modeling of pharmacokinetics or pharmacodynamics. The Sim One IOS provided readouts of the system's internal status and external outputs. Chart

recordings of multiple variables could be produced. The IOS provided toggle switches or buttons to actuate a variety of preprogrammed events, including cardiac arrest, bucking, increased and decreased blood pressure or heart rate, changes in respiratory rate, and occlusion of the mainstem bronchus.

Produced in 1968, Sim One was a technologic marvel, costing approximately $100,000 (on the order of $450,000 today) to design and build a single hand-crafted unit. It incorporated many features of today's simulators, and it even included a number of desirable features that are not currently implemented. Sim One was used for several training purposes, of which only a few involved anesthesiologists. The investigators used the simulator to speed the training of anesthesia residents in endotracheal intubation. [264] [266] Ten novice residents were randomly allocated to receive either no additional training or special training in intubation using Sim One (5.5-9.5 hours of training over a 2-week period). The investigators attempted to measure the proficiency of the ten residents at intubation by scoring blinded copies of the residents' anesthetic records. [266] The scoring for each record was a binary decision ("plus" or "minus") whether "On the basis of what you see on this chart, would you be willing to trust the anesthesiology resident in an operating room without supervision?" Performance criteria were set as (1) four consecutive plus ratings, (2) seven of eight consecutive cases with a plus rating, and (3) nine of ten consecutive cases with a plus rating. There was a statistically significant difference between the groups in the number of cases (and the number of days) to achieve the nine-out-of-ten criterion, but there was no difference in the time to achieve the other criteria. It took the simulator-trained residents 45.6 days to reach this criterion, whereas the control group took 77.0 days.

Although the investigators' intent was admirable, this study was seriously flawed. The simulator group received special one-on-one attention that the control group did not receive. The scoring system for the anesthetic records was poorly defined and ambiguous. The performance criteria established were completely arbitrary. Appropriate statistical techniques were not utilized to evaluate the results. In another publication, [267] the investigators stated that residents cut their number of errors in anesthesia induction by half and reduced the average time to perform an induction by one-third after training with Sim One; however, no details of these experiments were provided. These investigators also listed other training uses including teaching nurses to perform "ventilator application" (perhaps this referred to intermittent positive-pressure breathing treatments), intramuscular injection, recovery room care, and pulse and respiration measurement. They discussed the cost effectiveness of Sim One in terms of decreased faculty time to impart specific skills, improvements in student performance, and potential reduction in patient discomfort and risk. In many ways long before their time, they stated that:

> the effectiveness of simulation depends on the instructional method with which simulation is being compared. For example, if there is no alternative training method available ... the effectiveness of a simulation device probably depends on the simple fact that the device provides some kind of learning experience as opposed to none. When a simulation device is compared with conventional on-the-ward training, however, the device's effectiveness seems related to the degree to which learning a given task is facilitated by systematic presentation of that task. Systematic presentation is not easily achieved on the wards, whereas simulation devices can provide a number of systematic patterns, such as graduation of difficulty level or complexity.

The Sim One project drifted into oblivion (a planned Sim Two was never built) for a number of reasons. [268] It was clearly ahead of its time technologically, although changes in techniques of anesthesia and of monitoring have outstripped

Sim One's ability to replicate important aspects of the anesthesia work environment. For example, only four drugs could be used, and there were no outputs for electronic monitors. Sim One was costly, and many anesthetists of the time viewed computers and technology with suspicion. Finally, I believe that both the investigators and the profession as a whole did not have sufficient understanding of the relevant issues of human performance for which simulator training, testing, and research would be an ideal tool. Thus, although we can now see that Sim One had great potential for teaching personnel about the management of a variety of challenging perioperative situations, its use in anesthesia then was focused primarily on standard inductions and endotracheal intubation. We now know that, although simulator training in intubation can be helpful (and simulator training in complex airway management may be even more useful), most residents rapidly acquire reasonable skill at intubation through clinical experience. To be truly useful, the simulator must be targeted at a different set of skills. Thus, for these and for many other reasons lost in time, the legacy of Sim One essentially disappeared.

Reinvention of Anesthesia Simulators

Several anesthesia simulators were developed and introduced in the mid to late 1980s (see later). Each was an independent development, and none had any connection with the Sim One project. Several factors led to these developments. Most prominent was the new availability of powerful (compared with advanced minicomputers of a decade earlier) personal computers at a relatively cheap price. The popularity of a variety of simulators for personal computers (e.g., flight simulators, driving simulators) demonstrated that simulation of complex systems was possible using a personal computer, and a screen-based simulator could give users some degree of "feel" that they had been in the environment. For realistic simulators, inexpensive clinical waveform generators became available. These produced typical clinical signals for ECG and invasive pressure monitors, and the waveforms produced could be selected by an external computer. On the applications side, the public and the anesthesia profession had become more aware of the utility of simulation-based training for military and commercial aviation, space flight, automobile driving, shipping, military command and control, and operation of nuclear power plants. Media coverage of the space program and the corrective responses to the Three Mile Island nuclear accident highlighted the role of simulators. Another pivotal factor was a growing interest within anesthesiology in studying the anesthetist's performance and the human factors and ergonomics of the anesthesia work environment. [4] [14] [39] [148]

By the time of this writing, nearly every system has evolved through several generations of improvements. I briefly describe each of the systems and its evolution. Although several "homemade" simulators are still in use in the United States (University of Alabama) and in Europe (see later), two systems are being offered commercially. Commercialization has enabled many institutions to acquire simulators without having to invest in the engineering and clinical expertise to develop a system from scratch. The descriptions given in the following sections are very brief, and the introduction of new or upgraded features in all the simulation systems continues steadily. For up-to-date information about any of the current systems, the reader is advised to contact the manufacturers or authors directly.

Screen-Only Simulators: SLEEPER and BODY Simulation

In San Diego, Smith and associates [269] [270] [271] continued a long series of work concerning the modeling of the cardiopulmonary systems and of drug distribution. The group developed a set of linked physiologic and pharmacologic models that accurately reproduced major elements of the patient's clinical behavior. The early work used analogue and hybrid computers, [269] [270] [271] but for the last 10 years, the evolving systems have used standard personal computers. When the models were combined with an appropriate graphic representation of the patient and clinical data on the computer screen, and a graphic user interface for the input of clinically relevant actions, the system became a complete screen-only simulator known originally as SLEEPER. [272] SLEEPER used a complex transport model to deal with gas exchange and drug distribution. This model provided the opportunity to create "drugs" with characteristics unlike those of any existing drug, as well the ability to predict the concentration of drugs in specific anatomic regions (e.g., myocardium or gray matter).

In collaboration with Marquette Electronics, Inc., (Milwaukee, Wis) the SLEEPER software has evolved into a program called BODY Simulation. In addition to extensions to the original transport and physiologic models, a unique feature of BODY is that the monitoring equipment and anesthesia delivery equipment are high-resolution computer-screen replicas of actual or prototype Marquette Electronics equipment. This lends additional realism to the system as well as allowing it to be used to test the usability of the user interface of the clinical equipment.

Anesthesia Simulator Recorder and Anesthesia Simulator Consultant

At the University of Washington, Seattle, physician Howard Schwid, (formerly a research fellow with Ty Smith) and programmer Daniel O'Donnell developed a screen-based simulator originally called the Anesthesia Simulator Recorder (ASR, AneSoft Corporation, Bellevue, Wash). [261] [262] [263] This then evolved into the ASC. It was specifically geared to training anesthetists in managing patients, with more emphasis than SLEEPER (or BODY Simulation) on critical incidents and less emphasis on pharmacologic and physiologic plotting. This system provides graphic representations of mock monitoring displays and clinical equipment, as well as photographs to display the patient and actions taken on the patient (Fig. 80-11) (Figure Not Available) . Interaction with this system also uses a desktop pointing device. The ASC uses traditional pharmacokinetic and pharmacodynamic models drawn from the pharmacology literature to track drug levels and effects of more than

70 drugs, as opposed to the physical transport models used in SLEEPER and BODY Simulation.

Figure 80-11 (Figure Not Available) Computer screen display of the Anesthesia Simulator Consultant (ASC). The actual screen is in full color. Additional information and actions can be selected using a pointing device ("mouse") and menus. *(Courtesy of Howard Schwid, M.D., with permission)*

A unique feature of the ASC is that 80 cases have been contributed by nationally recognized experts. A number of critical events can be preselected by the user or selected at random by the system.

Schwid and his collaborators conducted evaluations of the original ASR with 44 anesthesia residents and faculty members at several teaching institutions in the United States. [262] The results showed that the ASR was easy to learn to use, was reasonably realistic, and was rated as an outstanding teaching device. More than 3,000 copies of ASR or ASC have been distributed throughout the world (H. Schwid, personal communication).

Realistic Simulators

Comprehensive Anesthesia Simulation Environment

In 1986, Gaba and DeAnda began developing the Comprehensive Anesthesia Simulation Environment (CASE) series of anesthesia simulators with a primary goal of conducting research into decision-making by anesthetists (the first transcript of an anesthetist responding to a simulated intraoperative crisis was obtained in spring, 1986). The architecture of the first-generation CASE 1.2-1.3 simulator [273] used commercially available clinical waveform generators to provide signals to actual clinical instruments. Other devices, such as the automated noninvasive blood pressure cuff were "simulated" as a virtual instrument using a computer program on a Macintosh Plus computer acting as a virtual instrument.

The CASE 1.2-1.3 mannequin was modified to enable occlusion of the left mainstem bronchus, infusion of CO_2, and the insertion of intravenous lines. This mannequin allowed mask ventilation, intubation, and auscultation of breath sounds, but it did not have palpable pulses or spontaneous ventilation. The behavior of all of the waveform generators and actuators was coordinated using a central control computer. The control logic of CASE 1.2 was provided by an operator typing commands at the IOS based on a written simulation script describing the appropriate changes for a variety of anticipated actions on the part of the subject in the simulation. An experienced anesthesiologist observed the activities of the subject and directed the simulator operator using a private headset intercom. This control logic and IOS enabled the simulator to respond to any actions on the part of the subject, not just those that were previously anticipated.

The CASE 1.2 system was evaluated by residents [273] (and later faculty and private practitioners) and was rated as very realistic, except for the plastic mannequin. The success of such a crude system, which lacked physiologic and pharmacologic models, lies in the exceptional variability of patients and in the ability of anesthetists to "suspend disbelief" if placed into a plausible clinical situation. No anesthetist can

predict the exact behavior of a *specific patient* in response to drugs and actions. The responses of the simulator only have to be plausible for the situation to appear very realistic. This is especially true for critical event training situations in which plausible but unusual events are presented. On the other hand, physiologic and pharmacologic models do offer substantial advantages, including greater consistency and reproducibility of situations, the ability to handle multiple physiologic changes simultaneously, and greater automation of the simulation process.

In 1989, CASE 2.0 was unveiled. This was a major redesign of the system that incorporated a physiologic model of the cardiovascular system. [274] Waveforms and electronic data streams, including heart sounds, were generated directly from the cardiovascular model. CASE 2.0 was used extensively in the conduct of the Anesthesia CRM (ACRM) training program described in a subsequent section of this chapter.

Commercialization

In 1992 to 1993, the CAE-Link Corporation (now called Medsim Eagle Simulation, Inc., Binghamton, NY), a manufacturer of military aviation and space flight simulators, licensed technology from Gaba's simulator group and from Schwid's group as part of its development of a commercial anesthesia simulator system. *

This simulator was originally called the Virtual Anesthesiology Training Simulator System, but the name was later changed to the Eagle Patient Simulator. Version 2.0 of this device was introduced in late 1995 (Fig. 80-12) (Figure Not Available) . It is completely operated by physiologic, pharmacologic, and finite-state models. The Eagle Patient Simulator contains complete models of cardiovascular, pulmonary, fluid, acid-base-electrolyte, and thermal physiology. It includes computer-controlled electromechanical lungs with dynamically changeable compliance, embedded totally within the mannequin's thorax, so that the patient mannequin can be moved onto an OR table, ICU bed, or emergency room gurney. The interface components are housed in a rolling cart that can be placed underneath or beside the patient's bed. The airway of the mannequin allows mask ventilation, endotracheal intubation, use of the laryngeal mask and the Sheridan Combitube (Kendall, Mansfield, Mass), and cricothyrotomy or transtracheal jet ventilation. The mannequin provides electronically generated heart sounds and breath sounds, dynamically changeable airway anatomy, palpable pulses, and a thumb twitch responding to stimulation by actual nerve stimulators.

Some variants of the mannequin provide eyelids that open and close, eyes that move, and pupils that constrict or dilate and respond to light. Arm movements support decerebrate or decorticate posturing. Traumatic injuries can be simulated, and procedures common in trauma settings (such as placement of a chest tube) are possible.

Quantitative physical elimination of CO_2 through the lungs is provided, so that a clinical gas analyzer can be used in its usual fashion. Other gases wash in and wash out appropriately but there is no uptake and distribution of O_2, nitrous oxide, or volatile agents in the standard unit.

The IOS in the Eagle Patient Simulator uses a graphic user interface (Fig. 80-13) (Figure Not Available) to provide a rich set of tools for the instructor to choose and implement different *events* (up to five events can run simultaneously), different simulated *patients,* and complete *scenarios.* The instructor can tailor each event in advance, altering features such as the onset time, severity, or manifestations of the event. Tailored events can be saved under different names, allowing the creation of a library of events or situations. A new drug editor allows alteration of drug kinetic and dynamic parameters.

Many inputs to the device are automatic. A gas analyzer recognizes all inspired gases and passes their values to the pharmacologic models. An automated drug recognition system detects and identifies the drug administered and its dose of drug administration through an electromagnetic

coding object affixed to each stopcock and detected by an instrumented stopcock manifold. Like the ASC, the system can track the kinetics and dynamics of more than 70 different drugs. The Eagle Patient Simulator also logs simulator outputs, state changes, and actions by the subject that are input to the simulator.

Other features include a model of CPB, so that cardiac surgical situations can be presented, including weaning from bypass. The bypass model can also be used to teach clinicians about the physiology and technical issues of CPB.

Gainesville Anesthesia Simulator

Shortly after the CASE simulator was developed, a similar simulator was produced at the University of Florida, Gainesville, by a team headed by Good and Gravenstein. [257] This system, called the Gainesville Anesthesia Simulator (GAS), also used commercially available waveform generators under the control of a central computer, along with a mannequin and real OR equipment. GAS could stimulate noninvasive blood pressure measurement devices and also provided palpable pulses. Unlike CASE, it was capable of spontaneous ventilation using a mechanical lung placed inside the operating table on which the mannequin was mounted. An interesting component of GAS was an anesthesia machine that was modified to incorporate a variety of mechanical faults that could be triggered electronically.

Over time, other important features have been added to GAS, including a complex quantitatively accurate physical simulation of multiple gas exchange. The lung concentrations of O_2 , nitrous oxide, N_2 , and one volatile anesthetic could be physically made to match the alveolar gas content predicted by a mathematical model of gas exchange and anesthetic uptake and distribution. Another added feature is a moving thumb that responds appropriately to stimulation from a nerve stimulator, based on the level of neuromuscular blockade. The Gainesville group then developed a simulator control system using physiologic and pharmacologic models.

Commercialization

The GAS was also commercialized, initially with Loral Data Systems, and later via an independent spinoff company, with Loral Data Systems as a minority shareholder, Medical Education Technologies, Inc. (METI, Sarasota, Fla). The METI Human Patient Simulator (Fig. 80-14) (Figure Not Available) also uses full physiologic and pharmacologic mathematic models. Its mannequin supports numerous clinical cues and interventions such as pulses, breath sounds, heart sounds, and invasive airway management. It provides outputs for nearly all modalities of invasive and noninvasive monitoring. Like its predecessor GAS, it continues to provide quantitative physical modeling of uptake and distribution of several gases. The newest version of the Human Patient Simulator

has moved the lung system to a remote interface cart, thus freeing the mannequin from its table and allowing for full-force cardiopulmonary resuscitation chest compressions.

The IOS of the Human Patient Simulator runs on a personal computer and allows real-time control of parameters and situations. A pen-based remote personal computer can be used as the IOS. The user interface primarily involves selection of files from menus and is less of a traditional graphic user interface than on the Eagle Patient Simulator.

Some unique features of the Human Patient Simulator include a genital/urinary system that allows user selectable urine output and Foley catheterization (the mannequin contains interchangeable genitals to provide for either patient gender), and an automatic drug-recognition system that uses a bar code scanner embedded in the stopcock manifold assembly (a design first sketched but not implemented for CASE 3.0).

Leiden Anesthesia Simulator

At the 1992 World Congress of Anesthesiologists, a group from Leiden, the Netherlands, led by Chopra and Bovill, unveiled the Leiden Anesthesia Simulator. [275] This simulator used the same architecture as CASE 1.2 and replicated many of its features as well as some of those of GAS. (In fact, the Leiden simulator was derived in part from technical information provided to the Leiden group by the Stanford investigators.) Like GAS, the Leiden simulator incorporated a mechanical lung capable of spontaneous ventilation. A new control logic IOS allowed the instructor to select from a number of scripted critical events and to control different physiologic variables directly. The addition of physiologic and pharmacologic models to the Leiden simulator was planned.

Anaesthesia Simulator SOPHUS

The Anaesthesia Simulator SOPHUS was developed by a group of anesthesiologists and scientists in Denmark (Herlev Hospital, Roskilde University, and Riso National Laboratory). All necessary physiologic parameters are animated and controlled by signals from the computer. Simulation of human response to anesthesia is based on detailed mathematic models of pharmacokinetic/dynamic processes and the cardiovascular system. However, the Anaesthesia Simulator SOPHUS does not appear to be quite as comprehensive as the Eagle Patient Simulator or the Loral Human Patient Simulator. The SOPHUS simulator is also in use at the University of Basel, where it has been adapted to form the Wilhelm Tell simulator. A unique feature of the Wilhelm Tell simulator is the addition of perfused bovine or porcine organs from a slaughterhouse, on which surgeons can perform laparoscopic procedures while anesthesiologists manage the patient.

Other "Homemade" Realistic Patient Simulators

A simulator apparently roughly equivalent to CASE 1.2 has been developed at Stavanger College, Stavanger, Norway (Stavanger College World Wide Web page). A less realistic simulator (ACCESS), which is a screen-based simulator with the addition of a nonintubatable mannequin as a "prop," was developed at the University of Wales. [276]

Virtual Reality Simulators

A prototype virtual reality anesthesia simulator has been under development by a commercial firm (headed by British anesthetists at the University of Nottingham) called Virtumed Limited. In a prototype discussed in the *Sunday Times of London,* [277] the display apparently uses an off-the-shelf visor display to depict slightly cartoonish renditions of the OR, the patient, and certain pieces of clinical equipment (e.g., anesthesia machine, a mock-monitor screen). As of this writing, there is no published experience with this system.

Although virtual reality simulators have many theoretical advantages over screen-based and realistic simulators (e.g., realism, virtual "hands-on" interaction, instantaneous reset of the environment), these advantages are currently offset

---

by the immaturity of the field. In spite of considerable hype about virtual reality, such systems are now either very limited in capability or very expensive, or in most cases, they are both limited and expensive. A true virtual reality "immersion" experience in a patient care setting comparable to that obtainable using a realistic simulator is not yet on the horizon.

Nonetheless, it is likely that virtual reality techniques will eclipse other types of simulators within 10 to 20 years. [278] In the interim, I believe that virtual reality will be used primarily to augment the display representation of current screen-based simulators.

Experience With Patient Simulators in Anesthesia

The new patient simulators have been in use in anesthesia for more than 10 years, and there has already been considerable collective experience with the devices. Their use for research on decision-making has been covered in preceding sections of this chapter. This section and those that follow cover the use of simulators for training, evaluation, and for future research in decision-making and human factors.

Training

Medical Students

Many simulation centers have used their devices for medical student training. Several curricula exist:

1. Educational sessions and demonstrations concerning basic cardiopulmonary physiology or pharmacology; in some institutions, these sessions replace animal laboratory exercises. [279]
2. Introduction to the integrated management (i.e., interleaving of diagnosis and therapy) of the critically ill patient; this training is offered to immediate preclinical medical students as part of their preparation for clinical medicine course.
3. Anesthesia practicum for clinical students during anesthesia clerkship. [280]

Anesthesia Residents

The ASR/ASC was highly rated by residents and faculty and is now available as a voluntary resource at approximately 50 percent of U.S. anesthesia training institutions. When asked, the vast majority of residents at the University of Washington expressed recognition of their own need for additional training in handling critical incidents and the likelihood that the ASC exercises would help them. Nonetheless, it was found that only 20 percent of residents completed the prescribed set of 12 simulations on a voluntary basis. Thus, the University of Washington program has made these exercises mandatory. The printed log of each simulated case is reviewed by a faculty member, who critiques the case management of the resident (H. Schwid, personal communication).

Good et al [281] reported on a randomized study of the effect of simulator-based training on novice resident performance. Twenty-six beginning residents, matched for previous training and gender, were randomized to receive either daily simulator training sessions or daily lectures on 10 predefined learning objectives during weeks 2 and 3 of the residency. Resident performance was assessed both by a written test and by evaluations of clinical ability by supervisors at weeks 1, 3, 8, and 13 of training. There was no difference in performance on the written test. Although there was a trend of improvement in the overall raw clinical ability scores for the simulator group at weeks 3 and 8, this was not statistically significant. However, the change in clinical score was significantly greater for the simulator group than for the lecture group at weeks 3 and 8, but not at week 13, by which time the change in clinical score was identical for the two groups. This study suggests that there may have been somewhat faster improvement in clinical ability when simulator-based training was used, but that by 3 months of anesthesia experience, all residents had improved their ability by the same amount. It was noted that additional work is needed to refine and coordinate the clinical and simulator curricula and also that continuing simulator exercises may have benefits over the single "bolus" of training over 2 weeks.

The Leiden group [282] reported that simulator-based training and practice in the management of malignant hyperthermia led to a significant improvement in handling of malignant hyperthermia when participants were tested in the simulator 4 months later. All participants had been given simulator training, but only half were trained concerning malignant hyperthermia. This design partially controlled for effects resulting solely from familiarity with the simulator environment. Gonzalez and Schaefer [283] reported training residents (and others) in the ASA difficult airway management algorithm using an Eagle Patient Simulator.

Anesthesia Crisis Resource Management

In 1989, based on the cognitive process model presented in the preceding section, Gaba, Fish, and Howard of the VA-Stanford group identified gaps in the training of anesthesiologists concerning several critical aspects of decision-making and crisis management that were not systematically taught during standard residency or postgraduate education. These gaps were as follows: (1) inadequate learning of precompiled plans for dealing with perioperative events; (2) inadequate skills of metacognition and allocation of attention; and (3) inadequate skill at resource management behaviors, including leadership, communication, workload management, monitoring, and cross-checking of all available information. Historically, it had been assumed that anesthetists would acquire these plans and skills "by osmosis," solely by experience and by observing role models who had these qualities. As indicated in a previous section, the aviation domain had learned that such skills were not acquired unless specifically taught, and CRM training was created to address these issues for flight crews. The VA-Stanford group modeled their ACRM training [93] after CRM. To target the identified gaps in anesthesia training, approximately 40 percent of the emphasis of ACRM training is on the medical and technical management of specific high-risk perioperative situations,

and 60 percent of the emphasis is on generic principles of crisis management that apply to nearly every complex patient care situation.

The ACRM curriculum used several teaching modalities to achieve these goals:

1. A comprehensive textbook on anesthesia crisis management (*Crisis Management in Anesthesiology*[41]). This includes didactic material on ACRM principles as well as a comprehensive catalog of critical incidents in anesthesia that provides in a uniform format guidelines for preventing, recognizing, and managing 83 perioperative situations. The catalog section of the text is intended to provide study material to increase anesthetist's stock of precompiled response plans to common and uncommon situations.
2. A brief presentation reviewing the principles of ACRM and anesthesia safety.
3. Analysis of a videotape of an aviation accident.
4. Small group exercises analyzing a videotape of an actual anesthetic mishap.
5. Several hours of complex multifaceted realistic simulations in which training participants rotate through different roles, including primary anesthesiologist, first responder (called "cold" with no knowledge of the situation), and scrub nurse. Other personnel play the roles of surgeons, nurses, and technicians as in a real OR. Each situation is followed by a detailed debriefing (lasting about the same amount of time as the situation itself) in which an experienced instructor leads the group to apply ACRM principles in analyzing their own performance.

There have been several publications detailing the response of participants of varying levels of experience to ACRM training. [93] [284] [285] Participants have been extremely positive about their experience in the ACRM course, and most believe that it contributes to their safe practice of anesthesia (Table 80-6) (Table Not Available) .

In addition to the inventors of ACRM at the VA-Stanford Simulation Center, several other simulation centers have adopted ACRM as a major focus of their training (Boston Center for Medical Simulation; Canadian Simulation Centre, Toronto; Washington University, St. Louis; Referral Hospital System, Edmonton, Alberta, Canada). Several variant curricula similar to ACRM have been developed based on the textbook *Crisis Management in Anesthesiology* and on the original ACRM experiences. These include the crisis management training at the University of Pittsburgh, the Rational Anesthesia curriculum in Denmark, and simulation training courses in Brussels, Belgium, and Fukuoka, Japan. Interest in ACRM is growing, but because it is very complex, special training for ACRM instructors has been developed by the Working Group on Crisis Management Training in Health Care (composed of the three pioneering centers in the development of ACRM: VA-Stanford Simulation Center, the Boston Anesthesia Simulation Center, and the Canadian Simulation Centre). This working group has developed and tested a 3-day ACRM Instructor Training Course, [286] and it has produced a 150-page training manual for ACRM Instructor candidates. Experience with the instructor training course suggests that the most difficult aspect of ACRM instructing is "debriefing," and new instructors require a significant period of experience, preferably under supervision by more senior instructors, before being ready to be fully independent ACRM instructors. ACRM instructor training continues at these three centers under the auspices of the working group.

Team-Oriented Medical Simulation

In 1994, a simulator-based CRM-oriented curriculum was developed independently by Helmreich, Schaefer, and colleagues at the University of Basel (Robert

Helmreich is a social psychologist who has long investigated aerospace crew performance issues and is one of the originators of CRM in aviation). [287] Although both ACRM and Team Oriented Medical Simulation (TOMS) share many features, and both derive from the model of CRM in aviation, the TOMS approach has somewhat more emphasis on the social psychology of team interactions in the OR, whereas ACRM has somewhat more emphasis on the cognitive psychology of the anesthesiologist in the context of team interactions. Using the Wilhelm Tell variant of the SOPHUS simulator (in which perfused animal organs are provided to allow laparoscopic surgery), the TOMS group conducts true combined team training of complete OR teams. An OR team of surgeons, nurses, anesthetists, and orderlies is assigned to the TOMS operating room on a given day instead of to their normal OR and conducts routine operative patient care of

TABLE 80-6 -- Evaluation of Anesthesia Crisis Resource Management Course in the Harvard Anesthesia Simulation Training

(Not Available)

the simulated patient just as they would of actual patients. During surgery, one or more adverse events may be triggered by the instructors. As in ACRM, a debriefing session using videotapes of the simulation follows. The TOMS approach emphasizes self-debriefing by the entire OR team and exploration of team communication and interaction issues. All subgroups of the OR team rated the simulations and debriefing sessions as highly realistic and valuable, suggesting to the investigators that "all groups benefited equally from training." [287]

Continuing Medical Education

Most simulation centers offer continuing medical education for experienced practitioners, and nearly all aspects of simulation training for residents (except novice training) can be expanded for this purpose.

Uses of Patient Simulation in Support of Biomedical Industries

Various simulation activities have related to the pharmaceutical or medical equipment industries. Numerous centers (perhaps Gainesville was the first) offer training to executives and sales representatives of equipment and pharmaceutical manufacturers. The simulator allows these individuals to gain some understanding of the clinician's task demands during patient care and of the situations in which their company's drugs or devices could be useful. At the Boston Center for Medical Simulation, this course is dubbed "Anesthesia for Amateurs." Other industrial uses include training personnel in the use of novel pharmaceuticals. Simulators have featured in a multifaceted approach to the launch of the opioid remifentanil. Simulators were used to train the manufacturer's representatives and clinicians in safe use of the drug. Besides offering important educational benefits, the industrial activities are an important source of income for simulation centers that helps to defray the costs of training students and residents.

Simulators have been used to conduct research on human factors issues in the development of new monitoring and therapeutic devices. [288] The simulator also provides a unique test bed and demonstration modality for the preprocurement evaluation of the usability of medical devices from different manufacturers. In my own hospital, this enabled us to conduct an evaluation of a prototype monitoring system that was not yet approved for clinical use and thus could not be evaluated in a preprocurement clinical trial.

Use of Patient Simulation for Training Health-Care Personnel Outside Anesthesia

At different centers, simulators have been used to train diverse groups of personnel in a wide spectrum of health-care domains. Many of the applications of simulation training in anesthesiology, particularly the CRM approach, can be translated to other high-dynamism, high-criticality areas such as ICU, PACU, emergency room, and obstetrics. The extension of CRM training to these areas has been under way at several centers, especially the University of Pittsburgh and at the Boston Anesthesia Simulation Center, which changed its name to Center for Medical Simulation to reflect their "growing interest in simulation among a wide-range of medical specialties" (D. Raemer, personal communication). Such training applications can be geared primarily to physicians in these areas or, better yet, to entire teams of personnel including physicians, nurses, orderlies, and clerks. The simulator can be particularly useful to nursing personnel for conducting in-service training on clinical skills or on the use of clinical equipment.

Other Uses

Other unique applications of simulators have surfaced. Some centers use simulators for conducting "outreach" programs with high school or college students interested in health care. Simulators have been used to help produce educational videotapes concerning various patient safety issues. It has even been suggested that a "Legislator Day" could be held in a simulator center to familiarize legislators with the demands of dynamic patient care.

Other Questions Regarding Simulator-Based Training in Anesthesia and Other Health-Care Domains

Effectiveness

The most important question concerning simulator-based training in anesthesia is its cost effectiveness. This is a complicated question that has two relatively independent components. The first component is: What are the impact and benefit of the training on the performance abilities of participants? The second component is: What does it cost to achieve that impact? In principle, simulation has many advantages as a training tool [273] :

1. There is no risk to a patient.
2. Exercises in routine procedures can be repeated intensively, whereas situations and events involving uncommon but serious problems can be presented at will.
3. Participants can learn to use actual complex devices (with a hands-on simulator).
4. The same situation can be presented independently to multiple subjects for evaluating individual or group performance.
5. Errors can be allowed to occur that in a clinical setting would require immediate intervention by a supervisor.
6. The simulation can be frozen to allow discussion of the situation and its management, and it can be restarted or begun anew to demonstrate alternative techniques.
7. Recording, replay, and critique of performance are facilitated, because there are no issues of patient safety or confidentiality.

The fidelity required of the simulator and thus the choice between screen-only and realistic simulators is dependent on the intended goals of the training and the relevant target

population. A spectrum of computer-based training is possible. Computer-assisted instruction programs and part-task trainers can be used to teach basic concepts and technical material, such as the uptake and distribution of inhaled anesthetics or pharmacokinetics of intravenous drugs. These are appropriate for students, novices, advanced residents, and experienced practitioners. Screen-only simulators are inexpensive and easy to use. They allow the presentation of and practice with the concepts and procedures involved in managing normal and abnormal case situations. They, too, are useful for a large number of user populations. Realistic simulators can be used to capture the full complexity of the real task domain including the human-machine interactions and the complications of working with multiple personnel. They are most appropriately used for residents and experienced practitioners. Regardless of the device used, the simulator is only a teaching tool that must be coupled with an effective curriculum for its use.

The evaluations conducted so far suggest that simulator-based training is a powerful technique that both novice and experienced anesthetists believe to be highly beneficial and that participants and instructors alike believe may improve clinical performance. As the developers of Sim One pointed out, when simulation provides an opportunity to teach material that cannot be taught in another way, as for the systematic instruction of anesthesiologists in handling severe critical events such as

cardiac arrest, anaphylaxis, or malignant hyperthermia, there is *nothing* with which to compare the simulator. Assessing whether the actual outcome of patients can be affected by this or any other training modality will be extremely difficult and expensive. Those investigating simulator-based training do not believe that such an outcome study is logistically feasible. [285] Determining the impact of a given type of simulator training on the intermediate variables of "performance" and "ability" is feasible, but it will not be easy. The Leiden group provided data supporting the contention that simulation training improves performance on handling a malignant hyperthermia situation. However, there is a potential for substantial bias when attempting to measure the impact of the simulator training by using performance in the simulator as a criterion. The control procedures as used by the Leiden group alleviate this bias, but they cannot eliminate it. [282]

Perhaps of even greater importance, there is currently no accepted methodology for measuring the clinical performance of anesthetists either in the simulator or in actual practice. Ironically, the simulator itself provides a tool for presenting the same calibrated situation to multiple anesthetists and may thus be a crucial tool in developing such performance measures.

Evaluation of Clinical Performance During Simulation Situations

Several research groups have been investigating performance assessment tools for use during simulation sessions. The VA-Stanford group has divided performance into two components: technical performance, which is the appropriateness and thoroughness of the medical and technical response to the critical event, and behavioral performance, which is the appropriate use of sound crisis management behaviors (such as leadership, communications, distribution of workload). [104] Simulation offers some benefits in assessing technical performance. Because the nature and cause of the critical incident are known, one can, in advance, construct a list of essential or appropriate technical activities with relative weights of importance. For example, in assessing technical performance in managing malignant hyperthermia, terminating the trigger agent and administering intravenous dantrolene would be essential items, whereas cooling measures, hyperventilation, and bicarbonate therapy would be among many appropriate (but less critical) technical responses. One can also predict in advance specific technical pitfalls. For malignant hyperthermia, these could include diluting dantrolene with the wrong diluent (not sterile water) or an insufficient quantity of diluent. These are pitfalls known to plague those unfamiliar with malignant hyperthermia therapy.

The behavioral component of crisis management must be assessed in a subjective fashion. Two research groups (VA-Stanford and University of Basel) are studying adaptations of the anchored subjective rating scales developed by the NASA/University of Texas Aerospace Crew Performance Project. The VA-Stanford group published preliminary data reviewing the interrater reliability of subjective ratings of behaviors on 5-point anchored scales. [104] Using a fairly stringent test of interrater reliability (the topic is quite complex in the statistical literature), they found only moderate reliability when 5 trained raters scored 14 anesthesia teams, each managing 2 different complex critical events (malignant hyperthermia and cardiac arrest) using a 5-point scale. Although there was some difficulty in agreement on the operational definitions of each type of behavior, the investigators stated that the largest problem in achieving agreement was the high variability of each behavior over the course of a simulation. For example, an anesthesia crew could show evidence of good communication at one instant, only to be shouting ambiguous orders into thin air at the next instant. Aggregating these behaviors into a single rating was extremely difficult, even for bounded time segments of the scenario. These data demonstrate the importance of evaluating performance by more than one rater, who, no matter how well trained, may produce scores that differ significantly from another single rater. The investigators suggested combining scores from a minimum of a pair of raters, showing that the mean of scores from two raters had a very low probability of differing from the mean of five raters by more than a single rating point.

The University of Toronto (Canadian Simulation Centre) demonstrated good interrater reliability between two raters of a simplified performance assessment rating scale. This was tested using scripted, role-played variants of standardized scenarios containing multiple anesthetic problems that were acted out for videotape using the simulator. [105] A subsequent analysis of the rating system showed that there was poor internal consistency among the different anesthetic problems presented in the scenarios. This suggests that the items acted "independently, reflecting different aspects of anesthesia care." When aggregated across the five problems, the results were affected by the "level of importance placed on each problem by individual subjects." [106] The Danish group also gave a preliminary report on their attempts to validate subjective and objective evaluation parameters, a

technique they named "PEANUTS" (Performance Enhancement in Anesthesia Using the Training Simulator). [107]

Can the "clinical" outcome of the simulator's mathematical physiology predict how a real patient would have fared under that individual's care? In extreme cases, this is likely to be true. A subject who demonstrates *totally* erroneous decision-making (e.g., failure to defibrillate a simulated patient with ventricular fibrillation) quickly allows the patient's state to deteriorate unmistakably. However, the mathematical models are not sufficient to predict what would happen to any actual patient after complex sequences of therapy and more subtle patient care judgments.

Thus, the clinical outcome of the simulated patient is one datum that can be used to assess the performance of the anesthetist on a simulation scenario, but for the forseeable future, any credible performance measurement technique *must* involve subjective and semiobjective judgments by clinical experts. The results from the various simulation groups suggest that it will be very difficult to develop a robust set of performance measures of anesthetists' skill, even using the simulator as a tool to present standardized patient scenarios. The data on performance show both a high interrater variance and a high interindividual (and interteam) variability. [53] [90] [91] [93] [104] [282] A definitive study is in principle possible, but it would require a very large number of subjects rated by multiple raters and would thus be complex and costly. Still other factors complicate the assessment of the effectiveness of simulator-based training. Studying the impact of a single session of a course that uses a new technology and a new approach to training may underestimate the course's impact when it is used on a regular and repetitive basis. For example, it is widely believed in commercial aviation that CRM training must begin with the initial training of pilots and must be continued throughout their career. Social psychologists Robert Helmreich and H. Clayton Foushee, two of the main architects of CRM training, have written [128] : "Data indicate that even intensive initial CRM training constitutes only an awareness phase and introduction to the concepts, and that continuing reinforcement is essential to produce long-term changes in human factors practice." Similarly, United Airlines states in its CRM manual [290] : "Command/Leadership/Resource management [United's terminology for CRM] cannot be a one-shot approach. It has to be a coordinated long range program. It must therefore be an integral part of the entire training effort: new hire training, transition and upgrade programs, and recurrent training." Finally, the principles and procedures taught in training must be reinforced within the operational environment. Simulator-based safety training can be totally negated if production pressures or latent failures in the workplace make it impossible to implement its teachings effectively.

Costs

What are the costs of simulator-based training? The costs of simulator-based training depend on many of the same factors that determine the curriculum:

1. Types of training involved, ranging from technology in-service to training in basic anesthesia skills, critical incidents management, or CRM.
2. Target populations for the training, whether equipment technicians, medical students, novice residents, experienced residents, nurse anesthetists, teaching faculty, or private practitioners.
3. Organizational and financial characteristics of the institution.

The hardware and software costs of the screen-only simulator are quite low (as low as $1,500), whereas the equivalent cost of a complete hands-on simulator is relatively high (the prices of commercial simulators are more than $175,000 depending on features; one should contact the manufacturers for detailed information) and do not include the necessary clinical equipment and space. However, even these large expenditures do not dominate in the cost equation because the capital equipment can be amortized over a relatively long useful life, with appropriate provisions for service and upgrades. The dominant cost is likely to be the salaries of expert instructors. An expert must oversee the curriculum, but the type of training and the target population will determine the amount of expert instruction that is required. For example, a single faculty member can review the summaries of exercises performed by residents on a screen-only simulator in a few hours per resident per year. A single instructor can use the simulator to demonstrate pulmonary or cardiovascular physiology to a whole class of medical students. When training novice residents in basic anesthesia skills, it may be possible to have senior residents or fellows conduct the sessions at a low marginal cost. However, when training experienced residents and practitioners in complex material, such as the handling of critical events, there is likely to be no substitute for expert instructors. The cost of expert instruction depends on the organizational arrangements of the institution.

Another organizational factor that affects the cost has to do with making trainees available for what can be complex, exhausting, and lengthy training sessions. Removing residents from revenue-producing work for training purposes is expensive. On the other hand, if simulator training could allow residents or other anesthetists to work more safely and more efficiently, the benefit would outweigh the cost. Some residency programs are restructuring to make the residency supernumerary to the demands of the clinic. In such cases, residents are nearly always available for educational activities, but faculty time may be even more scarce.

As anesthesiology has become less popular as a choice for graduating medical students, many programs have used simulation training as a recruiting tool. These factors support the belief that if simulator-based training is deemed to be desirable, innovative changes in organization will evolve to allow it to occur.

Simulation Centers

Although one can install a simulator in a laboratory or conference room, many institutions have equipped complete simulation centers. Typically, these centers provide a separate control room to allow complex simulations to be presented without an instructor intruding on the simulated case. The center also provides a debriefing room where videotapes of the simulation session can be reviewed. Some centers have elaborate computer-controlled audio-video

systems allowing the recording of multiple views with real-time annotation of the tapes and rapid search to marked portions of the tape. Dedicated centers facilitate all types of research and training applications of simulators, but they are especially important for intensive activities such as ACRM. Typically, a technician, an anesthesia fellow, or an administrator manages the center, coordinating scheduling and logistics, as well as assisting the experienced clinicians conduct training and research.

The costs of a simulator training program can be shared among the anesthesia departments of multiple institutions, as was the case at the Boston Anesthesia Simulation Center. The cost can also be shared among departments within a single institution because the simulator can be a resource tool for other training in other areas besides anesthesia. The anesthesia simulator is really a simulator of the critically ill patient, which can be a suitable platform for training of physicians, nurses, technicians, and other medical and technical personnel. Multiple different simulator-based curricula have been developed at the various simulation sites.

Proliferation of Simulation Centers

At this time, despite the lack of definitive cost-effectiveness data, training with realistic simulators is under way in more than 100 sites around the world, with many of them choosing to conduct fairly "high-end" crisis-management and critical-incident training sessions. These programs have already "voted with their feet" on the issue of cost versus benefit. With so many centers exploring the realities of simulation training, we can expect to see some data on efficacy and cost within the next few years.

Therefore, it is too early to make definitive statements about either the benefits or the costs of simulator-based training in anesthesia. To some extent, a catch-22 is involved. One cannot attempt to determine the true costeffectiveness until simulation is widespread enough for complex and expensive studies to be undertaken and until there is more experience concerning the different organizational aspects of providing the training. On the other hand, many institutions will shy away from taking the risk until the cost-effectiveness is proven.

Uses of Patient Simulation for Research

The utility of simulators for studying the cognitive processes of anesthetists has already been discussed. Simulators will be important tools for addressing numerous questions concerning the fundamental limitations of the human performance envelope in the anesthesia domain. A sampling of these questions is listed in Table 80-7 .

Can Simulators Be Used for the Evaluation and Testing of Residents or Practitioners?

As discussed previously in this chapter, patient simulators should be useful tools for evaluating the performance of

TABLE 80-7 -- Research Issues That Can Be Addressed Using Anesthesia Simulators

Cognitive science of dynamic decision-making
What is the interaction of precompiled procedural knowledge versus deep medical knowledge and abstract reasoning?
How does supervisory control of observation relate to vigilance, data overload, and visual scanning patterns?
What is the information content of watching the surgical field?
How are optimum action planning and scheduling implemented?
How does reevaluation fail, resulting in fixation errors?
Human-machine interactions
What is the distraction penalty of false alarms?
Is there an advantage to integrated monitors and displays versus multiple stand-alone devices and displays?
How easy to use are the controls and displays of existing anesthesia equipment in standard case situations and in crisis situations? Do they invite mode errors?
What is the mental workload imposed by a new diagnostic device such as transesophageal echocardiography?
Teaching anesthesia in the operating room
How much teaching can be accomplished in the operating room without sacrificing the anesthesia crew's vigilance?
How well can faculty detect and categorize the performance of anesthesia trainees?
What teaching styles are best integrated with case management in the operating room?
Teamwork
How does the anesthesia crew (attending plus resident or CRNA pair) interact during case and crisis management? How is workload distributed among individuals? How do crew members communicate with each other, and how do they communicate with other members of the operating room team?
Effects of performance-shaping factors on anesthetist performance
How do sleep deprivation, fatigue, aging, or the carryover effects of over-the-counter medications, coffee, or alcohol affect the performance of anesthetists?
Intelligent decision support
Can smart alarm systems or artificial intelligence provide correct and clinically meaningful decision support in the operating room or intensive care unit?

trainees and others. However, scoring or certifying competence using the simulator is more problematic than is using it as a teaching tool.

Anesthetists have discussed the possibility of using the simulator as a tool for examinations, either for graduation from a residency or for the American Board of Anesthesiologists. This use would require independent evaluation of the simulation scenarios and of the predictive power of the subjective judgments made by experts scoring the examinee. Here, too, an obstacle is the lack of any well-accepted gold standard for performance evaluation. Another difficulty with using simulation for Board certification testing is that the OR equipment would rarely be the same as that used by the candidate, and the OR staff's operational protocols could differ from those familiar to the candidate. In the training situation, these difficulties can be overlooked as part of the global "suspension of disbelief" needed to maximize the benefits of simulator training. In the test situation, these differences could potentially skew the results.

Despite these difficulties, it is likely that if the use of anesthesia simulators does become more widespread, anesthetists will become more interested in using them to assist in evaluating performance. The existing system of performance evaluation that uses a relatively haphazard system of subjective judgments of clinical competency in residency

along with written and oral examinations has itself never been validated. Many believe that the written examination does not correlate well with clinical ability, and the degree to which the oral examination process tests actual clinical skill is unknown. Simulation could offer candidates the ability to demonstrate the clinical abilities in a controlled clinical domain, while still demonstrating their consulting and language skills through oral examination.

The first trials of evaluation using simulators may occur in situations for which the evaluation is a nonthreatening critique or is graded "pass/fail." Another situation would be for the evaluation of residents who have been placed on probation or for whom dismissal from the residency program is already a distinct possibility. For these residents, the burden of proof is on them to demonstrate their skills. The simulator could offer a more controlled environment for them to do so. The same could be true for practitioners who wish to return to clinical work after a hiatus.

Future of Patient Simulation in Anesthesia

Although past its first decade of consistent development, the field of anesthesia simulation is still new. Simulators have become more sophisticated, and users can now choose from different models offered by multiple manufacturers. Improvements in simulators will depend on the demand for the devices and on the tradeoff between fidelity and cost. Many otherwise desirable improvements may be too costly for the impact that they can be expected to produce.

The physiologic and pharmacologic models used in the simulators have become more sophisticated, supported by ever-improving computer hardware. However, medical simulators will remain far behind those used in aviation. Unlike aeronautical engineers, physicians do not design and build the system they wish to model. The fundamental differential equations of fluid mechanics and aerodynamics are firmly established, allowing supercomputers to provide technically meaningful simulations as replacements for many wind tunnel tests. Furthermore, there still are wind tunnel tests as well as test flights of actual prototype aircraft. Sophisticated instrumentation can be built into test structures to define their behaviors accurately. Physicians will never have this type of knowledge about the human body.

A profound milestone will be the development of virtual reality simulators that will eventually allow the subject to be completely immersed in a simulated situation without physically replicating the OR environment. Hardware and software will soon be released for consumer-level virtual reality games. As the field expands and matures, the tools will become available to convert screen-only simulators or realistic simulators to virtual reality. For some time, however, realistic simulators will offer some advantages over virtual reality. A virtual reality system would have to contain computer models of all available monitoring equipment. The realistic simulator deals with this by simulating actual clinical equipment. Realistic simulators will have an advantage for simulation scenarios involving multiple personnel such as ACRM and other combined team training until the technology is available for complex linking of multiple individual virtual reality simulators. The early 21st century will probably see virtual reality simulations take over from computer screen and realistic simulations. Virtual reality will become the norm for training in many complex work fields, and virtual reality technology is likely to change the nature of work itself.

Patient simulators have emerged from their purely experimental phase to become an accepted, although still new, component of research and training in health care. It is highly likely that simulators will become a regular part of the initial and recurrent training of most anesthetists and of many other clinicians. The anesthesia community can be proud of its pioneering role in developing patient simulation technology and simulation-based training curricula. As this process continues, it is also likely that anesthetists will continue to lead the rest of health care in the evolution of this technology and of its educational, research, and evaluation applications.

Chapter 81 - Teaching Anesthesia

Alan Jay Schwartz

"Pedantic" is a description teachers wish to avoid. In the interest of doing this, I offer a fifth grader's biography of the great teacher Socrates: [1]

```
Socrates was a man.

Socrates was a Greek.

Socrates went around telling people what to do.

They poisoned him!
```

INTRODUCTION

This chapter on anesthesia education is not intended in such a manner that I risk Socrates' fate but rather is intended to be provocative, to give cause for thought to an important subject not often reflected on. All of anesthesia education can be easily considered in the following question (Greenhow DE: personal communication, 1982):

> How shall who teach what to whom for what purpose now and in the future?!

Anesthesia education is presented using this question as the framework for consideration. This chapter provides a philosophy of teaching anesthesia rather than a detailed account of the many aspects of anesthesia education (e.g., operating room anesthesia versus critical care medicine versus cardiopulmonary resuscitation versus chronic pain management).

TEACHING AND EDUCATION

Teaching, in a narrow sense, the way most of us think about it, is an activity by an individual aimed at causing another person to know some new fact or to know how to accomplish some new task. The focus appears to rest on the teacher and the activity of teaching. It does not take long to realize, however, that this way of looking at the teaching/learning activity has misplaced emphasis. If not with the teaching activity, where does the emphasis belong? The answer to this question lies in understanding the definition of education.

Education is an all-encompassing process (not merely a specific activity) resulting in a change in behavior on the part of the student/learner. The focus of education is the learner, not the teacher. It is the student who is educated by interacting with an environment that provides experience(s). *Education is a change in behavior based on experiences.* The experiences most often include the student's interacting with a teacher but are almost never limited to that alone. The entire milieu defines the total experience (Fig. 81-1) (Figure Not Available) . When the milieu changes, so may the education; that is, the change in behavior exhibited by the student may vary dramatically if the milieu is varied.

Picture the educational setting in which an anesthesiology resident is learning how to use epinephrine when weaning a patient from cardiopulmonary bypass. The knowledge and skills that must be learned include application of the pharmacologic principles of catecholamines to the pathophysiology of cardiovascular disease by turning on a mechanical infusion pump to deliver the indicated dose of a medication while technically monitoring for dose response and toxicity. Learning these facts and the skills sufficient to employ them is much different when done from a textbook or a preoperative conference with a staff preceptor than when done during the operating room interaction between the surgeon and anesthesiologist, where varied opinions may consider dopamine a more sound physiologic choice or intermittent boluses a better administration technique. The interposition of the concerned surgeon and real-time patient setting between the student and the knowledge and skills to be learned changes the learning environment and, hence, the educational experience for the resident. More is learned than the facts and psychomotor skills. As the attitudes of both the anesthesiologist and the surgeon are displayed during the resolution of the questions about the "best" drug to use and the "right" way to give it, the resident learns how these two types of practitioners are supposed to relate to one another.

It seems obvious, therefore, that there is more to consider than just teaching. What more is there to the anesthesiologist's responsibility than just teaching those around him or

Figure 81-1 (Figure Not Available) Diagrammatic representation of the educational experience. The two major components are the plan for teaching and the process of education that actually occurs. At the core is the content (cognitive, psychomotor, and/or affective) to be taught and learned. Growing out of the content are the planned goals of education, the methods and the program of instruction, and the environment in which the teaching and learning will occur. In the diagram, each building block of the plan is added to the previous one in an all-encompassing fashion. What is planned as education and what is experienced may or may not be the same. As represented by the diagram, the educational process that actually occurs includes all of the plan and layers on it, both the real environment and teacher/student interactions that provide the education, that is, the experiences on which the student's behaviors ultimately change. *(Modified from Atkins [43])*

her? The answer is provided by answering the component parts of the question posed at the beginning of this chapter.

```
Teach to whom?

Why teach?

Who teaches?

What to teach?

How to teach?
```

THE STUDENTS

The simplest answer to the question "Who learns anesthesiology?" is "those who will provide anesthetic care to patients." Included are the anesthesiologist, nurse anesthetist, and dentist who administers anesthesia for dental procedures. [2] [3] Also to be included are the many varied paramedical personnel who participate in patient care activities related to primary anesthetic care; the anesthesia technician, anesthesia aide, postanesthesia recovery room nurse, physician assistant, surgeon assistant, respiratory therapist and aide, intensive care/critical care/emergency room/trauma nurse, perfusionist, emergency medical technician/paramedic, cardiopulmonary technologist, pulmonary function technician, and blood gas laboratory technician. [2] [3] Each of these occupations is intimately related in some way to the body of knowledge that constitutes the practice of anesthesiology.

In a much broader sense, the entire medical community can be considered appropriate learners of anesthesiology. Medical students, for example, are appropriate candidates for learning a core of anesthetic knowledge and skills, specifically those that are essential for the training of all physicians. Basic central nervous system, cardiovascular, and pulmonary diagnostic monitoring, as well as emergency airway management and the clinically applied pharmacology of local anesthetics, are some of these essentials. Medical students, graduate physicians, and paramedical personnel of many types are appropriate learners because all are often faced with the task of educating the lay public about anesthesiology. Who learns anesthesiology, therefore, are those who practice it or perform related duties that require some understanding of the subject.

Another way to address the question of who learns anesthesiology is to answer, adult learners. *What describes an adult learner?*[4] How are adult learners unique? Adult learners are those with strong *motivation* to participate in a set of experiences, for example, a curriculum, to learn a specific discipline. The discipline they want to learn is one they are interested in and/or need to know. The resident actively seeks out education in anesthesiology. The sixth grader (a child learner) in contrast does not seek out education in arithmetic. Adult learners participate in *life-centered* situational learning in the area(s) in which relevance is most likely.

Adult learners enter the learning activity with a wealth of *prior experiences.* They therefore view the current educational experiences in light of their background. The internist who enters an anesthesiology residency in preparation for a career in intensive care medicine has a rich resource background in medical practice. Adult learners can capitalize on this prior learning. At the same time, however, the previous learning may color how the current learning takes place. The key for the teacher is to acknowledge the adult learner's expertise and build the new education on it, rather than downplay it and in essence, "reject" the adult learner.

Working together in a mutual peer relationship with the teacher, adult learners are *self-directed.* Where the child learners need a set of directions that originate from the teacher, the adult learners initiate their own activities. Because adult learning is goal oriented toward relevant life-centered needs, the adult learner tends to pick and choose some, not necessarily all, of the educational activities available.

Strong commitment and specific intentional attachments uniquely characterize adulthood. Marriage and child rearing are examples of such commitments and attachments. At the same time that adults make commitments, their lives are evolving and they pass through many *critical life stages* (e.g., assuming financial responsibility, coping with the illness or death of a parent). These strategic choice points in life impact

---

adult learning. The decision by an anesthesiology resident, for example, to extend his or her education an additional year to learn a subspecialty or to participate in research training may be based on the total financial debt incurred for medical education up to the time of residency and the need to repay that, weighed against the acuteness of the family financial needs.

Inherent differences among people tend to increase with aging. Adult education must provide for the difference in style, time, place, and pace of learning among adult learners. The time factor for learning is especially crucial for adults. Adults perceive that time passes more rapidly, that is, there is *less time available* to learn, or do anything, for that matter. With time perceived to be in short supply, adult learners tend to be selective in their learning in order to use what time they have more efficiently. The anesthesiology resident may devote time to learning in the operating room and weekly departmental case conference but may choose to skip the journal club to spend time with the family.

Recognition of the special traits that adult learners possess allows the anesthesiology educator to provide an educational program acceptable to the student rather than one that is rejected. Assessing the needs of the adult learner and using this as a springboard from which a curriculum is designed is more likely to result in a good educational outcome than to impose on the learner what the teacher alone thinks is right.

THE REASONS

An obvious reason for teaching anesthesiology is that we as a specialty have defined this as part of our identity [5] (Ch. 1) :

> The American Board of Anesthesiology, representing the medical specialty of anesthesiology and perioperative management, exists in order to: ... maintain the highest standards of practice by fostering educational facilities and training in anesthesiology and perioperative management which the ABA defines as the practice of medicine dealing with but not limited to: ... teaching of cardiac and pulmonary resuscitation. ... supervision, teaching and evaluation of performance of personnel, both medical and paramedical, involved in perioperative care.

In addition to our own description, others define anesthesiology in similar terms [2] :

> [An anesthesiologist] may instruct medical students and other personnel in characteristics and methods of administering various types of anesthetics, signs and symptoms of reactions and complications, and emergency measures to employ.

Teaching anesthesiology is clearly one component of an anesthesiologist's daily activities. In some instances, this means providing the experiences necessary so physician trainees can achieve consultant anesthesiologist status. In other settings, this means providing the experiences necessary so other medical and paramedical professionals can achieve a level of expertise appropriate to their required competencies: for example, for an internist, the ability to understand anesthesiology sufficiently to relate to anesthesiologists and educate patients about anesthesiology; for a postanesthesia recovery room nurse, the ability to understand anesthesiology sufficiently to care appropriately for patients emerging from anesthesia and to be versed in the critical care aspects of the preanesthesia and postanesthesia periods to provide life support if necessary.

Another major purpose for teaching anesthesiology is to provide a common set of learning experiences that when mastered by students will lead to relatively standardized behaviors. These standards (minimum standards though they may be) become the criteria by which a student candidate can be evaluated for entry into a specified mastery level. [5] [6]

Becoming a consultant anesthesiologist certified by the American Board of Anesthesiology (ABA), for example, depends on being able to demonstrate that one possesses a minimum standard of knowledge and skills in, and attitudes about, anesthesiology. [5] The public trust is gained by this process of specialty certification because this ensures that the certified specialist has met the defined standards of anesthesia practice. [5] Although specialty certification culminates in evaluation mechanisms (achieving clinical competence as attested to by the training program and successfully passing written and oral examinations), the certification process is driven by the educational activities focused at teaching the resident how to become a consultant anesthesiologist. [5] [6] A key part of this is the establishment by the ABA of the training curriculum or continuum of education in anesthesiology. [5]

The resident trainee in anesthesiology voluntarily enrolls in a training program and accepts the ABA's approved curriculum and evaluation (testing) protocol. Coupled with the physician candidate certification process is the residency training accreditation process. [7] Training program accreditation is a voluntary process whereby an institution applies for recognition of its anesthesiology residency as meeting a minimum set of teaching standards. Such recognition is achieved from the Accreditation Council for Graduate Medical Education (ACGME). The ACGME represents the combined "wisdom" of all specialty residency review committees in its publication of *Institutional Requirement of Accredited Residencies.*[7] The more focused training guidelines published as *Program Requirements* are defined by the Anesthesiology Residency Review Committee, a group representing the ABA, the American Society of Anesthesiologists, and the American Medical Association. [7] These include Program Requirements for Residency Education in (1) Anesthesiology, (2) Anesthesiology Critical Care Medicine, (3) Pain Management, and (4) Pediatric Anesthesiology. [7] [8]

The teaching responsibilities addressed by the candidate certification and residency training accreditation processes are clearly articulated by the ABA [5] :

> Establish and maintain criteria for the designation of a Board-certified anesthesiologist.
>
> Inform the ACGME concerning the training required of individuals seeking certification as such requirements relate to residency training programs in anesthesiology.
>
> Establish and conduct those processes by which the Board may judge whether a physician who voluntarily applies should be issued a certificate indicating that the required standards for certification or recertification as a diplomate of the ABA have been met.
>
> A Board-certified anesthesiologist is a physician who provides medical management and consultation during the perioperative period, in pain management and in critical care medicine. A diplomate of the Board must possess knowledge, judgment, adaptability, clinical skills, technical facility and personal characteristics sufficient to carry out the entire scope of anesthesiology practice. An ABA diplomate must logically organize and effectively present rational diagnoses and appropriate treatment protocols to peers, patients, their families, and others involved in the medical community. A diplomate of the Board can serve as an expert in matters related to anesthesiology, deliberate with others, and provide advice and defend opinions in all aspects of the specialty of anesthesiology. A Board-certified anesthesiologist is able to function as the leader of the anesthesiology care team.

Because of the nature of anesthesiology,
the ABA diplomate
must be able to manage emergent life-threatening situations in an independent and timely fashion. The ability to independently acquire and process information in a timely manner is central to assure individual responsibility for all aspects of anesthesiology care. Adequate physical and sensory faculties, such as eyesight, hearing, speech and coordinated function of the extremities, are essential to the independent performance of the Board-certified anesthesiologist. Freedom from the influence of or dependency on chemical substances that impair cognitive, physical, sensory or motor function also is an essential characteristic of the Board-certified anesthesiologist.

Establish and conduct those processes by which the Board
may judge whether a physician who voluntarily applies should be issued a certificate indicating that the required standards for subspecialty certification or recertification in an ABA designated subdiscipline of anesthesiology have been met.

The ABA-ACGME model addresses the purpose of education in anesthesiology and clearly outlines the anesthesiologist's responsibilities in teaching colleagues. Other organizational models similar to the ABA-ACGME example serve the same function for teaching physician anesthesiologists outside of the United States.

Meeting the teaching responsibilities for nurse anesthesia is standardized in similar fashion to the ABA-ACGME model. For nurses, the Council on Accreditation of Nurse Anesthesia Educational Programs and the Council on Certification of Nurse Anesthetists serve similar functions to the ABA-ACGME model. In 1996 to 1997, 85 nurse anesthesia educational programs of 24 to 36 months' duration educated nearly 2,200 students in approximately 700 clinical training sites using 2,737 certified registered nurse anesthetists and 1,416 anesthesiologists as faculty (Council on Accreditation of Nurse Anesthesia Educational Programs: personal communication, 1998). After the first 2 years of certification, certified registered nurse anesthetists are required to achieve biennial recertifications under the auspices of the Council on Recertification of Nurse Anesthetists. Education for other health care professionals is coordinated by 13 agencies accrediting training programs in 40 professions. [9] These agencies provide the guidelines for education in a standardized fashion so that professionals in 40 allied health occupations can gain certification in their respective disciplines. [9] Forty-eight professional organizations (including, for example, the American Society of Anesthesiologists), serve as experts in their fields, working hand-in-hand with the 13 agencies to accredit the educational programs for the health professions. [9] The magnitude of this teaching responsibility becomes clear when one realizes that in 1997 to 1998, 2,094 institutions sponsoring nearly 5,000 accredited programs trained approximately 150,000 students. [9]

Occupations that are related to anesthesiology and for which standardized educational programs have been defined, benefiting from the Commission on Accreditation of Allied Health Education Program's (one of the 13 accrediting agencies referred to earlier) blending of experts' guidance about teaching, include anesthesiologist's assistant, cardiovascular technologist, emergency medical technician- paramedic, perfusionist, physician assistant, respiratory therapist, respiratory therapy technician and surgical technologist. [9] These occupations are taught in 834 accredited programs. [9] Students enrolled in these training programs during the 1995 to 1996 academic year numbered 31,820. [9] This teaching responsibility for other health care professionals compares with the commitment to educate 3,708 resident anesthesiologists in 147 accredited American anesthesiology residency programs in 1997. [10] Adding the tasks of teaching medical and allied health care students, participating in continuing education for anesthesiologists, and teaching other practicing physicians and allied health care professionals increases the educational responsibilities of anesthesiologists in an exponential fashion.

One reason we teach anesthesiology is that we recognize the need to provide uniform educational experiences so students participating in these activities can reach a goal; that is, they will be acknowledged as competent in the discipline. So important is this process that it has been incorporated into the very definition that we use to describe ourselves. Now more than ever, competence and physician performance are concepts that are key in the minds of the public consuming medical care, the agencies paying for medical care, and the institutions and individuals providing medical education. [11] [12] [13] The United States has a system designed to assess medical competence by defining and ensuring the processes of education, licensing, accreditation, and certification. [11] [12] More and more, recredentialing is being added to this list.

To address the multitude of questions that have been posed about recredentialing and continued "competence" of physicians initially certified as consultants, especially questions related to the public trust, in 1989 the ABA established a mechanism for revalidation of the primary certificate called continued demonstration of qualifications (CDQ). [5] [14] [15] This program allowed anesthesiologists to demonstrate their continuing qualifications through a voluntary recredentialing program that had been years in development. [15] The first implementation of CDQ, with its two components--(1) documentation of an anesthesiologist's approved practice credentialing and (2) administration of a secure written examination to assess an anesthesiologist's current knowledge of anesthesia practice--took place in 1993. The CDQ certificate allowed anesthesiologists a means to accomplish recredentialing for needs defined by governmental, health care finance reimbursement, hospital, or other regulatory bodies.

Since the development of the voluntary CDQ recredentialing mechanism, the ABA has developed a more formal recertification process. In 1994 and 1995, the ABA adopted time-limited certification, that is, all specialty (anesthesiology) certificates issued by the board on or after January 1, 2000 will be valid for 10 years from the time of completion of the examination for the initial certification. [5] [16] To complement this, in 1996, the ABA converted the CDQ mechanism

into the recertification process containing the same two components described earlier. Anesthesiologists who are Board certified in the next century and wish to remain so after the end of the time limit on their certification will be required to formally recertify and obtain a new Board certificate rather than revalidate the primary certificate. [5] [16]

Since 1985, the ABA has had a certification process for the subspecialty of critical care medicine. As of December 1997, the ABA has not deemed the critical care certification process time-limited. In 1991, the ABA began certification of pain management subspecialists. The ABA pain management certificate is time-limited, that is, it is valid for 10 years from successful completion of the examination for pain management certification. Recertification in pain management, therefore, will be operative in a fashion similar to that described earlier for recertification in anesthesiology. Similar models for continuing medical education and documentation of physician competence are being developed in other countries as well as the United States. [17] [18]

Anesthesiology education for physicians and other health care professionals is, as described earlier, a specific application of assessing medical competence by process evaluation. An equal and perhaps even more important question is how to evaluate the outcome of the education rather than the process by which it is achieved. [11] [12] The question of why we teach medicine, specifically anesthesiology, is best answered by saying that we want physicians and other health care professionals to perform the activities of anesthesia practice at a specific level of achievement. Although we are very good at evaluating knowledge, outcome assessment of practice is not easily measured. Outcome assessment, that is, evaluation of the practice aspects of anesthesiology, represents the greatest challenge for the future. [11] [12]

One such assessment demonstrates the value of the ABA-ACGME model of educating and certifying physician anesthesiologists. Silber et al, [19] in their study of almost 6,000 patients undergoing prostate or gallbladder surgery in multiple hospitals, demonstrated that patient recovery or "rescue" from an adverse event correlated with the proportion of Board-certified anesthesiologists in the hospital.

Outcome analysis is also becoming a part of the training process for anesthesiologists. [20] An example of this type of approach in an educational setting, employing quality improvement concepts developed in industry, has been described. [20] This is also appearing in posttraining practice settings as a form of continuing medical education as well as a quality assessment tool. [21] We will undoubtedly see more of this type of approach as the pressures of health care economics help restructure

our clinical practice.

/das/book/view/29494766/875/890.html

THE TEACHERS

Anesthesiology is taught by physician anesthesiologists, the experts in the field, and other expert individuals in related disciplines, examples of whom include pharmacologists, physiologists, biomedical engineers, pediatricians, and neurosurgeons. Full-time anesthesiology faculty positions in United States medical schools in 1997 to 1998 numbered 4,860. [22] The majority (96.5%) of these budgeted positions were filled. [22] Anesthesiologists represent approximately 6 percent of the clinical teachers and 5 percent of all American medical school teaching faculty. [22] The 4,860 anesthesia faculty in medical schools bear the major responsibility for teaching some or all of the more than 66,700 enrolled undergraduate medical students, the 3,708 graduate trainees in anesthesiology residency training programs, as well as many of the approximately 98,100 other physician house-staff trainees. [10] [22]

Clinical care, teaching, research, and administration are major roles assumed by faculty. For anesthesia faculty, clinical care is the prime activity for obvious reasons. The other functions are attended to as time and resources permit. For this reason, teaching is often relegated to a lower level of priority, not always adequately acknowledged in career advancement decisions. Junior faculty are frequently expected to take on a large part of the teaching load. This expectation, however, could be viewed as a case of reversal of the proper roles for the junior and senior faculty. [23] Junior faculty have the heavy teaching load during the phase of their career when they lack experience. [23] Senior faculty, on the other hand, are responsible for departmental, institutional, and/or specialty roles that limit their availability for teaching, though these same individuals have vast experience and could teach much. [23] The extreme example of this dichotomy is the expectation that house staff teach the more junior of their ranks and/or medical students. Perhaps the teaching role for house staff would be best accomplished by making the resident a teaching apprentice who not only receives general medical and anesthesiology specialty education but also is educated about education.

Little specific information exists about the teaching credentials or qualities of anesthesiologists. These have been described for other physician groups. [24] [25] These descriptions can be used to infer what does or could characterize anesthesiology teachers. Physician teachers in general are not trained as educators. [24] They have not had formal training in educational psychology or methodology. [24] Physicians who teach do not use the educational resources available. [24] When faced with a new or difficult educational assignment, physician teachers rarely read the medical education journals, nor do they consult educational experts as they might seek help, for example, from a cardiologist when treating a difficult patient. [24] Physician teachers, for the most part, mimic their own teachers, who also had little or no formal training as educators. [24] Although we would not trust a general surgical resident to perform a complicated neurosurgical dissection and achieve a good outcome for the patient, we do entrust an anesthesiology trainee to faculty who have limited educational expertise, hoping for a good learning outcome.

What characterizes a good teacher? Effective clinical teachers, who are able to succeed at the bedside teaching encounter, display specific actions noted by their students and themselves. [25] Table 81-1 (Table Not Available) presents a schema that was developed by observing internists teaching internal medicine residents and medical students. The similarity of the attending anesthesiologist teaching at the bedside in the intensive care unit and/or in the operating room is striking.

A teaching responsibility that anesthesiology faculty might consider is how to blend their "expert" status as anesthesiologists with their "novice" status as teachers. As the experts, teachers of anesthesiology can define educational objectives based on the competencies they believe newly

TABLE 81-1 -- Traits of Effective Clinical Teachers

(Not Available)

Adapted from Mattern et al [25]

trained anesthesiologists need. Having set the objectives, the teacher can direct the educational process by selecting the appropriate learning activities and then designing tests that assess the learning. As described, the "authoritarian" teacher, the expert, determines the educational ends that must be met, defines the means to those ends, and requires conformity to these ends by the student.

Although anesthesiology faculty provide education using this type of curriculum design, few if any know they are employing Tyler's model, nor do they realize that there might be equally good alternatives. [26] Dewey's progressive education offers one such alternative. [27] The philosophy of education elevates students to a level where they can join in a partnership with the teacher. For students of anesthesiology, the adult learners described previously, this type of student-teacher relationship may make good sense.

An example of these two philosophies put into action clarifies their differences. Let us consider teaching/learning how to manage a patient who is being mechanically ventilated in the operating room. The Tyler teacher might lecture to the residents on how to use the ventilator. It is hoped that the residents will remember what they heard and be able to put what they learned into action. In contrast, the teacher using Dewey's approach might create a patient simulation exercise in which residents can "experiment" with differing ventilator setups to infer what might occur clinically. A much more meaningful learning environment might be provided by the simulation--coupled with the anesthesiologist faculty member's reactions to and guidance about how the residents tinkered with the ventilator--than might be provided by the lecture format. In addition, the teacher using Dewey's philosophy might be more likely to encourage the student with prior experience, like residents who used different types of ventilators during their internship, to share their know-how with other, less experienced, peers.

This chapter is discussing the component parts of the question "How shall who teach what to whom for what purpose now and in the future?" It should be obvious that individually studying the component parts of the question is an artificial separation for teaching purposes. To fully understand the question, its parts must be linked to one another. The consideration "Who teaches anesthesiology?" is an example of how the blending of the individual parts of the total picture of anesthesia education must occur. It is virtually impossible to talk about the teacher without bringing the student and the educational needs into the discussion. This key concept, that is, the importance of knowing not only the component parts of education but how they interrelate, is essential for understanding and implementing anesthesiology education.

THE CURRICULUM

The table of contents from any standard anesthesiology textbook provides a broad outline of what to teach in anesthesiology. Similar to a medical school course outline, anesthesiology is a mix of the fundamental basic sciences applied to clinical practice as they relate to specific pathophysiologic disease entities. Patients with these problems present in preoperative, intraoperative, and postoperative settings; therefore, the content is taught as it specifically applies to these different patient environments. This framework of basic and clinical science is used for teaching anesthesiology to all health professionals with particular emphasis placed on those areas most pertinent to the particular group being taught (e.g., detailed teaching about the mechanics and clinical application of ventilators is provided to student respiratory therapy technicians).

An accepted uniform content outline that has been agreed on for teaching physician anesthesiologists has been updated. [28] The major outline headings are listed in the Appendix. Few teachers would be at a loss to define the content of anesthesiology teaching. Anesthesiology education, however, is not limited to content teaching alone.

There are three major areas for teaching/learning all subjects: cognitive, psychomotor, and affective. For anesthesiology, it appears that the *cognitive teaching/learning* area is well defined. It is the responsibility of the anesthesiology teacher, however, to go further than just listing the content topics. Teaching in the content area requires attention to increasingly complex cognitive functions. Described by Bloom, [29] teaching/learning in the cognitive domain for any topic addresses the following:

1. Knowledge--recall
2. Comprehension--understanding
3. Application--use of abstractions
4. Analysis--break down; seeing the relationship of parts
5. Synthesis--put together; creating a new entity
6. Evaluation--judgment of value

Knowing the facts about pulmonary function is obviously much more basic than being able to apply them to the management of a multiple trauma patient on a ventilator. The teacher of anesthesiology serves the students well by considering the more complex aspects of cognitive learning.

A general taxonomy of *psychomotor skill teaching/learning* for universal application to all educational settings does not exist because of the great variability of this type of domain among disciplines. A broadly accepted, standardized outline of psychomotor skill learning for anesthesiology also does not exist. There are many psychomotor skills that anesthesiologists and other related health-care professionals need to learn. Perhaps a major challenge for the teachers of anesthesiology is to codify the fundamental and supplemental

---

psychomotor skills that must be taught and learned. This is beginning to occur with the introduction of practice parameters or practice guidelines developed by medicine in general and anesthesiology in particular. [30] [31] [32] [33] [34] [35] [36]

Affective teaching/learning deals with feelings or emotions. The taxonomy of affective learning addresses the following [37] :

1. Receiving
2. Responding
3. Valuing
4. Organizing
5. Value complexing

While we actively and consciously teach in the cognitive and psychomotor areas, we are much less aware of our affective teaching. Even though we may not be aware of it, however, we are constantly teaching in the affective arena by therole modeling we perform. Earlier in this chapter an example of how affective teaching and learning takes placewas described. In the real-life setting, the aggressive,passive-aggressive, or passive posture of the anesthesiology teacher interacting with the surgeon provides a lasting lesson in the affective domain for the resident anesthesiology learner.

Thinking about affective learning results in arriving at the goals for such learning, which permits development of teaching plans to achieve the goals. Only if we decide how we believe we as anesthesiologists and health-care professionals in related fields need to behave in relation to others, will we be able to teach professionalism and these psychosocial skills to our students. [38]

Another example of the importance of affective learning concerns our approach to the teaching task. When our students sense our own enthusiasm about and commitment to a particular topic, their attitudes about it follow suit. In similar fashion, if we as teachers are negative about some aspect of learning, we can expect our students to mimic these feelings.

The charge that teachers of anesthesiology must accept is that they must be conscious of the emotions they display and prospectively decide on the values they wish to teach because affective teaching and learning occurs all of the time.

Defining the areas of learning (i.e., what to teach) makes it possible for the teacher to devise methods to evaluate the success of the teaching endeavor. For anesthesiology education of physicians, the ABA examination and certification protocol evaluates the three areas of learning. The written examination tests cognitive learning, although perhaps at its more simple levels. Psychomotor and affective learning is evaluated in an ongoing manner by anesthesiology faculty of residency training programs and is attested to by the faculty granting a certificate of clinical competence to the successful learners. The oral examination evaluates cognitive learning, one hopes at its more complex levels. In addition, the oral examination may assess affective learning, although this is accomplished in an unsystematic approach.

/das/book/view/29494766/875/892.html

THE METHODS

When faculty members talk about education, one of their first considerations is how to teach. Although this is obviously an important aspect of instruction, it is of relatively minor importance when viewed in the entire context of education. Before one can decide if a lecture is a better method to teach a specific topic than a group discussion, or whether slides, a chalk board, or computer-assisted instructional software should be used to facilitate making a concept clear, it is essential to understand the student, the student's needs, the purpose of the education, and the content to be taught.

Too often, the instructional methodology, which is easy to consider, receives the major emphasis, while the difficult questions about education, such as what is its rationale, are glanced over or never even considered. After the fundamental questions about educational philosophy are answered, the selection of a particular instructional technique becomes critical. The specific teaching method selected is intended to be the one best suited to the specific educational goal desired.

Use of simulation games is a good example of how the method satisfies the educational goal. In cardiopulmonary resuscitation training, the simulated cardiac arrest is an exercise in which students play the resuscitator roles using all of the real-life equipment in a real-time setting. The involved students as well as other students and the teacher or teachers who observe the simulation review and critique the resuscitation to point out correct actions and those that could have been performed better. The goal of the exercise is to teach the students to coordinate the entire cardiopulmonary resuscitation effort, bringing together the facts and skills in an atmosphere in which reasonable attitudes are exhibited despite the tense nature of the emergency situation, all without jeopardizing any patient. A lecture, a slide show, or even a small group discussion could not achieve this goal.

Simulation is becoming an integral teaching methodology in anesthesia education. [39] Borrowed from flight simulation, which is an essential part of the training and certification of commercial and military pilots, anesthesia patient simulators have been developed and utilized to educate individuals in the discipline of anesthesiology in two major ways: (1) for specific recognition and management of critical events and (2) in the general comprehensive education about all aspects of anesthesia patient care. By coupling a mannequin with a computer and anesthesia patient care equipment, a simulation setting is created that so closely mimics real life that it is a virtual reality. Physiology, pharmacology, pathophysiology, and crisis management are a few of the curricular areas that can be most effectively taught via the anesthesia simulator approach, that is, modeling a real patient scenario for students to manage with zero risk to the simulated patient and with no real risk to the student (except for the trainee's self-imposed stress to achieve). Use of this technology is limited only by the ability of the educators and students to create and "live" the scenarios. [40] Additional advantages of the human patient simulators include their use in teaching all types of students (e.g., medical students, student nurse anesthetists, allied health professionals in a wide variety of disciplines, practitioners in continuing education programs) and the ability to conduct educational research and to collect "simulated" patient management outcome data. Undoubtedly, the field of human simulator education and research will continue to grow exponentially in the next few years.

An in-depth study of the individual teaching techniques is appropriate after the links between the questions about educational

philosophy and rationale and the methods of teaching have been established. Lectures, small group discussions, use of questions, clinical problem solving at the bedside or in the classroom, psychomotor skill learning at the bedside or in the classroom, and use of adjunc-tive educational media, such as slides, chalk board, videotape, audiotape, overhead projector, computer, and teaching models, are all at the teacher's disposal for effective use in the proper situation. Each of these can be used more effectively and efficiently when the method is studied and understood.

Effective use of questioning, for example, occurs when the teacher understands the difference between closed and open questions. [41] The teacher uses *closed questions* when he or she is interested in having the student remember facts. Because the range of responses to closed questions is limited, students answer with facts and have a limited opportunity to delve into more complex cognitive learning, that is, problem solving. The teacher who wishes to direct the teaching/learning activity toward application of knowledge to new settings or analysis of information for conceptual learning, rather than mere regurgitation of facts, employs *open questions* as the teaching device. There is a considerable difference in learning that might occur when a question such as "What might explain postanesthetic stupor in a patient operated on for head trauma?" is asked of a student as compared with asking a question such as "What are the signs and symptoms of increased intracranial pressure?"

Developing a psychomotor skill lesson is another example of how understanding instructional methodology can lead to effective teaching and learning. The old adage about teaching psychomotor skills in medicine is "see one, do one, teach one." The absurd nature of this approach has been highlighted in the following way: "This is akin to a piano instructor playing 'The Minute Waltz' for a beginner and then saying, 'Now, try it yourself.' " [41] Rather than employing the repetitive trial and error approach to teaching/learning psychomotor skills, a systemic methodology can be employed. [41]

1. Analyze and separate the skill into its component parts and determine which aspects of the skill are most difficult to perform.
2. Provide students with a model of the skill they are expected to perform, demonstrated effectively in its entirety.
3. Make provisions for students to practice until the expected behavior is mastered.
4. Provide adequate supervision and an evaluation of the final performance.

Anesthesiology instructors need only think of the protocol they are using to teach, for example, pulmonary artery catheterization via the internal jugular venous route, to assess whether they are expecting their students to perform (learn) with the type of plan outlined above or rather to "learn as they go" on each successive patient as they probe in the neck.

A final example of an answer to the question of how to teach comes from review of the effective use of audiovisual aids. Although it is true that "a picture is worth a thousand words," the anesthesiology teacher must be sure that this image is the "text" the teacher wishes the students to read. Slides, for example, focus the viewer's attention on an idea(s) that the lecturer wishes to amplify in some manner. By definition, the entire lecture cannot be put on slides. Only a few important portions of the presentation are conveyed by slides, and these are emphasized in some specific way by the visual image(s), which add to the verbal presentation. Slides are not the TelePrompTer, although they are often used this way.

Even more basic is the need to understand the proper production formatting of slides so that the message on a 35-mm transparency can be clearly seen when projected onto a 12-foot-high screen in a large 800-seat lecture hall. If format is not considered, the slide is not visible and undoubtedly detracts from, rather than enhances, the lecture. Finally, even the best-produced slide is useless if nobody, including the lecturer, knows how to troubleshoot the nonfunctional projector. Surely, the thousands of hours that have been devoted to slide lectures about anesthesiology could have benefitted from the teachers' taking more responsibility in the preparation of effective visual aids.

SUMMARY

What is the anesthesiologist's responsibility in teaching colleagues and other health care professionals? The answer lies in the answers to the many aspects of the following question:

> How shall who teach what to whom for what purpose now and in the future"?!

For many, however, this type of review of education is "soft" material that lacks the "hard" research data to prove its validity. Perhaps this is true. Perhaps by its very nature (i.e., psychosocial) the science of education has its limits. On the other hand, however, enough experimental studies of education may not have been performed. A model to conduct

Figure 81-2 (Figure Not Available) Diagrammatic representation of a model to conduct educational outcome analysis. The six components are joined in "chain-link" fashion to signify that the outcome analysis is as strong as its weakest link. Essential to the model, therefore, is sound development and implementation of the educational plan and process. This includes definition of the educational objectives, understanding of both the teaching faculty and student participants, and execution of the instructional activity. Having established the educational experience, its outcome can be assessed by applying an appropriate evaluation design [42] and employing the measurement techniques to collect the data for analysis. The final step in the analysis is to apply the results to the program objectives and instructional activities to enhance future desired learner outcomes. *(From Hutchins [44])*

---

such studies might view the preceding question in terms of educational outcome analysis (Fig. 81-2) (Figure Not Available) . Although the educational setting is not a pure, controlled laboratory environment, accepted quasi-experimental design techniques exist for this naturalistic research setting. [42]

What then is the anesthesiologist's responsibility in teaching? It is 2-fold: to understand all aspects of education and then to scientifically study educational outcome so the future students of anesthesiology will be more effectively taught and better prepared as experts in the field.

ACKNOWLEDGMENT

I wish to thank George E. Miller, M.D., for the insight on Socrates, and Denise Distefano for her expert preparation of this manuscript.

Chapter 82 - Operating Room Management

William Mazzei

INTRODUCTION

An excellent example of the maxim that "not all progress is forward" is the evolution of operating room (OR) management. The typical structure for administrative leadership of this crucial area of health care often seems more suited for creating disorder and waste rather than providing efficient, effective, and seamless care. This chapter describes the history that produced this common organizational structure, the forces that are prompting changes in this structure, and most importantly, the ideal arrangement for the management of the OR.

HISTORY OF OPERATING ROOM MANAGEMENT

Up to the 1960s, surgical procedures delivered revenues so far in excess of expenses that little thought was given regarding how to efficiently structure either management or service. Hospital builders calculated how many ORs should be constructed by use of empirically determined ratios of number of ORs per number of inpatient beds. [1] Once these ORs were built, enough nurses and support staff were hired to staff all of the operating rooms every day. Equipment to satisfy almost all surgical requests was rapidly purchased as fee-for-service medicine and indemnity insurance gave confidence to administrators that all new costs could be counterbalanced with charges that would surely be collected. In fact, the acceptable charges (i.e., those reimbursed by insurance companies) often exceeded five times the actual costs, a rate of return that made the ORs a significant revenue center for hospitals and encouraged ever greater expansion of surgical services.

Before the duration of elective surgery exceeded the normal daytime hours of facility availability, surgery was scheduled on a first-come, first-served basis with a large degree of acceptance. As surgical specialties developed, the various services were granted specific rooms and blocks of OR time in order to provide specialty care. As long as all of the surgeons perceived that they had adequate access to the operating room, very few rules or structures were put in place to deal with scheduling and other management concerns, such as cost containment.

As the volume of elective surgery grew beyond the daytime capacity of the existing ORs, the medical staff of a hospital generally formed OR committees to establish rules for the distribution of OR time and the function of the OR. Although policy was created by these OR committees, multiple lines of authority still remained for operational decisions. [2] In private institutions, rules were generally enforced by the OR nurses. In academic institutions, some of the departments of anesthesia were also involved in their enforcement. Typically, high-level administrators, who were not working in, or knowledgeable of, the OR, were responsible for capital equipment and other budgetary decisions for the OR; OR nurses, working for the department of nursing, were in charge of preparing patients and handling the equipment; housekeepers and technicians, reporting to a different administrative structure, kept the supplies and ORs clean; anesthesiologists, working individually or as part of a specialty group, had only unofficial authority in the OR; and surgeons sought service for their individual patients or specialty group, but not for the OR as a whole. These multiple lines of authority caused a lack of continuity for daily operations and also prevented any long-term planning. Few people had any vested interest in the overall performance of the OR, and certainly the modern idea of customer responsiveness was not contained in such a structure. Utilization was also grossly inefficient, although this did not become a major issue in most institutions until the 1980s, when government-mandated limitations on the number of hospital beds and OR suites forced medical staffs to use only those ORs that were present rather than build more ORs as access became limited. [3] As surgeons attempted to perform more procedures within the same number of operating rooms, the OR day grew longer, elective cases on Saturday became commonplace, and scheduling "games" began. [4] The

combination of a limited supply of ORs, ineffective administration, and demanding users prompted a chorus of complaints about how ORs function.

The management problems produced by this history of development are common to most hospitals. [5] Generally, no one person is in charge of the daily functions of the ORs, and operational authority is shared (or declined, depending on the problem) among the highest-ranking OR nurse, the anesthesiologist in charge for that day (typically, the one who created the daily anesthesia assignments), the clerk answering the central phone, and the surgeon. Because usually no one has vested authority for management decisions, the rules that do exist are variably enforced. Rules, in fact, vary, depending on the institutional memory of the person making an operational decision. Even when carefully crafted policy and procedures have been created by OR committees and medical staff, shrewd physician-users of the OR can effectively lobby to higher authorities (high-ranking administrators, department of anesthesiology or surgery chairs, even deans) to have rules temporarily overturned in their favor. These "end-arounds" discourage existing leaders from making correct but unpopular decisions. Absent an established leader, long-term planning for the operating rooms is difficult to create.

FORCES PROMPTING CHANGE

In spite of these administrative and organizational problems, poor management structures continue to exist unless significant institutional pressure arises to force changes. Occasionally, such pressure is brought to bear by visionary leaders of anesthesiology, hospital administration, or surgery. For example, the president of the Johns Hopkins Hospital, faced with dramatic monetary losses and poor utilization of the hospital, created the first physician-led OR directorship by appointing the acting chair of the department of anesthesiology as the administrative leader for the OR. At times, external regulatory bodies, such as the Joint Commission on Accreditation of Healthcare Organizations, force changes. [6] Impending inspections prompt full-scale evaluations of administrative structure so as to correctly divide areas of responsibility (or allow assignment of blame). These evaluations may produce permanent changes in the organization of the OR. Trends in management, such as continuous quality improvement or re-engineering, may also provoke alterations in practice. [7]

In the 1990s, the overwhelming concerns over health-care costs and competition for patients have provided the major impetus for improving OR performance. Hospitals and health-care systems wish to simultaneously reduce the cost of surgical care while providing service that is viewed by patients and physicians as efficient and accommodating. This desire is prompting creation of new OR management structures in multiple hospitals throughout the United States, in both private practice and academic institutions.

IDEAL MANAGEMENT

Centralization of Authority: The Director of the Operating Room

The most important step to improving OR management is to centralize authority over the critical personnel and processes involved in OR services under one individual (Fig. 82-1) . Several consulting firms have labeled this position the "OR czar," although the official title often used is director of the OR or perioperative services. [2] The extent of control granted for this position reflects the local politics and the extent and the urgency of problems, but reasonable effectiveness requires supervision of the areas of scheduling; preoperative clinic (or its equivalent); day-in-progress decision-making; postanesthesia care and sometimes acute pain management; and perioperative information services. If the person chosen to fill this post is a physician, debate usually arises over whether the OR nursing director should report to the OR director or to a higher-level nursing administrator. Although medical supervision of nursing practice is probably not warranted, it is very important that the OR director have control over nursing deployment and practice patterns to address both efficiency and service issues. Similarly, a reasonable degree of authority over anesthesia services is necessary.

To whom this position should report is controversial, as is the source of the director's salary. In this author's opinion

Figure 82-1 Organizational chart for director of the operating room (OR). Solid vertical lines imply direct reporting relationships, dashed lines imply important informal relationships, and horizontal lines imply important collaborative relationships.

the greatest perceived neutrality is created if the OR director works for hospital administration rather than a specific clinical department. To achieve the greatest level of authority, the OR director should report to as senior a level of administrator as is practical in a given hospital. In medical centers where a sense of urgency exists, this is often the hospital director. Clearly, the OR director must work closely with the chairperson of anesthesiology, surgery, and other departments that provide operating or procedural room care. From a practical standpoint, however, it is easier if the OR director reports to only one direct superior.

If problems in OR finances are to be addressed, then the director of the OR should be given control over the OR budget. If this is not possible, then, at the very least, the immediate supervisor must have budgetary authority over perioperative services. In order to maintain a clinical practice, the OR director may continue with a clinical appointment in an appropriate department. For a physician, the time required away from direct patient care responsibilities requires a sacrifice of clinical income that few would accept. Thus, as a practical matter, an administrative stipend is usually required to secure a physician to fill the post.

Several personal characteristics are vital for success of the OR director. A vested interest in overall performance of the OR, as opposed to one department or an individual service, is crucial for objective decision-making. Strong interpersonal skills and the ability to plan and perform long-term projects involving multiple personnel are necessary. Because of the need to lead groups that are extremely diversified along socioeconomic, ethnic, and educational lines, sensitivity to human relation issues is important. Likewise, leadership by consensus gathering, rather than single-minded determination, is more likely to produce long-term success. Although personality and human management skills are most important, strong clinical skills and frequent presence in the OR are a tremendous advantage. Respect from surgical colleagues is most often gained through the clinical arena, and the person who is perceived to be an excellent and omnipresent clinician is more likely to be listened to than the distant, nonclinical administrator. Knowledge of the internal history of an institution is also an asset, although the problems in providing perioperative service are so universal that experience in one hospital will certainly aid in improving performance in another.

Why should an anesthesiologist be interested in serving as an OR director? There certainly is a shared interest between hospital administration and departments of anesthesia, because an efficiently run OR is economically advantageous for both parties. Anesthesiologists are intimately familiar with the medical aspects of the perioperative process and have already established themselves as leaders in the areas of preoperative evaluation, intraoperative management, and postoperative care. Anesthesiologists' working familiarity with all of the surgical specialties makes them cognizant of different service needs but permits an overall perspective to be maintained. Further, application of clinical judgment in day-to-day issues by "front-line" personnel permits more effective problem solving than is possible through a distant administrator and is consistent with the current useful trend of physician management of medical processes. Of course, other scientific skills commonly possessed by anesthesiologists, such as knowledge of data processing and modern communication systems, provide invaluable assistance in addressing OR concerns.

There are disadvantages for anesthesiologists involved in OR management. Anesthetists are accustomed to a high degree of personal control over the service they provide in the OR and may find the lobbying necessary for personnel management slow and frustrating. In distinction to the singlepatient focus of OR care, productive managers must deal with multiple patients and issues on a daily basis. Absent an administrative stipend, personal income decreases if clinical time is sacrificed for administrative duties; conversely, personal time may disappear if one chooses to maintain a full clinical responsibility while serving as manager as well. The need to occasionally make unpopular decisions that affect surgeons who are providing one's customer base creates conflicts of interest that may be difficult to bear. Lack of formal business training may also be a disadvantage.

To make the responsibilities of the OR director clear to all interested parties, a well-defined job description is invaluable. One developed by the Association of Anesthesia Clinical Directors (see the appendix to this chapter) is an excellent guide if an anesthesiologist is chosen as OR director. Modifications to accommodate local conditions and other health-care professionals are clearly appropriate. Relationships to other OR personnel and governing bodies are as important as are the supervisor and job description (see Fig. 82-1) . To assist in gathering support of key players (powerful physicians and leading OR administrators) but still allow rapid decision-making, the OR director would be wise to create an executive committee to meet with on a regular (weekly) basis. An ideal group is the lead hospital administrator for the OR, the OR nursing director, the chairperson of anesthesiology and surgery, and a rotating group of two or three clinically active physician users of the OR. An OR committee made up of a much broader representation of surgical and procedural specialties is essential for examination of large issues. The OR committee should serve as an opinion-gathering and consensus-creating body and is an excellent forum for dissemination of information back to the medical staff.

Scheduling: Definitions and Guidelines

On the practical level, allocation of resources in perioperative services occurs via creation of the OR schedule; the effective OR director thus focuses much of his or her attention on this process. Whether done by hand or sophisticated computer systems, creation of the OR and out-of-OR schedule represents the implementation of all of the openly acceptable rules and regulations and the hidden biases and behind-the-scenes agreements, for perioperative service at a given institution. Frequently, arguments over scheduling arise from perceptual differences over the meanings of certain times, time periods, and utilization indices. The use of common definitions reduces such misunderstandings. Well-accepted definitions can be found in the procedural times glossary, a lexicon for scheduling and monitoring of

diagnostic and therapeutic procedures. [8] A few critical definitions from this glossary are repeated here, along with an explanation of their use, to aid in subsequent discussion.

Case time = time from room setup start to room cleanup finished.

This definition includes all of the time for which a given procedure requires an OR. It allows for the different duration of room setup and room cleanup times that occur because of the varying supply and equipment needs for a particular procedure. For purposes of scheduling and efficiency analysis, this definition is ideal because it includes all of the time that an OR must be reserved for a given procedure.

Resource hours = total number of hours scheduled to be available for performance of procedures (i.e., the sum of all available block time and open time).

For a given institution, this is the time during which the appropriate personnel are expected to be available to work on cases. This may include more than one shift of personnel, or personnel working extended shifts (e.g., >8 hours) in order to gain vertical expansion of OR hours. It may also include electively scheduled time on weekends to gain horizontal expansion of OR hours. Resource hours do not include time gained through overtime or use of on-call personnel, even though this time may be routinely accrued at a given institution.

Raw utilization = for the system as a whole, this is the percent of time that patients are in the room during resource hours.

For an individual service, this is the percent of time in which a service has a patient in the OR during its block time.

Adjusted-percent service utilization = (in-own block hours + outside-own block hours) × 100/block time.

This measures the percentage of time a service utilizes their block time during resource hours. It is adjusted, compared with raw utilization, in that it gives a service "credit" for the time necessary to set up and clean up a room, during which time a patient cannot be in the room. It may exceed 100 percent because of the inclusion of cases performed during resource hours that are outside a service's .

Adjusted-percent utilized resource hours = (total hours - evening/weekend/holiday hours)/resource hours × 100.

This calculation provides the percentage of time that the ORs are being prepared for a patient, are occupied by a patient, or are being cleaned after a patient is taken care of during resource hours. It is adjusted, compared with raw utilization, in that it includes the time necessary to set up and clean up a room, during which time a patient cannot be in the room.

Frequently, institutions attempt to assess the extent to which a service uses its allotted block time by calculating a utilization percentage. Such a calculation should be performed for the system as a whole to measure the extent to which the normal hours of operation are actually used for patient care. If one considers only the time that a patient is in the OR (raw utilization), then the percentage of time that a service uses their block time is artificially decreased because the time necessary to set up and clean up a room, during which time a patient cannot be in the room, is not analyzed. Similarly, the calculation of percentage utilization of resource hours is artificially reduced if only patient in room time is used. The larger the number of procedures done in a given room during resource hours, the greater the error.

Cost-effective utilization requires highly effective scheduling and optimum utilization of the resource hours, with minimal overtime and/or use of more highly paid on-call personnel. For proper assessment of the extent to which a service or system utilizes its block or resource hours, respectively, the utilization calculations should be adjusted as defined earlier. For the individual service, this provides a fairer determination of how much of their block time is truly used. For the system as a whole, it provides the actual percentage of time that the ORs are being used for patient care. Perhaps as important, it provides an accurate percentage of time that is not used and therefore available for efficiency improvements.

Room ready = time when room is cleaned and supplies and equipment necessary for beginning of next case are present.

To maximize efficiency, the patient should be brought into the OR as early as possible. Although some wish to have all the supplies and equipment necessary for the entire case present and open before the patient enters the OR, institutions that have minimized turnover times move patients into the OR as soon as it is clean with only the minimum supplies and equipment (i.e., those needed to start the case) present, but not necessarily open. In those institutions, room preparation continues as anesthesia is induced, allowing an overlap of processes (anesthesia induction and room preparation) that saves time.

Start time = patient in room time

Significant debate, indeed, even argument, exists over the proper definition of start time. This author has listened to this debate at many national meetings. Often, nurses, anesthesiologists, and surgeons define the "start time" differently. Operating and procedural room nurses often feel that they have properly accomplished their preparatory tasks if the room is ready at the scheduled start time, regardless of where the patient is at that time. Anesthesiologists often feel that they are "on time" if anesthesia induction has been completed by the scheduled start time. Surgeons generally believe start time should be the time at which the skin incision is made. Because room setup time is procedure-specific and therefore generally known at the time of scheduling, one can reasonably predict room ready time. Anesthesia preparation time, however, depends on both the procedure and the patient's needs. It is thus more variable and is not known at the time a procedure is scheduled, making accurate prediction of anesthesia ready time impossible. This variability in anesthesia preparation time also makes prediction of surgery start time inaccurate. Variability in case times, resulting from varying lengths of surgery, makes prediction of start times after the first scheduled case of the day even more inaccurate.

Much of the concern over start time is for the first case of the day, particularly if a service or a surgeon follows himself or herself in the same OR throughout the day. Prediction, then, of accurate start times for the first case of the day is most critical. Once the procedure is known, it is almost always possible to have the room ready at any time that is desired for the start of the day. It should also be possible, and desirable for maximizing efficiency, to have the patient in the room for the first case of the day as soon as the room is ready. For maximizing scheduling accuracy and attempting to encourage the most efficient patient flow, it is optimal to define start time as patient in room time.

Turnover time = time from prior patient outof room to succeeding patient in room time.

Strong perceptual differences exist over the definition of turnover time. Anesthesiologists and OR nurses usually consider turnover time to be the time between cases when the room is not occupied by a patient. Surgeons consider any time when they are unable to operate as "downtime" and thus more often consider turnover time to be the time between the end of surgery on one case and the beginning of surgery on the next case. The latter may appear to be particularly long to an academic surgeon who leaves an OR before the wound is closed (allowing the residents to close and dress the incision) and does not re-enter the OR until the next patient is ready for incision.

As with start time, the variability of anesthesia preparation time makes prediction of turnover times inaccurate if anesthesia preparation time were to be included. Thus, to maximize scheduling accuracy and to encourage distinction of time spent preparing the OR from time spent preparing the patient, it is preferable to define turnover time as time from prior patient out of room to succeeding patient in room for sequentially scheduled cases. Because this definition attempts to include the time spent cleaning and preparing the OR for the next case, it should be calculated only if a subsequent case is scheduled to immediately follow.

Before the era of surgical specialization, the long-term schedule could be created by granting individual surgeons OR time on a first-come, first-served basis, a

completely "open" schedule. As surgical care advanced, each specialty developed its own equipment needs that were not interchangeable with the needs of other specialties. Configuring an OR for a single specialty became a practical necessity for those services whose equipment was large and relatively immobile (e.g., cardiac surgery, with its cardiopulmonary bypass machine, or ophthalmology, with its ceiling-mounted microscope). Also, regardless of specialty, it was more convenient for individual physician users of the OR to schedule several cases in a row in the same OR. This sequential scheduling became increasingly difficult in a completely open schedule as competition for OR time increased. In order to reserve either space or time for a surgeon or a service (a group of surgeons performing the same specialty operations), portions of the available OR time were divided into blocks into which only one service could schedule. In the ideal system, enough ORs existed to grant each service that needed specialty equipment its own OR, while enough generic ORs remained to fulfill the needs of those who preferred to schedule as needed, and sufficient surgery was performed to occupy all of the ORs for an entire business day. This ideal was never attained. Invariably, surgical demand for OR time exceeded the available daytime hours of both block and open time. Services responded by requesting more block time so as to guarantee reasonable time availability. If additional block time was not granted, some services scheduled first into open time before utilizing their block time. Once this practice was recognized by surgeons who used only open time, it led either to new rules to outlaw this practice or to requests by the surgeons now crowded out for their own block time. In many institutions, this pattern has led to schedules that are 100 percent blocked. Of course, such systems effectively eliminate access to new users.

When using block time in long-term scheduling, one must decide which services will be granted it and how much use of a service's block time is required in order to maintain it. The former is most often historically determined (i.e., which services were granted it first), and the latter is often fruitlessly argued over. No studies have been conducted to determine what rate of utilization is most cost-effective or efficient for an institution. In the author's experience, adjusted utilization rates that average less than 70 percent are not associated with full use of available block time and lead to significant waste of personnel time, whereas rates above 90 percent are frequently accompanied by the need for overtime hours. Reducing block time for services that do not maintain at least 70 percent adjusted utilization and granting more block time to services who consistently use more than 90 percent of their available time are reasonable guidelines. The situation at a given hospital must be considered when local set points are established. A hospital with sufficient resources but local competition may wish to encourage surgical use through granting of more block time and lower rate of utilization requirements, whereas a financially challenged center may be forced to require higher rates of utilization in order to reserve a block.

Adjustments in availability of block time can also be made though setting of the "hold" time, that is, the time before the procedure date that a given block is held for a service before it is released for open scheduling. Services prefer short hold times because this maintains their OR access for as long as possible. Of course, OR time that is reserved and not used results in wasted resources and may deny another physician the opportunity to schedule a case. A single hold time for all blocks rarely pleases the majority of users. Improved satisfaction may be realized by using service-specific hold times. Services that are able to schedule electively and far in advance may be comfortable with blocks that are held only up until 2 weeks before the day of surgery, whereas specialties that frequently must provide services to patients admitted the evening before may do best with blocks held up until the day of surgery. Special circumstances arise for surgeons treating patients with suspected malignancies. Although waiting for even a few weeks may not change the course of medical therapy in such patients, the anxiety associated with the suspected diagnosis creates a great deal of psychological urgency. Similarly, acute personal needs may arise for patients or surgeons that produce an unanticipated nonmedical urgency. In systems in which OR time is usually fully booked within a few days of surgery, the use of an "urgent" room may assist in expeditiously handling these needs. An

urgent room is an OR that is held open for any service but into which no case can be booked until a few days before surgery and whose availability is held until a day before surgery. Such rooms permit access for an important subset of patients that would normally be crowded out of a busy OR system.

In creating the long-term schedule for a single medical center, the location of different operative and procedural sites may have to be considered. During the 1980s and 1990s, most medical centers established outpatient surgery suites because of the belief that surgical care could be provided more cheaply if it were performed on an outpatient basis [9] (Ch. 65) . Opening of such suites increased the complexity of scheduling because surgeons needed to choose between two locations within the same system. They were forced to consider whether it would be better to schedule all of one's outpatients on one day and inpatients on another, in order to maintain block time in both sites, or whether to use only open time and schedule both inpatients and outpatients on the same day, at the risk of needing to be two places at the same time. How should the system monitor the latter? Centralization of scheduling for all sites into one office, and preferably on one computerized system, is the most important step for handling multisite problems. Review of the schedule for personnel conflicts, either manually or automatically, can prevent duplicate scheduling of one physician. In certain situations, however, scheduling of simultaneous procedures by a single physician is warranted. The use of residents or surgical assistants may permit concurrent scheduling of procedures in a staggered fashion, as in cardiac surgery in which the primary surgeon only performs the maneuvers required on bypass. This is acceptable as long as the two procedures are performed within close enough geographic proximity to permit rapid availability to both sites (rapid availability implying within accessible walking distance).

Another arena of burgeoning growth that must be accommodated is the out-of-OR sites where therapeutic or diagnostic procedures are performed that require anesthesia care (Table 82-1) (Ch. 66) . Although OR committees may wish to ignore these sites as simply a problem for the department of anesthesiology to solve, the same issues of access and prioritization arise as with OR procedures. In order to apportion the hospital-based resource of anesthesia care

TABLE 82-1 -- Out-of-OR Locations Where Elective Anesthesia Care May Be Required

Angiography suites
Bronchoscopy suites
Burn unit (e.g., dressing changes)
CT scanner
Catheterization laboratories
Endoscopy offices
Evoked potential laboratories
Interventional radiology
ICU
MRI scanner
PACU (for brief nonsurgical procedures, e.g., electroconvulsive therapy)
Radiation therapy center

CT, computed tomographic; ICU, intensive care unit; MRI, magnetic resonance imaging; PACU, postanesthesia care unit

in a manner that is consistent with overall institutional goals, it is better to include the scheduling of out-of-OR sites with the same guidelines and processes as for the ORs. In most commercially available computerized scheduling systems, this can be accomplished by designating one or more OR numbers above the actual number of ORs for these outside sites (e.g., a hospital with 20 ORs could assign ORs 21 and 22 for out-of-OR procedures).

Setting the resource hours, which requires deciding the number and the duration of OR and out-of-OR sites to staff, is perhaps an even more contentious issue than allocation of block time. The ideal arrangement depends on one's vantage point. To the hospital administrator counting salary costs, OR and procedural rooms that are completely filled during straight time hours but empty just before overtime pay accrues is the optimal solution. Salaried employees generally prefer the same solution, as long as adequate resources exist to provide the union-mandated breaks and lunch time. Salaried anesthesiologists may feel similarly, whereas fee-for-service anesthesiologists prefer to work constantly without interruption until their desired quitting time and could happily exist without any evening and weekend hours. Surgeons with afternoon clinics seek OR time that runs from 7 AM until their clinic opens and then additional OR time after the clinic closes to complete urgent cases. Of course, patients would prefer to schedule elective surgery at their convenience and wish to be transported immediately to the OR for any urgent or emergent care that they require.

As with block time utilization, no study has been completed that defines the optimal amount and arrangement of resource hours. Indeed, tradeoffs between access, convenience, and cost preclude a solution that will satisfy everyone. Patient needs certainly mandate around-the-clock availability of emergency care. Beyond that,

the amount of OR time required is primarily driven by the service needs of the various surgical and nonsurgical specialties, needs that may vary over time and are relatively unpredictable. This author's experience suggests the following guidelines:

1. Enough resource hours should be available to permit scheduling of elective cases within a reasonable waiting period. In competitive markets, an acceptable wait period is between 1 and 2 weeks (i.e., one can schedule an elective case within 1 to 2 weeks).
2. Hours for electively scheduled surgery are best confined to the normal working shift of OR personnel (generally, 7 AM-3 PM). Routinely performing surgery that exceeds these hours leads to expensive use of overtime pay and leads to strife among nonsalaried OR personnel.
3. To accommodate urgent procedures that arise during the day, sufficient hours should be available to permit these cases to start within 2 to 4 hours of the request for OR time. First priority should be given to placing these cases into gaps that occur because of case cancellations, thereby minimizing wasted personnel time. Likewise, these "add-on" cases should be placed into any available OR that has the equipment to perform the necessary surgery.
4. Sufficient staffing should be provided to accommodate the average emergency load, based on historical data (6 months). Although this suggestion may appear obvious, it is striking how many hospitals routinely interrupt elective

cases for emergencies that could have been reasonably anticipated.
5. After providing these suggested hours, if the adjusted percent utilization of the ORs is greater than 80 percent, additional OR hours are warranted. Options for increasing these hours include staffing for longer days, staffing for elective evening or weekend hours, or opening new ORs. If new ORs are already available, they represent the best path for providing more service. Commonly, however, all of the ORs are already in service, and one must choose to expand hours in the existing ORs. It is often suggested that improvements in OR efficiency will permit more cases to be performed within the same number of hours at existing sites. Although significant improvement in start times and turnover times is possible, such improvements rarely provide enough time to schedule even one additional case during the electively scheduled day. [10] [11]

Although appropriate creation of the long-term schedule is critical, proper Management of Day-in-Progress schedule is equally important. Multiple medical, social, and environmental events produce changes in the anticipated cases that cannot be foreseen before the day of surgery. One should thus expect that a few to many changes will have to be made in the daily schedule. To efficiently deal with these changes, a single person working in the OR should have the authority to adjust the schedule as the day progresses. Although the guidelines and the policies for schedule adjustments can be established in larger forums, enforcing these rules is best left to a single OR manager each day. This person is often referred to as the floor runner, or the person running the floor. In large academic centers, this person is usually an anesthesiologist, but in private centers, a senior OR nurse may perform this function. Ideally, however, the director of the OR performs this function on the overwhelming majority of days, sharing the responsibility with a very limited number of others.

The most common day-in-progress problem is scheduling of add-on cases. Procedures that are booked to be performed on the same day as they are scheduled can produce tremendous conflict. Both the patient and the scheduling physician may wish to proceed to the OR as soon as possible, but frequently, no time is immediately available. When is an add-on case of sufficient urgency that the electively scheduled cases should be interrupted and delayed? Further, if there is more than one add-on case, who should go first? The most common and medically reasonable approach is to separate add-on cases into three categories: elective, urgent, and emergent. Elective cases are those that can be performed at any time without risk of medical harm to the patient. Examples include cosmetic and joint replacement surgery. Add-on cases that are truly elective should be scheduled to follow after the days that electively scheduled cases are completed. Depending on resource hours available, it may be acceptable to ask the scheduling physician to defer the procedure until the following day. Emergent cases are those that must be performed immediately in order to prevent loss of life or limb, such as penetrating trauma with hypotension and fractured extremity that has lost its vascular supply. Organ transplants may be placed in this category if the donated organ cannot be preserved. Emergent cases must proceed in the next available OR. If emergency cases routinely interrupt regularly scheduled procedures, it is wise to maintain an unoccupied emergency OR during the electively scheduled hours. Enough anesthesia and nursing staff should be available to immediately provide care if an emergency case arrives.

Urgent cases are the most difficult to define, although many types are proposed to be in this category. To many, a procedure is urgent if it must be performed within 24 hours to avoid significant morbidity. This establishes the need to complete the procedure on the day it is scheduled. Several strategies exist to accommodate these cases. If, as suggested earlier, sufficient openings in the schedule exist, because of either cancellations or flexible staffing, to accommodate all urgent requests within 2 to 4 hours, then further clarification of need is rarely required. If such flexibility is not available, it is wise to determine whether the scheduling physician has any cases already scheduled that he or she may delay in order to accommodate the urgent case. Similarly, such "bumping" of cases may be the rule within service lines (i.e., if the urgent case is being performed by general surgery, then one of the general surgery cases should be bumped to accommodate it).

In questionable cases, a formal anesthesia evaluation may provide valuable information for determining priority. Occasionally, suggesting that the case will be performed, but not until the late evening, may lead to a voluntary deferment on the part of the surgeon to the next or another day. Absent any clear priority, the OR manager running the floor should have discretion to settle the final order of cases.

A Rational Approach to Solving Problems

Because of the ineffective manner in which OR management systems have developed in the United States, problems in the delivery of perioperative services are similar and commonplace in American hospitals. However, even though these problems are universal, it is the local milieu that determines which problems are most important for a single institution to solve. A financially struggling hospital may need to stress cost reduction, whereas a more economically advantaged site facing local competition may wish to concentrate on improving service. The concerns of all parties may not deserve equal attention. A few powerful physicians may require careful consideration, whereas union presence may instead demand accommodation of a much larger number of rank and file personnel. It is important to remember the perspective of the patient, who may be completely unaware of the departmentalized structure of the hospital and wishes seamless travel through the health-care system. Finally, the interests of the insurers demand that one demonstrate the value of services provided. Given this variation in priorities, how does one decide which issues to address first?

The local political situation may dictate the answer, or regulatory requirements may demand certain corrections. Overwhelming financial constraints may similarly demand draconian solutions. For the medical center not faced with such restrictive requirements, a consensus-building approach is preferable. This should start with a generalized survey of all operating room staff and physician users, asking,

TABLE 82-2 -- Typical Structural Problems

Locker room is too small.
Too many scheduling sites.
Too many numbers to call to schedule.
No waiting room for families.
Time clocks are inaccurate.
Insufficient scrub suits are available.
OR hallways are too crowded with equipment.
Surgical lights are poor in some ORs.
OR climate control does not work adequately.
Insufficient anesthesia specialty coverage.

for example, for the top ten problems faced in the delivery of perioperative care. Once a list of problems is accumulated, it is helpful to separate them into structural versus process problems because the approach to solving these problems differs. Structural problems are those requiring a change in the physical environment or

alterations of the function of a single job (Table 82-2) . Problems that affect only one service, such as anesthesiology and nursing, may also be placed in the structural category if alteration in practice for a single group can produce improvements. Process problems are those involving multiple services and/or sites (Table 82-3) . To solve process problems, changes in the way several personnel do their jobs may be required.

After creating a separate structural and process problem list, prioritization of which problems should be addressed should take place. Depending on where the pressure for change comes from, one may want to give more weight to the concerns of the surgeons, the administrators, or the OR staff. A way to effectively try to please all parties is to use a multiattribute decision model, in which problems are judged on the basis of their affect on desirable goals (Appendix). A committee of key players, representing all services involved in OR care, ranks each of the problems according to how likely solving that problem will achieve these goals, and then a summated score for each problem is generated. The advantage of this technique is that it allows all parties to express their opinion and generally produces a list of prioritized problems that has several of each group's "pet peeves" in the top ten of the list. Once this prioritized list is formulated, it is wise to share them with as large an audience as possible, partly to engender a feeling of universal input and also to ensure that no glaring errors were made in the process.

Structural problems are solved most quickly if they are assigned to a single individual. The OR director should assess

TABLE 82-3 -- Common Process Problems

First cases start late.
Turnovers are too long.
Surgery takes too long.
Incorrect or missing surgical supplies.
Low morale among staff.
Patients arrive to OR too late.
Too much suture is wasted.
Surgical preference cards are inaccurate.
Surgeons/anesthesiologists are not available on time.
Records and x-ray studies are not available at time of surgery.

the problem, decide which individual can most likely address the entire issue, and then enlist that person. An initial meeting with this person should clarify the goal desired and then establish the resources necessary to achieve that goal, including personnel, money, and space. From a practical standpoint, if the problem requires the input of more than five people, then it should be broken down into smaller components before proceeding.

Process problems require greater effort and a different approach than structural problems. Because process problems involve multiple services, each service has its own particular view on what the real cause of the problem is. Attempting to solve process problems by appointing a single individual or service to determine and dictate a solution leads, at best, to a solution that considers only one service's viewpoint, or, at worse, a deepening of the problem and an alienation of all the other parties. In almost all instances, process problems require a total quality management (TQM) approach in order to achieve an effective and long-lasting solution.

Total quality management, also referred to as continuous quality improvement, is the management method originally developed by Deming and others in Japan to improve their automobile industry. It requires that an independent team be created for each problem. This team must follow a rigorous path for forming, installing, and monitoring a solution (Table 82-4) . Details of team function are beyond the scope of this chapter but are provided in the references. [12] [13] [14] [15] Practical points in the use of continuous quality improvement teams for improving OR performance are as follows.

To properly address the concerns of all parties involved in a problem, it is critical to form a team that is composed of a member of each group or service that has an interest in solving the problem. Generally, effective team sizes range from six to 12 people (if >12 individuals are needed, the problem is too large and should be broken down). Choosing members of the team is an important task. It is necessary that the members chosen have firsthand knowledge of the problem assigned and that they have no previously existing personality conflicts. Equally important is that the entire team receive adequate training in TQM so that they have the tools to address their given problem. Ideally, this happens by having all team members attend an institutionally provided training course. If this is not feasible, it may be sufficient for the leader of the team to be expertly trained. It is extremely helpful if this leader has previously served on a TQM team. In addition to the regular team members, a person familiar with TQM, whose usual job is not involved with the team's problem, should be chosen to be the facilitator, a person who is responsible for keeping the team focused and moving. The facilitator serves as an objective moderator when

TABLE 82-4 -- Total Quality Management Approach to Solving Process Problems

Stage 2	Understand and measure the process
Stage 3	Eliminate errors and implement solutions
Stage 4	Remeasure the process
Stage 5	Identify and reduce variation in the process
Stage 6	Plan for continuous improvement

TABLE 82-5 -- Prioritization of Problems Using a Multiattribute Decision Model

PROBLEMS	GOALS							GOAL-WEIGHTED PRIORITY SCORE
	IMPROVED SURGEON SATISFACTION 25%	*IMPROVED ANESTHETIST SATISFACTION 25%*	*IMPROVED NURSING SATISFACTION 25%*	*IMPROVED EFFICIENCY OR PRODUCTIVITY 10%*	*IMPROVED PATIENT SATISFACTION 5%*	*IMPROVED QUALITY OF CARE 5%*	*IMPROVED FINANCES 5%*	
First cases start late	5	4	3	4	1	1	3	3.65
Turnovers are too long	5	3	3	4	1	1	3	3.40
Surgery takes too long	2	5	5	4	2	3	4	3.85
Incorrect/missing supplies	5	2	4	3	1	2	3	3.35
Patients arrive to OR too late	3	4	3	3	3	2	3	3.20
Locker room is too small	2	2	5	2	1	1	1	2.60
Too many scheduling sites	3	1	1	4	1	1	3	1.90

No family waiting room	4	1	2	1	5	1	1	2.20
Time clocks are inaccurate	1	3	4	3	1	1	3	2.55
Insufficient scrub suits	3	2	5	2	1	1	1	2.85

Each problem is graded on whether its solution will achieve the designated goal, using a scale of 1 (extremely unlikely to achieve goal) to 5 (extremely likely to achieve goal) if the problem is solved. The goal-weighted priority score is the sum of the products of the percent priority assigned each goal times the grade assigned to a problem for that goal.

disagreements arise. The OR director should meet with the team leader and the facilitator on a regular basis, but compared with the structural problem teams, it is extremely important that the OR director allow the process problem team to set its own time line. A critical aspect for success is the development of team spirit, or buy-in, for the problem. The best-functioning teams are those that feel the problem is theirs to solve. Overriding external input can negate this feeling and thus should be avoided. Just as it is important for the team to deal with the problem on its own terms, it is important for them to make regular announcements about progress and results. This forces the team to clarify what it is doing and to defend its approach so as to mollify outside criticism. Although at times it may seem counterproductive, when individual members of the team hear criticism and relay this to the rest of the team, it forces re-examination of ideas and allows the team to become more secure in its actions.

How many problems should be addressed and how many teams should be formed are dependent on the urgency of the issues and the resources available to the OR director. To establish momentum and to demonstrate progress early, it is wise to initially address a few high-priority problems that can be solved quickly. Frequent and wide promulgation of actions and results also promotes an atmosphere of continuous improvement. Once a significant number of structural and process problems have been solved, a resurvey of interested parties is helpful to ensure recognition of progress and to reassess the extent of remaining problems (Table 82-5) . Although it is true that there will always be a top ten problems list, priorities change. [16] The continuously successful OR director will want to approach problems with an eye toward the most current general concerns.

SUMMARY

The usual evolution of OR management has typically produced an administrative structure that is not well suited to provide efficient perioperative services or to address the multiservice problems that are indigenous to this area of health care. Changes in the medical marketplace, which demand both reductions in cost and improvement in service, are pressuring medical centers to improve the way OR services are provided. This can be accomplished by centralizing authority over the essential personnel and processes involved in OR services and then systematically addressing the issues that are most important at a given institution. Establishing the appropriate hours of OR availability via datadriven selection of resource hours, block times, and hold times leads to a fair and equitable distribution of OR access for the various physician and service users. Careful assignment of cases according to locally determined priorities and policies should ease accommodation of add-on cases. Limiting day-in-progress administration to a small, select group of floor managers permits consistent interpretation and application of these policies, which then encourages collegial and efficient use of OR time.

I. Responsibilities to the department of anesthesiology
   A. Personnel management
      1. Long-term faculty schedule
      2. Daily faculty/resident/CRNA assignments; assurance of comprehensive resident case exposures/coordination with program director
      3. Manpower calculations and planning; recommendations to chairman
      4. Creation of management team representing all clinical aspects of the department
   B. Subspecialty coverage
      1. Develop appropriate faculty daily and on-call coverage
      2. Participate in resident subspecialty rotation development
   C. Daily operations
      1. Early morning review of schedule
      2. Morning clinical/manpower conference
      3. Assignment changes during the day
      4. Chief arbiter of clinical and interstaff problems
   D. Participative roles (with significant institutional variations)
      1. Preoperative evaluation clinic/preadmission testing procedure
      2. Anesthesia equipment/monitoring
      3. Quality assurance/quality management process
      4. Disaster planning
   E. Evaluation and promotion of the clinical director
      1. Clinical management-oriented job may require special criteria
      2. Clinical tract appointment most likely
      3. Teaching time may be limited
      4. Research areas may exist in management, statistical, and clinical studies

II. Responsibilities to the OR/hospital/medical staff
   A. Scheduling and data gathering
      1. Daily reviewer/final arbiter of OR scheduling
      2. Supervisor of scheduling/data processing personnel
      3. Enforce scheduling policy
      4. Management of OR utilization data and submission of reports to appropriate governing body
   B. Communications center (OR front desk)
      1. Establish practices that provide expeditious service
      2. Supervise front desk personnel
   C. Clinical director's role with OR nurses, PACU nurses, and support staff (with significant institutional variation)
      1. Leadership and supervisory role for OR personnel
      2. Strong working relationship with nursing hierarchy and hospital administration
      3. May function as OR manager with budgetary, materials management, and quality assurance functions
   D. Chief liaison to:
      1. Hospital administration (formal position)
      2. Nursing administration
      3. OR committee (may serve as chairman of the committee). Authority must be delegated from surgical and anesthesiology departments and hospital administration
   E. Basic support from hospital administration
      1. Office, secretary, scheduler, and other personnel as necessary
      2. Financial subsidy may be appropriate
      3. Administrative authority

III. General qualifications
   1. Seniority, appropriate academic rank--associate or professor level may facilitate the role
   2. Clinical proficiency/commitment--being respected for clinical abilities is a significant attribute
   3. Educational qualifications--formal training or experience in negotiation and interpersonal relations and business administration may be desirable

Chapter 83 - Electrical Safety in the Operating Room

Lawrence Litt

INTRODUCTION

Despite modern safeguards and alarm systems, unsafe electrical configurations still cause injury during surgery and anesthesia. Although surgical equipment by itself can be the culprit, anesthesia and physiologic monitoring equipment are also often involved.

Tragic events reported in the medical literature show the serious consequences of inattention to electrical safety. Patient electrocution, once a well-recognized hazard of surgery and the operating room, [1] is now uncommon. Even so, during the past 20 years, electrocution has still occurred four times outside the operating room: in 1975, from connections to a dialysis machine [2] ; in 1976, from a faulty endoscope [3] ; and in 1987 and 1993, from electrocardiographic leads that were mistakenly plugged into a power cord. [4] [5] More usual, however, have been severe burns caused by inadequate grounding, faulty equipment, and induced currents from radiofrequency fields. One neonate had third-degree burns after application of an external cardiac pacing device for a prolonged period. [6] Serious burns have also occurred from direct currents; in one instance, the source was a battery-powered neuromuscular stimulator. [7]

Although much modern equipment appears different from its ancestral counterparts, injuries now caused by electricity are similar, if not identical, to those occurring generations ago. Electrical malfunctions in the operating room continue to cause fires and explosions, central and peripheral nerve stimulation and damage, muscle stimulation and contracture, tissue burns, pacemaker interference, and sudden loss of power to important equipment. Because safety standards for medical equipment have been improving, most complications can be avoided by preventive maintenance of equipment, careful attention to the electrical contacts used on patients, and appropriate responses to alarm signals. Understanding electrical safety is an especially important responsibility for anesthesiolo-gists because perioperative electrical dangers can often be identified before they lead to disruption of patient care or to injury. [8] [9] [10] [11] [12]

Before the important issues affecting electrical safety and the guidelines for safe clinical practice can be discussed, some basic concepts must be reviewed.

ELECTRICAL GROUND

Discussions of electrical safety often center on whether circuits are grounded. To the clinician, an electrical ground is the wire connected to the third prong on plugs that are inserted into electrical wall outlets. With regard to a circuit, an electrical ground is any object connected to the circuit that is capable of instantaneously supplying or receiving arbitrarily large amounts of electrical charge. The National Electrical Code (National Fire Protection Association [NFPA] *) defines "ground" as a conducting connection, intentional 0or accidental, between an electrical circuit or equipment, and earth, or a connection to some conducting body that serves in place of the earth. Because the earth is an infinite reservoir of electrical charges, having a limitless ability to give up or receive electrons, any charged object connected to earth loses its charge and assumes the same potential as the earth. [8] Relative to earth and to each other, the voltage between two grounded objects is zero.

When a circuit is intentionally grounded, the actual physical objects chosen to serve as the electrical ground can vary. In a remotely located Mobile Army Surgical Hospital unit, equipment might be grounded by connections to a spike that goes into the earth. In a large urban medical center, ground might consist of a subterranean network of pipes. For a very small hand-held radio, a human being might serve as the connection to ground.

In hospital settings, it is generally not necessary for the clinician to understand the details regarding the choice of ground. However, clinicians must often know whether they, their patients, or their pieces of equipment are grounded.

* National Fire Protection Association, 1 Batterymarch Park, P.O. Box 9146, Quincy, Mass 02269-9959.

Living organisms tolerate only small amounts of electric current. Contacts with electrical ground are dangerous when they enable large electric currents to travel through the body--or when they render circuits one step away from the establishment of large currents. Human protection from large currents can be ensured if connections to ground always occur through a sizable resistance. An unrealistic but vivid hypothetical example illustrating the danger of electrical grounding is that of a person standing at the center of a giant copper cylinder that extends to the molten core of the earth. This situation would be quite unsafe because the person would essentially be a fuse, poised to suffer whatever large electrical current is applied. The need for additional electrical resistance between the person and the copper cylinder explains a requirement that was established in the days when explosive anesthetic gases, such as cyclopropane, were used. Operating rooms were then required to have conductive floors made of specific resistive materials. Such substances had high carbon content, so that they were not as conductive as metal. The high carbon content imparted a dark black color, one that can commonly be found today in operating room tables and cushions made of resistive materials.

In the United States, electrical plugs have three prongs: two that provide voltage (or, equivalently, power) and a special third prong that serves only as a connection to ground (i.e., to an object that makes an electrical connection with the earth). Travelers to Europe and elsewhere will recall seeing electrical outlets for plugs that have only two prongs and no separate ground wire. A two-wire system becomes especially unsafe if three-pronged equipment is plugged into it, leaving the third prong unattached to anything.

A *ground fault current interruption* (GFCI) electrical outlet allows one to test that the third connection in the outlet is indeed connected to a functional ground. More significantly, GFCI outlets enhance electrical safety by serving as emergency circuit breakers that shut off power when one of the two power lines in the outlet is accidentally connected to ground. GFCI outlets, found in hospitals (and homes), have two buttons: "test" and "reset." Pushing "test" causes a special resistor to be connected across the power and ground terminals in the receptacle. If the ground connection (the third wire) is in place and connected to the system ground, as it should be, current flows through the resistor and causes a circuit breaker in the outlet to open. No electricity can then be delivered by the outlet. Pushing the "reset" button resets the circuit breaker and restores electrical power. Pushing "test" would not cause the circuit breaker to open if, for example, a contractor accidentally forgot to install the ground wire or if an earthquake or other mishap caused a break in an installed ground wire. Protection against accidental grounding of one power line in an outlet is required by the NFPA for "wet environments," such as operating rooms. The installation of GFCI electrical outlets is one way to satisfy NFPA protection requirements. As is discussed further on, a second way (the traditional but more expensive way) is to have power come from an isolation transformer equipped with a line isolation monitor. [13] [14]

Electrical engineers commonly choose ground as the place where the electrical potential (voltage) is defined to be zero. Therefore, the voltage at any point in a circuit is the difference between the voltage at that point and the voltage at the electrical ground. Because of this, ground connections in commercial circuits help professional personnel check for proper functioning. A technician connects one voltmeter probe to ground while touching different circuit elements with the other voltmeter probe. The manufacturer's table can be used to compare readings and, in this way, identify problems in the circuit. Specifying the location of ground helps people communicate standards for circuit performance.

THE ISOLATION OF ELECTRICAL POWER FROM GROUND

Electrical contacts with ground can cause injury when they complete a circuit that permits a large flow of current. One strategy for ensuring safety is to isolate all electrical power sources from ground, making it impossible for ground to be used as a path for injurious or damaging currents.

Traditionally, implementation of this strategy in the operating room has been accomplished by means of isolation transformers, which usually take the form of large wall panels having outlets and meters. The term "isolation transformer" comes from the fact that power outputs are isolated from ground.

Electrical power for an operating room comes from a primary hospital source that usually originates from a connection to an alternating-current (AC) station of the local power company. (Sometimes an emergency gasoline-powered electrical generator is the primary source.) After arriving at an operating room, electrical power is modulated, isolated, and dispensed to electrical outlets in the room by the secondary coils of one or more large isolation transformers. Connections in three-hole power outlets in operating rooms, therefore, are somewhat different from connections in standard outlets found elsewhere in the hospital. [12] In operating rooms, a circuit cannot be completed by connecting one of the two power contacts to the ground contact.

The panel of each isolation transformer is required to have a *line isolation monitor* (LIM), which is simply an electrical current meter that demonstrates the isolation of the transformer's output power from ground. The large isolation transformers seen in operating rooms are somewhat anachronistic because the NFPA requires their presence only for environments in which inflammable anesthetics are used. [14] This does not mean that basic notions of safety have changed with respect to the need to isolate circuits from ground. However, isolation of electrical power is now accomplished with advanced technology that was unavailable when large isolation transformers were initially required. In principle, manufacturers are capable of incorporating good electrical isolation into the design of each piece of electrical equipment used in the operating room. Indeed, it is possible to argue that the obsolescence of central isolation and LIMs has already been demonstrated by the absence of these items in the intensive care unit (ICU) and the postanesthesia care unit (PACU). All electrical instruments that are permitted in the operating room are also used in ICUs and PACUs, yet one does not see isolation transformers and LIMs in ICUs and PACUs. Should one then assume that isolation transformers and LIMs should be eliminated from operating rooms or not installed in new operating rooms? The answer is neither yes nor no, [13] [14] as suggested earlier.

Figure 83-1 Schematic diagrams of (A) an isolation transformer and (B) electrical grounding for an ECG in the operating room (outlet to equipment).

The issue of safety for surgical patients who are wet with fluids that conduct electricity is better understood after a review of some fundamentals of electrical isolation.

Figure 83-1 A shows a schematic diagram of an isolation transformer. For each power outlet, two hot-wire contacts come from the secondary coil of the transformer. The primary circuit of the transformer is attached to ground, but the secondary circuit of the transformer is not. The third contact, which is at the end of the ground wire in the plug, is connected to the standard hospital ground and not to the isolation transformer.

When an ECG monitor is plugged into a power outlet in the operating room (Fig. 83-1 B), neither of the two "hot wires" from the secondary coil of the transformer is connected to ground by the ECG circuitry. This demonstrates the general principle that electrical circuits within an apparatus need not be grounded, although the metal case that houses the circuits is always grounded. Indeed, for many circuits, proper functioning depends on good isolation. Thus the statement "all operating room equipment must be grounded" is always true regarding connections between ground and the external case but is not always true regarding powered circuits within the apparatus.

In the example given in Figure 83-1 B, the ECG case is connected to the hospital's electrical ground, and the internal circuitry is connected to the output of the isolation transformer. This safe system is worthy of further discussion.

Let us suppose that mechanical or electrical damage causes us to worry about the electrical safety of an ECG monitor. Could a failure occur inside the ECG monitor that would place the patient or the anesthesiologist in contact with the internal circuitry? If so, would electric current travel through the person from the ECG circuitry to ground, causing injury or distress? Thanks to isolation of the ECG circuitry, the answer is no.

Figure 83-2 A shows how isolation provides safety. In Figure 83-2 A, a grounded person is touching the internal circuitry at point B. The isolation transformer supplies current to pathways that connect the two "hot" leads in the outlet, indicated by points A and D. However, the only way for electric current to get from point A to D is through impedance Z. Because each of the hot points in the wall outlet is not grounded, the person in Figure 83-2 A is safe from shock.

Figure 83-2 B, however, shows that two inadvertent ground contacts could produce a dangerous situation, especially if one of those contacts is a human being. Suppose that a fault occurs near point D, causing the internal circuitry to come in contact with the external metal case. A dangerous shock would result from touching the circuit at point B. Because of the fault, current could complete a pathway through the person and ground (i.e., from point A to D). Thus, it is useful to isolate power lines from ground and to know when isolation is compromised by a fault.

As mentioned, every isolation transformer has a LIM that monitors the isolation of the transformer's two power output lines from ground. Figure 83-2 C shows how the LIM (an ammeter) replaces the smiling and frowning people in Figures 83-2 A and B. When very low amperage is indicated, the LIM verifies that the power output lines of the transformer are indeed isolated from ground, as in Figure 83-2 A. The reality of the LIM connections is actually different because either of the hot wires could become grounded accidentally. Therefore, the LIM is actually connected to both sides of the isolated power output (Fig. 83-3) and is set to sound an alarm when either side has an impedance to ground that is less than 25,000 ohms, or when the maximum current that a short circuit could cause exceeds 2 mA. Note that the LIM is insensitive to currents below 2 mA. As is discussed later, the LIM provides no protection against microamp currents and microshock.

One event that occurs commonly in the operating room could produce a short circuit between power and ground, causing the LIM to go off. This event is the dripping of saline, blood, or other conducting liquid into the receptacles of an electrical extension cord that is on the floor near the operating table. For this reason, electrical extension cords in operating rooms frequently have watertight covers that flip into place over unused outlets. If wet receptacles on an extension cord appear to set off an LIM, the extension cord should be changed. If, on the other hand, the LIM rings suddenly and unexpectedly or immediately after a new piece of equipment is plugged in, that equipment should be unplugged immediately. If plugging in a piece of equipment repeatedly causes the LIM to sound an alarm, the equipment should not be used until it is checked. Similarly, if use of a particular power outlet repeatedly causes an alarm, it, too, should not be used until it has been checked. When an

LIM alarm indicates a "first fault," that is, that one power line is grounded, large, potentially damaging currents may subsequently occur through ground connections if there is a second ground fault. The path of damage might include the anesthesiologist, the patient, or an essential piece of equipment. Thus, an alarming LIM warns that someone in the operating room might receive an electrical shock or burn when touching connections to electrical equipment.

As mentioned earlier, detection of a first fault in grounding is possible without the use of isolation transformers and LIMs. The direct-installation GFCI outlets provide protection against a first fault. However, it provides protection, as described earlier, by suddenly shutting off all power from

Figure 83-2 Diagrams showing that (A) no electric shock occurs if an isolated power line is touched, (B) an electric shock *does* occur if a faulted secondary power line is touched, and (C) a line isolation monitor can watch for a fault.

the outlet. An advantage of the LIM is that one learns about a first fault without losing electrical power. A disadvantage of the LIM is its susceptibility to newly developed artifactual causes of alarm. Certain new devices used in operating rooms emit electrical radiation, intentionally or incidentally, that falsely cause LIMs to sound an alarm. These include instruments that generate ultrasonic sound waves for tumor disintegration and aspiration and stereotaxic monitors that use radio waves to track sensors attached to patients.

Figure 83-3 Schematic showing complete connections of the line isolation monitor (LIM). The alarm sounds that there is a "first fault" if either isolated power line has less than 25,000 ohms impedence, corresponding to 2 mA or more being drawn through the LIM.

CAPACITIVE COUPLING

Resistive coupling, the direct connection of two circuit elements by a wire or resistor, is the easiest kind of coupling for an anesthesiologist to recognize and understand. The connection is visible, and the effects of the connection are apparent for circuits carrying either direct current (DC) or AC at all frequencies. More subtle and abstract is the concept of capacitive coupling, which applies only to AC current. This concept is relevant to the anesthesiologist because it can account for electrical connections being present at high but not low electrical frequencies. If the alarm of an LIM goes off only when the electrosurgical electrode delivers high-frequency current to the patient, the dangerous pathway to ground might be caused by capacitive coupling. The power outlets might be safe for low-frequency currents but not high-frequency currents. Grounding pads, connections to electrical plugs, and equipment might need to be separated even farther from each other before the problem is remedied. The rationale will become more apparent after a review of the basic principles governing capacitive coupling.

The parallel-plate capacitor (Fig. 83-4) is a circuit element that permits the temporary storage of electrical charge and the passage of alternating electric current. However, the parallel-plate capacitor does not permit the passage of direct electric current. The electrical impedance of an object is the

Figure 83-4 Schematic diagram of a parallel-plate capacitor. f, frequency of alternating current; C, capacitance in farads.

total number of ohms that obstruct the flow of current. This term is a generalization of the term "electrical resistance." Electrical impedance includes contributions from capacitive, resistive, and inductive elements and is dependent on frequency. Using a simple formula, however, permits one to quantitate the impedance (Z) of a pure parallel-plate capacitor (of C farads) as a function of the AC frequency (f):

$$Z\ (\text{ohms}) = 1/(2\pi f C)$$

In this instance, capacitance (C) is directly proportional to the area of the capacitor plates and is inversely proportional to the space between the plates. As frequency (f) increases, impedance to the flow of current decreases.

At very high frequencies, the coupling to ground occurs through fewer ohms of impedance than would occur at low frequencies. Because any two conducting objects in a room have surface area and an average distance of separation, they form a kind of capacitor. Thus, any two objects have a capacitive coupling. This means that each of the two output lines of an isolation transformer is always coupled to ground at AC frequencies.

Although such capacitive coupling is usually insignificant, it can sometimes be significant at frequencies of 60 cycles/s (or 60 Hz) and is more commonly a problem during electrosurgery, which occurs at higher frequencies, typically hundreds to thousands of kilocycles/s. Capacitive coupling, which lets high-frequency currents pass easily, is commonly used by manufacturers in the connection between the electrosurgical unit and the electrosurgical pencil (cutting/coagulation tip) and in the connection between the electrosurgical unit and the large-area "grounding pad" that attaches to the patient. (The proper term for this conducting pad is "dispersive electrode.") Therefore, high-frequency currents used during electrosurgery have a low impedance path to and from the patient. At the same time, capacitive coupling prevents the electrosurgical pencil and the large-area conducting pad from participating in dangerous low-frequency grounding of the patient.

Capacitive coupling, which is not present in the connection of an older electrosurgical unit to its ground pad, might have prevented a serious DC burn caused by a 9.5-volt battery within a damaged nerve stimulator used by an anesthesiologist. [7] In laparoscopic and endoscopic surgery, it is important for surgeons to avoid unwanted capacitive coupling between the unipolar cautery tool and neighboring metal conductors, such as trocar cannulas. Stray currents from unwanted capacitive coupling can involve and injure organs such as the bile duct and bowel. [15] [16]

Anesthesiologists should be aware of such potential surgical complications, which might be erroneously attributed to anesthesia.

Capacitive coupling may have been responsible for severe patient burns from pulse oximetry in patients anesthetized for magnetic resonance imaging (MRI). [17] [18] [19] However, the possibility of being burned by a faulty pulse oximeter probe exists independently of capacitive coupling or radiofrequency currents induced by the MRI environment. [20] [21] In such a burn, the patient is external to a malfunctioning electrical circuit that causes the probe (i.e., the unit that contains the photodiode and attaches to the patient) to overheat and burn tissue. Such a catastrophe can be caused by connecting the wrong kind of probe (e.g., one from another type of unit) to an oximeter console.

Surprisingly, the MRI environment can transform a perfectly safe pulse oximeter setup (probe and console) into a dangerous, burn-causing device when attached to a patient lying in an MRI magnet. The problem arises from changing magnetic and electric fields that occur both at megahertz frequencies (in radiofrequency coils) and at kilohertz frequencies (in gradient coils) during taking of MRI data. Capacitive coupling can connect the patient to wires in a pulse oximeter cable and to metal in a pulse oximeter probe. In such an instance, the patient can become part of a high-frequency loop circuit, with currents entering and exiting at the points of capacitive coupling--particularly at the site of probe attachment. [22] [23] [24] [25] Fortunately, newer pulse oximeter cables have long, nonconducting fiberoptic attachments between the photogenerating and photodetecting parts. These attachments stay outside the magnet, so that only nonconducting components are connected to the patient, who is inside the magnet. The absence of metal or conducting components to the cable or probe attachment eliminates the possibility of patient burns from induced currents during MRI.

Anesthesiologists monitoring patients with pulse oximetry in MRI magnets should use such units, which have a long fiberoptic cable. These are generally available in radiology departments. Severe burns might result if one simply takes a pulse oximeter setup from an operating room and innocently attaches it to a patient in an MRI magnet.

ELECTRIC SHOCK

The passage of even small amounts of electric current through the body can interfere with normal functioning of muscles and nerves.

Figure 83-5 Frequency dependence of the "let-go" and pain-threshold currents. RMS, root-mean-square average.

Macroshock

Macroshock, which refers to the application of large voltages or currents to the skin or tissue, can cause injury when contact is made at locations remote from the heart. For example, macroshock was responsible for the death of a patient when ECG leads were accidentally attached to a power cord. [4]

The response to electric current flowing through a person's arm depends on the amplitude and the frequency of the current. Sensation of a 60-cycle current occurs at approximately 300 muA, and pain occurs at approximately 1 mA. After a certain current (the "let-go" current) has been exceeded, the person is unable to release objects. [26] The value for the let-go current varies with frequency and also among individuals. Figure 83-5 shows the range of average values as a function of AC frequency. The 50- and 60-cycles/s currents have the lowest values and are therefore the most dangerous. The response of cardiac muscle to electroshock is also dependent on frequency. Electric current is more important than voltage when issues of safety arise. Table 83-1 (Table Not Available) indicates physiologic responses to increasing total body currents.

Continuous total body currents that reach 0.1 to 2.5 A (approximately 10 times the let-go value) can cause ventricular fibrillation. The electric current generated in one pulse by an implanted cardiac pacemaker ranges from 0.1 to 10 mA. Only a small part of the total body current needs to pass through the heart to affect cardiac function. An electrosurgical unit generates so much power that it can induce microshock currents when it is used near implanted pacemaker wires. However, thanks to compliance with the safe grounding practices described earlier, the last convincing report of ventricular fibrillation induced by electrosurgery occurred in 1968. [27]

Defibrillation is often based on the same principle: that the skin is a good electrical insulator requiring large electrical fields at its surface in order to produce small electrical fields internally. A jolt of 400 watt-seconds (or joules) during closed-chest cardiopulmonary resuscitation delivers the same amount of energy to the body as that produced by a large-caliber handgun. (A 0.45-caliber bullet weighs 250 grains and has a muzzle velocity of 860 ft/s when fired. This corresponds to an energy of approximately 540 watt-seconds.) Only a very small portion of the energy dose of a defibrillator is needed to depolarize the heart.

Microshock

Microshock refers to the direct application of very small voltages or currents to the heart, often intentionally, by means of external or internal cardiac pacemaker electrodes. Inadvertent microshock, however, is dangerous because it can produce ventricular fibrillation. Arterial and central venous pressure transducers were once a potential source of microshock because they brought electrodes very close to heparinized saline that is in contact with the intravascular compartment. [28] [29] However, in recent years, pressure transducers have decreased in size and are now connected to monitors by means of low-voltage telephone cables. That they are generally safe is shown by their frequent use without reported complications. Nevertheless, microshock delivered by a faulty endoscope and faulty dialysis equipment has caused deaths. [2] [3]

TABLE 83-1 -- Average Effects on Humans of 60-Hz Currents Applied at Body Surface and Passing Through the Trunk

(Not Available)

Modified from Bruner [8]

Electric current is the variable most convenient to address when setting safety limits. Because investigators have reported that electric current passing through the human heart needs to be at least 50 muA before ventricular fibrillation occurs, [26] [30] [31] the American National Standards Institute (February 5, 1990) or the NFPA code sets 10 muA as the maximum leakage of current allowable through electrodes or catheters contacting the heart. This amount of current is considerably smaller than the peak electric current generated by an implanted pacemaker during a single pulse (0.1-10 mA). Recalling that 2 mA is the LIM warning level, one can see that the LIM does not provide protection against microshock hazards.

Electrocardiogram (ECG) monitoring electrodes are electrically isolated from the power circuits in the monitor by an isolation transformer in the main unit (a second level of isolation). However, an anesthesiologist who wishes to perform intravenous or intracardiac ECG monitoring, as occurs during the placement of a central venous pressure catheter, should have qualified personnel check the ECG monitor for leakages of current. In some ECG and electroencephalogram (EEG) systems, the electrode signals from the patient are translated into light by a battery-powered amplifier having a photodiode output and are then optically coupled to the main ECG or EEG unit (an even more thorough second level of isolation).

Endovascular procedures performed by interventional neuroradiologists now include the placement and activation of electrical coagulation coils inside certain types of intracranial aneurysms. Electricity in such coils causes coagulation more slowly than occurs in conventional electrosurgery. So far, currents in these unipolar devices have not caused macroshock or microshock. Nevertheless, despite the good safety record for such equipment, anesthesiologists monitoring the care of patients in an interventional neuroradiology suite should be aware of potential electrical hazards that come with new techniques. [32]

/das/book/view/29494766/875/911.html

ELECTROSURGERY

Most of our concerns with electrical safety in the operating room come from the need to use electrosurgical units, which can cause electric shock, burns, explosions, arrhythmias, and disturbances in pacemaker functioning. [33] Electrosurgical units operate at frequencies of approximately 300,000 to 2,000,000 cycles/s (300 kHz-2 MHz), so as to minimize the likelihood of ventricular fibrillation (see Fig. 83-5). During electrosurgery, high currents enter the patient through the small area on the surface where the tip of the electrode is applied. The combination of high resistance (R), which is attributable to the small area, and high current (I) causes local tissues heating proportional to $I^2 R$, which in turn produces cutting or coagulation. The tip of the electrode is also designed to produce lower current densities (low $I^2 R$) at points farther than a few millimeters from the electrode tip. Figure 83-6 shows the fanning out of the electric current. Electrosurgery is therefore a form of highly controlled localized burning of tissue.

Because there is often smoke where there is fire, concerns have been expressed regarding the safety of inhaling the smoke from the electrocautery. One group, assisted by the National Institute of Occupational Safety and Health, used the Ames test to examine the potential mutagenicity of electrocautery smoke collected during breast surgery. [34] Although the compounds collected were mutagenic, it is not known whether electrocautery smoke represents a serious health risk to operating room personnel. Nevertheless, the study recommended that surgeons minimize not only the production of electrocautery smoke but also the exposure of human beings to the smoke.

Because there is fire where there is smoke, it is also important that nonflammable materials be used during electrosurgery. Fires have occurred in operating rooms because highly combustible surgical boundary drapes were placed close to electrosurgical units. [35] The smoke from such fires can contain toxic substances.

From the preceding discussion, it is not surprising to find that electrosurgical units are powerful enough to provide excess electric current that is sufficient to cause extensive tissue burns. Surgical patients who become wet with blood, saline, urine, or other conducting fluids can form electrical contacts with the operating table, ground, or other conductors (e.g., monitoring electrodes and surgical retractors). Such contacts become potentially dangerous pathways for current. For example, current from an electrosurgical unit might enter a patient through the grounding pad and return to the unit via one or more ECG electrodes. In this situation, the electrosurgical unit could provide current that burns the patient but never passes through the tip of the electrosurgical pencil used in the operative procedure.

The dangers of electrosurgery in a "wet" environment, especially the possibility of establishing ground faults through wet connections, once accounted for the presence of an isolation

Figure 83-6 The flow of electric current through the body when small-area versus large-area grounding pads are used.

transformer (and LIM) in every operating room. As mentioned earlier, compared with GFCI outlets, which cause sudden power deprivation, isolation transformers, by turning on an LIM alarm, permit less disruptive detections of ground faults. For example, loss of electrical power during cardiac surgery can be a serious concern, and anesthesiologists must know how to hand-crank cardiopulmonary bypass pumps. [36] Sevoflurane vaporizers, of course, require electricity for operation. The NFPA requires first ground fault detectors in the wet environments of operating rooms. However, anesthesiologists, surgical colleagues, and hospital administrators are free to choose either GFCIs or isolation transformers with LIMs, whichever best suits local conditions and practices. [13] [14]

Unipolar Electrosurgery

It is important to understand the difference between unipolar and bipolar electrosurgery. In unipolar electrosurgery, the more common of the two, the surgeon applies current from the tip of a cutting/coagulation electrode to the relevant tissue location. The second electrode of the electrosurgical unit is connected to a large ground pad attached to a wide area of skin outside the surgical field. Skin burns can occur if the grounding pad is dry (most of the conducting gel is gone) or otherwise in poor contact with the patient. In both situations, electric current is again required to traverse a small surface area. The skin would then present high electrical resistance (R) to the returning current. Because $I^2 R$ can increase substantially, such increases in resistance can cause electrical burns of the skin. [37] Electrical burns have also occurred at the site of ECG leads when the grounding pad was defective and the leads became an alternate path for the returning high-frequency electrosurgery current. [38] [39]

A new, more powerful unipolar electrosurgical tool, the argon beam coagulator (ABC), has become available to surgeons. [40] Operating room personnel unfamiliar with its design and use can easily mistake the ABC for an argon laser because a well-collimated brightly colored beam of argon light glows at the tip of the electrosurgical pencil. The glow, which has the same color as light emitted from an argon laser, represents a continuous electrical discharge in a small, flowing column of argon gas having a density that supports electric current.

One problem with metal coagulation/cutting tips is that during electrical surgery, sticky, burnt tissue often adheres to and coats the tip, electrically insulating the tip and making it impossible to use for surgery. Surgery must then stop while the tip is scraped clean. When large areas of vascular tissue must be traversed (e.g., as in hepatic resection or repair of traumatic lacerations of the liver), conventional metal tips become difficult surgical tools. With the ABC, no metal surface is present to attract sticky, burnt tissue. The tip of the pencil is a cushion of argon gas that can transmit current as long as it touches tissue.

The anesthesiologist must understand that use of the ABC means that a lot of electrosurgery is taking place and that safety measures are more important than ever. As in conventional electrosurgery, surgical cutting and coagulation with the ABC come from local $I^2 R$ heating losses at the point where the electrosurgical pencil is applied--in this case, where the argon gas meets the tissue. ABC operation therefore resembles conventional arc welding. Because the ABC is perhaps the ultimate spark generator, its use illustrates the extent to which we have abandoned one safety concern that was prominent in the days of inflammable anesthetic gases.

Bipolar Electrosurgery

Some locations of the body are never safe for unipolar electrosurgery. For such locations, which are encountered frequently during neurosurgery, one employs bipolar electrosurgery. In bipolar electrosurgery, two pencil-point electrodes are applied to the area of surgery, and the electric current flowing through the tissue is confined to the few millimeters between the two electrodes. Bipolar devices are required when electrosurgery is performed on an ovary or a fallopian tube. Several cases of

fatal bowel injury have been reported after female sterilizations with unipolar devices. [41] [42]

Patients with implanted pacemakers frequently come to the operating room for procedures entailing electrosurgery. Even though bipolar devices are used whenever possible for these types of patients, pacemaker interference does sometimes occur. The avoidance of pacemaker interference depends on the type of pacing electrodes (unipolar or bipolar) in the patient, how well the pacemaker circuitry is shielded, and the strength and the proximity of the discharge from the electrosurgical unit. The grounding pad should be placed as far away as possible from the pacemaker and its wires. Additionally, the path from the grounding pad to the electrosurgical tip should not traverse the pacemaker circuit. Because of capacitive coupling, it is possible for electrosurgical noise to inhibit or turn off any pacemaker or to disrupt the pacing program in a programmable pacemaker. Such interference can result in complete heart block and no pacing, or in severe tachycardia. Anesthesiologists should always be prepared to reset a pacemaker to the asynchronous mode (i.e., regular, uninhibited pacing). Isoproterenol, a pharmacologic pacer, should be available to the anesthesiologist when the patient has a cardiac pacemaker.

SAFE PRACTICE

Because explosive anesthetic agents are no longer used, [43] hospitals are no longer required to regulate the conductivity of operating room floors and tables. Therefore, problems resulting from poor electrical grounding might occur more frequently in the future. The following general guidelines describe safe electrical practice.

1. All electrical equipment used in the operating room should be grounded (such equipment will contain ungrounded circuits). If the power plug for the electrical outlet has only two prongs, the equipment should not be in the operating room.
2. Do not connect patients to the operating room electrical ground.
3. When electrosurgery is in use, do use a grounding pad

to connect the patient to the ground connection provided on the electrosurgery machine. Be sure that the grounding pad is in contact with the patient across a large area and that the pad is well gelled. Inspect the pad during long cases and re-gel or replace the pad if necessary. Place the electrosurgical ground plate as near the operative site as possible and as far from pacemaker wires and ECG wires as possible.

4. If increasing levels of current are required for electrosurgery, beware of faulty connection of the electrosurgical grounding pad. Beware also of errant current paths that include the grounding pad and another electrical contact (e.g., an ECG electrode) but not the electrosurgical pencil.
5. If the line isolation monitor alarms after someone activates equipment, immediately unplug the piece of equipment that caused the LIM to sound. This piece of equipment has allowed the secondary side of the main isolation transformer to be coupled to ground. It is also possible that so many items were plugged in simultaneously that their combined capacitance coupled the secondary side to ground. You could therefore unplug another piece of equipment and then plug in the item, causing the LIM alarm to sound. If, however, the LIM alarm goes on after the other piece of equipment has been unplugged, remove the offending item from the operating room. It has an unwanted connection to ground somewhere.
6. Use a bipolar unit when a patient with an implanted cardiac pacemaker needs electrosurgery. Understand the type of pacemaker your patient has and have the appropriate magnets and equipment available for immediate use in case of pacemaker interference or dysfunction. For patients with complex, programmable pacemakers, this might require preoperative consultations with cardiologists and cardiac electrophysiologic personnel. Understand how you would initiate pharmacologic treatment of complete heart block for any of your pacemaker-dependent patients.
7. Make sure that all electrical equipment is tested periodically by experienced personnel, that the equipment is maintained properly to ensure that standards of performance are met, and that the entire electrical environment also meets NFPA standards. [14] [44] [45] [46] [47] [48] [49]
8. When using a pulse oximeter to monitor oxygen saturation in an MRI magnet, make sure that the connection between the oximeter console and the patient occurs through a long fiberoptic cable having no wires or conducting segments.
9. If the cause of an electrical burn is uncertain, have experienced biomedical personnel participate in a thorough investigation that might include simulation of patient conditions. [7]

Chapter 84 - Environmental Safety Including Chemical Dependency

William P. Arnold III

INTRODUCTION

In the past, perhaps the greatest threat both to patients and to anesthesiologists was the potential for fires and explosions. With the advent of nonexplosive anesthetics, these hazards gradually vanished. Newer anesthetics, modern intravenous drugs, state-of-the-art electronic equipment, and patients with transmissible diseases are now part of our everyday practice and consequently have introduced another generation of hazards. The purpose of this chapter is to discuss these contemporary risks and appropriate preventive measures. This review includes many of the well-known sources of apprehension, such as waste gases, radiation hazards, and infections; emphasis is placed on infection and chemical dependence.

For the past 30 or more years, interest in the hazards presented by the operating room environment has been directed at several issues. Figure 84-1 shows the distribution of the National Library of Medicine (NLM) database of references from 1966 through late 1997, indexed by both "occupational diseases" and "anesthesiology." One hundred forty-nine publications were identified, not including letters. Although the search was influenced by the NLM's method of indexing and obviously did not identify all the relevant work, it provides some indication of the general concerns as reflected in the literature. From 1966 to 1972 , waste anesthetic gases dominated the publications. More recently, infection has become the predominant topic.

WASTE GASES

The central points concerning waste gases (Ch. 6) are that (1) anesthetic vapors do enter the operating room atmosphere, (2) their concentrations may be well controlled with proper scavenging, and (3) although there are data to suggest that chronic inhalation of trace concentrations of anesthetics may be harmful, these studies are inconclusive. At this writing, a task force composed of internationally recognized experts on waste anesthetic gases, working by direction of the American Society of Anesthesiologists, is preparing an up-to-date document on the issue. Publication in mid-1999 was anticipated.

Concentrations of waste gases are usually reported on a volume per volume basis in parts per million (ppm). Thus, 100 percent halothane, such as in the saturated vapor above the liquid in a bottle or vaporizer, has a concentration of 1 million ppm. Similarly, 1 percent halothane represents 10,000 ppm. Waste nitrous oxide and halogenated agents in the absence of scavenging may approach concentrations of 3,000 and 50 ppm, respectively. [1] The National Institute for Occupational Safety and Health (NIOSH) has recommended that the upper limits in the atmosphere of operating rooms be 25 ppm for nitrous oxide and 2 ppm for halogenated agents (or 0.5 ppm for halogenated agents used in combination with nitrous oxide). [2] To put these figures in perspective, assuming that 1 mL of a volatile liquid anesthetic produces 200 mL of vapor, that volume of liquid spilled in a closed room measuring 20 by 20 by 9 feet results in a concentration of vapor of nearly 2 ppm. In practice, the NIOSH recommendations are nearly impossible to achieve,

Figure 84-1 Relative interest in occupational diseases. One hundred forty-nine publications, excluding letters, were identified in a MEDLINE search from January 1966 to late 1997 using the strategy *explore occupational diseases* and *anesthesiology.* In the 1970s, operating room pollution was of significant interest. Over the past 15 years, the number of publications relating to infection has increased. The apparent paucity of citations on addiction reflects the methods by which these articles are indexed.

although proper scavenging methods decrease concentrations by about 90 percent. [1] The maximal concentration of halothane recommended by NIOSH is several-fold lower than the lowest concentration that humans can recognize. Fifty percent of volunteers are able to detect halothane at concentrations as low as 33 ppm. The threshold of perception ranges from less than 3 to more than 100 ppm. [3] Thus, if one smells the anesthetic, its concentration is well above the maximum recommended level.

Health Risks

Until the late 1960s, there was little concern about the potential for adverse effects on operating room personnel from inhaling trace concentrations of anesthetic gases and vapors. For the decade that followed there was a flourish of interest that more recently has apparently declined in intensity (see Fig. 84-1). The inaugural report suggesting that there was a problem appeared in 1967 in the Russian literature. [4] A multitude of retrospective reports followed, each suggesting that trace concentrations of anesthetics presented considerable risk to operating room personnel. Of these, three large studies conducted during the mid-1970s in the United States and in the United Kingdom all concluded that the prevalence of abortion was substantially higher in female anesthesiologists than in female physicians working outside the operating room. Furthermore, the incidence of congenital anomalies seen in children of both male and female anesthesiologists was higher than in the control groups of physicians. Although the prevalence of malignancy was similar in both anesthesiologists and controls, liver disease was reported more often by male anesthesiologists. [5] The authors of each of the reports recognized that problems were associated with reporting retrospective data; nevertheless, their observations provoked significant concern among anesthesiologists. Some readers may have discounted the possibility that other environmental factors in the operating room, such as radiation, stress, and contact with organic chemicals, might also be culpable.

In addition to fear, the reports also stimulated the appearance of numerous review articles, many of which critiqued the original data and reinterpreted them. Methodologic concerns, including the retrospective cohort design based on questionnaires completed by each respondent, were prominent in these critiques. Biases may have arisen for many reasons, including (1) inadequate response rates; (2) lack of control for confounding variables, such as age, nutrition, obstetric history, drinking, smoking, exposure to methylmethacrylate, and radiation; (3) lack of quantification of the exposure to anesthetic vapors; (4) losses to follow-up; (5) inappropriate comparison groups; and (6) lack of independent verification of the reported data. [6] [7] Even the titles of some questionnaires, for example, "Effects of Waste Anesthetics on Health" and "Anesthetic Practice and Pregnancy," may have introduced bias by stimulating respondents who work with anesthetics to overreport their past experiences. [8] [9] In any study of this type, self-reported historical information and disease outcomes are certain to be biased if the respondents have a preconceived idea of its goals. To summarize, all the data may be inconclusive.

Rather than continuing to reexamine the data already obtained, what is needed is a well-planned long-term prospective assessment of the health of appropriately selected cohorts and controls. [6] [7] These groups will require close monitoring to eliminate bias. Such a study involving 11,000 women in Great Britain was completed in the mid-1980s, but at this writing, the long-awaited results remain unavailable. [10]

Even though no firm evidence suggests that trace concentrations of anesthetic agents present a health hazard, there is no definite proof to the contrary. Perhaps for this reason, the Occupational Health and Safety Administration (OSHA) requires compliance with its Hazard Communication Standard on toxic and hazardous substances (29 CFR Part 1910.1200). This includes required courses for operating

room and recovery room personnel on the potential for harm from these agents. In any case, it makes sense to minimize our exposure to waste gases by exercising care when filling vaporizers with volatile anesthetics and preventing gases from venting into the operating room. [11]

Effect on Performance

The possibility that waste anesthetic gases could adversely affect the intellectual and motor skills of anesthesiologists was also addressed during the 1970s. In a laboratory setting using male volunteers, Bruce and Bach [12] demonstrated that concentrations of nitrous oxide as low as 50 ppm, either alone or in combination with 1 ppm of halothane, resulted in decreased behavioral performance; however, 25 ppm of nitrous oxide combined with 0.5 ppm of halothane had no effect. It was from these data that the NIOSH recommendations arose. [2] Subsequently, three other groups of researchers studying volunteers in laboratories have been unable to confirm the findings of Bruce and Bach. [12] The lack of agreement between investigators has led some to conclude that "it is reasonable to state that there is no convincing evidence that anesthetic agents in concentrations equal to those found in unscavenged operating theatres have any effect on the psychomotor performance of healthy subjects in the laboratory." [13] A study conducted on volunteers in an operating room during normal clinical activities in which trace

concentrations of nitrous oxide and halothane ranged from zero to 2,300 and zero to 37 ppm, respectively, also failed to detect impairments in psychomotor performance. [14] Although there is no incontestable proof that inhaling trace concentrations of anesthetics alters higher mental functions, common sense dictates that care should be exercised to keep levels as low as possible.

RADIATION

During the course of patient management, the anesthesiologist is almost routinely exposed to both ionizing and nonionizing electromagnetic radiation. The former is primarily from x-rays and occasionally from radioactive isotopes that release gamma rays, and the latter is from lasers. Less common is contact with ionizing radiation from radioactive isotopes that release either alpha or beta particles. Ionizing radiation has enough energy to create both free radicals and ionized molecules in tissues by driving electrons completely out of their stable orbitals. If the radiation exposure is severe enough, tissues may be destroyed or chromosomal changes may cause malignant growth. Nonionizing radiation may excite electrons to move from ground state to higher orbitals in molecules, but the electrons remain in the molecule. In this case, damage to tissues may result from the heat produced by the absorbed radiation.

Ionizing Radiation: X-Rays

The increasing use of x-rays during the past 2 decades in the operating room and in remote locations has revolutionized the practices of several surgical specialties (Ch. 66) . Fluoroscopy coupled with image intensifiers and video displays has significantly improved the surgical care of patients by providing immediate information to the neurosurgeon, orthopedic surgeon, urologist, gastroenterologist, and others. It may also have decreased operating time by preventing delays inherent in waiting for films to be processed. The disadvantage of this increased use of fluoroscopy is the exposure of operating room personnel to ionizing radiation. Because this type of radiation is undetectable with our normal senses, it occasionally creates undue fear, termed *radiation mystique* by some. A basic understanding of its features may reduce some of the unwarranted concerns, while permitting one to keep personal exposure to a minimum. Film badges, although not protective, provide a means of monitoring exposure.

Exposure is commonly reported in units of rem *(roentgen equivalents man).* The rem is essentially a measure of the biologic damage from radiation adjusted to apply to all tissues. [15] Estimates of radiation exposure from natural sources vary, depending on geographic location. The average in the United States ranges from 80 to 200 millirems (mrem) per year. Natural radiation comes primarily from cosmic rays (about 40 mrem at sea level, with an increase of 10 mrem/1,000 ft) and also from radioactive compounds found in soil, brick, and concrete. An isotope of potassium contained in body fluids is an internal source of beta particles. For most physicians, the additional radiation from occupational exposure is no greater than that from natural sources. Although the maximum yearly occupational exposure is mandated to be no more than 5 rem, radiology personnel rarely absorb more than 10 percent of this dose. Their greatest source of exposure is fluoroscopy. [16] During pregnancy, radiograph personnel are advised to limit their exposure to a maximum of 500 mrem.

Occupational exposure to radiation comes primarily from x-rays scattered by both the patient and the surrounding equipment. One chest radiograph results in about 25 mrem of exposure to the patient; procedures requiring multiple films occasionally involve more than 1 rem. The amount of radiation generated during fluoroscopy depends on how long the x-ray beam is on. Although radiograph machines are designed to minimize stray radiation, some radiation scatters and is absorbed by personnel who are near the patient. Just as light is reflected from surfaces, x-rays are reflected from surfaces on which they impinge (Fig. 84-2) . This scattering accounts for most occupational exposure. Because the intensity of scattered radiation is inversely proportional to the square of the distance from the source, the best protection is physical separation. A distance of at least 3 feet from the patient is recommended. Six feet of air provides protection the equivalent of 9 inches of concrete or 2.5 mm of lead. [17] Although they are uncomfortable, aprons containing the equivalent of 0.25 to 0.5 mm of lead sheet are effective in blocking most scattered radiation, and such devices are recommended to be worn whenever there is an exposure risk. [18] Uncovered areas, such as the lens of the eye, still bear risk of injury. Intraoperative radiation measurements have shown that exposure is inversely related to the experience of the surgeon and also that the amount of radiation received by the anesthesiologist during orthopedic procedures is unmeasurable. [19]

Radiation physicists recommend adhering to the ALARA

Figure 84-2 Scattering of radiation. Most of the radiation striking the target and table is reflected upward; some of it passes through and strikes the detector. Personnel adjacent to the table are struck by scattered radiation.

program: radiation exposure should be kept *as low as reasonably achievable.* The staff of departments of radiology have been extensively schooled in the physics of radiation as applied both to its diagnostic use and to the safety of occupational exposure. Attention to their methods of protection will limit exposure to minimal levels for all. As questions of radiation safety arise, they should be directed to health physicists at your hospital.

Nonionizing Radiation: Lasers

Laser (Ch. 64) is an acronym for *light amplification by stimulated emission of radiation.* Lasers produce infrared, visible, or ultraviolet light. Although the radiation from lasers is nonionizing, it is potentially unsafe both because of its intensity and because of the matter released from tissues during treatment.

Lasers are used in many surgical specialties, including ophthalmology, plastic surgery, gynecology, neurosurgery, urology, head and neck surgery, and gastrointestinal surgery. The surgical laser produces intense focused electromagnetic radiation to cut or destroy tissues. The radiation is usually infrared or visible light and is created in a "laser medium" that is stimulated by high-intensity energy to release photons of identical wavelengths (coherent or monochromatic light) from a laser chamber. The material in the medium (e.g., carbon dioxide, argon) is responsible for the wavelength produced by the laser. Of those in common clinical use, carbon dioxide and neodymium:yttrium-aluminum-garnet (Nd:YAG) lasers emit light in the far-infrared and near-infrared wavelengths, respectively; the argon and tunable dye lasers produce visible light. [20] The choice of laser used is based on the surgical goal.

Eye injuries are the greatest risk to personnel working near lasers. Strict standards for protection have been developed on the basis of current understanding but are subject to periodic revision as more experience is gained with these instruments. Either direct exposure or reflected radiation may cause eye damage. Injuries include burns to the cornea and retina, destruction of the macula or optic nerve, and cataract formation. Protective eyewear is designed to filter out the radiation produced by a specific type of laser, while still permitting vision. For example, clear plastic lenses block the far infrared (10.6 mum) radiation from carbon dioxide lasers but provide no protection against the nearinfrared (1,060-nm) radiation emitted by Nd:YAG lasers. The type of protection provided by a given filter is marked on the frame of the goggles and should be checked before use. Filters that are scratched or crazed should not be used. Because certain filters block portions of the visible spectrum, it is prudent to confirm preoperatively that patient monitors can be seen and interpreted correctly with goggles in place. Protective eyewear is recommended for all personnel because reflected radiation can be as hazardous as direct radiation, and the intensities are not diminished significantly in the distances traveled in the average operating room. [20]

Although the *plume,* the vapor and cellular debris produced during laser surgery, is commonly malodorous, until recently, it was not considered to be other than unpleasant. Now, there is concern that the plume may present a significant risk. The median size of particles in plume samples obtained intraoperatively is 0.31 mum in diameter and ranges from 0.1 to 0.8 mum. Most surgical masks do not trap such small particles. [21] Even after filtration of particles greater than 0.5 mum in diameter, exhaust smoke from tissues treated with a carbon dioxide laser causes pulmonary lesions in laboratory animals. If all particles larger than 0.1 mum are scavenged, no lung damage occurs, pointing out the importance of scrupulous removal of the plume. [22] Under experimental

---

conditions, viable bacteria have been recovered from the plume emanating from laser irradiation. [23] In addition, intact DNA from human papillomavirus (HPV) has been detected in the vapor from both laser-treated plantar warts and genital condylomata. [24] [25] More frightening is that human immunodeficiency virus (HIV) proviral DNA has been found in laser smoke produced by vaporizing cultures of HIVpositive cells. Although these experiments, which used tissue cultures, do not replicate the clinical situation, they stress the importance of strict attention to smoke removal. [26] With adequate evacuation and filtration using equipment specifically designed to scavenge such vapors, it is unlikely that operating room personnel will be contaminated by laser-dispersed HPV DNA. [25] However, a case report documents the appearance of laryngeal papillomata in a laser surgeon who, without the benefit of a laser smoke evacuator, had previously treated several patients infected with anal condylomata. Tissue from the surgeon's laryngeal tumors contained HPV DNA types 6 and 11, the same viral types that are commonly harbored by anogenital condylomata. Although not conclusive, these findings suggest that the laryngeal papillomata may have been caused by inhaled virus particles. [27] It therefore seems prudent to ensure that utmost care is taken to scavenge all vaporized debris.

INFECTION

While managing patients, the anesthesiologist is exposed to a multitude of communicable diseases, most of which present no significant threat to healthy people. [28] For example, infection with herpes simplex virus, particularly herpetic whitlow (infection of the digits), a self-limited disease, may result from contact with contaminated secretions from the airway. The recommended use of appropriate precautions usually prevents this and other types of viral infection, including cytomegalovirus (see *Standard Precautions*). However, some still recommend that pregnant health care workers avoid patients with cytomegalovirus because of its teratogenic effects. Although the potential of infection is low, it is important to consider the possibility and take the necessary precautions.

The greatest concerns stem from contact with patients infected with viruses causing HIV, hepatitis C, or hepatitis B. As a rule, the probabilities of becoming infected from a needle contaminated with one of these viruses are 0.3, 3, and 30 percent, respectively. This section concentrates on these three catastrophic diseases while also addressing tuberculosis, the incidence of which has declined appreciably in the United States during the past few years, although it remains unabated in many parts of the world.

In March 1992, OSHA issued comprehensive, enforceable standards designed to minimize occupational exposure to blood-borne pathogens. The employer is responsible for maintaining an exposure control plan that protects all health care workers who have the potential for contact with blood or blood products. Protective equipment, including gloves, gowns, and eye shields, must be supplied by the employer at no cost to the employee. The standard also provides for hand-washing facilities, proper receptacles for contaminated materials, methods for handling contaminated laundry, and management of waste, among many other things. [29]

Acquired Immunodeficiency Syndrome

Since the early 1980s, the word AIDS (acquired immunodeficiency syndrome) has come to instill fear in many health-care workers. [30] The possibility of a slow demise resulting from contact with an unseen but deadly virus that gradually destroys the immune system, that promotes a multitude of opportunistic infections, and that may result in progressive dementia is frightening. HIV, which is responsible for the syndrome, is a relatively fragile virus. With proper attention to cleanliness and care in performing invasive procedures, the likelihood that an anesthesiologist will develop the disease in the course of patient management is exceedingly low.

Two human immunodeficiency viruses, HIV-1 and HIV-2, are responsible for infections in humans. The former is found worldwide, and the latter occurs principally in northwest Africa, although it is now spreading into Europe. [31] Both are retroviruses that attach to cells having CD4 surface antigen (predominantly T-helper lymphocytes) and ultimately replicate by integrating virally produced DNA into the nucleus of the host cell. [32]

Initial infection with HIV follows within 2 to 10 weeks of inoculation. It is usually a self-limited, nonspecific, febrile viral syndrome lasting 1 or 2 weeks. An individual is considered to be both infected with HIV and infective if the results of both a serologic screening test, the enzyme-linked immunosorbent assay (ELISA), also called enzyme immunoassay (EIA), and a supplemental, more sensitive test, either Western blot or indirect fluorescent antibody, are repeatedly positive. ELISA tests are relatively easy to perform in a clinical laboratory but may be subject to false-positive results. Supplemental tests are time consuming but are necessary for confirmation. Results of the tests become positive within weeks of inoculation, but the median latency for the first opportunistic disease may be as long as 11 years. [32]

Epidemiology of AIDS

The apparent incidence, death rates, and other epidemiologic features of AIDS are influenced by methods used to obtain these values. Although AIDS is a reportable disease in the United States, infection with HIV is not. Because the incidence of HIV is derived from studies of population cohorts rather than from individual cases, its numerical significance is less precise than are data concerning AIDS. [33]

On January 1, 1993, the criteria for defining AIDS were expanded from those of 1987 to include objective laboratory data and illnesses not previously used in confirming the diagnosis. With these changes, all HIV-infected patients with CD4 T-lymphocyte counts of less than 200/muL, and also those with opportunistic infections, including pulmonary tuberculosis, recurrent pneumonia, and cervical cancer, were defined as having AIDS. The result was an apparent 200 percent increase in cases of the disease reported in early 1993. [34] At that time, nearly 900,000 persons in the United States were estimated to be infected with HIV. In spite of these methodologic changes, the proportional rate of the annual increase in cases of HIV has declined in recent years, and the downward trend in both incidence and deaths that

began in the mid-1990s is apparently continuing. [35] [36] These encouraging observations can perhaps be attributed to an expanding body of information concerning the virology, biology, and treatment of HIV. In spite of these overall declines, the incidence of AIDS appears to be increasing certain subpopulations, including black men and women and persons born after 1960. [35] [36] Since 1993, infection with HIV/AIDS has been the leading cause of death in persons aged 25 to 44 years. [37] At present, more than one in five of those with AIDS is female, a significant increase from the one in seven reported less than 5 years ago. A consequence may be an increased incidence in children, because perinatal transmission of HIV-1 occurs in as many as 25 percent of the offspring of infected mothers. Transplacental infection and possible transmission via breast milk have been implicated. [32]

AIDS and Health-Care Workers

Health-care workers comprise about 5 percent of the cases of AIDS in the United States. Although there are some reports of occupationally related infections, most of the cases have been attributed to nonvocational contact. [38] However, epidemiologic data, coupled with the observation that more than 4 percent of 2,300 patients presenting to an urban emergency department had unrecognized HIV infections, [39] suggest that the potential for health-care workers to have contact with an unidentified carrier of the disease is significant. By mid-1998, the Centers for Disease Control and Prevention (CDC) had documented 54 cases of occupationally acquired HIV infection in the United States, 88 percent of which were the result of an injury from a sharp object. [40]

Injury from a needle is the most likely route of infection for anesthesiologists. Of 493 anesthesia personnel surveyed in a multicenter study, 32 percent reported having been stuck with a contaminated needle at least once in the preceding 12 months. Of those, only half sought treatment. [41] The risk of infection is greater with hollow-core than with solid needles and is further increased with large-bore needles and deep intramuscular injection. [32] In a study evaluating percutaneous injuries in anesthesia personnel, nearly 90 percent were from hollow-bore needles, were self-inflicted, most commonly involved the nondominant hand, and were deemed preventable. A significant number of the injuries occurred during disposal of contaminated needles. [42] The minimal dose of contaminated blood needed to infect humans is unknown, although one patient became HIV positive after the accidental intravenous injection of 100 to 200 muL of infected blood. [43] The likelihood of developing antibodies to HIV is related to the volume of the inoculum and the concentration of viral particles. [44] Consequently, most seroconversions have been associated with deep intramuscular injection of contaminated blood through large-bore needles. The theoretical risk for occupational infection in anesthesiologists

over a 30-year exposure period has been calculated to range from 0.05 to 4.5 percent, depending on infectivity of the patient population; however, these estimates are based on incomplete data. [45] The overall risk to health-care workers of seroconversion after documented percutaneous exposure to HIV-infected body fluids is usually said to be about 0.3 percent. Although seroconversion has been documented after nonintact skin has been in contact with infected blood, the incidence from this route is far lower than from needle injuries. [44] [46]

The risk of transmission of HIV from health-care workers to patients, with the exception of errors in technique, is extremely small. No infections were identified in more than 19,000 patients who had been treated by 57 infected health-care workers comprising 29 dentists, 12 surgeons, and 16 physicians in nonsurgical specialties. The only documented infections have been in 6 of 1,100 patients treated by a dentist in Florida. [47]

With proper attention to routine methods of disinfection, sterilization, and housekeeping, the AIDS virus on instruments, surfaces, and laundry can be destroyed. When at concentrations of five orders of magnitude greater than normally found clinically, HIV may survive for several days after being dried. This represents an extreme. Several hours of drying usually inactivates 90 to 99 percent of viable virus. The amount of HIV usually found on contaminated surgical instruments and equipment used in anesthetic management can be killed with "high-level disinfection." This involves careful cleaning, followed by exposure either to one of the commercially available germicides or to a 1:10 to 1:100 dilution of sodium hypochlorite (household bleach). These methods annihilate bacteria and viruses but may not be effective against bacterial spores. If the instruments are to be sterilized, they should first be thoroughly cleaned. Contaminated hospital linen should not be washed or rinsed in the operating room or another patient care area; instead, it should be placed directly in sealed, water-impenetrable bags. It can be safely laundered by normal methods. Infective waste, including secretions, blood, and other body fluids, should be incinerated or autoclaved. Alternatively, large volumes of fluids may be discarded in a sanitary sewer. [48] Personal protection and protection of patients is afforded through standard precautions.

Hepatitis

Viral hepatitis may result from infection with any of several different pathogens. Of greatest interest to the anesthesiologist are the viruses responsible for hepatitis B virus (HBV), and hepatitis C virus (HCV), the major cause of non-A, non-B (NANB) hepatitis. In contrast to these hazardous pathogens, hepatitis A is an insignificant occupational threat. It is normally transmitted by the fecal-oral route and almost never by contact with blood. It is usually self-limiting, and although it may produce jaundice, it has few long-term sequelae. The appearance of antibodies to the virus several weeks after exposure confirms the diagnosis. Treatment is limited to one dose of gamma globulin. [49]

Hepatitis B

Hepatitis B is a serious disease that may be life threatening, but it can be prevented. In the 1980s, it was estimated that 200 to 300 health-care workers would die annually from the effects of HBV. Fortunately, the introduction of an effective vaccine for hepatitis B has dramatically decreased the incidence, morbidity, and mortality of the disease. [44] Infection

may be documented serologically by the appearance of HBV surface antigen (HBsAg), HBV surface antibody (anti-HBs), or HBV core antibody (anti-HBc) in serum. Before routine vaccination, the development of covert seropositivity for hepatitis B during residency was common. In a multicenter study involving hospitals in both rural and metropolitan areas, the overall prevalence of serologic indicators for hepatitis B in anesthesiology residents who had received neither hepatitis vaccine nor hepatitis B immune globulin (HBIG) was 17.8 percent of 267 tested. Most seropositive residents were unaware of having been exposed to hepatitis. There was no correlation between incidence and geographic location, but the incidence of seropositivity increased in parallel with clinical experience. Thirty percent of residents with more than 11 total years of experience, including their current residency and previous work in other specialties, were seropositive for hepatitis B. The routine use of gloves and attention to obtaining detailed histories from patients did not appear to decrease the incidence of infection. [50]

An estimated 200,000 new cases of HBV infection occur each year. Of these cases, 50,000 will develop jaundice, and 10,000 will require hospitalization. As many as 12,000 to 20,000 annually become asymptomatic carriers of HBsAg, with the total number of carriers in the United States estimated to be nearly 800,000. [51] It is this group that threatens the nonimmunized anesthesiologist. The epidemiologic features of HBV and AIDS have much in common, although intravenous drug abuse has surpassed homosexual activity as the most common risk factor associated with HBV infection. [52] The likelihood of nonimmunized health-care workers developing hepatitis from contact with infected body fluids is much higher than that for AIDS. The incidence of seroconversion after parenteral inoculation with HBV can be as high as 40 percent, depending on the infectivity of the host and the magnitude of contact with the blood. [53] In comparison to HIV, HBV is much more robust. Neither treatment at 60°C for 4 hours nor use of disinfectants containing phenol or chlorine is sufficient to inactivate the hepatitis B particle with certainty. It remains viable on needles, environmental surfaces, and gloves for longer than 14 days. [26] Because gloves do not guarantee protection from accidental needle sticks, and because HBV is relatively resistant, accidental contact with live virus may occur in the course of patient management and also during the cleaning of equipment.

Active immunization of seronegative health-care workers with hepatitis B vaccine is imperative for prophylaxis against infection. The first vaccine was composed of inactivated particles of surface antigen prepared from sera of HBsAg carriers. Ninety percent of recipients of the vaccine became seropositive and are thus were protected against infection. [51] In spite of the efficacy and the safety of the early vaccine, in the mid-1980s, substantial numbers of anesthesia personnel refused to be immunized for unspecified reasons. [50] Some were concerned that because the vaccine for hepatitis B was prepared from sera obtained from patients at high risk for developing HIV infection, it might also transmit HIV. In the late 1980s, a vaccine was developed in yeast by use of recombinant DNA methods. Although there is no possibility that HIV could be present in this vaccine, it is less effective in producing antibodies to HBV than is vaccine prepared from plasma. [54] The OSHA standard on blood-borne pathogens mandates that employers must make vaccine against HBV available at no cost to all employees who have a reasonable chance of exposure to the virus. [29] In spite of its proven safety and economic appeal, a substantial number of health-care workers have continued to refuse the immunity conferred by this vaccine. [55]

Anesthesiologists in whom no antibodies are present in serum who suspect that contact with HBV has occurred should be passively immunized with HBIG and should also receive a series of three injections of hepatitis B vaccine. [44] Prior vaccination and seroconversion eliminate the need for HBIG, whose acronym is an appropriate description of the discomfort it produces after injection.

Hepatitis C

Hepatitis C virus is now recognized as one of the major causes of NANB hepatitis. This disease, whose symptoms and signs are nonspecific, is the predominant source of hepatitis from transfusion. Chronic hepatitis develops in more than 85 percent of hepatitis C infections, with 20 percent progressing to cirrhosis and 3 percent to hepatocellular carcinoma. It may also result in the development of a chronic carrier state. [56]

Important discoveries in the diagnosis of HCV were reported in 1989 when (1) a segment of the genome of an NANB virus was isolated, cloned, and designated "hepatitis C virus," and (2) an assay for circulating anti-HCV antibodies was developed. [57] [58] Like HBV, HCV appears to be transmitted principally by infected blood. Studies with the anti-HCV assay have shown that HCV is responsible for up to 90 percent of transfusion-related NANB hepatitis. [59] With this assay, some have reported only a 1 to 2 percent incidence of antibody to HCV in health-care workers (similar to that seen in volunteer donors), suggesting that HCV is not easily transmitted. [59] [60] Reports based on the same assay indicate that transmission of HCV by contaminated needles occurs in less than 4 percent of these injuries. [61] More sensitive assays for HCV are currently under investigation. One of these, the detection of HCV RNA by polymerase chain reaction, documented an incidence of HCV infection of 10 percent in health-care workers. [62] This method is limited to laboratory investigation, it is not licensed for clinical use, and its accuracy is widely variable. [63] However, with further refinement, it may become an important method for determining precisely the incidence of occupationally acquired HCV infection.

Unfortunately, at present, there is no treatment for HCV infection. Even so, health-care workers who are exposed percutaneously to HCV should have liver function tests and baseline testing for antibody to the virus as soon as possible after the injury and should be retested 3 and 6 months after exposure. [63] Some institutions offer immune serum globulin to these persons as prophylaxis against infection. However, this is of little value because anti-HCV antibodies are not consistently found in production lots of immune globulin. [44]

Tuberculosis

Tuberculosis, the leading cause of death in the early 20th century, appeared to be steadily decreasing in incidence

with the advent of streptomycin in 1946, isoniazid in 1952, and rifampin in 1970. However, in 1985, the incidence in the United States began to climb significantly. Between then and 1990, reported cases increased by 16 percent, with a 10 percent increase in 1990 alone. This was the largest increase since national reporting began in 1953. [64] Most cases were from reactivation of old infections in immigrants or in patients whose immune system had been compromised, and many involved multidrug-resistant strains of *Mycobacterium tuberculosis.* Epidemic transmission between hospitalized patients and from patients to health-care workers also occurred. [65] [66] Common to most of these cases was a low index of suspicion for tuberculosis, occasionally not confirmed prior to postmortem examination. [67]

In response, in 1990, the CDC issued new guidelines for preventing the transmission of tuberculosis in hospitals, and in 1992, the CDC published recommendations for managing multidrug-resistant tuberculosis. [68] [69] Since then, there has been a steady decline in the number of new cases of tuberculosis, resulting in the lowest number of reported cases since 1953, the first year of reporting in the United States. [70] In 1994, the CDC replaced all previous guidelines with a comprehensive new program for the prevention of multidrug-resistant tuberculosis in health-care facilities. [71] The program places the responsibility for managing tuberculosis prevention on individual health-care facilities rather than requiring identical standards for all hospitals. Paramount are the identification and treatment of patients with tuberculosis; the development of engineering controls, including isolation rooms, filters, and ventilation; the use of personal protective equipment; and the implementation of educational programs for health-care workers. Anesthesiologists should be aware of the applicability of these guidelines to the specialty. [64]

In 1996, the overall incidence of tuberculosis in the United States was 8 cases per 100,000 population. The incidence was highest in the District of Columbia (26/100,000), followed by Hawaii (17/100,000) and California (14/100,000). The rate was highest in foreign-born persons (31/100,000), most of whom were from Asia and the Caribbean. The goal of the CDC is to decrease the rate to 3.5 cases per 100,000 population by the year 2000 and to less than 1 per million by 2010. Close attention will be paid to these cohorts. [70]

Tuberculosis spreads by small (1- to 5-mum) airborne droplets released when an infected person speaks, coughs, sneezes, or sings. Transmission of the bacillus is more likely in small, poorly ventilated areas and during coughproducing procedures, including bronchoscopy and laryngoscopy. The probability or transmission is also directly related to the concentration of infectious droplets and the duration of exposure. In healthy persons who have inhaled contaminated droplets, the resulting systemic infection is usually limited by the immune system within 2 to 10 weeks. In these individuals, the risk of developing active tuberculosis after infection is about 10 percent. The likelihood is higher in patients with HIV. [71]

All health-care workers who are at high risk for exposure to *M. tuberculosis* should be skin tested at the time of employment. Those whose test results are negative should be retested annually. The appearance of a positive tuberculin skin test (purified protein derivative) in an individual who has never had such a reaction suggests that a new infection has developed. Subsequent progression to active tuberculosis can usually be prevented by 6 to 12 months of preventive therapy, which should be considered for all persons who are newly infected. Nosocomial transmission of tuberculosis is a significant threat to health-care workers. Prevention should include (1) increased awareness of the disease, (2) appropriate isolation and treatment of infected patients, and (3) a national program of education [71] similar to that already mandated for blood-borne pathogens. [29]

Isolation Precautions

In the late 1980s, the CDC prepared a series of guidelines for health-care workers who have contact with patients or body fluids. [48] [72] They were subsequently incorporated into the OSHA standard on occupational exposure to blood-borne pathogens. [29] The recommendations can be best summarized by stating that because there are no symptoms or signs that conclusively reflect the presence of blood-borne pathogens, all patients, blood, and body fluids should be considered potentially infective. The same safeguards should be used for all, hence the guidelines were given the title *universal precautions.*

In 1996, the CDC published an all-encompassing guideline on nosocomial transmission of diseases. The new guideline, termed *isolation precautions,* addresses the potential that contact with any bodily emission may be hazardous to health-care workers. In addition to direct contact, the hazards include all body fluids, secretions, and excretions, and airborne droplets. The guideline includes methods of hand washing and gloving, patient placement, transport of infected patients, design and use of protective gear for medical personnel, equipment used in patient care, linen, laundry, and cleaning of spaces inhabited by infected patients. [73]

The guideline is composed of two tiers, *standard precautions* and *transmission-based precautions. Standard precautions* merges the principles of *universal precautions* and *body substance isolation,* which was proposed in 1987 to reduce the risk of transmission of pathogens from moist body substances through the use of gloves. Standard precautions should be used during *all* encounters with patients. *Transmission-based precautions* are necessary in the management of patients known to be or suspected of being infected or colonized with epidemiologically important pathogens. The isolation methods employed depend on the pathogen involved. [73]

Standard Precautions

Standard precautions should be practiced at all times. The following are taken almost verbatim from CDC publications. [29] [72] [73] Barrier precautions appropriate for the procedure being performed, including gloves, gowns, masks, and eye shields, should be worn when the potential for contact with blood or body fluids is present. Precautions apply to (1) blood; (2) all body fluids, secretions, and excretions except sweat, regardless of whether or not they contain visible blood; (3) nonintact skin; and, (4) mucous membranes. Strict attention should be given to hand washing after gloves

are removed, even if there has been no direct contact with blood or fluid. Needles should not be recapped, bent, or broken by hand but should instead be discarded in a puncture-resistant container. Resuscitation equipment that prevents the need for mouth-to-mouth contact should be available. All specimens sent to laboratories should be handled as if they are infected.

Transmission-Based Precautions

Transmission-based precautions should be followed when patients are known to be or are suspected of being infected with highly transmissible or epidemiologically important pathogens. They are based on the properties of specific pathogens and are to be used in addition to standard precautions.

1. *Airborne precautions* are to be used when transmission of small particles or droplets (<5 mum) is likely. Because these particles can be carried for long distances, special filtration and air handling are necessary. Diseases in this category include measles, varicella, and tuberculosis.
2. *Droplet precautions* apply to diseases transmitted by large particles (>5 mum). Because of their size and because the droplets do not remain suspended in air, transmission is limited to short distances; a meter or less is the norm. Examples include invasive *Haemophilus influenzae* type b (meningitis, epiglottitis), mycoplasma pneumonia, streptococcal pharyngitis, and rubella.
3. *Contact precautions* apply to direct skin-to-skin contact, including hands. Indirect contact may also occur if surfaces in an infected patient's environment are contaminated. Included are colonies of antibiotic-resistant organisms, hepatitis A, herpes simplex, viral conjunctivitis, and major abscesses. [73]

Latex Allergy

Since 1992, health-care workers who come in contact with infectious materials have been required to use barrier precautions, including protective gloves. [29] Coincidental with this mandate has been a progressively increasing number of allergic reactions to latex-containing products, especially in health-care workers. Components used in making gloves, including latex, accelerators (used to shorten the manufacturing process), and glove powder, have been implicated as causes. Responses may be limited to irritant contact dermatitis, a delayed type IV reaction mediated by T cells, or may be manifested by more serious IgE-mediated type I

reactions. The latter include contact urticaria, rhinitis, conjunctivitis, asthma, and occasionally full-blown anaphylactic shock. [74]

Prevalence appears to be higher in persons who have regular contact with latex-containing products. One report indicated that nearly 16 percent of the staff of a single anesthesia department had positive skin test results to latex, although of those tested, far fewer developed respiratory changes during work hours. [75] Allergic responses to latex are also associated with a history of atopy and with allergies to certain foods such as avacado, potato, banana, tomato, chestnuts, kiwi fruit, and papaya. Some individuals have developed such a severe sensitivity that they are no longer able to work in areas containing airborne latex particles or to eat food that has come in contact with latex.

NIOSH has developed recommendations for the prevention of latex allergies as they currently exist. These include protection of workers from undue exposure to latex, hand washing after removing gloves, and educational programs for hospital workers. [76] Modifications of manufacturing processes for latex products, more accurate methods to assess allergies to latex, and perhaps development of substitutes are additional goals of the recommendations. Up-to-date information concerning this dynamic area of interest is available on several Internet Web sites.

STRESS

Stresses in the practice of medicine and in one's personal life are inevitable. Sources of stress come from the job--dealing with suffering and death; uncertainty; selfperceptions of inadequacy; recurring academic deadlines, including recertification; and recent changes in the health- care system, including loss of autonomy that stems from managed care--and also from outside pressures, including family and finances. Some physicians seem to thrive in a stressful environment; others are unable to cope. [77] Stress has been implicated as a cause of drug abuse among physicians, but this is disputed by some (see *Chemical Dependence*).

Some sources of job-related stress are unavoidable, but others may be controlled. The former include the moral pressure placed on physicians by society for successful outcomes in all cases, uncertainty of the future in the era of managed care, and aging. In the latter category, at least two warrant discussion: the relationships between job performance and fatigue and between job performance and noise.

Unavoidable Stress

Management of stress is rarely addressed in medical school or in continuing medical education seminars for anesthesiologists, but it should be. Rather than being a sign of weakness, stress is a universal phenomenon to which *no one* is immune. Vital to our interactions with others is the ability to recognize stressed behavior, not only in them but also in ourselves. Healthy means of coping with stress include ability to communicate, appropriate assertiveness, interactive management of conflicts, adequate time with family, and time for recreational pastimes totally unrelated to professional activities. Irritability, anger, and aggressive behavior are common signs of improperly managed stress. A willing ear from a friend may be all that a stressed colleague needs to deal with the situation, although professional counseling may be indicated.

In a study conducted in Great Britain, the most significant source of stress for those beyond their training years was lack of control of circumstances at work. [78] Specific causes included professional relationships (especially with surgeons), work overload, threats of litigation, peer review, and increasing administrative responsibilities. Added to these were conflicts between professional pressures and personal

life. Although moderate levels of stress serve as healthy stimuli for productivity, excessive levels may impair clinical skills, resulting in potential risks to patients.

Professional dissatisfaction with medicine, an additional source of stress, is becoming an international phenomenon. It has been attributed by some to increasing health problems in the expanding elderly population, to the rapidly rising cost of health care, and to advancing technology. [79] Managed care, an evolving force in the practice of medicine in the United States, has become a source of stress that has stimulated a significant number of physicians to leave medicine (*The Washington Post,* February 16, 1998). To date, these responses to change have not been documented in anesthesiologists. [79]

Avoidable Stress

Altered Sleep Patterns

Regulation of physiologic functions, such as body temperature, sleep, alertness, and hormone release, is indexed to the 24-hour day by environmental cues that include light and temperature. These cues, termed zeitgebers by sleep physiologists, interact adversely with variable work schedules. The interactions may contribute to the higher rates of job stress, heavy drinking, and emotional problems seen in shift workers and in those working irregular hours. [80]

Well-defined periods of vulnerability to sleep have been identified in humans. The major peak occurs between 2 and 7 AM, and a smaller peak occurs in the midafternoon. These peaks appear to be enhanced by irregular work schedules and sleep disruption, and they may also contribute to diurnal variations in the frequency of mishaps. For example, single-occupant motor vehicle accidents occur with alarming regularity in the early morning. Their timing is attributed in part to this cycle. Similar relationships have been observed in the timing of catastrophic industrial accidents. The nuclear reactor accidents at Three Mile Island, Chernobyl, and two other sites in the United States all began between 1 and 5 AM. Human error was a significant factor in each mishap. Critical errors in judgment involving both the Challenger space shuttle accident and another near-disaster in the shuttle program were made in the early morning by personnel working irregular hours. Again, human error was a contributing element. Although none of these accidents can be conclusively attributed to sleep-related processes, all involved a lack of proper response by well-trained personnel working to the best of their abilities at the time of the accident. [81] On the basis of these observations, the Committee on Catastrophes, Sleep, and Public Policy of the Association of Professional Sleep Societies has made the following recommendations: (1) management should be made aware that performance errors are more common between 1 and 8 AM, (2) programs should be developed to identify signs of sleep-related error, and (3) because inadequate sleep or irregular sleep patterns enhance the tendency for error, work hours should be limited in order to permit adequate sleep. [81]

Altered patterns of sleep are a way of life for anesthesiologists. [82] As in industry, sleep deprivation may have subtle effects on vigilance in the operating room and may contribute to critical incidents. [83] Some published abstracts have documented subtle performance deficits and an increased likelihood of automobile accidents in sleep-deprived anesthesiologists. [84] [85] Considering the observations in industry and these new reports, further investigation of these relationships in anesthesiology is warranted. Changes in practice patterns may be warranted.

Noise

The effects of noise on people depend primarily on the duration and the timing of the sounds. The intensity of sound, also called sound pressure level, is displayed on a logarithmic scale and is reported in decibels (dB). A measured increase of 10 dB implies that the intensity of a sound has increased 10-fold. Sound-level meters are commonly biased to the A-weighted scale (dBA), which is thought to give a reasonably accurate measure of the response of humans to sound, although other scales are preferred by some. Conversational speech, lecture level speech, and nearby shouted speech have intensities of about 55, 65, and 75 dBA, respectively. These levels are far below OSHA standards that mandate the use of protective devices in environments where continuous sound intensities and duration of exposure are at least 90 dB and 8 hours, respectively. In addition to disrupting communication, unpleasant or unexpected noises may hinder concentration, contributing to physiologic stress. [86]

The flat, water-impermeable walls of the modern operating room are outstanding reflecting surfaces for sounds. Noise levels in operating rooms can easily approach those from a diesel engine. Particularly loud are such actions as opening packages of gloves (86 dBA), striking instruments together (80 dBA), moving equipment (60-80 dBA), conversing (66-72 dBA), power drills, and various objects striking floors. [87] The intensities of most of these sounds are greater than the intensity of normal conversation. Nonspecific tones from monitors and surgical equipment, especially when several are alarming at once, although perhaps not loud enough to impair communication, may also add to confusion. Simultaneous conversations and other distracting sounds are frequently louder than tones produced by monitors

such as electrocardiography machines, pulse oximeters, and equipment alarms. If these unnecessary auditory diversions hamper communication between anesthesiologists during stressful events in patient management, they should be stopped. Loud sounds have been shown to contribute to stress, as measured by responses of the pituitary-adrenal axis. In addition to affecting health-care workers, the din of the operating room and other acute care areas can be disconcerting to conscious patients. [88] Although noise is not known to cause problems other than hearing loss, it appears prudent to limit unnecessary sources in the operating room.

CHEMICAL DEPENDENCE

The morbidity from self-administration of drugs is far more common among anesthesiologists than are adverse effects from other potential threats in the operating room. For example, with the exception of the rare anesthesiologist who has contracted hepatitis after administering halothane to patients, no serious effects have been reported from waste

gases. By contrast, although unexplained, the suicide rate of anesthesiologists has been reported to be three times higher than that of an appropriate control group. [89] Although one may only speculate that substance abuse may play a role in this frightening figure, it is unequivocally involved in the four to eight deaths of residents by overdose that are reported each year (Arnold WP: personal observation).

The signs and symptoms of chemical dependence are so subtle that the disease is usually not obvious until it has reached its late stages. However, it occurs frequently enough in our profession to be of concern. Even those who understand the disease find it hard to imagine that a friend could be addicted to drugs and may feel powerless or hostile when it occurs. This section provides information about chemical dependence in anesthesiologists and guidance with the initial steps required to help a colleague or yourself. However, it is no substitute for the invaluable help available from experts.

The terminology in the section is based on recommendations of experts in the field of substance abuse. [90] *Addiction* is the compulsive continued use of a substance in spite of adverse consequences. Drug *dependence* is either physical or psychologic dependence on a drug. It is the result of an inability to control drug use. Drug or substance *abuse* is use of drugs in a detrimental way, but not to the point of addiction. Put simply, the drug abuser can quit without help; the addict cannot. *Recovery* is the process of conquering the disease. People who have previously been chemically dependent are referred to as *recovering,* rather than as recovered. This terminology emphasizes that chemical dependence is an incurable disease; chemical dependence, like other chronic diseases, such as diabetes and hypertension, can be controlled but not cured.

Disease

A growing body of scientific advances has proved that addiction is a chronic, relapsing disease resulting from long-term effects of drugs on the brain. [91] Acceptance of this incontrovertible fact is crucial for those dealing with chemically dependent physicians and other addicts. By considering an impaired colleague to be ill rather than an object of disdain, one will be better equipped to provide the initial guidance that the impaired physician so desperately needs.

During the 1980s, independent genetic, neurophysiologic, and biochemical observations demonstrated the complex etiology of addiction to drugs. For example, alcoholism is four times more common in the offspring of alcoholics than in appropriate controls and is related more to genetic than to environmental influences. [92] [93] Familial transmission of drug addiction has also been documented. [94] Alcoholics metabolize their drug of choice differently from nonalcoholics. [95] In inbred strains of alcoholic rats, condensation products that form between alcohol metabolites and catecholamine precursors fit opiate receptors. Similar compounds in humans may be responsible for the opiate-like euphoria that some alcoholics report. [96]

It has been discovered that essentially all drugs of abuse work through a single pathway in the brain. The mesolimbic reward system, extending from the ventral tegmentum to the nucleus accumbens with projections to other areas of the brain, is not only activated by drugs of abuse but is also irreparably altered by chronic exposure to these drugs. The molecular, structural, cellular, and functional changes that result from continued drug abuse are felt to be responsible for relapses that frequently follow periods of abstinence. At the outset, drug abuse is a voluntary event. However, once these neural changes have begun to develop, it becomes an addiction that is characterized by compulsive, irrational, drug-seeking behavior. Treatment should be directed at these changes through pharmacologic and behavioral approaches based on an understanding of the pathologic effects that the drugs have produced. A detailed presentation of these fascinating neurologic responses to chronic drug use, including upregulation of central cyclic adenosine monophosphate pathways in the locus caeruleus and the nucleus accumbens, alterations in drug receptor-G protein coupling, changes in gene expression, and modification of central neurotransmission, is beyond the scope of this chapter. The interested reader is encouraged to read several informative review articles, all of which appear in a single issue of *Science*. [90] [97] [98] [99]

The Problem in Anesthesiologists

The true prevalence of substance abuse and chemical dependence in physicians is unknown. [100] However, a national survey estimates a 2.1 percent annual and a 7.9 percent lifetime prevalence among physicians, substantially lower than the corresponding rate of 16 percent reported for the general population. [101] In the 1980s, the disease was believed to be more common in some specialties, especially anesthesiology and family medicine. [102] Estimates of the scope of chemical dependence in anesthesiologists have come primarily from two sources: questionnaires and treatment centers. Three retrospective surveys suggest that the prevalence of the disease in the specialty ranges from 1 to 2 percent. [103] [104] [105] These studies either are based on cases that have come to the attention of a superior or have relied on the honesty of those responding to the surveys. A prospective survey evaluating the incidence of the disease in training programs confirms these figures (Arnold WP, manuscript in preparation). It is unlikely that the extent to which substances are *abused* without the development of addiction will ever be known.

Treatment programs provide another source of data. Twelve to 14 percent of physicians treated in three well-known programs were anesthesiologists, although only 4 percent of physicians in the United States practice the specialty. [106] [107] [108] Anesthesiologists made up 146 of 1,225 physicians treated in one of these centers. [106] Although all of these anesthesiologists were chemically dependent, about 10 percent of the remaining physicians had other forms of impairment, such as depression. Of the anesthesiologists, nearly 50 percent were younger than 35 years of age, and one-third were residents. One-half of anesthesiologists used both drugs and alcohol, 40 percent used drugs alone, and a minority used only alcohol. Narcotics were more frequently preferred by younger anesthesiologists. Fentanyl was the most commonly abused narcotic, followed by sufentanil, meperidine, morphine, and oral agents. Some use of benzodiazepines, cocaine, and marijuana was also reported.

These data imply that the incidence of chemical dependence

is significantly greater among anesthesiologists than among physicians practicing other specialties. They also suggest that anesthesiology residents are particularly vulnerable to opiate addiction. Some believe that this apparently high incidence is indicative of the diligence of anesthesiologists in recognizing the disease in colleagues. [106] However, referral patterns may also have influenced the observations of these programs because anesthesiologists may have been sent to the programs preferentially. Other successful programs report a lower percentage of anesthesiologists in their series. [109]

Causes

Chemical dependence is a complex disease with multiple factors modifying the genetic predisposition. Although it is tempting to point to a single factor, such as stress and availability, as the cause in anesthesiologists, this approach overlooks many possibilities. Other elements to be considered are the addictive potential of the drug of choice, the prior use of drugs, and a family history of drug abuse.

Stress

Exposure to stress is a universal feature of medical school, residency, and the practice of medicine. Most physicians are able to manage these stresses through the use of acceptable outlets, such as athletics, exercise programs, social interaction, and occasional drinking of alcoholic beverages in moderation. A few do not have these abilities and instead withdraw from others. Roughly 10 percent of medical students are not graduated, and of those who are, nearly one-half need counseling. [77] Residency is particularly difficult for some. The working environment is usually highly competitive. Long hours preclude much time for true relaxation, and certain patients may evoke negative emotions. In addition, there are nonprofessional pressures, such as separation from parents, marriage, raising of children, and financial matters, to contend with during time spent away from work. A sense of professional inadequacy is nearly universal. [110] Perhaps the death of a patient after an outstanding resident has provided hours of high-quality medical care in a hopeless situation may cause these feelings to surface for the first time. Residency may breed a form of social isolation, resulting in withdrawal from friends and family and avoidance of contacts except with other physicians. The withdrawal itself may contribute to further stress because the physician senses social failure. The reluctance of physicians to acknowledge such feelings to themselves or to others contributes to a self-imposed isolation that may extend well beyond the resident years. [77] All these elements may prompt certain physicians to seek unhealthy escapes, such as the inappropriate use of alcohol and the abuse of drugs.

Availability

Anesthesiologists are unique among physicians in that they administer drugs directly, rather than order their administration by others. Thus, drugs are immediately available. This is perhaps the most important cause of addiction in the specialty. To quote many recovering anesthesiologists: "We work in the candy store." One report indicated that 85 percent of anesthesiology residents treated in one large program stated that having drugs within reach influenced their career choice. [106] Some institutions have developed elaborate control measures to combat drug pilferage. However, all such measures can be rendered inadequate by an addict who is desperate for drugs.

Drug Potency

Abuse of drugs by physicians is much more common than addiction. Some physicians abuse drugs "recreationally" to get high; others "self-medicate" to treat either a perceived illness or stress. Casual abuse of alcohol obviously does not always lead to addiction, and although exceedingly risky, neither does abuse of morphine, meperidine, or codeine. [111] In contrast, the addictive potential of fentanyl and other potent opioids is so great that anyone who experiments with these drugs is at enormous risk of becoming chemically dependent (Fig. 84-3) . [106] Some have said that a single experience with sufentanil is so overwhelming that it is impossible to stop using the drug. The doses needed to sustain a habit or to prevent the symptoms of withdrawal skyrocket once abuse begins. Rapidly developing tolerance stimulates the ever-increasing doses needed to attain the desired sensation. The use of 50 to 100 mL of fentanyl or 10 to 20 mL of sufentanil per day is common in the addicted physician. These doses are easily reached within a few months for fentanyl and a few weeks for sufentanil.

Other Factors

Some other factors predispose to the development of chemical dependence. A history of experimental use of drugs increases the risk of future addiction. [111] Genetic predisposition to chemical dependence may contribute to the progression from abuse to addiction. Lack of self-respect, denial that one's pattern of drug abuse can lead to addiction,

Figure 84-3 Time course of addiction, illustrating the relative addictive potential of several drugs. Its intent is to display a concept visually rather than to present data; thus, no numerical values appear. Dependence on alcohol typically requires years to become apparent, whereas addiction to sufentanil develops almost instantaneously. The slopes are roughly proportional to the addictive potential for each drug.

and the false assumption that an understanding of pharmacology prevents one from becoming addicted are all involved.

Management

Management of physicians who are chemically dependent includes identification, intervention, referral for treatment, and help with reentry. Having established mechanisms facilitates dealing with an impaired colleague. [112]

Identification

Identification of the chemically dependent physician usually does not occur until the disease is in its late phases, when performance at work becomes significantly impaired. Although none of its signs and symptoms is diagnostic, an awareness of the usual sequence of events may help one identify an ill colleague in the earlier stages of the disease (Table 84-1) .

Normally, withdrawal from outside interests is the first sign. Examples include giving up athletics, community activities, church, and getting together with friends. Next comes increased turmoil at home. Domestic arguments, sexual problems, and lack of interest in family matters are common. Third is the appearance of frequent unexplained illnesses, personality changes, multiple jobs, and frequent moves between cities. This progression, which may take years to become apparent, is common with addictions that develop slowly. It is uncommon in addictions to fentanyl and sufentanil because of their rapidity of onset (see Fig. 84-3) .

The last activity to be affected usually is job performance (Table 84-2) . Page operators and nurses may be the first to recognize behavioral changes. Record-keeping may become sloppy. Excessive use of certain drugs becomes apparent, perhaps accompanied by an unusual compulsion to explain the need for these drugs in patient management. Colleagues may note similar changes. Direct observation of selfadministration confirms the diagnosis, but it is not common. [113]

Denial is a keystone of the disease. Impaired physicians disclaim their illness by using superficially logical reasons to

TABLE 84-1 -- Signs and Symptoms of Chemical Dependence Seen Outside of the Workplace

1. Withdrawal from family, friends, and leisure activities
2. Changes in behavior (e.g., wide mood swings)
3. Fights and arguments at home
4. Frequent unexplained illness (common in alcoholism)
5. Gambling
6. Extramarital affairs
7. Legal problems (e.g., arrests for driving while intoxicated)
8. Decrease in sexual drive

9. Drugs and syringes found in the home
10. Seclusive behavior at home
11. Odor of alcohol on breath
12. Weight loss
13. Pinpoint pupils (in persons addicted to opioids)
14. Symptoms of withdrawal (e.g., diaphoresis, tremulousness)
15. Denial of drug or alcohol use if confronted

TABLE 84-2 -- Signs and Symptoms of Chemical Dependence Seen in the Hospital

1. Unusual changes in behavior (e.g., wide mood swings, depression, anger, euphoria)
2. Gossip by others
3. Progressive increase in apparent narcotic use for anesthetic management
4. Careless charting
5. Preference for working alone
6. Frequent requests for bathroom breaks
7. Unusual willingness to provide relief for others
8. Inappropriate willingness to take call
9. Often appears in the hospital when not on call
10. Frequent unexplained absences
11. Difficult to find when on call
12. Excessive postoperative pain in patients cared for by an individual
13. Commonly wears long sleeved gowns (to prevent chills often seen in early withdrawal and to hide needle tracks)
14. Pinpoint pupils
15. Weight loss
16. Found comatose
17. Found dead
18. Witnessed self-administration (the only pathognomonic sign)

explain their bizarre patterns of behavior. Colleagues, too, use denial. Typically, they would rather accept these explanations than consider that a friend is a drug addict. For these reasons, the diagnosis is usually not made until its manifestations are clear. Only when the pieces of puzzle have been assembled is the picture obvious.

Intervention

Although contempt for a chemically dependent physician may be felt by some, the appropriate initial response is to seek help. A call to a person experienced in managing chemically dependent physicians initiates the next steps. [108] [114] In the United States, all state medical societies have committees on impaired physicians to act as advocates for sick physicians. Advocacy continues as long as the physician cooperates with the committee's recommendations. These committees serve as a buffer between the physician and the medical board or licensing agency. They also provide advisers to aid in confirmation of the diagnosis and to intervene and refer impaired physicians to appropriate treatment centers. Although laws vary, the committees are usually required to notify the board of a physician's recalcitrance at any stage of treatment. In many states, the board does not censure impaired physicians who comply with the committee's recommendations.

Intervention is the process of demonstrating to a chemically dependent person that he or she is ill and needs treatment. [115] (Although both the masculine and the feminine pronouns are used here, statistically, most addicted anesthesiologists are male.) Interventions should *never* be attempted with less than two concerned persons and ideally should be directed by a person with prior experience, frequently a member of a state committee. The key is to be caring and compassionate, in spite of the patient's arguments, but to be persistent. The addicted physician is a superb con artist. He or she is able to counter all ploys attempted by a single individual and usually gives a group of people a good

workout. Hours of preparation are needed to collect information, to assemble appropriate participants (including coworkers, family, friends, and a recovering physician, if one is available), and to rehearse. Pertinent pharmacy records, anesthetic records, and other documentation of the illness should be gathered. All involved must be prepared to present their nonjudgmental observations in as much detail as possible. Many suggest that each participant prepare written notes to be used for reference during the intervention. The objectives are to present irrefutable proof of the addict's symptoms, to describe the disease, and to get him or her to an appropriate treatment facility. It is not a kangaroo court but rather a caring act of compassion for an ill colleague who is unable to recognize his or her illness. A recovering physician at the intervention is invaluable as a role model for the patient. Arrangements for treatment and travel, should they be required, must be made before the intervention.

In spite of meticulous planning, it is important to realize that an intervention may be like a football play in a downpour--although it may sound great in the huddle, once the ball is snapped, the play may go awry. Just as in football, the intervenors must anticipate the "broken play." They may need to improvise during the intervention, but they must keep the goal of referral for evaluation and treatment (if needed) continually in sight.

When all is in order, the patient is invited into a room in which the other participants are already seated. Each in turn should express concern for the colleague's well-being and, without passing judgment, should describe the aberrant behavior that he or she has seen. If necessary, the documents at hand can be shown. The basics of the disease and its treatment should be explained, and the patient should be urged to accept the proposed plan. If the patient refuses, as many do initially for fear of losing control, he or she should be told that the ultimate decision regarding therapy will not be made until the patient has been thoroughly evaluated by a group of specialists at the facility. [114] If the evaluation does not confirm the diagnosis, the patient will be discharged. Otherwise, formal treatment perhaps lasting several months will start. If the patient is still reluctant, he or she should be advised that the intervenors must, by law, report him or her to both the medical board and the controlled substance authorities. The patient has diverted narcotics, a felony subject to prosecution. Although acceptance of treatment does not provide legal immunity, it is looked on favorably by many courts.

After the intervention, someone should stay with the patient continuously, not only to prevent the possibility of self-inflicted injury but also to provide friendship. With adequate preparation, most interventions are successful.

Principles of Treatment

Treatment consists of an in-depth evaluation, which is usually followed by both inpatient and outpatient therapy. Formal therapy may last for as long as several months, [107] [114] but on the basis of the initial work-up, some programs permit the recovering physician to continue practicing medicine during what may be several years of outpatient care. [108] Although debated by some, physicians often fare better if treated at a facility experienced in managing physicians. On admission, many feel guilty, ashamed, and totally alone. Just seeing that other physicians share their disease is therapeutic. Philosophies of treatment vary between programs, but the

common goal is to provide the recovering physician with the ability to remain sober. The physician is assisted in developing a strong relationship with peer support groups, such as *Alcoholics Anonymous* and *Narcotics Anonymous.* In the last stage, the physician may become involved in evaluating new patients. This permits personal reflection on his or her own course, referred to by some as "mirror imaging." As understanding of the biology of addiction expands, specific pharmacologic treatment may become more common. [99]

Return

Return from treatment is a difficult process for the recovering physician. The comprehensive treatment program has provided a structured environment that is much different from the work place. During treatment each person has learned a great deal about his or her disease but those with whom the person interacts after discharge are far less knowledgeable and perhaps fearful of both the individual and the disease. For this reason, reentry is greatly facilitated by understanding, compassionate peers who are willing to provide emotional support to the recovering physician. Gradual return to work, perhaps with others initially managing narcotic administration, is important. Without this support, the likelihood of relapse may be much greater.

In many states, the committee on impaired physicians plays a vital role in recovery. At discharge from formal treatment, the committee prepares an "aftercare contract" with the physician, who agrees to be bound by the committee's recommendations. The contract usually stipulates the number and the type of meetings the physician must attend, the name of a "monitoring physician," the requirement for random urine samples on demand, and the procedures to be used in the event of a relapse. [107] [109] [116] Many recovery programs insist on the use of naltrexone or disulfiram, or both, for 6 months or more after returning. Novel treatments with drugs such as acamprosate, bromocriptine, selective serotonin reuptake inhibitors, and buspirone are under investigation. [117] As long as the physician adheres to the contract, the committee continues to serve as his or her advocate.

Federal law in the United States (the *Americans with Disabilities Ac*[ADA]) provides limited protection against employment discrimination for recovering individuals. [118] Although persons who are currently using drugs are not protected by this law, those who have been successfully treated and are otherwise capable of working are considered to be "qualified individuals with a disability." The ADA thus defines a history of chemical dependence as a disability. Although it does not require an employer to provide for treatment, the ADA may require that "reasonable accommodation" be made for a qualified individual who wants to return to practice. For a recovering physician, this might include a modified work schedule, such as no call for several months and assistance with administration of narcotics. An employer is not required to make accommodation if "undue hardship" for the employer would result. For example, it could be argued

in court that accommodations needed to permit a recovering physician to return might have a negative impact on other employees or could result in prohibitive costs for the employer. Whether or not the ADA can be used also depends on the type of employer-employee relationship between an individual and a hospital or group practice. Clearly, any person or entity who seeks the support of the ADA needs competent legal guidance.

Prognosis

As indicated by reports from treatment programs, most recovering physicians are able to return to a productive professional life. [109] [119] Successful outcomes are dependent on lifelong participation in aftercare programs, total abstinence from drugs and alcohol, and continual acknowledgment of one's disease. Unfortunately, these data include all physicians treated rather than indexing rates of recovery by medical specialty. Although no data are yet in print, some now believe that the prognosis for long-term sobriety in anesthesiologists depends on the age and the status of the physician at the time of identification. Residents who have been dependent on fentanyl appear to have a significant rate of relapse. [105] Although each case must be handled separately, strong consideration should be given to a change in specialty for junior residents who become addicted to potent opioids.

The American Board of Anesthesiology permits a physician recovering from alcoholism or other drug dependence, who is otherwise qualified, to take both the written and the oral examinations. After a candidate with this history has satisfied the requirements for certification, "the [board] will determine whether it should defer awarding its certification to the candidate for a period of time in order to avoid certification of a candidate who poses a direct threat to the health and safety of others." [120] If the American Board of Anesthesiologists deems that such deferral is appropriate "the [Board] will determine the length of time the candidate's certification is deferred following an individual assessment of the specific circumstances of the candidate's history of alcoholism or illegal use of drugs." This is in keeping with the intent of the ADA. [120]

Addiction is a lifelong disease. Its acute effects can be overcome, but its sequelae leave an indelible mark on each victim. Recovering physicians have a disease that makes them guilty in the eyes of others, forcing them to prove their innocence whenever they are challenged. Because there is no way to ensure that substance abuse will not lead to addiction, the only absolute protection is to avoid the illicit use of drugs entirely.

SUMMARY

There are many aspects of environmental safety in the operating room involving waste gases, radiation, infection, stress, and chemical dependence. Because anesthesiologists are the physicians who are most consistently in the operating room, they are expected not only to be knowledgeable in these areas but also to provide leadership in developing policies to protect operating room personnel and patients.

Chapter 85 - Ethical and Legal Aspects

Jerome H. Modell
A. Joseph Layon
Charles S. Modell

INTRODUCTION: ETHICAL ASPECTS OF ANESTHESIA

The practice of medicine, in general, and to no lesser extent, anesthesiology, has been altered and continues to undergo changes that significantly affect our practice and the social and biomedical context in which we live. If legal behavior is the "minimal" accepted standard and ethical behavior is the standard that we strive to achieve, then study of medical ethics becomes critical, given the moral issues that these changes encompass. This chapter discusses some ethical issues significant to the practice of anesthesiology. Several topics are presented to show how medical ethics influence both clinical practice and research. First, however, we review the nature of moral philosophy.

Values Versus Facts

In the Platonic dialogues, Socrates asks his students the questions "What is virtue?" "What is justice?" The response to the question, which the young student thinks is obvious, is then criticized by Socrates. For example, the student may have responded that virtue is doing one's duty or listed roles taught by parents or leaders. Socrates tried to convince his students that such answers are inadequate because it is the rationality of the good that we must try to understand. A behavior is good not *because* it is taught, rather, it *is* good and that is *why* it is taught.

In moral philosophy, the problem is similar. A person first exposed to the subject may think that an issue can be solved by repeating the dictates of religious or political authorities. Indeed, it is precisely the tendency to rely on authorities that is the central question of moral philosophy: Are conflicts about values settled in the same way as conflicts about facts? Attempting an answer shows that invoking a higher authority can lead to ultimate incoherence. For example, if torture is wrong, then it remains so even if ordered by authority of God or political leaders. Wrong is wrong, independent of authorities. Furthermore, our obedience to an authority is mandated only as long as that authority commands actions that we, after careful consideration, agree are good.

Once the infallibility of authority is eliminated, we must answer the question "What is good?" in the same manner that we answer other questions about our world. Yet, factual problems are normally settled by the collection of observable data. For the question, "How many chairs are in the room in which you sit as you read this?" collecting observable data may be simple, but for the question, "What is a virus?" the data are relatively abstract and difficult to understand. Further, when we say, "It is wrong to kill," "It is wrong to have an abortion," "It is wrong to eat the flesh of animals," we are evaluating human actions *rather* than describing *facts.* Evaluative, as opposed to factual, judgments are resolved differently. We can know, from observable data, that prolonged deprivation of oxygen results in death, that a woman is pregnant, and that some humans do eat meat. We frequently agree on matters of fact, but we may disagree profoundly on the judgment or evaluation of actions.

How then do we decide whether an action is good or bad? In the premise of any moral argument, there is always a principle defended; by doing so, we also defend our ethical standards. Historically, a moral principle has been defended by using either *consequentialist* or *nonconsequentialist* models. When defending a principle, the consequentialist, sometimes called utilitarian, tries to evaluate the outcome (consequences) of a given action, whereas the nonconsequentialist considers the future effects of an action either irrelevant or impossible to determine and, thus, defends a moral principle on its merits alone. *Goodness* to the consequentialist is that which is best for the greatest number of people. This method of analysis, in which all relevant members of a group affected by a moral issue are taken as equals, is called *utilitarianism.* We can see that there are problems with this method of analysis, however. How can we be sure we agree with a consequentialist on what is best for the majority or who comprises the majority? How do we know when a consequentialist is simply acting on personal, cultural, or social biases?

The view of the nonconsequentialist, an ethicist who emphasizes rules and principles, seems to be stronger. However, would an ethicist uphold rules that made things worse for everyone? Further, what do we do when moral and ethical principles conflict?

To answer such questions, we must probe more deeply into the reasoning behind morals. For example, because the consequentialist determines *good* or *bad* by the effect an action has on the greatest number of people, to say that killing is wrong simply means that most frequently, but not always, killing produces great harm to those involved. Thus, within this moral framework, there are situations in which killing would be beneficial, and in such a case, killing would be morally right. For example, it is normally considered wrong for physicians to harm a patient; the consequentialist would defend this view on the grounds that the greatest good is served when the physician considers the patient's welfare as primary. However, what if a patient is mortally ill, coherent, and suffering and wishes a rapid, painless death? The consequentialist would then reject as hopelessly dogmatic the assertion that it is wrong to kill under these conditions. Thus, killing is not wrong in itself; rather, it is the consequence of killing (in this case mercy killing) that is right or wrong. It is not necessary to accept this line of reasoning to recognize that it is one approach to moral dilemma. Those who support physician-assisted suicide utilize such consequentialist logic.

There are several problems with the consequentialist framework. The first is that, depending on the problem being considered, morality changes. The general rule, killing is wrong, exists but is subject to modification. A second problem has been termed the " *slippery slope*" *phenomenon:* if we make an exception to a moral rule for one difficult case, the next time we are faced with a similar conflict, further exceptions will be easier to make. This position was forcefully argued by Alexander in his landmark article on Nazi medicine. [1]

For the nonconsequentialist, principles always supercede consequences. Thus, it is never justifiable to kill, even to ease the suffering of a terminally ill patient whose imminent death causes great pain. The nonconsequentialist warns that there can always be some justification devised for killing. The slippery slope argument suggests that, if we start justifying euthanasia or physician-assisted suicide in some cases, we will soon be killing with impunity. As with consequentialism, there also are problems with nonconsequentialism, or fixed moral principles. First of all, although we can identify a moral principle--for example, do not kill--it is relatively difficult to be clear about what we mean by this phrase. For example, is it wrong to kill in self-defense or during war?

A different problem arises when two or more principles contradict each other. To take an extreme case, what is to be done with the principles do not lie and do not kill when the Gestapo asks us in 1940, "Do you have a Jewish family in your cellar?" If we make an exception and lie, we are exhibiting the behavior of a consequentialist, with all the potential dilemmas that that entails. On the other hand, could we do anything *but* lie to preserve the lives of the family in our cellar?

The reason for discussing moral philosophy is to show that moral decisions must be based on more than just opinions or fleeting emotion. We must know the facts of the moral dilemma and how the dilemma occurred, but we must also be able to reason about our moral principles in order to make sound decisions.

Conflicting Values

People of goodwill and conscience may disagree. Perhaps the classic example of value conflict is the physician asked to care for a Jehovah's Witness (Chs. 25 , 46 , and 47). This religion prohibits its followers from receiving banked blood products. The belief stems from scriptural passages suggesting that "life" or the "life force" is found in blood and, thus, must be treated respectfully. [2] [3] This belief generally precludes receipt of banked blood products, but it may not, at the patient's discretion,

preclude receipt of albumin, plasmanate, or clotting factors or even bone marrow transplantation. [4] Jehovah's Witnesses consider their time on Earth as a temporary period followed by eternal life after death and resurrection. [5] Witnesses who voluntarily allow the transfusion of blood, unless repentant, may be "cut off" from the deity they believe in, eliminating the possibility of "eternal life," which constitutes damnation on Earth. [5] Receipt of blood by a Jehovah's Witness without the person's permission causes "loss of innocence," a serious transgression, but with no negative religious consequences for the Witness. However, loss of innocence is considered serious enough that the believer may bring a charge of assault against the health worker. Conversely, although there have been suits against physicians for withholding blood or blood products when requested to do so by the patient, no negative legal decisions have been found when this is done under clearly defined preoperative conditions. [5]

Many ideologic systems serve as a framework for living. No person's belief system, even if it seems to us extremely unusual, should be denigrated. Under medically elective conditions, if one cannot consent to the patient's requests, the only moral solution is for the physician to withdraw from that patient's care and to make a serious attempt to locate a colleague who does not feel morally compromised by the request. In an immediately life-threatening situation, as may happen with Jehovah's Witnesses, there is often no time to

determine whether the patient would sacrifice his or her life for a religious belief and even less time to find a colleague who would agree to provide the necessary care under the apparent religious constraints. In this situation, we think that it is better to err such that life is preserved rather than lost. This is even more true when a child is involved. If we accept that there are many valid ways to live a life, it must also be recognized that the world views of a child and a parent do not always agree once the child reaches the age of reason. In our experience, Jehovah's Witness parents are very easy to work with when their children require surgical intervention. They wish their child to receive optimal therapy while blood is, under all circumstances, withheld. Although we respect the parent's central moral beliefs and attempt to be faithful to them, we inform the parents that, in the event of an unexpected or uncontrollable hemorrhage that jeopardizes the child's life, blood will be transfused if deemed absolutely lifesaving. A court order allowing transfusion may be obtained if time allows, but this will clearly not be the case in an emergency unless procedures that predate the emergency and a relationship between the court and hospital to implement these procedures exist. Such legal intervention is required very rarely when communication, as noted earlier, is maintained.

When a competent patient has received our promise not to transfuse blood, that promise should be rescinded only in the most extreme situation. Some clinicians view that significant hemorrhage while the patient is anesthetized justifies breaking faith with the patient. [6] Others may believe that consideration of whether the patient was competent or the consent was freely given preoperatively should be overriding. [6] Finally, transfusion need not be performed simply because blood is being or will be lost. In an otherwise healthy individual, the hematocrit level may be diluted to as low as 15 to 20 volumes percent with crystalloid or colloid and still provide adequate reserve for tissue oxygen extraction.

Rationing Care

Expensive Health Care and Not-So-Expensive Health Care

Many third-party carriers ration expensive types of health care by excluding certain conditions, therapies, or both in their coverage policies. In such situations, health-care providers are frequently placed in the position of denying such care to patients unless the cost can be funded by private sources. In other cases, the care is provided, but, because of the large unreimbursed expense, the cost is shifted to other patients. The managed care organizations (MCO) go even further. [7] [8] Emergency department physicians are obligated under federal law to determine, for each person presenting to the emergency department, whether or not an emergency medical condition exists. This must be done irrespective of the patient's payer class. Denial of authorization of payment for these federally required services by MCOs reached such proportions that some states have passed legislation requiring MCOs to pay the cost of such evaluations. Clearly, abuses of these situations must be resolved via social policy rather than by physicians on a case-by-case basis.

Intensive Care

When are resources allocated to health care sufficient? At some point, does the consumption of a specific portion of the national economic output for health care become excessive? Health care consumed $511 billion (11.4% of the gross domestic product [GDP]) in 1987 [9] ; in constant dollars, this is a 133 percent increase in expenditures for health care since 1960 (Ch. 71) . Each year, the amount spent has increased further: $666 billion in 1990 (12% of GDP), $736 billion in 1991 (13% of GDP), and an estimated $820 billion in 1992 (13.9% of GDP). [10] Yearly, approximately 15 percent of this amount is used for intensive-care services. [11] Despite this outlay of funds, at present, 30 to 37 million people in the United States are without any access to health-care services. [12] Thus, at a minimum, the allocation of resources is inadequate. Nonetheless, many insist that society must decrease the cost of health care or at least stem its steady climb. [9] [11] [12] [13] Because physicians are responsible for directing the use of approximately 70 percent of health-care expenditures, [9] it comes as no surprise that physicians are asked to assist in conserving these funds. There are, however, potential problems and even conflicts of interest that arise once physicians take on the role of advocate of *both* society and patients. This is a prototypic ethical issue. We have neither laws nor collective experience clearly showing us the way to decrease health expenditures, to limit health-care services, or to continue on the present course. In any case, the role of the health-care team, and particularly physicians and nurses, in this debate is exceptionally important.

When consulting a physician, the patient expects that the decisions and choices made by that professional are competent, respectful, disinterested, and uncolored by social judgments. [14] Therefore, in a debate with politicians, economists, health-care planners, and our patients, physicians must argue forcefully for those whom they serve, which is no more than an extension of the "ethic of agency," which states that the physician's role is to help the person under his or her care to obtain every possible resource necessary. In general, it is potentially dangerous, from an ethical viewpoint, for the active clinician (as distinguished from the physicianadministrator) to make rationing judgments that may affect the patient under his or her care. The peril is even greater if the physician receives some form of financial incentive to limit resources used on the patient, especially if there is no serious evaluation of how alterations in the resources used will affect the patient's outcome.

The basic conflict surrounding the concept of rationing care in the intensive care unit (ICU) is that of casting the physician in a role as gatekeeper. If physicians accept the ethic of agency, it would be difficult to rationalize keeping certain types of necessary care from their patients. A key concept here is the word *necessary.* There is no conflict when physicians do not arrange for an ICU bed for a healthy outpatient who undergoes a tonsillectomy and is discharged hours after the procedure. However, the situation is not always so clear. For example, it had been suggested that, among patients with acquired immunodeficiency syndrome (AIDS) and *Pneumocystis carinii* pneumonia (PCP) who require tracheal intubation and mechanical ventilation, mortality was approximately 85 percent, [15] but several reported

series showed that, with aggressive therapy, mortality could be decreased to approximately 50 percent. [16] [17] [18] In spite of this improvement in short-term survival, until recently, the mortality from the human immunodeficiency virus (HIV) after an AIDS-defining illness was nearly 100 percent over a period of approximately 2 years. [19] The introduction of protease inhibitors, in conjunction with dual nucleoside analogues, has led to a decrease in HIV-related mortality. Unfortunately, however, these medications are very expensive. What is the appropriate response of the physician in charge of such a patient? Being an agent of the patient justifies, indeed mandates, the physician's obtaining every *necessary* resource for that patient. Would this be possible if, at the same time, the physician were in some way forced, as an agent of society, to conserve scarce resources? The answer is, we think, self-evident.

As a patient's agent, the physician is not required to use every available resource but must use those that the patient *and* the physician deem necessary. Aggressive treatment, however, does not mean unintelligent or uncompassionate care. In the recent past, outpatient men with AIDS questioned about their desire for life-sustaining treatment in the face of PCP opted for hospitalization and antibiotic therapy 95 percent of the time, 55 percent would accept aggressive care, and 46 percent would agree to cardiopulmonary resuscitation (CPR), were it required. [20] In the presence of PCP and concomitant severe memory loss, only 19 and 17 percent, respectively, wanted ICU therapy including mechanical ventilation and CPR. Although 73 percent wanted to discuss the matter with their primary physician, only 33 percent had done so; the reasons for this discrepancy are unclear, but they could relate to discomfort in discussing such matters on the part of either the physician or the patient. Other data suggest that, in general, these discussions occur infrequently (4-19%), [21] [22] even though patients want the opportunity to discuss such options with their physician. [22]

When considering the case for rationing any health service, we must consider the moral implications of attempting to salvage a health-care system in which equity plays such a small role. Economic and political decisions that work to maintain a fair health-care system must meet two general criteria: (1) the health-care system must be closed, meaning that saying no to one therapy (e.g., heart transplants) allows us to say yes to another (e.g., prenatal care for all mothers); (2) the system must be governed by the principle of equity in decisions about technologic advances. The present health-care system in the United States fulfills neither of these criteria. [14] [23] There is some evidence that rationing imposed by the Oregon Health Plan has resulted in a system that comes much closer to fulfilling these two criteria than the present market-driven system. [24]

Under present circumstances, the function of the physician in cost containment and rationing of services must be to maintain the ethic of agency. As with all moral principles, this one is not infallible. However, it may be the most morally appropriate decision. Additionally, we physicians can argue for decreased waste in our system, [25] [26] and we can educate ourselves, our colleagues, our political leaders, and our fellow citizens about problems, modifications, or alternatives to the current system. [27] [28] [29] This has always been important, but it is even more critical now.

Life as the Ultimate Value

When, if ever, is it appropriate to cease attempting to salvage the life of a patient? How far do we physicians go and how hard do we try to maintain life when survival is unwanted by the patient, unlikely to result from any therapeutic regimen, or unlikely to be attended by normal function?

From the moral point of view, there are limits to our obligation to save or prolong life. Decisions about limitation of treatment or about nontreatment are frequently made when a patient appears to have a rapidly progressing, terminal illness for which no curative or adequate palliative therapy is available. With regard to palliative therapy, a key term is *adequate.* Although therapeutic modalities often prolong existence, frequently it is not simply the length of life, but its quality, that concerns patients and their families. When this quality can no longer be maintained, it is professionally and socially acceptable to let the dying process take its course. Clinically, this process usually involves do-not-resuscitate (DNR) orders.

Do-Not-Resuscitate Orders

Are we not, as physicians, always required to preserve life? Is a DNR order simply euthanasia disguised? If by euthanasia we mean an intervention that anticipates a terminal pathophysiologic process and purposefully speeds that process to minimize suffering, a DNR order is clearly not euthanasia. The DNR order allows the natural process of dying to take its course without interference. Although some call this *passive euthanasia,* we reject such formulations, which would make all therapy, short of extraordinary care, passive euthanasia. Further, the assertion that physicians *must always* strive to save life is uninformed. As one moral philosopher states [30] :

> The success of intensive care is not, therefore, to be measured only
> by the statistics of survival, as though each death were a medical failure. It
> is to be measured by the quality of lives preserved or restored; and by the
> quality of the dying of those in whose interest it is to die; and by the
> quality of human relationships involved in each death.

Although some may disapprove, most physicians accept and use DNR orders. In these cases, there are several points to be made [31] [32] :

1. The medical order to withhold resuscitation in the event of a cardiopulmonary arrest must be documented on the patient's chart. A physician does not become less liable in a legal or moral sense by making DNR orders verbal rather than written formally on the medical record.
2. The order should specify exactly what should be withheld. Is it just CPR that will not be administered, or are pharmacologic agents to be withheld as well?
3. Decisions regarding DNR status must be made in conjunction with the patient, if possible, with the patient's family, or both, and must be documented in the chart. This is both moral and strengthens the relationship between physician and patient. [33]
4. Considerations regarding DNR status should be discussed with the other members of the health-care team involved in the care of a patient. Frequently, nurses first identify

patients who are considering rejecting life-sustaining treatments. Encouraging the participation of fellow health workers, in ICU rounds, for example, enhances patient care and, by allowing varied input, decreases reactionary and emotional responses to limitation of care orders.
5. The DNR status of a patient should be reviewed regularly, because a patient with a DNR order may recover. Indeed, up to 38 percent of hospitalized patients with DNR orders do not suffer a cardiac arrest and are discharged from the hospital. [34] There should be a clear mechanism for revoking a DNR order when and if this is deemed appropriate.
6. Patients and their families must be made to understand that DNR status is not cryptic terminology for abandonment, either medically or psychologically, nor is it the same as withdrawal of therapy.

These considerations would seem to pertain more to ICU patients than to routine surgical patients. However, DNR orders when patients must undergo surgical intervention have become an issue. Patients with a DNR order on their medical record may require one of several operative interventions, depending on the underlying pathophysiology. Exploratory laparotomy for lysis of adhesions resulting in a small bowel obstruction in a patient with cancer, and tracheostomy, gastrostomy, and jejunostomy for a patient in a persistent vegetative state are but two possible situations. Several groups have noted that the requirement for an operative intervention in these patients places both surgeon and anesthesiologist in some difficulty. [35] [36] [37] [38] [39] [40] The reason is an apparent contradiction in our actions if we physicians are faithful to the central principles of medical ethics. The principle of autonomy would lead us to accept a patient's choice to undergo operation with a DNR order. In case of an untoward event, we would not resuscitate the patient. The principles of beneficence and nonmaleficence, however, would lead us to intervene in case of some untoward event.

The resolution of this apparent quandary lies in focusing on the specific patient in each case and ensuring that channels of communication are both open and well used. When obtaining informed consent and explaining what will occur in the operating room, including the potential for complications, we physicians must also point out therapeutic options if problems occur. Once again, it is only through careful and responsive discussion that we can resolve our dilemma. As best as possible, the patient or surrogate must understand the nature of the physiologic insult entailed by the anticipated surgical procedure, as well as the possible surgical and anesthetic complications involved and their consequences. These complications range from hypotension on induction of anesthesia to cardiac arrest. If appropriate, the surgeon and anesthesiologist could request that the DNR order be rescinded for 24 to 48 hours. This would allow the surgical team to intervene with any mode of therapy for that period of time, after which the DNR order would be reestablished. It should be clear that any therapy would be discontinued when no longer necessary or no longer effective in reversing the acute physiologic abnormalities induced by surgery. Thus, the patient or surrogate could consent to the procedure with one of three options: with the DNR order rescinded, with some stipulations of what therapies could be administered, or with the DNR order intact. [35]

After weighing the moral risk of proceeding with the intervention, if the second or third aforementioned option is chosen by the patient or surrogate and the surgical team decides not to proceed, the team is obliged to refer the patient to others who could be inclined to perform the operation. This assumes an elective situation in which there is time to discuss options rationally. In an emergency, especially when the patient has come from a medical ward to the operating room, all therapies should be used to preserve life; these may be withdrawn at a later time, if appropriate. Finally, when the patient or surrogate agrees to the procedure with any therapy deemed necessary intraoperatively and for the first 24 to 48 hours postoperatively, what is to be done if the patient does not improve and cannot be tracheally extubated or weaned from vasoactive agents after 48 hours? Because this possibility would have been discussed prior to the operative intervention, consideration of withdrawal of life support would be appropriate. [35] [36] [38] [39] [41]

In difficult cases, and when disagreements arise, the hospital ethics committee can be extremely useful. [26] [29] [32] [42] At our institution, the hospital ethics advisory committee is multidisciplinary, composed of representatives from pastoral, social, nursing, medical, and surgical services, as well as from administration. The committee functions include education of hospital personnel on ethics, advisory consultations performed at the request of a primary service, and advisement and review of hospital policy matters involving ethical concerns.

Withdrawal or Withholding of Therapy

Withdrawal-of-therapy decisions, although not fundamentally different from a DNR order, are usually made in a different clinical setting. The decision to withdraw or withhold a specific therapy or therapies is almost always made in the setting of terminal care. *Terminal* must be defined. Although one may glibly state that we are all terminal, in as much as to be alive is to progress toward death, we define *terminal* as the imminence of death despite aggressive intervention. Precision in predicting the date of a patient's death is difficult, if not impossible, and, in addition to necessitating complete knowledge of the natural course of the disease process, it requires honed clinical judgment.

Having concluded that death is imminent, the next consideration is the competency of the patient. A competent person may request further heroic measures or may request that supportive therapy be withdrawn. Either of these options is entirely within the legal and moral rights of a patient. Although a physician may have moral reservations about a competent patient's requests to reject terminal care, the patient's choice should be preeminent over the physician's moral stance. If the physician strongly opposes withdrawing or withholding therapy, care of the patient should be turned over to a colleague not so constrained.

All these considerations are affected when a patient is incompetent. Incompetent patients fall into one of three subgroups. [43] The first is a patient currently incompetent but who, while competent, expressed a choice regarding terminal care. Such a choice is usually considered to be valid when a patient becomes incompetent. An example of this is the case of Brother Fox. [44] A member of the Society of Mary,

a Roman Catholic religious order, for more than 66 years, this man had expressed his wish at least twice, the final time being shortly before he became incompetent, that nothing extraordinary be done if his medical condition were hopeless. In 1979, while undergoing a herniorrhaphy, Brother Fox suffered an intraoperative cerebral ischemic event that left him in a persistent vegetative state. Despite a request by family and friends to discontinue mechanical ventilation, the hospital refused to do so without a court order. The New York State Supreme Court ruled that, because Brother Fox had made clear his opposition to use of a ventilator to maintain him in a vegetative state, he had the right to decline treatment. Although not without controversy, [45] [46] [47] [48] cases like that of Brother Fox helped to stimulate the movement for "living will" or "natural death" legislation.

The second group of incompetent patients comprises those who have either never been competent or who have never expressed themselves while competent regarding their wishes about terminal care and who are without family members or friends who could take on the role of guardian. An exemplary legal case is that of *Superintendent of Belchertown State School v Saikewicz.*[49] The patient, Joseph Saikewicz, was a 67-year-old mentally retarded man, with a mental age of 2 to 3 years. He had previously enjoyed reasonably good health and had been ambulatory, but he was unable to communicate aside from gestures and grunts. During the course of medical treatments for conditions arising during his stay at the Belchertown State School, Mr. Saikewicz had been unable to respond intelligibly to inquiries as to whether or not he was in pain. In April 1976, Mr. Saikewicz was diagnosed with acute myelomonocytic leukemia. The legal case revolved around the issue of the appropriateness of chemotherapy. Mr. Saikewicz had, of course, never been competent, and the only two members of his family who could be found preferred not to become involved. The court determined that chemotherapy would cause the patient significant suffering with very little chance of changing the ultimate outcome of the disease. Thus, chemotherapy was withheld, and the patient died in September of 1976 from an infectious complication. In making this decision, the court invoked the doctrine of substituted judgment, which states "that the decision in cases such as this should be that which would be made by the incompetent person, if that person were competent, but taking into account the present and future incompetency of the individual as one of the factors that would necessarily enter into the decision-making process of the competent person." [49]

Veatch [43] expressed his displeasure with some of the wording of this decision. In substituted judgment, the decision maker takes into account the idiosyncratic factors that the patient has expressed, even if they are not in the "best interest" of the now-incompetent patient. With a person such as Mr. Saikewicz, this was not possible because he never had the ability to express himself intelligibly. Thus, the "best interest" rule should have been invoked, rather than substituted judgment. For this group of patients, it is reasonable to turn to the courts for help in decisions of withholding and withdrawing therapy.

The final group of patients comprises those who are incompetent or who have never addressed the question of terminal care while competent but have family members available to act as guardians, as in the Dinnerstein case. [50] Shirley Dinnerstein was admitted to a nursing home in 1975 for intensive nursing care secondary to Alzheimer disease. Three years later, she suffered a massive stroke. Her physician wished to write a DNR order but thought the Saikewicz case had made it impossible to do so, even though the patient's family agreed to it, without seeking the permission of the court. Although the court in the Saikewicz case did not set out a complicated set of rules that had to be followed before denying treatment to a ward of the state, [49] the Massachusetts Appeals Court stated clearly that the Saikewicz decision did not mandate the resuscitation of dying patients. Because CPR would not change the outcome of Dinnerstein's illness, the court ruled that the attending physician could take "what measures are appropriate to ease the imminent passing of an irreversibly, terminally ill patient in light of the patient's history and condition and the wishes of her family." [50] The implication here is that the patient's family, along with the patient's physicians, should choose the best course for the patient; the courts should be involved only if family and physician disagree.

Thus, with regard to incompetent patients, the following conclusions may be drawn [43] :

1. Incompetency must be proved, not assumed, especially if the patient appears to make decisions in ways that seem unusual to the physician.
2. With incompetency, priority should be given to following instructions that predate the patient's incompetence.
3. If no written instructions exist, the family should be relied on as the guardian. This should hold unless and until the family makes judgments that seem unreasonable, at which point judicial review should be requested.
4. If written instructions conflict with the family's position, the safest course is to seek an opinion from the court.
5. In rare cases, the courts may intervene from the outset, as when no guardian can be found.
6. Decisions about which therapies are appropriate to withhold or withdraw must be individualized. It is unlikely that a single list of criteria will hold for all persons.

Euthanasia

Euthanasia, from the Greek "an easy or happy death," is defined as the act of putting to death painlessly one who is suffering from an incurable condition (Table 85-1) (Table Not Available) . [51] Only because we now have the technical ability to delay imminent death indefinitely do the problems of active and passive euthanasia, or withdrawal of therapy, arise. Withdrawal of therapy is now considered, *under the appropriate circumstances,* reasonable, humane, and legal. [52] [53] [54] [55] [56] [57] [58] [59] Several courts have addressed circumstances from which we may derive an idea of the appropriate circumstances.

```
1976, Quinlan/New Jersey Supreme Court. The court stated that if
family and physician agreed there is no hope of the patient's ever
emerging from a coma, and the hospital ethics committee consented, ventilator
therapy could be withdrawn. The court acknowledged that this action would
likely result in the patient's death.
```

[55]

```
1980,
Severns/Delaware Supreme Court. The court ruled that it would consider a
request to withdraw therapy from a 55-year-old comatose woman after an
evidentiary hearing to clarify the patient's medical status. The court
stated its preference, however, for action by the General Assembly of Delaware
because of the "community values at stake."
```

TABLE 85-1 -- Definitions Related to Active Life-Ending Interventions

(Not Available)

Modified from Emanuel [51]

1980, Spring/Massachusetts Supreme Court. The court ruled it was permissible to invoke substituted judgment to withdraw therapy from a severely ill, profoundly demented patient. In addition, while supporting the concept of substituted judgment, the court added that if the judge hearing the case was not persuaded that the incompetent patient's choice, as determined by the substituted judgment standard, would have been to forego potentially lifeprolonging treatment, or if the interests of the state required it, therapy would not be withdrawn. The court further stated that it wanted judicial review of withdrawal before action was taken because it "disapproved the delegation of the ultimate decision-making responsibility to any committee, panel or group, ad hoc or permanent."

[57] [57]

1985, Conroy/New Jersey Supreme Court. When the patient is an elderly demented person with a clearly limited life expectancy, the court determined the following: withdrawal of therapy is not suicide; a living will is significant, whether legally binding or not; what the patient, not some theoretical "reasonable" person, would have desired under the circumstances is significant; the Office of the Ombudsman for the Institutionalized Elderly must be involved in a contemplated action to withdraw therapy and must appoint two physicians to confirm the patient's medical condition and prognosis; and the court has to determine incompetency and appoint a guardian whose approval, along with that of ombudsman, physician, and in some cases the family, is required for therapy to be withheld or withdrawn. This ruling has been criticized as too complicated to be workable, bureaucratizing death, not being in the patient's best interest because it could lead to widespread disregard of the law or to continuation of futile therapy.

[58] [59] [60] [61]

No legal cases have supported active euthanasia. The case for this form of euthanasia is based on two central claims [62] : relieving unbearable pain, which is a medically straightforward rationale, and respecting individual autonomy, which is generally interpreted as a patient's right to take part in treatment-related decisions, even to reject therapy. This does not mean a health-care worker must do everything a patient asks. Indeed, we physicians are obliged to abridge autonomy when it would result in harm. In the case of a patient dying in pain, however, it is difficult to conceive of the harm that would result from a physician's granting a patient's request and making a patient's death less prolonged and agonizing. The cases of active euthanasia we are most familiar with are those of Dr. Kevorkian and "Debbie," both of which gained great national attention. [63] [64]

The uproar created in both the medical literature and the lay literature by these cases must be addressed thoughtfully. Even while criticizing the Kevorkian "series" and the Debbie case, clinician-ethicists have been careful to point out the real fears and concerns that many patients have with regard to their deaths. [65] Dying patients are afraid that their terminal suffering may be prolonged by technology over which they have no control, that they will be "held hostage to our inability or unwillingness to be responsible for knowing right from wrong in each specific situation." [65] Although arguments against euthanasia raise the point that there are no procedural safeguards to prevent abuse, this issue appears to be a lesser consideration to the dying. The concern of one man with a terminal malignancy makes most vivid the fear and anger that coexist in the hearts of many: "If a patient opts for either active or passive euthanasia, it is a craven abdication for the physicians to hide behind moral or religious dogma and deny that person the right to die a pain-free and dignified death." [66] One ethicist holds that, although he is opposed to killing generally, physicians must on occasion actively help to speed death to stop a patient's suffering. [67] That abuses could accrue if active euthanasia were allowed is noted by many investigators, [62] [65] [67] [68] even those generally supportive of the action.

The extreme positions taken by Kevorkian and the Debbie resident are the result of clinicians avoiding the issues of terminality and pain and of granting patients control over their deaths. An explicit and open approach to euthanasia, however, would likely lead to fewer, rather than more, mistakes and abuses. In Holland, for example, four criteria are used in euthanasia cases to determine its legitimacy:

1. The patient must be under severe mental and/or physical anguish, with no prospect of relief.
2. The patient must make the request freely, frequently, consistently, and without coercion; the physician may not solicit the patient.
3. Assisted death may not be an answer to pain, fear, failing care, or loneliness; further, alternatives to euthanasia must be offered by the physician.
4. A colleague must be consulted by the primary physician to confirm the diagnosis and prognosis and the lack of other treatment options and to ensure that all legal requirements for euthanasia have been met.

In spite of the possible benefits of euthanasia, it may be both perilous as public policy and corrosive as medical practice. [62] The public policy concern is centered around the issue of potential involuntary euthanasia. Marginalized and disempowered persons could face discriminatory euthanasia.

Moreover, euthanasia could be used, in our present environment of cost-containment and social-injustice, as a means of "rationing" care. Euthanasia could have a corrosive effect on the practice of medicine by detracting attention from other issues such as the need to improve pain control, patient-physician communication, and care for the dying. Finally, euthanasia could strike a lethal blow at the heart of what it means to be a physician--the social and professional role of physicians as healers would be destroyed. [62]

Data [69] [70] evaluating the Dutch experience with euthanasia and physician-assisted suicide, during the period 1990 to 1995, suggest no decrement in the care given when making decisions that result in the patient's death. Other investigators, [71] however, note that the "slippery slope" border may have been broached. Indeed, a worrisome and disturbing trend, noted in physician interviews, was that 16 of 84 unreported euthanasia deaths were not voluntary; that is, informed consent was not obtained. [69] Fifty percent of these patients were judged incompetent, and 95 percent of the time, discussion took place with the family and/or colleagues prior to the act of euthanasia. [70] Nevertheless, the patients were killed without their consent. In the patient groups studied, the frequency of euthanasia/physician-assisted suicide was approximately 2 percent. In another Dutch study of homosexual men with AIDS, the frequency of euthanasia/ physician-assisted suicide was approximately 24 percent, a 12-fold difference. [72]

How then do we as physicians handle cases in which a competent patient makes an informed request for assisted death? There are several possibilities. One is to use a variation of the Dutch system, in which strict criteria would have to be met prior to euthanasia; the cases would be carefully scrutinized after the act by state or county judicial officials. This system would clearly require some changes in the penal code as well as in the ethical codes of the medical profession. Our opinion, and that of others, [73] is that legalization of euthanasia would multiply the problems we now face; in attempting to protect patient autonomy and to prevent abuse, the rights of patients and physicians would suffer. Another possibility is to handle euthanasia as is currently the case, without any clear criteria but by implicit agreement. Euthanasia is performed in the United States today, but without any checks or balances. This approach is simply an adaptation to legal constraints. The ideal system

for voluntary euthanasia should be a hybrid. Patients, physicians, nurses, and families would discuss and choose (or reject) the option of euthanasia. As in the Dutch system, a hospital ethics committee (or other appointed board) would ensure that the four criteria determining legitimacy were met; if these were fulfilled, euthanasia could be performed. The committee would ensure that the potential for abuse was minimized; this safeguard, in turn, would provide a rationale to keep our legal colleagues out of the clinical decision-making arena, except in cases of abuse. Indeed, this system would likely ensure that abuse would be kept to a minimum. [74] [75] Whether the Patient Self-Determination Act and emphasis on advanced directives has made it less difficult for health workers to take part in either active or passive euthanasia is unclear. In our institution, however, querying patients on admission as to whether they have an advanced directive and ensuring, whenever possible, that the issues involved with terminal care are discussed before patients become critically ill have made end-of-life conflicts less common. One study suggests that advanced directives are frequently difficult to interpret and that a surrogate decision maker be appointed at the time the advanced directive is drafted. [76]

Finally, physician-assisted suicide has, as a concept, moved into our collective consciousness. This variation on the theme of life-ending interventions involves the prescription of, usually, a lethal quantity of a drug by request to a terminally ill patient (see Table 85-1 (Table Not Available)). Although the Oregon physician-assisted suicide law was invalidated by the United States Supreme Court, a more narrowly crafted law could possibly meet with the Court's approval. Thus, the concerns raised earlier with regard to active euthanasia will be of no less concern with regard to physician-assisted suicide. [77] The ultimate role that physician-assisted suicide will play in our society, and whether it may be rendered irrelevant by appropriate use of hospice care, [78] remains to be seen.

We have reviewed some of the major medical-moral questions of our time. Moral decision making is an area in which people of goodwill can disagree and in which ambiguities persist. Because of the ambiguity, moral decisions require wide discussion and debate; this may be frustrating to the practicing physician, but it is a necessity from a moral point of view. Moral questions cannot be answered in private or by monologue because they are social as well as personal.

Ethics and Research

Are there special problems created when human subjects are used in medical research? In 1966, Beecher [79] reported that 12 of 100 consecutive human studies published in a well-referenced medical journal appeared to be ethically questionable. In another part of this protocol, he found 50 examples of studies that appeared to contain ethical violations. Some of the categories of research that raised ethical questions included evaluations of physiologic effects of known toxic drugs, pathophysiology of disease states, new drugs, new invasive techniques, new treatments for a disease that had accepted therapy, and studies that appeared to have no basis in science. Beecher concluded that three things were necessary to ensure that ethically sound research would be carried out in the future: (1) true informed consent; (2) intelligent, compassionate, informed, and responsible principal investigators; and (3) an unmistakably clear message from journal editors that no data are so important that they may be obtained unethically and that data thus obtained will not be published.

Although true informed consent may be difficult to attain, its importance as a legal and moral principle is unquestioned. [80] [81] In fact, based on the difficulty of attaining true informed consent, some investigators have suggested that a surrogate system be used as an adjunct to institutional review of proposed projects. [81] The technique involves having persons who are not candidates for a protocol listen to the investigator give the rationale and risks of the project. The surrogate may ask questions or make comments at any point in the process. It was thought that such surrogacy, although not substituting for the research subject's personal decision making, would provide comments, questions, and criticisms that may not normally arise during the institutional review

process. A further aspect of the problem of informed consent is whether certain captive populations can give informed consent because of their coercive environment. [82] [83] For example, if consent is to be free and informed, the subject must be able to withdraw from the project without adverse consequences. For example, short-term studies involving small numbers of prison inmates may be ethically appropriate if the investigator is not a prison authority and if informed consent is given several times over the course of the study. [82]

Even in noncaptive populations, significant barriers impede true informed consent. [84] One of these barriers is that, rather than being a series of discrete events, medical decision making usually evolves, and, although patients may want to be informed, they may not want to be involved in the decision making. In addition, physicians may view informed consent as a legal obstruction, rather than as an integral part of excellent care. Obtaining informed consent from any patient considered a candidate for a research protocol merits special emphasis. Equally important, a patient's physician has the responsibility of the "ethic of agency" and therefore cannot hesitate to encourage a patient to withdraw from a protocol if it appears to be against that person's best interests.

Finally, a very disturbing aspect of research that increasingly has come to the attention of both the scientific community and the public at large is scientific fraud, an extreme form of misrepresentation. There are three ways an investigator can make inaccurate statements: (1) justifiable mistake, by which the scientist misunderstands a phenomenon and, thus, misrepresents it; (2) negligence or carelessness, by which data that would prove or disprove a hypothesis are overlooked; and (3) fraud, by which facts are deliberately misrepresented or data are forged. [85] Although any scientist can, and most do, make mistakes, some have deliberately sought to mislead their colleagues. Whether this is a result of "bad" persons or a "bad" scientific system cannot be resolved here. [85] Research directors, department chairpersons, and the entire scientific community as well as coauthors, editors, and reviewers have a responsibility to be vigilant and rigorously honest to help prevent misrepresentation. [85] [86]

One editorial suggested that guidelines now in place will allow editors of biomedical journals to deal with allegations of research fraud better. [87] Furthermore, the authors commented favorably on criteria devised by the Harvard Medical School [87] (Table 85-2) (Table Not Available) , which may begin to deal not with the results of fraud, but with its prevention. For instance,

TABLE 85-2 -- Guidelines for Prevention of Research Fraud

(Not Available)

From Angell [87]

the Harvard criteria address the issue that, to improve chances of promotion or tenure, some people may be prone to take shortcuts to increase their numbers of publications. Unfortunately, the jump from shortcut to outright fraud may be small.

MEDICAL MALPRACTICE

One of the most frightening experiences in the life of an anesthesiologist may be receiving a subpoena for alleged malpractice. A conscientious anesthesiologist can be devastated by such an experience; indeed, suicide as a consequence of this experience is not unknown. Although representatives of the plaintiff's bar may proclaim that the malpractice crisis is the result of bad doctors, [89] and although physicians frequently attribute the spiraling number of alleged malpractice cases to greedy attorneys, [89] the truth is certainly somewhere in between. There clearly are patients who suffer harm because standards of care are not followed. Likewise, there are other patients who suffer an untoward event despite excellent care by the anesthesiologist. This chapter does not settle this debate but, rather, addresses factors that determine the outcome of such litigation.

The Process

Although untoward events during anesthesia can lead to dramatic adverse outcomes, in other situations, the severity of the alleged damage is in the eyes of the beholder. In either case, when an adverse or unexpected outcome occurs, the onus is on the plaintiff to prove that the outcome resulted from substandard care. [89] The defendant must demonstrate that the level of care administered to the patient was acceptable, based on the standards of that specialty and subject only to the surrounding circumstances (which may allow for a lesser standard of medical care in rural communities, where sophisticated equipment and subspecialty care are not available). Otherwise, the national standards of the board-certified specialist, especially in anesthesiology, apply. [89] In many situations, standards as such do not exist. Furthermore, adverse events occur in medicine without an obvious cause, in which case the cause is determined by exclusion or, in some cases, speculation. In this situation, a jury, virtually always composed of nonphysicians, is left to decide what caused the untoward event and whether it was due to the negligence of the physician.

It is curious to us that, even though a physician may go through a detailed medical history and physical examination of the patient, appropriate laboratory tests, and a differential diagnosis and still not pinpoint the cause of the medical problem, a jury of nonphysicians is expected to determine, by "a preponderance of the evidence," the cause of an alleged adverse outcome. The jury's decision is based on information gleaned from direct and indirect questioning of medical experts for both the plaintiff and the defendant. Persons who testify as medical experts may not necessarily be considered expert by their peers, and yet the expert's testimony, for what it is worth, may be admitted as such by the courts. Although the legal system in the United States professes that a defendant is innocent until proven guilty, in the

case of alleged malpractice, if the defendant cannot prove an alternative cause of the adverse outcome, the physician may be judged guilty of malpractice. Although an identifiable cause of death at autopsy may assist in a physician's defense, many juries are led to believe that the physician has erred if the autopsy does not conclusively demonstrate an alternative cause of death. This logic precludes the possibility that an adverse outcome or death may occur without obvious anatomic cause. It further, for lack of a specific, established cause of the outcome, assumes that the defendant must be guilty of negligence, although the care delivered to the patient may have been completely consistent with accepted standards of practice. The legal process of identifying a diagnosis, evaluating whether the therapy was appropriate, and judging the competence of the physician in the courts is an environment completely foreign to a person whose entire life has been spent practicing medicine. This chapter deals with some of the elements that contribute to this process.

Patient Rapport

Perhaps the single most important factor in whether or not a lawsuit is filed is the rapport the physician has with the patient. The practice of anesthesiology is such that the anesthesiologist can spend a significant amount of time in the preoperative and postoperative periods establishing rapport with the patient or, conversely, can limit time with the patient, who then thinks of the anesthesiologist as "that doctor behind the mask in the operating room." Clearly, a patient will be far more reluctant to initiate a lawsuit if there is confidence in the physician and if the physician has demonstrated compassion, welcomes the opportunity to answer the patient's questions, is attentive to the patient's psychologic as well as medical requirements, and is ever present. The preoperative and postoperative visits, therefore, become extremely important, not only in determining the appropriate choice of anesthesia and whether postanesthetic complications occurred, but also in cementing a mutually satisfactory relationship.

During the preoperative visit, the anesthesiologist should give patient and family ample opportunity to ask questions and to receive answers. At no time should questions be evaded, nor should the patient be given answers that only reflect what the physician thinks the patient wants to hear when that differs from the appropriate answer. When options exist in anesthetic management, these options should be explained to the patient, but the anesthesiologist has a responsibility to recommend the method that he or she believes is indicated and to explain the reasons for the selection. Potential complications should be explained; however, the physician must use some discretion. There is no question that some patients really do not want to hear all the potentially terrible things that can happen to them under anesthesia. It is possible to frighten patients to the point that they refuse operations. In this situation, if an adverse result occurs, the anesthesiologist may be sued for dissuading the patient from obtaining the appropriate care. However, we are unaware of any physician who has been held liable by the courts for such action. Therefore, in making it clear to the patient that, although anesthesia is safe from a statistical standpoint, it is not innocuous, and severe complications can occur, even to the point of death, the patient should receive as detailed a description as wanted. If the patient does not want to hear all the complications or the "gory details" and tells this to the anesthesiologist, we personally believe that the patient should be spared this detailed information. In this case, a note should be written, dated, and signed in the patient's medical record.

Many institutions use a common-consent form for both surgery and anesthesia. Although this is acceptable, a separate consent form for anesthesia is preferred; it can be tailored more directly to the anesthetic management. The contents of this consent form should either be read by the patient or read to the patient, as appropriate, before it is signed, and certainly any questions that arise should be addressed. A brief narrative note, either on the consent form, or a separate preanesthetic form, or in the progress note section of the patient's record, should record any pertinent events that occurred during this process, any discussion of importance, and the anesthetic plan, if a specific plan was agreed on at that time. When a specific anesthetic plan is presented to the patient and agreed on, the patient must be informed that the plan may have to be modified as conditions dictate intraoperatively. Because patients, not infrequently, are moved from one operating room to another to facilitate efficient operating room scheduling, if the anesthesiologist practices in a group setting where the actual anesthesiologist or anesthetist may differ from the one who conducts the preoperative visits, the patient should be so informed, particularly if the patient requests such information.

Policies and Procedures

Each department of anesthesiology should have a policy and procedure manual (Chs. 79 and 82). All too often, preparation of these manuals is delegated to administrative personnel who may have little knowledge of the practice of anesthesiology. In other circumstances, a manual may be adopted verbatim from another institution. When this occurs, it is not uncommon that the manual guiding practice procedures conflicts with the actual practice in that institution. This creates an intolerable situation for the defense attorney, who then has the responsibility of defending both the institution and the physician when the standards of practice differ

between them. Although there may be common policies and procedures among institutions, many are applicable to one institution but are not appropriate for another. Therefore, it is essential that policies and procedures manuals be individualized. Responsibility for development of these manuals should rest with the chief or chair of anesthesiology within the institution. It is the responsibility of each anesthesiologist who practices within the institution to be familiar with the policies and procedures of that institution. Revision of these manuals on a regular basis ensures that the policies and procedures specified are appropriate and enforceable and that outdated methods or methods impossible to follow in that specific institution are eliminated. We recommend that these manuals should be reviewed and updated by the chief of anesthesiology at least annually.

Preoperative Preparation

During the preanesthetic visit, it is essential that an adequate history and physical examination be available (Chs. 23 and 25). Furthermore, supplemental information must be gathered as appropriate. For example, frequently the patient's other physicians do not elicit or record information important to the anesthesiologist, such as airway anatomy, drug allergy, previous anesthetic history, and familial disease with anesthetic implications. The anesthesiologist should know the intricacies of the patient's medical problems and treatment. For elective surgery, patients should be in optimal health whenever possible. Anesthesiologists frequently are caught between the surgeon and the patient in regard to the timing of the procedure. This conflict may occur because the surgeon influences the patient's choice of anesthesiologist and because "cooperative" anesthesiologists may be preferentially assigned to more profitable patients. It is all too easy to overlook, or to minimize, severe but treatable medical problems to meet an operating room schedule. Fortunately, for the majority of patients, this seldom results in a severe, irreversible adverse occurrence, yet it is not a practice that should be condoned. Furthermore, if an adverse event does occur, the onus is on the anesthesiologist to justify why anesthesia was administered for an elective procedure when further work-up or treatment would possibly have made it safer. To state that the surgeon insisted on proceeding even though it was an elective procedure is not an adequate defense.

In the legal climate of joint and several liability, a physician who is found even 1 percent at blame may end up funding virtually the entire settlement if the other physician is uninsured and does not have sufficient assets to cover the judgment. [89] Therefore, if the surgeon is shown to have exerted undue pressure on the anesthesiologist to proceed with a case when the latter thought it should be postponed pending further testing or therapy, it may be very costly financially for the surgeon. It is in the best interest of both parties not to subject a patient to elective anesthesia and surgery when additional time for evaluation and treatment will improve the patient's physical status.

Importance of Records

The medical record is the cornerstone of defense in a malpractice suit. If information is missing from the medical record, the plaintiff's attorney will argue to the jury, "If it is not on the record, it did not occur" or will question the anesthesiologist's motive for not recording the data. It is imperative, therefore, that the anesthesiologist record all pertinent events on the record in a timely fashion. Should an emergency event occur that necessitates the anesthesiologist's undivided attention, someone else should be enlisted to serve as a scribe, if possible, to continue recording events. The routine elements of an anesthetic record, such as gas flow rates, drug dosages, timing of events, and frequent vital sign recording, must be performed diligently.

With emerging technology, the anesthetic record can be prepared electronically via automatic processing. [90] Such records can be extremely helpful, but when erroneous data are entered on such a record, they must be noted immediately. These recorders not only can note the patient's vital signs but also can be used to monitor aspects of the case such as equipment, gas flows, and neuromuscular transmission. When a monitoring tool is deliberately interrupted, such as interrupting capnographic monitoring of end-tidal carbon dioxide tension when an endotracheal tube is inserted, it should be noted on the automatic record so that it does not appear as if it were an adverse event, such as a ventilator disconnection.

Detailed attention to the record should not stop the moment the anesthetic agents are discontinued. All events that occur up to the time that the patient is left in the care of the nurse in the postanesthesia care unit (PACU) should be appropriately recorded. Before leaving the patient in the care of the PACU nurse, the anesthesiologist should note and record the status of the patient. A PACU or Aldrete score [91] should be recorded and initialed by both the PACU nurse and the anesthesiologist. This method minimizes the potential for subsequent disagreement between nurse and physician if both are named in a lawsuit. If the patient is not stable on arrival to the PACU, it is the anesthesiologist's responsibility to remain with the patient, or, before leaving the patient's bedside, to ensure that adequate personnel are available to care for the patient appropriately. To leave an unstable patient to press on with an elective operating room schedule is unacceptable.

Monitoring

We have heard anesthesiologists claim that they do not want to monitor the patient extensively with capnography, pulse oximetry, automatic record keepers, and the like, because this would only provide additional material for a plaintiff's attorney (Chs. 28 - 38). We personally believe that we are obligated to monitor all appropriate systems for each patient when we have the capability to do so. Furthermore, we believe that recording the data gives a clearer picture of the cause of adverse events and, thus, facilitates the defense of an anesthesiologist who has practiced appropriately. At a minimum, the Harvard standards should be followed. [92] In addition, monitoring by pulse oximetry and capnography is now considered the standard of care in most, if not all, parts of the United States. [93]

Risk Management

Physicians should be aware of the incident-reporting requirements of the hospitals where they practice and their duty to report adverse incidents to the insurer as delineated in the insurance contract (Ch. 79) . When an unexpected event occurs, the appropriate individuals must immediately be informed, notwithstanding that, when two or more health-care professionals are involved in the same incident, there is the possibility for conflicts of interest, which can be exacerbated by financial considerations when different insurance companies or self-insurers are involved. It is often required by law and/or hospital bylaws and is in the physician's best interest to contact the hospital risk-management office to review the case with the risk manager, with the concurrence and full participation of all interested parties.

When the cause of the untoward event is not readily apparent, convening a meeting of a medical review committee, which should consist of all persons involved in the care of the patient at that particular time, such as the anesthesiologist, surgeon, circulating nurse, and scrub nurse, is frequently helpful.

Such committee meetings called to evaluate and improve the quality of health care must be structured to protect them from discovery and subpoena. [94] Many states have passed laws to encourage the open and candid review of incidents by protecting peer review reports from discovery or from use as evidence; therefore, it is very important that the proceeding be deemed a peer review. In states where such laws do not exist, counsel representing the involved parties should be present, so that the attorney-client privilege will apply. A senior member of the staff who was not directly involved in the care of the patient should chair the meeting and play devil's advocate, to ensure that all pertinent material is brought forth, whether or not it is a matter of record in the patient's chart. Areas of disagreement among participants in the care of the patient should be aired at that time to help uncover the facts of the case and to put the puzzle together.

Recordings of these meetings should be kept by the risk manager, insurers, and legal representatives, so that, if a claim or suit were filed in the future, the defendant could review the material collected at the time of the event and would not have to reconstruct the facts from memory several months or years after the event. Needless to say, it is extremely difficult, if not impossible, to reconstruct events accurately subsequent to the filing of a lawsuit and notification thereof years after the event, which can happen. Moreover, insurance carriers require that they be promptly notified of an adverse outcome that could result in a liability claim. Failure of timely notification of the carrier may compromise coverage and may result in denial of responsibility on the part of the insurance company for the case in question, if the carrier can establish that a delayed notice prejudiced its ability to settle or defend the suit.

Expert Witness

Frequently, the outcome of a suit does not depend as much on exactly what was or was not done by the physician in the care of the patient as on the opinion of "expert witnesses" for both plaintiff and defense. For some time, many physicians were reluctant to serve as expert witnesses, particularly on behalf of the plaintiff.

This resulted in the plaintiff's attorney's frequent use of physicians who proclaimed to be expert in many fields, but whose credentials were at times unimpressive, to say the least. If the patient clearly has been harmed by inappropriate care from a physician, it is the responsibility of the medical community to facilitate the process and to deal with the physician's lack of competence. On the other hand, if the patient suffered an untoward event despite appropriate therapy, it is inappropriate for a physician, no matter what the compensation, to distort the facts or to give questionable professional opinions that could aid the attorney in convincing a jury that malpractice has been committed. Some states have passed legislation that defines "physician expert witness" according to specialty or percentage of time devoted to clinical practice, teaching, or both. One such state is Ohio, where legislation passed in 1991 states:

> No person shall be deemed competent to give expert testimony on the liability issues ... unless: (1) The person is licensed to practice medicine and surgery, osteopathic medicine and surgery, or podiatric medicine and surgery by the state medical board or by the licensing authority of any state; (2) the person devotes three-fourths of his professional time to the active clinical practice of medicine and surgery, osteopathic medicine and surgery, and podiatric medicine and surgery, or its instruction in an accredited university.

[95]

Legislation of this type limits the use of "professional experts," who may testify on virtually any medical subject, although they may never have been trained in or practiced the specialty in question in recent years. The Supreme Court of the United States signaled in 1993 that it was ready to tackle the subject of the quality of science acceptable in court or, at least, to set some standards for expert scientific testimony in court. [96] To date, this has not occurred. Any resultant ruling by the Supreme Court will have an enormous impact on medical liability, not only for alleged malpractice, but also for product liability. Absent such legislation, the jury is left to weigh the credentials of the expert in determining the level of credibility to give to the expert's testimony.

Unfortunately, a lawsuit frequently seems to be played in the courtroom as a sporting event, and the players seem more engrossed in winning or losing than in determining justice. This results from the adversary system, by which "justice" is done by the jury or judge, who decides between two advocates. In addition, the influence of television has had a dramatic effect on the way many lawsuits are tried. In part, this happens when jurors, and even attorneys and judges, watch too many legal dramas and try to emulate the actors and actresses in those shows. Even more important, lawyers who know they are being televised may have a tendency to "act" more than "practice law." The legal field of malpractice has become a very specific subspecialty, and many attorneys trying such cases frequently have acquired a great deal of medical knowledge applicable to the specific case. It is in the best interest of both plaintiff and defendant to have attorneys of the highest quality in this field represent them. Anything less than this places them at a distinct disadvantage in the legal process and in the courtroom.

Establishing Standards of Care

Establishing the standard of care is frequently based on the testimony of expert witnesses rather than on published authoritative documents. Many physicians have resisted attempts to develop and accept strict standards, which could dictate specifically what care patients should receive. These physicians argue that medicine is not a precise science, and a physician's judgment should be exercised in determining what is best for each individual patient. However, there has been increasing interest in the development of practice parameters, which may serve as a guide to acceptable practice. Some clinicians think that, if a physician adheres to such practice parameters but an adverse outcome nevertheless results, simply following such parameters may prove helpful in the defense against an alleged malpractice suit. The

---

American Society of Anesthesiologists (ASA) has been quite active in developing a series of parameters related to the specialty of anesthesiology. These parameters, as well as standards, guidelines, and statements related to practice and patient care issues, have been published by the Society. [93]

Assigning Responsibility

Not infrequently, when an adverse reaction occurs during anesthesia, the question of who is legally responsible arises. A lawyer for the plaintiff frequently sues everyone who has come in contact with the patient. Anesthesiologists, certified registered nurse anesthetists (CRNA), surgeons, operating room nurses, postanesthesia care nurses, and hospitals have all been sued individually as well as collectively. [97] One person may be liable for the acts of another under the doctrine of *respondeat superior* or on a "right to control" theory. The law must not be clear on this point, however, because courts have not applied respondeat superior consistently. In the past, a Colorado court, holding a surgeon liable for the acts of an independent licensed anesthesiologist, stated that "once the operating surgeon assumes control in the operating room, the surgeon is liable for the negligence of all personnel working under the surgeon's supervision." [98] The question must be raised, however, whether the surgeon has the necessary level of expertise to "supervise" the anesthesiologist. We maintain that he or she does not. The Supreme Court of Kansas ruled that the surgeon is generally not liable for the negligence of an anesthesiologist but is liable for the negligence of a nurse anesthetist under the doctrine of "captain of the ship." [99] The Supreme Court of West Virginia in 1987 rejected the "captain of the ship" doctrine and concluded that the surgeon was not responsible for the alleged negligent acts of a nurse anesthetist who was working under the medical direction of an anesthesiologist. [100]

Attempting to clarify responsibility in this area often has led to debate. [101] [102] Our position is that the practice of anesthesiology by an anesthesiologist is a specialty unto itself, just as the practice of surgery is a medical specialty of the surgeon. An anesthesiologist who personally administers anesthesia to a patient is alone responsible for the outcome. If a CRNA administers anesthesia, the picture becomes clouded by the employment relationships of the CRNA. Most state laws that govern the practice of CRNAs license them to practice under the medical direction or supervision of a licensed physician. In that situation, if the CRNA is both employed and medically directed by an anesthesiologist, clearly both the anesthesiologist and the CRNA should be held liable. If the CRNA is employed by the hospital and is medically directed by an anesthesiologist, all three should be held liable. If the CRNA is self-employed and is performing anesthesia under the medical direction of the surgeon, then both the CRNA and the surgeon should be held liable, whereas if the CRNA is employed by the hospital and is medically directed by the surgeon, in our opinion, the hospital, the CRNA, and the surgeon all should be held liable. In this situation, if the surgeon takes the position of knowing little about anesthesia and states that the CRNA is more expert than the surgeon in this area, we think that this is not an adequate defense, because, unless one is prepared to diagnose and treat the medical problems that occur, one cannot medically direct the services of others. Several state legislatures have considered legislative proposals to establish CRNA as independent practitioners not requiring medical direction or supervision by a licensed physician. One would think that such laws, if passed, would make the CRNA solely responsible for his or her actions. However, we are not aware at this time of any cases tried in which claiming that the CRNA was an independent practitioner released the physician from liability.

Preparing for the Defense

We believe that the most important single item in the defense of an anesthesiologist whose practice is appropriate and who has been sued for alleged malpractice is the quality of the defense attorney. It is in the anesthesiologist's best interest to have the most knowledgeable individual available, even if this means hiring counsel separate from that hired by the anesthesiologist's insurer. It is then imperative that the attorney be provided with all the facts of the case, whether they are perceived to be beneficial or detrimental to the defendant. It is very difficult for an attorney to deal with surprises in court. Furthermore, the selection of expert witnesses should be a decision made in concert by the attorney and the defendant anesthesiologist. It is important to obtain experts who are knowledgeable in the field and who also will make a good court appearance before lay jurors.

During the process of working through the defense, there will be a period when the defense attorney essentially conducts an independent investigation. The defendant anesthesiologist, the risk manager, and anyone else involved in the suit must be open and frank in providing all the details about the care of the patient, again, whether or not they are perceived to be important or beneficial. The expert witness should be asked for a frank opinion about the case and, even if this person believes in the defendant's cause, should be asked to play the devil's advocate to ensure that all pertinent information is accounted for during the preparation. The expert should also be asked to predict the strategy of the plaintiff's expert, even if it must be purely speculative. Such speculation may provide information that will help the defense attorney to prepare for dealing with the testimony of the plaintiff's expert.

Statements regarding the case should be given only to the risk manager and to the defendant's attorney. Whether it is appropriate to share information with others is a decision that should be made by counsel. Anything said in deposition may be read verbatim before the jury in court. Therefore, before giving any deposition, the

defendant should review the patient's record and also should study the standard of care, as well as appropriate pharmacologic, physiologic, and clinical-care decisions, that may be addressed by the opposing attorney. Giving a deposition without prior review of the record and then reviewing the record before a court appearance and giving different answers at that time can be disastrous. In fact, some attorneys use this technique to impeach or frustrate the witness or to cause the witness to decompensate before the jury. The medical defendant should always retain composure and should answer questions in a forthright and professional manner. After all, it is the appearance that the defendant projects to the jury that frequently

---

makes the difference in whether the defendant is perceived as the type of doctor they would want to treat them. This perception has a strong psychologic impact on the jury's final decision.

In short, it is the attentive, compassionate, meticulously vigilant physician who strives to maintain currency in the field who is least likely to be judged negligent in the care of a specific patient. Anything short of this type of practice increases the exposure to lawsuits and the potential for financial loss.

Financial Impact of Malpractice Claims

It is well recognized, even in the legal literature, that the dramatic growth of medical malpractice litigation in recent years has contributed significantly to an overall increase in health-care costs in this country. [103] Although lawmakers, physicians, and others have proposed numerous solutions to curb the crisis, these proposals generally have been ineffective. Some states have legislated reforms such as arbitration panels, a cap on recovery for noneconomic damages, and a briefer statute of limitation. Each alternative has weaknesses and strengths. For example, whether an alleged claim for malpractice is heard by an arbitration panel frequently is at the discretion of the plaintiff, not the defendant. Placing a cap on recovery for noneconomic damages is a rational approach, particularly because pain and suffering are subjective, not objective, factors, and tolerance to discomfort varies widely among people. Although some states have passed legislation regarding these issues, on the appeal of plaintiff's bar, some have overturned it as unconstitutional. Still other states have not addressed these issues at all. We believe the ultimate answer to this costly problem is rational tort reform that is uniform among the 50 states, rather than sporadic and independent action by each state.

The legal literature refers to the finding that "nuisance suits" are frequently filed by attorneys who are confident that the suit will never go to court because the defense costs of such suits may well exceed what would be acceptable in settlement. [103] Indeed, in many cases, insurance companies settle such suits out of court even though that is not the wish of the physician, who is the client. In such situations, the physician has little or no recourse and must accept the implication that some may infer--that he or she performed in a manner that was below standard, even though there may be no evidence of that. Nevertheless, the insurance company can make such a decision based on finances, rather than on whether the physician was innocent or guilty. Any such settlements should contain statements that the physician admits no guilt and is held harmless from further action in this matter.

In some situations, physicians have countersued the plaintiff's attorney, the claimant, or both and have been successful. [103] This process is very difficult and potentially very costly, however. Not only does a physician have to have been tried already and to have received a defense verdict in court, but he or she may then have to prove that "malicious prosecution" has occurred. For an action against alleged malicious prosecution to succeed, the plaintiff, in this case, the physician, must prove that the suit was instituted without probable cause, that the suit was decided in favor of the physician because the suit was instituted maliciously, and that the physician sustained special damages. [103] Even the last point can be difficult to prove. In one case, the court held that litigation expenses, increase in insurance premiums, and injury to professional reputation did not constitute special damages. The rule in Georgia is even more extreme, where the court concluded that a "cause of action ... will not lie absent a showing that the defendant was arrested or his property attached." [103] Thus, in some states, a patient who alleges out-of-pocket expenses or inability to function in his or her chosen field of employment as a result of injury from the alleged action of a physician can be reimbursed for economic damages based on past and future expenses and earning potential for a lifetime and can obtain hundreds of thousands, if not millions, of dollars. When a physician who is harmed brings forth an action, however, the same elements of determining economic damages do not apply. Such an inequity results in a double standard and should not be permitted to stand unchallenged.

LEGAL CONTRACTS IN MEDICAL PRACTICE

Contractual Agreements Restricting the Right to Practice Medicine

Apart from state licensing requirements, a contractual agreement can limit the right to practice when and where an anesthesiologist chooses. An anesthesiologist encounters noncompete agreements in a number of situations. As a condition of employment with a hospital, an anesthesiologist may be asked to sign a noncompete agreement, which prevents the applicant from seeking employment or privileges at a competing hospital during and after termination of employment with the contracting hospital. An anesthesiologist may be required to sign a similar agreement on joining a group practice, in large part because the new anesthesiologist will have access to the group's existing patients. Moreover, when an anesthesiologist in private practice sells that practice, the buyer will seek to acquire the goodwill of the practice and therefore may require a noncompete agreement. Finally, an indirect form of agreement can also restrict competition; for example, hospitals sometimes enter into an exclusive contract with a physician, which gives that physician access to the hospital and excludes the physician's competitors.

The legal system has reacted with mixed views toward contracts that limit the ability of one party to conduct its trade or business freely. On the one hand, the capitalistic system on which our legal system is based is premised on the ability of private parties to contract freely among themselves. The civil legal system exists to uphold such contracts. On the other hand, the Sherman Anti-Trust Act [104] was enacted to make contracts that restrain trade unlawful.

Almost any business contract literally restrains trade simply because the contract binds two parties to conduct business in a prescribed manner. The United States Supreme Court, therefore, established a "rule of reason," by which a court looks at a contract in light of all the facts, circumstances, and the advantages gained by the contract, as a

whole, to determine whether the restraint on trade is reasonable. [105] However, some restraints are considered so egregious that they are held to be per se unlawful regardless of any legitimate business reasons for the restraints; for example, those that involve fixing prices, [106] those that enable one party to establish or maintain a monopoly on a market, [107] those that enable a group of competitors to boycott another competitor, [108] and those that involve an illegal "tying" arrangement, that is, a contract by which one party having market power to control a product "ties" the purchase of that product (the "tying" product) to the purchase of a second product (the "tied" product) (discussed in detail later). [109]

Covenants Not to Compete

When a covenant not to compete is challenged as a restraint on trade, the challenge is almost always initiated by one of the parties to the contract itself, namely, the physician who agreed to the covenant. This is contrary to per se violations, which usually involve a claim by a third party that the contracting parties' actions were designed to injure the third party; for example, entering into an agreement to fix prices or to exclude the injured party from a market. Therefore, covenants not to compete are judged by the rule of reason, and courts will strike down a covenant only if the restraint on trade and resultant injury are greater than the reasonable interest of the party seeking to enforce the covenant.

Noncompete Agreements in the Sale of a Practice

Generally, noncompete agreements ancillary to the sale of a medical practice are enforced if the agreement is supported by consideration, is reasonable in scope, is protective of the buyer's legitimate business interests, and is not unduly harmful to the public. Every contract must be supported by consideration to be enforceable, regardless of whether the consideration is adequate. Generally, a noncompete agreement given in exchange for a practice's goodwill is supported by adequate consideration, because the noncompete agreement is intended to preserve the goodwill being acquired. [110] However, a noncompete agreement ancillary to the sale of a practice may be void for lack of consideration, if separate consideration is not paid and the practice's goodwill is not purchased (when only tangible assets are transferred). Likewise, a noncompete agreement entered into subsequent to the sale of a practice is not supported by consideration, absent separate, specific consideration given in exchange for the noncompete agreement.

Most of the cases that have enforced noncompete agreements against a physician turn on the question of the reasonableness of the restriction. Cases look to whether a particular restriction is necessary to secure the benefits and goodwill purchased and whether the restriction unnecessarily injures the rights of the seller or the public. The very nature of the service rendered by a physician to a patient is personal; when a physician contracts away the right to serve a particular patient, the patient, not the physician, may suffer the greater loss. Therefore, before enforcing a noncompete agreement involving physicians, the courts look carefully at the public interest, the benefits gained from the agreement, and the harm caused by it.

If the sole purpose of the covenant is to ensure that the seller is excluded from competing with the buyer (as opposed to protecting the goodwill purchased by the buyer), then the exclusion bears no relation to the tangible benefits of the purchase, and the noncompete agreement is unenforceable. For example, a noncompete agreement is unenforceable if it bars an anesthesiologist from practicing not only in the town where the practice is located but also in another county not served by the practice. [111] The issue here is not the geographic scope of the noncompete agreement but the tangible benefits bargained for in connection with the acquisition of the practice. Thus, if the practice serves several communities, the noncompete agreement may extend to all those communities, but not to additional communities into which the buyer merely seeks to expand. Similarly, an agreement that excludes a seller from competing with another practice owned by the same buyer in another community is not enforceable. [111]

Whether a covenant not to compete injures the rights of the seller depends on the reasonableness of the covenant's time and territory restrictions. Therefore, a covenant not to compete should specify a definite duration and a definite geographic area. Covenants that are unlimited in both time and area are not likely to be enforced. [112]

In looking at the time period specified by a covenant, courts are more liberal when the covenant is connected with the sale of a business, as opposed to an employment contract. Because the goodwill of a business is usually built over an extended period of time, contracts not to compete within a limited area for an unlimited duration have been enforced in some courts, [113] but it is more likely that the court will apply a time limit to a contract of unlimited duration. [114] Time restrictions of up to 10 years in connection with the sale of a business have routinely been held to be reasonable.

Courts scrutinize the territory covered by a covenant not to compete more carefully than the time limits. Covenants not to compete in a particular community or county served by a practice are routinely considered reasonable. The larger the territory, the more carefully the court scrutinizes whether the practice serves a sufficient number of patients in the outer reaches of the restricted territory to justify imposing a greater restraint on the seller. As early as 1946, one court acknowledged "the reduction of barriers of space and time made possible by modern transportation and communication," in enforcing a covenant not to compete covering more than one

county. [115] Thus, it is possible for a court to find a covenant overly broad if it covers all of Los Angeles County, but valid if it covers several sparsely populated counties in Alaska. However, a restricted territory's reasonableness also depends on the service provided. A covenant not to compete against an anesthesiologist who, with a particular sophisticated specialty, serves patients from a broad area is more likely to be enforced over a larger territory than one sought to be enforced against a general practitioner who serves patients from a particular neighborhood.

A covenant that is found to interfere unduly with the interest of the public will not be enforced. Thus, the court must be satisfied that, if the agreement is enforced, other

physicians in the area can serve the community. Although early courts considered only the number of practitioners in an area, without regard to specialties, an anesthesiologist seeking to avoid a noncompete agreement would be permitted to introduce evidence that other anesthesiologists are lacking in the community. A Nebraska court, more than 70 years ago, in a case involving a proctologist, considered not only whether there were other proctologists in the area but also whether the other physicians were qualified to practice "the seller's method of proctology." [116]

If the physician's recognized methods of treatment are unique in the community, a court could carve out an exception to the covenant and allow the physician to offer the unique services but not the readily available services. For example, a Texas court enforced a covenant not to compete against a radiologist, but it permitted the radiologist to perform certain subspecialties of radiology that were not generally available from other radiologists in the community. [117]

Perhaps the most difficult issue in these cases involves the rights of patients. Should a physician have a right to contract away a patient's right to the physician's services? If a patient had no other options, the court would void the noncompete agreement as contrary to public policy. However, when other physicians are available, a patient does not have specific rights to the services of a particular physician, because the desire of the patient is outweighed by the rights of a physician to acquire the goodwill of a practice and to secure the value purchased with a noncompete agreement. In fact, some courts have rationalized that patients outside the restricted area profit from the services of the physician who, because of the noncompete agreement, can no longer practice in the restricted territory. [118]

Noncompete Agreements in an Employment Setting

Although the rules for enforcing a noncompete agreement between an employer and an employee are similar to those between seller and buyer, there are important differences. Some state legislatures have specifically outlawed noncompete agreements between employers and employees. [119] When such a statute is unavailable, courts generally note that an employee lacks the bargaining power that a seller of a business has and therefore may sign an employment contract containing a noncompete provision without any ability to negotiate such a provision.

Courts are concerned that employers may take undue advantage of the employee in requiring a noncompete agreement. [120] The position of an employee differs from that of a seller of a business, who receives payment for the goodwill of the business in return for an agreement not to compete. If there is no fraud on the part of the employer, these cases usually turn on the question of consideration. To be enforced, such an agreement must be supported by valid consideration, must be reasonable in scope, must protect a legitimate business interest of the employer, and must not unduly harm the public. A court will not find consideration to exist if the only consideration is the employer's decision to continue employing the physician. [121] Therefore, a noncompete agreement cannot be imposed as an afterthought by an employer once employment has commenced without specific consideration for the subsequent noncompete agreement. An increase in compensation that would otherwise have been due to such employees would not represent new consideration, [122] but a promotion could. [123]

Compared with decisions in past decades, courts are now tending to disfavor noncompete agreements within the employment context and therefore are scrutinizing these agreements more closely. More than 70 years ago, courts enforced noncompete agreements covering an entire city for 10 years after the termination of employment, [124] but more recent courts have found a 35-mile radius from the employer clinic for 2 years after termination, [125] and a 50-mile radius for 3 years after termination, [126] to be unreasonable.

One factor sometimes considered is whether the physician has reasonable alternatives available to practice his or her profession. Thus, a Georgia court upheld a covenant that prevented a surgeon from practicing in ten populous counties in and around Atlanta because the covenant left the surgeon free to practice in at least three other heavily populated counties in the metropolitan area. [127]

These cases turn on the facts of each situation, and decisions vary from state to state. In 1986, an Arkansas court struck down a noncompete agreement that covered a radius of 30 miles for only 1 year after termination. [128] Apparently, the size of the restricted area was not even an issue, because the physician, an orthopedic surgeon, had joined a clinic practicing in the same building as his former employer. The court noted, however, that there was no evidence that the surgeon either attempted, or succeeded in, enticing any of his former employer's patients to continue to see him (even though he did perform "normal medical follow-ups" on patients on whom he had operated while employed by the former employer). The doctor had received his training and skills before employment, he acquired no special skills during the employment, and he even performed some procedures the employer did not. Based on these factors, the restrictions were an unreasonable restraint of trade and unduly interfered with the public's interest in the availability of this orthopedic surgeon.

As in the case of noncompete agreements ancillary to the sale of a business, a noncompete agreement given by an employee will be stricken if it imposes an undue hardship on the public that results from the unavailability of physicians performing similar services in the area. Indeed, the trend is to look more carefully to find undue hardship in cases arising out of employment relationships.

Noncompete Agreements Among Members of a Group Practice

Another time physicians may be asked to enter into a noncompete agreement is when they join a medical group. A noncompete agreement among members of a group practice is a hybrid: the contract is one of employment, but, when a physician leaves a group practice, the physician's share in the partnership property, including its goodwill, is transferred, as in the sale of a practice. Courts have held that covenants in an employer-employee relationship require "a stricter scrutiny in determining the reasonableness of the restrictions" than one given among partners. [129]

Courts frequently use the sale of goodwill to justify enforcement

of noncompete agreements against former members of a group practice, [130] even though a state statute may prohibit employers from requiring employees to agree to noncompete agreements. [131] Noncompete agreements, given by physicians on joining a group practice, have been enforced in the following contexts: a covenant covering a 25-mile radius for 3 years after a physician leaves the partnership, [132] a covenant not to practice in a 5-mile radius for 5 years, [133] and a 5-year noncompete agreement covering a radius of 30 miles, for a physician who had repeatedly changed professional associations within a range of thousands of miles. [134]

As with any noncompete agreement, the covenant must be found to protect a legitimate interest of the group practice, and if the court finds that competition from the terminating partner will not affect the group, the covenant will not be enforced. [135] The court also must find that enforcing the covenant would not cause undue hardship in the general public.

Exclusive Agreements Between Hospitals and Physicians

Hospitals may enter into an agreement with a physician or a medical group that gives a few physicians exclusive hospital privileges. Although such agreements are not noncompete agreements because the right to practice in a given area has not been contracted away, they have the same effect of restraining competition because other physicians are deprived of access to that hospital for the treatment of patients. In recent years, exclusive agreements have been executed in which the physicians must give up their right of due process, because their hospital privileges remain in effect only so long as the exclusive agreement is in effect. This, in

essence, results in economic credentialing.

Exclusive Contract as an Unlawful Tying Agreement

Because a third party may claim injury from the agreement, these contracts are examined carefully to determine whether they are illegal. Such contracts have been attacked under a number of theories, the most prominent being that the contract violates federal antitrust laws because it constitutes an unlawful tying arrangement. As related to physicians and hospitals, a patient can only obtain the tying product or service (access to the operating room) by purchasing from the seller another product or service, the tied product (the services of a particular physician).

For a court to hold that a contract is a tying agreement under federal antitrust laws, there must be two separate products. Once this is established, a tying agreement will be considered unreasonable per se if a party has sufficient economic power over the tying product (the operating room) to restrain free competition for it. [136] (An additional requirement, that interstate commerce be affected substantially, is addressed separately.)

In a 1984 decision that has had a significant impact on how the courts view tying arrangements, the United States Supreme Court addressed a claim involving a hospital's exclusive contract with a group of anesthesiologists. In *Jefferson Parish Hospital District No. 2 v Hyde,*[137] an anesthesiologist who was excluded from the hospital because of an agreement between the hospital and another group of anesthesiologists sought to have the agreement set aside as an unlawful tying arrangement under federal antitrust laws. The Court decided that a hospital's services and the services of an anesthesiologist are two separate products, separately priced and purchased, from the perspective of the patient. Anesthesiologists may be treated differently from radiologists, pathologists, and other hospital-based physicians in this regard. The demand for anesthesia services was considered separate from the demand for hospital services, as evidenced by the unique phenomenon of patients' and physicians' requesting a specific anesthesiologist. [138] Therefore, the hospital's services and those of the anesthesiologist are considered two separate products, whereas the services provided by some hospital-based physicians may not be considered separate from other services provided by the hospital.

The next question to be determined by the Court was whether the hospital had sufficient "market power" to force a purchaser to do something the purchaser would not do in a competitive market, namely, purchase the tied product (the services of the chosen anesthesiology group) to obtain the tying product (access to the operating room). The hospital need not have an absolute monopoly in the area to have sufficient market power to enforce a tying arrangement. Generally, if a business seeking to enforce a tying arrangement had a significant presence in the market, the business was found to have sufficient market power to enforce a tying arrangement. However, in *Jefferson Parish,* the Supreme Court declared that a significant market share, even when teamed with market imperfections such as minimal price and quality competition, is not sufficient to establish market power in the relevant market, absent some significant restraint on trade other than a tying of two services.

On the question of market power, the individual Justices of the Supreme Court differed. Five Justices held that, absent a significant restraint on trade other than the tying of these two products, the hospital did not have sufficient market power to enforce the tying arrangement because 70 percent of the patients residing in the parish entered different hospitals. Although concurring in the judgment, four other Justices disagreed with the majority's reasoning and instead decided that, based on prior precedent, a 30 percent market share was sufficient to give the hospital market power, but, more important, they determined that the Court should apply the rule of reason rather than per se illegality in judging tying arrangements. In applying a reasonableness test to the agreement, the concurring Justices found valid business reasons for the agreement and found that it foreclosed "only a small fraction of the markets in which anesthesiologists may sell their services, and a still smaller fraction of the market in which hospitals may secure anesthesiology services." [139] The concurring Justices implied that a hospital with an even greater market share could be able to enforce an exclusive agreement if there were valid reasons for the agreement.

The majority and concurring opinions used different reasoning, but both clearly signaled the Court's intent to constrict

the scope of the antitrust laws, at least as they apply to tying agreements. Since *Jefferson Parish,* the Supreme Court has expressly counseled against extending per se analysis to rules adopted by professional associations and to restraints imposed in the context of business relationships in which an anticompetitive economic impact is not immediately obvious. [140] Thus, many lower courts have expressed a reluctance to apply the per se rules and instead apply the rule of reason, which, in turn, requires proof of economic impact on competition and an extensive examination of the challenged conduct. [141] This is significant because most contracts considered under a rule of reason analysis are upheld. Even in a rule of reason case, at least one court has stated that "substantial" market power must be proven in order to sustain a claim. [142]

Other Antitrust Grounds for Voiding Exclusive Contracts

Following *Jefferson Parish,*[143] exclusive contracts between hospitals and non-hospital-based physicians are likely to be upheld unless an ulterior motive for the agreement is shown. Those seeking to uphold such an agreement will argue they have valid business reasons for signing an exclusive contract, such as maintaining or improving the quality of medical care or increasing efficiency. Persons excluded by these contracts must show that other, impermissible reasons are behind the agreement.

There are several possible means by which to attack such a contract. If an exclusive agreement (or any agreement) is found to be an attempt to fix prices for the services offered by hospitals or physicians, the contract will likely be stricken because such practices are per se unlawful under federal antitrust laws. [144] If the challenging party can show that the exclusive contract has a substantially harmful effect on competition, such as by "a reduction of output," or by proof of increased prices, the contract may be held to be unlawful. [145] Likewise, an exclusive contract found to be nothing more than a conspiracy to boycott certain physicians from obtaining hospital privileges will be set aside as an unlawful group boycott. [146] However, the plaintiffs must show the exclusive contract has "predominately anticompetitive effects" and essentially has no other valid purpose. [147] An exclusive contract that is an attempt to monopolize a market is also unlawful, because all contracts designed to monopolize a market are per se violative of federal antitrust laws. [148] In making such a claim, a competing physician must prove that one of the defendants possesses monopoly power in the relevant market and that this defendant willfully acquired or maintained that power through the exclusive contract, as opposed to having acquired a monopoly through ordinary growth or development as a consequence of superior service, business acumen, or historic accident. [149]

A competitor seeking to challenge an exclusive agreement as creating or furthering a monopoly is required to show the relevant market involved, the monopoly power of the defendant, and proof that the purpose of the exclusive agreement was to drive others from the market. [150] Once this threshold is satisfied, the defendant can establish a prima facie case of lawful conduct if valid business reasons justify the agreement. Therefore, the plaintiff must also prove that any proffered justifications are merely pretextual. [151] As a result of these many requirements, competing parties, medical or otherwise, have had difficulty proving that an exclusive contract constitutes a monopoly or an attempt to monopolize.

Defenses Against an Antitrust Claim

Even if an exclusive contract does violate federal antitrust laws, there are two defenses by which a hospital may prevent a challenge to the contract. First, federal antitrust laws apply only when interstate commerce is affected, although the courts have disagreed about whether the challenged conduct, itself, must be a form of interstate commerce or whether it must only have more than a de minimis effect on interstate commerce. [152] Thus, the size and drawing power of a hospital may have an influence on this decision. It should be noted, however, that even if interstate commerce is not affected, most states have their own antitrust laws, which do not require that interstate commerce be affected. Therefore, not affecting interstate commerce provides a complete defense to a claim under federal antitrust laws, but not to a claim under state antitrust laws. The individual states generally follow the federal courts in interpreting their own antitrust laws, but they are not obligated to do so.

The second defense against antitrust liability, and one that may apply more often in a hospital setting, is referred to as the "state action exemption doctrine." Under this doctrine, a hospital will be exempt if it can demonstrate that its anticompetitive activities were authorized by the state "pursuant to state policy to displace competition with regulation or monopoly public service." [153] This doctrine applies directly only to state hospitals, but county and municipal hospitals can also use the state action doctrine if they show they acted "pursuant to clearly articulated and affirmatively expressed state policy." [154] For a private hospital, such a defense would be available only if it could be shown that the state is actively supervising the hospital's activity and that the activity is in compliance with state regulatory policy. A federal appellate court, however, has ruled that when a state statute gives private hospitals the power to determine which physicians may practice in those hospitals, then all hospitals in that state are authorized to restrict those who are allowed to practice at the hospital, and the hospitals are immune from claims by competing

practitioners under the state action exemption. [155]

The state action exemption doctrine is a powerful exemption, as evidenced by the 11th Circuit's declaration that, with the possible exception of actual market participation, any action that qualifies as state action is ipso facto exempt from the operation of the antitrust laws, even if the state action takes the form of an unauthorized conspiracy to restrain competition. [156] Therefore, under the state action exemption, conduct that is the result of state regulations is not actionable even though it may otherwise be improper under federal antitrust laws. Once again, although state antitrust laws vary, most states recognize the state action exemption doctrine, and some even specifically include this exemption in their antitrust laws. [157]

Use of Anesthesiologists or Nurse Anesthetists: Antitrust Considerations

Numerous legal challenges have been made to actions taken by hospitals to exclude or to limit the practice of nurse anesthetists in their hospitals. The hospital practices that have come under attack are those requiring nurse anesthetists to be supervised by physicians or those dealing exclusively with anesthesiologists and not using the services of nurse anesthetists.

A hospital policy will be judged by the rule of reason, unless a plaintiff can show a policy was adopted as a means of imposing a restraint that is per se unlawful under federal antitrust laws (see the earlier section on *Exclusive Contract as an Unlawful Tying Agreement*). Pursuant to that analysis, it is likely a hospital will be able to show that its procedures were adopted as a reasonable means of ensuring efficiency and quality of anesthesia services. Thus, most attempts by nurse anesthetists to set aside hospital policies that exclude or limit the practice of nurse anesthetists have been unsuccessful. This is true even in spite of cases acknowledging that anesthesia services may affect interstate commerce in more than a de minimis way and that actions affecting these services are therefore covered by federal antitrust laws, [158] that nurse anesthetists and anesthesiologists do compete in a single market that can be monopolized, [159] and that it is possible for a hospital to conspire with its staff physicians in violation of federal antitrust laws. [160] Most nurse anesthetist- plaintiffs have failed because they could not prove that an exclusive contract between a hospital and a group of anesthesiologists unreasonably restrained competition or that the defendants were not pursuing permissible independent business (medical) interests. [161]

If a plaintiff successfully shows there was a reason other than a unilateral effort to provide quality care most efficiently to the patient for a hospital to exclude nurse anesthetists or to require their work to be supervised by an anesthesiologist, then the policy may be successfully challenged. In *Oltz v St. Peter*' *s Community Hospital,*[162] the plaintiff anesthetist, in bringing an action against both the hospital and a group of anesthesiologists, alleged that the hospital's granting an exclusive right to the anesthesiologists to furnish anesthesia services in that hospital and subsequently terminating the plaintiff's contract constituted an unlawful conspiracy to grant a monopoly to the anesthesiologists. In that case, the defendant hospital was the only hospital equipped to do general surgery in Helena, Montana, and had a market share of 84 percent. The trial court acknowledged that the hospital had a monopoly, but the mere fact that one has a monopoly does not make all of one's contracts unlawful. If the hospital had acted unilaterally, its actions would have been upheld. The evidence, however, showed that statements made by the anesthesiologists and exchanges of letters among the anesthesiologists and between the anesthesiologists and members of the hospital's Board of Trustees urged that the policy be adopted. Under these facts, the court held that the hospital had conspired with the anesthesiologists to exclude the plaintiff from the market and therefore had violated federal antitrust laws.

The *St. Peter*' *s Community Hospital*[162] [163] example should be noted by all medical practitioners. Its principles apply in every contract: conduct that has a valid business (or medical) purpose will generally be upheld under scrutiny of federal antitrust laws as long as the agreement and the resulting restriction are reasonably necessary to advance such legitimate business (or medical) purposes. When that conduct goes further and involves an attempt by one party, or a conspiracy among several, to exceed these legitimate purposes, the contract may not withstand antitrust scrutiny.

Publication of Relative Value Guides, Scales, and Studies for Medical Services

On several occasions, medical associations have sought to establish guidelines for fees charged for specialized medical services. Such concerted action, whether through mere communication of relative values for services or through the imposition of maximum fees for services rendered, has been viewed by courts and the U.S. Federal Trade Commission (FTC) as disruptive to a competitive market. [164] The distribution of price information has been attacked under two of this nation's broadest legal prohibitions. As noted previously, price fixing in general is prohibited by Section 1 of the Sherman Act. [165] The FTC also has attacked price guidelines under Section 5 of the FTC Act, which prohibits "unfair methods of competition in or among commerce, and unfair or deceptive acts or practices in or affecting commerce." [166]

In *State of Arizona v Maricopa County Medical Society,*[167] the United States Supreme Court reviewed the effect of the publication by the Maricopa County Medical Society (MCMS) of relative values for services and establishing maximum fees for such services in the Phoenix market. The MCMS was formed in 1969 to promote fee-for-service medicine and to provide the community with a competitive alternate to existing health insurance plans. Approximately 70 percent of all practitioners in the county were members. The MCMS published a relative value schedule for each medical service and a conversion factor to multiply by the relative value to establish maximum fees, which participating doctors agreed to accept as payment for services performed for patients insured under MCMS-approved plans. Doctors were permitted to charge higher fees to uninsured patients.

The Supreme Court determined that this concerted action constituted an agreement to fix prices in restraint of trade--a per se violation of the Sherman Act. The Court's application of the per se rule precluded examination of possible procompetitive justifications. In refusing to examine such possible procompetitive justifications, the Court stated, "The anticompetitive potential inherent in all price fixing agreements justified their facial invalidation even if procompetitive justifications are offered for some." [148] The fact that it established maximum rather than minimum fees was considered irrelevant by the Court. The issue whether the fixing of maximum prices or maximum fees should constitute a per se violation of the antitrust laws is expected to be heard by the United States Supreme Court. [168]

In 1962, the American Academy of Orthopaedic Surgeons (AAOS) published a booklet entitled *Relative Value Systems*

for Orthopaedic Procedures.[169] In the book, numeric values were assigned to medical procedures and were convertible into a monetary fee. The AAOS did not, however, impose a maximum schedule for fees to be charged for services based on such values. The FTC alleged that, notwithstanding the absence of a direct price-fixing scheme in violation of the Sherman Act, the publication of such information distorted the competitive balance in the market in violation of Section 5 of the FTC Act. [170] The AAOS eventually entered into a consent decree whereby it was required to cease publication and circulation of relative values that established and maintained fees for orthopedic services.

Although the FTC has been unwavering in its attacks against publication of any type of relative value study, the ASA successfully fought an attack against publication of a relative value study in 1979 in *United States v the American Society of Anesthesiologists, Inc.*[171] In contrast to the schedules published by the MCMS a few years later, the ASA had not ascribed any conversion factor to their guides but merely set forth a list of medical procedures, individually described in medical terminology and referenced by an abstract number known as a "unit of value." The District Court in *American Society of Anesthesiologists* pointed out that the mere adoption, publication, and dissemination of a relative value guide did not constitute a restraint on trade. The critical question was whether there was an agreement, express or implied, that the guide would be used to price anesthesia services, which the court did not find in this case.

Notwithstanding the success of the ASA in overcoming the FTC's objection to publication of relative value guides, it remains the official position of the FTC that publication of such studies is improper. [172] State attorneys general have likewise taken the position that any discussion leading to an understanding, whether tacit or explicit, about prices to be charged to consumers is considered a violation of Section 5 of the FTC Act and of comparable state statutes. Relative value studies and minimum or maximum price guidelines, discussed or distributed among competitors, whether among members of the medical profession or in other industries, will continue to be viewed with suspicion regardless of the stated purpose, because such practices can lead to an express or implied understanding among competitors as to the prices that can be charged. This presents an interesting dilemma because the U.S. Health Care Finance Administration (HCFA) has adopted a uniform relative value method to calculate physician payment for services rendered to Medicare recipients. [173] This method resulted from an extensive study conducted by Professor Hsaio and his colleagues [174] [175] [176] [177] and is now known as the Resource-Based Relative Value Study (RB/RVS). [173] Thus, it appears that two separate agencies of

the United States government, the FTC and HCFA, have completely opposite positions on the issue of relative value publications. When this chapter was written, that conflict had not been formally addressed, but it is clear that the RB/RVS published by HCFA will be used to calculate Medicare reimbursement for physicians' professional services.

Of interest to anesthesiologists is that the anesthetic section of the RB/RVS is basically the same as the ASA relative value guide. [178] The HCFA, however, has not accepted the section on modifiers and has published its intent to eliminate time units. This decision will destroy the time-tested appropriateness of considering concurrent disease, duration of effort, and complexity in determining the relative value of anesthetic care for one patient compared with another. Clearly, concurrent disease and time frequently play a larger role in the relative value of anesthetic care than simply the surgical procedure alone. This concept was understood by both houses of Congress when they passed legislation mandating the use of time in calculating relative value for anesthesia. This was signed into law by President Bill Clinton as part of the Omnibus Budget Reconciliation Act (OBRA) of 1993. [179]

Physician Self-Referral Issues

The practice of self-referral has been traced back at least as far as the 1920s, and the rules controlling such practices have seldom, if ever, been enforced. However, in the 1980s, the U.S. Department of Health and Human Services (HHS) began enforcing Section 1128B of the Social Security Act, [180] otherwise known as the Medicare and Medicaid AntiKickback Statute. This statute is broadly worded and is intended to restrict the corrupting influence of money on a physician's decision of when and where to refer patients. The statute is violated "whenever an individual or entity knowingly and willfully offers or pays anything of value, in any manner or form, with the intent of exercising influence over a physician's reason or judgment in an effort to cause the referral of a program-related [Medicare and Medicaid] business." [181] The statute was enacted in 1972, but dramatic increases in competition and in interrelationships among health-care providers since then have caused the HHS to take a more aggressive position in enforcing the statute.

In 1991, two events dramatically changed the legal and ethical landscape for physicians referring Medicare and Medicaid patients to health-care facilities or joint ventures in which the physician has an ownership (financial) interest. First, the HHS issued its "safe harbor" regulation. [182] This was followed by the landmark decision of the HHS Appellate Board in *The Inspector General v The Hanlester Network et al.* [180] The safe harbors were Congress' way of narrowing the scope of the overbroad Anti-Kickback Statute, so as to protect legitimate or innocuous business arrangements. Two investment-interest safe harbors were created. The first applies to physicians who may own less than a controlling interest in a publicly traded entity. The statute does not prohibit referral to that entity if the entity has assets of $50 million or more and the physicians' stock was purchased through public trading. [182]

The second safe harbor is for smaller entities, such as joint venture limited partnerships. [182] This safe harbor provision requires that all eight of its standards be met before protection is granted. [182] These requirements include, among others, that no more than 40 percent of the entity's ownership interests be held by persons who can make referrals to the entity. It is also required that at least 60 percent of the entity's revenue must come from noninvestor referrals. Furthermore, the entity cannot require investors to refer patients to it or to base profit distributions on the amount of referrals made or expected to be made by each physician. Therefore, the safe harbor provision narrows the scope of the Anti-Kickback Statute by creating a well-defined, albeit limited, safe harbor.

The *Hanlester* case is important because the Departmental Appeals Board declared that no agreement to refer is required in order to find a violation of the Anti-Kickback Statute. A violation now exists any time an inducement exists, which creates the potential for a conflict between the physician's self-interest and the patient's interests. A physician has a fiduciary duty to act in the patient's best interest, which means that a referral should be based on the cost, quality, and necessity of the relevant services. A physician's self-interests, such as investment and self-referral, are inconsistent with the fiduciary duty owed to the patient. [183]

Although these developments have dramatically altered the self-referral issue, the changes are not complete. Therefore, when referring patients to health-care facilities in which the physician has an ownership interest, the physician must be careful to comply with the safe harbor provisions or will risk prosecution under the Anti-Kickback Statute. In addition, the Council on Ethical and Judicial Affairs of the American Medical Association (AMA) developed recommendations for determining when self-referrals are appropriate. [183] * Under the AMA recommendations, physicians generally should not refer patients to a health-care facility outside their office practice if they have an investment in the facility but do not directly provide care or services at the facility (recommendation 1). [182] An exception to this general principle exists when the physician's investment is made in a facility for which there is a demonstrated need in the community, and alternative financing for the facility was not available. In these instances, however, certain other conditions must be met. The conditions require disclosure of the investment to patients and third-party payers and are otherwise designed to prevent preferential treatment to patients of the referring physician or any requirement or inducement for referrals to be made to the facility (AMA recommendation 2). [183]

LAWS AND REGULATIONS AFFECTING THE PRACTICE OF ANESTHESIA

Before the implementation of the Medicare program in 1965, the U.S. Government rarely passed laws or implemented regulations dealing with the practice of medicine. Since that time, however, legislators have been more interested in describing appropriate methods of medical practice and financial reimbursement for same. Regulations finalized in 1983 to implement the Tax Equity and Fiscal Responsibility Act for the first time specified requirements for the practice of anesthesiology that anesthesiologists would have to meet to be paid for their services under the Medicare program. [184] This was the first description in law of specific requirements for the practice of a medical specialty. Since that time, in an effort to contain costs, additional laws have been passed that mandate lower levels of financial reimbursement for certain services rendered to Medicare recipients, [185] as well as reductions based on the level of supervision or medical direction by an anesthesiologist. [186]

In 1992 and 1993, there was considerable effort to enact a diagnosis-related group mechanism for reimbursing anesthesiologists and to eliminate actual time as a method of calculating anesthesiology fees. Neither of these initiatives survived the legislative process, and, at least as of 1999, the diagnosis-related group mechanism for reimbursement does not apply to anesthesia, and actual time units are now, by law, part of the method for determining the appropriate value for professional anesthesia services. [179] Also passed in 1993 was a method for reimbursing for anesthesia services provided by an anesthesia care team, when an anesthesiologist medically directs the anesthetic care of up to four patients simultaneously with the assistance of CRNAs.

On January 1, 1994, the HCFA changed its policy on reimbursement of physicians in the teaching environment, so that the supervising or teaching anesthesiologist is compensated as though he or she were administering anesthesia as part of an anesthesia care team. The HCFA policy for reimbursement of an anesthesia care team permits the attending anesthesiologist to supervise, or medically direct, four cases concurrently. The essentials for accreditation of residency programs in anesthesiology, however, suggest that an attending anesthesiologist supervise no more than two concurrent cases. As a result, reimbursement is more restrictive when an anesthesiologist medically directs resident physicians than when CRNAs are medically directed. The teaching anesthesiologist will receive 50 percent of the fee from each of the two patients whose care he or she so supervises. However, the HCFA will not pay the other 50 percent to the resident or to the sponsoring institution, because the HCFA claims that reimbursement for the resident is already covered under part A of Medicare. Thus, in essence, there is a negative financial incentive to administering anesthesia while teaching residents as opposed to administering anesthesia while supervising nurse anesthetists.

The HCFA published in the Federal Register [187] its intent to discontinue the requirement that CRNA-administered anesthesia be supervised by the operating surgeon or an anesthesiologist who is immediately available in order to qualify for reimbursement by Medicare. The conference report language of the FY99 Omnibus Appropriations Bill [188] suggests that the secretary request the Agency for Health Care Policy and Research to work with HCFA in the design and implementation of an outcome approach that would examine, utilizing existing Medicare operating room anesthesia data, mortality and adverse outcome rates by different anesthesia providers, adjusted to patient acuity, and other relevant scientific variables. A bill, HR 632 Safe Seniors Assurance Study Act of 1999, was introduced in the House of Representatives on February 10, 1999. This bill requires the Secretary of Health and Human Services to conduct a study of mortality and adverse outcome rates of Medicare patients by providers of anesthesia services. A report containing the results of this study is to be submitted to Congress not later than June 30, 2000. If the secretary determines that the lack of physician supervision of providers of anesthesia services results in an adverse impact on outcome rates of Medicare patients, then providers of anesthesia services furnished under the Medicare or Medicaid program

* The AMA recommendations obviously do not have the same legal effect as the Social Security Act. However, whereas the Social Security Act applies only to referrals of Medicare and Medicaid patients, the AMA recommendations apply to all referrals of patients to facilities in which the physician has a financial interest.

shall be supervised by a physician in the same manner as such providers are supervised under regulations of the Department of Health and Human Services in effect on January 1, 1999.

At the time this chapter is submitted for publication, proposals for health care reform continue to be heavily debated both in Congress and by the public. Although the details of any plan that may be adopted by Congress are not available, it appears that such a plan will further reduce reimbursement for anesthesia services and may affect the methods of practice of anesthesiologists. The reader is encouraged to follow such legislation and any rules and regulations that may result from it, to evaluate their impact on the practice of anesthesiology.

ACKNOWLEDGMENT

Special thanks go to professor Robert D'Amico, Department of Philosophy, University of Florida, for his help with the section on ethics, and to Ms. Lynn Dirk and Ms. Anita Yeager, editors, Department of Anesthesiology, University of Florida, for their editorial assistance.

APPENDIX: Practice Guidelines for Pulmonary Artery Catheterization[D]

A Report by the American Society of Anesthesiologists Task Force on Pulmonary Artery Catheterization

I. Introduction

The balloon-flotation pulmonary artery (PA) catheter was introduced in 1970. [1] It has become an important tool for the evaluation and treatment of critically ill patients. PA catheter monitoring has expanded rapidly and broadly in clinical practice since the late 1970s. An estimated 2 million catheters are sold annually in the United States. [2]

The appropriate indications for PA catheter monitoring have been debated for over a decade. The potential benefits of using the device are well known. Its ability to measure important hemodynamic indices (*e.g.,* PA occlusion pressure, cardiac output, mixed venous oxygen saturation) allows more accurate determination of the hemodynamic status of critically ill patients than is possible by clinical assessment alone. The additional information can be important in caring for patients with confusing clinical pictures, in whom errors in fluid management and drug therapy can have important consequences. In surgical patients, PA catheter data often help to evaluate serious perioperative complications from hemodynamic changes. Preoperative PA catheter data are purported to be helpful in determining whether it is safe for high-risk patients to proceed with surgery.

PA catheterization can also have important adverse effects. Catheter insertion can result in unintended arteriotomy, pneumothorax, and arrhythmias. The catheter can be associated with potentially fatal pulmonary artery hemorrhage, thromboembolism, sepsis, and endocardial damage. The widespread use of PA catheters in the United States is also costly. Precise figures are lacking, but some authors have estimated that as much as two billion dollars may be spent each year in the United States on PA catheter use. [3] [4]

Several groups have issued statements on the appropriate indications for PA catheterization and on competency requirements for hemodynamic monitoring. These groups include the American College of Physicians/ American College of Cardiology/American Heart Association Task Force on Clinical Privileges in Cardiology, [5] a panel established by the Ontario Ministry of Health, [6] and an expert panel of the European Society of Intensive Care Medicine. [7] Few groups have performed a comprehensive review of evidence regarding the benefits, harms, and costs of PA catheterization.

The American Society of Anesthesiologists established the Task Force on Pulmonary Artery Catheterization in 1991 to examine the evidence for benefits and risks from PA catheter use in settings encountered by anesthesiologists. This report summarizes the task force's recommendations on PA catheterization and its rationale, based on scientific evidence and expert opinion. A complete description of the evidence reviewed by the task force is available in the full-length report.

Developed by the Task Force on Guidelines for Pulmonary Artery Catheterization: Michael F. Roizen, M.D. (Chairman), Department of Anesthesia and Critical Care, University of Chicago, Chicago, Illinois; David L. Berger, M.D., (Private Practice) Piedmont; California; Ronald A. Gabel, M.D., Department of Anesthesiology, University of Rochester, Rochester, New York; John Gerson, M.D., (Private Practice) Syracuse, New York; Jonathan B. Mark, M.D., Department of Anesthesiology, Duke University Medical Center, Durham, North Carolina; Robert I. Parks, Jr., M.D., (Private Practice) Dallas, Texas; David A. Paulus, M.D., Department of Anesthesiology, University of Florida, Gainesville, Florida; John S. Smith, M.D., (Private Practice) Las Vegas, Nevada; and Steven H. Woolf, M.D., M.P.H., (Methodology Consultant) Washington, D.C.

II. Methodology

Task force documents and primary evidence are available at the Wood Library, American Society of Anesthesiologists, Park Ridge, Illinois.

A. Task Force Composition

Members were selected by the American Society of Anesthesiologists Committee on Practice Parameters and by the task force chairman. The task force included four university-based anesthesiologists, four private-practice anesthesiologists, and a methodologist. Mean experience with PA catheter use was 14 yr (range of 7-28 yr). Task force members used an average of 11 PA catheters per month (range of 0-18 per month), primarily for cardiovascular surgery cases. Additional details about panel composition are in the full-length report.

B. Purpose and Focus

The objectives of the task force were to develop guidelines on the appropriate indications for PA catheter use. The purpose was not to describe how to perform the procedure or to interpret results. The task force sought to develop guidelines based on scientific evidence, supplemented by expert opinion, and to follow a systematic methodology for reviewing evidence and developing recommendations. The guidelines were intended for situations encountered by anesthesiologists and the perioperative care team. They do not address the use of PA catheters in non-surgical settings or by other medical specialties.

C. Process

The task force developed its recommendations following a systematic review of the clinical benefits and harms of PA catheterization. Benefits and harms were evaluated by reviewing relevant scientific evidence and expert opinion about effectiveness. The review was guided by an evidence model developed by the task force (fig. 1) . In addition to clinical effects, the panel also considered public policy issues, such as costs and implementation issues.

D. Review of Scientific Evidence

The review of scientific evidence included a detailed literature search, a critical appraisal of individual studies to assess methodologic quality, and a synthesis of the results.

1. Literature Search

The computerized and manual literature search was conducted in November 1991 and was updated in May 1992. It sought all relevant English-language literature published after 1972. A total of 860 clinical trials, controlled observational studies, uncontrolled case series reports, and individual case reports were considered.

2. Exclusion Criteria

Detailed exclusion criteria are described in the full-length report. The task force focused its review on evidence of effectiveness based on clinical outcomes. The task force did not directly examine the accuracy of PA catheter monitoring, the value of PA catheter data as predictors of morbidity and mortality, or evidence of

Figure 1 Evidence model for literature review. The outcomes (benefits, harms, costs) listed in this model represent the potential effects of PA catheterization that were identified by the task force before performing its literature review. The literature review was organized around this model to determine whether evidence existed to validate the potential benefits and harms that it had identified. Supporting evidence was found only for those linkages identified by an asterisk (*). Linkages not identified by an asterisk, which represent potential benefits that have not been studied, define important priorities for future research. [1] Decreased incidence of myocardial infarction, arrhythmias, congestive heart failure; [2] Length of surgery, duration of stay in post-anesthesia care unit and intensive care unit, and total hospital stay; [3] *E.g.* , trauma, infection, dysrhythmias due to catheterization.

the effectiveness of treatment for PA catheter-detectable conditions. Issues related to the performance of PA catheterization, such as rates of utilization, practitioner skill, resource constraints imposed by staff and equipment availability, medicolegal concerns, and reimbursement were not a specific focus of the literature review.

3. Evaluation of Individual Studies

The methodologic quality of individual studies was assessed in a systematic manner by considering study design category (*e.g.,* observational *vs.* experimental design) and the quality of the research methods (*e.g.,* statistical power, selection bias, measurement error, confounding variables, internal and external validity).

4. Synthesis of Results

The synthesis was narrative and utilized traditional evidence tables. Evidence of effectiveness was not suitable for formal meta-analysis. [*]

E. Assessment of Expert Opinion

The expert opinion of the task force was assessed by informal consensus development. Opinions of outside experts were obtained through critical peer review. Consensus within the task force was unanimous except where noted. All conclusions and recommendations that were based on expert opinion are documented explicitly.

F. Assessment of Public Policy Issues

Costs and implementation issues were considered by the task force only after the clinical benefits and harms of PA catheterization were studied. The task force's recommendations were based on perceived clinical benefits and harms and not on the cost-effectiveness of PA catheterization. Cost information provided in published clinical research was reviewed, but the task force did not seek out cost data from other sources (*e.g.,* payers, manufacturers). The panel's consideration of public policy issues was informed by a widely publicized open forum on the proposed guidelines, which was held in San Francisco in March 1992 at a large meeting of anesthesiologists.

G. Peer Review

The guideline underwent peer review by experts in PA catheterization and by relevant specialty societies and organizations. Reviewers are listed in table 1 .

III. Clinical Effectiveness of Pulmonary Artery Catheterization

Clinical effectiveness was judged by considering the benefits and harms of PA catheterization. Clinical benefits and harms were evaluated by reviewing relevant scientific evidence and expert opinion of effectiveness.

A. Scientific Evidence of Effectiveness

The results and design of individual studies are reviewed in detail in the full report. The following provides an overview of the findings. The results of controlled studies are summarized in table 2 .

1. Benefits

a. Effect on Treatment Decisions:

Survey studies in postoperative and intensive care units have demonstrated that PA catheter data appear to change therapy in 30-62% of cases. [8] [9] [10] [11] [12] [13] The clinical significance of these changes is uncertain. Treatment modifications were judged important in 25% of adults [11] and in 10% of children [14] monitored by PA catheter. Studies have found no effect on mortality among patients whose therapy is altered based on PA catheter data. [12] [13]

The quality of this evidence is poor. The conclusions are based largely on self-reported data in questionnaires,

* The task force recommends consideration of a meta-analysis of data on the adverse effects of PA catheterization.

which are subject to measurement and recall biases. Most studies were unblinded and, in many cases, judgments about whether treatment was altered based on PA catheter data were made subjectively. Sample sizes were inadequate to conclude that alterations in treatment had no effect on mortality, and clinical outcomes beside mortality were not examined.

b. Preoperative Catheterization:

Uncontrolled case series reports have shown that preoperative PA catheterization is associated with cancellation or modification of surgical procedures, and investigators have concluded that it therefore prevents mortality. [15] Post-hoc data analysis in one trial demonstrated a lower mortality rate in patients who were monitored preoperatively than in patients who were first monitored after surgery. [4] Another trial suggested that preoperative catheterization reduced intraoperative complications and graft thrombosis in patients undergoing peripheral vascular surgery. [16] Catheterization 12 h before surgery did not produce better outcomes than catheterization 3 h before surgery. An observational study found no difference in outcomes between elderly patients who did not undergo preoperative catheterization and unmatched patients who were admitted to the hospital during the same time period for other reasons. [17] The similar outcomes may have been due to selection biases.

c. Perioperative Monitoring:

A randomized controlled trial involving 146 patients found no difference in intraoperative mortality, length of hospital stay, length of intensive care unit (ICU) stay, ventilator usage, or postoperative mortality when surgical patients monitored by PA catheter were compared with central venous catheter (CVC)-monitored patients. [18] However, sample size may have been inadequate to reveal a true benefit. Patients monitored by PA catheter who were managed with the goal of achieving supranormal metabolic goals appeared to have significantly lower postoperative mortality, length of ICU stay, and ventilator usage. Due to uncertain methodology and inconsistent data reporting, it is unclear whether this group of patients differed in case mix from other patients monitored by PA catheter.

An observational study of 733 patients found that patients with previous myocardial infarction who underwent noncardiac surgery during a period when invasive hemodynamic monitoring was common had lower reinfarction and mortality rates than patients in previous years during which invasive monitoring was less common. [19] It is unclear from this study whether hemodynamic monitoring or other temporal factors were responsible for the improved outcomes and whether the two groups of nonrandomly selected patients were comparable in terms of case mix and severity of illness.

i. Cardiac Surgery:

Uncontrolled observational studies that examined outcomes in cardiac surgery patients who were monitored by PA catheter [20] [21] [22] [23] [24] [25] have been limited by the lack of comparison data from unmonitored patients. A small study that included historical controls found that patients who underwent PA catheterization for repair of left main coronary artery stenosis had lower rates of perioperative myocardial infarction, ventricular fibrillation, and deaths than patients from the previous year who were monitored by CVC. [26] However, the historical design leaves unanswered questions about whether the results were due to temporal factors or differences in case mix.

Studies that included internal controls found little difference in outcomes. A controlled retrospective observational study of 1094 patients found no difference in measured outcomes (*e.g.,* mortality, cardiac ischemia, postoperative myocardial infarction) among coronary artery bypass graft patients who were monitored by CVC, elective PA catheterization, or emergency PA catheterization. [27] High-risk patients who underwent elective PA catheterization had longer ICU stays and were more likely to receive vasopressor agents. These differences and the lack of observed differences in other outcomes may have been due to case mix, since patient assignment to groups was made selectively.

A randomized controlled trial involving 226 patients found no difference in measured outcomes (deaths, length of ICU stay, use of vasopressors) between coronary artery bypass graft patients monitored by PA catheter and CVC, but this may have been due to small sample size and selection biases. Patients were removed selectively from the control group after randomization if the anesthesiologist thought that they required PA catheterization. [28]

ii. Peripheral Vascular Surgery:

A randomized controlled trial found that patients undergoing peripheral vascular surgery were less likely to experience intraoperative disorders (tachycardia, hypotension, arrhythmia) if PA catheters were placed preoperatively and if hemodynamic status was optimized. [16] The overall incidence of postoperative complications (renal failure, congestive heart failure, myocardial infarction, graft thrombosis, death) appeared to be lower in the patients monitored by PA catheter. This was due mainly to a higher incidence of postoperative graft thrombosis

TABLE 2 -- Controlled Studies of Pulmonary Artery Catheterization with Clinical Outcomes *

Study	Location	N	Clinical Setting	Study Design	Significant Clinical Outcomes	Comments
General Surgery						
Shoemaker *et al.* (1988)	Los Angeles, California	146	General surgery in high-risk patients	RCT; groups = CVC, PAC-normal,PAC-supranormal	Post-operative mortality, mean ICU stay, ventilator use lower in PAC-supranormal group	Small sample size, poor control for confounding, uncertain case mix
Rao *et al.* (1983)	Maywood, Illinois	733/364	Noncardiac surgery in patients with prior myocardial infarction	Obs-historical controls; 1977-1982 cohort vs. 1973-76 cohort	Lower perioperative reinfarction and mortality rates in study cohort	Historical controls, nonrandom selection, uncertain case mix, role of hemodynamic monitoring unclear
Cardiac Surgery						
Pearson *et al.* (1989)	Iowa City, Iowa	226	Elective cardiac surgery	RCT; groups = CVC, PAC, PAC With mixed venous oxygen	None	Small sample size, significant crossover between groups
Tuman *et al.* (1989)	Chicago, Illinois	1094	Elective coronary artery bypass graft surgery	Controlled prospective cohort	Mean ICU stay greater in PAC high-risk group than CVC group	Nonrandom selection, uncertain case mix
Moore *et al.* (1978)	Beaumont, Texas	28/20	Surgery for left main coronary artery stenosis	Obs-historical controls; study cohort vs. previous year	Lower rates of perioperative myocardial infarction, ventricular fibrillation, deaths in PAC vs. CVC	Historical controls, nonrandom selection, statistical significance not reported
Peripheral Vascular Surgery						

Berlauk *et al.* (1991)	Minneapolis, Minnesota	89	Vein graft arterial bypass for limb salvage	RCT; groups = PAC 12 and 3 hrs before surgery, no preoperative PAC	Fewer intraoperative hemodynamic disorders and postoperative graft thromboses	Uncertain group assignment methods, discrepancies in data reporting regarding cardiac morbidity
Aortic Reconstruction						
Isaacson *et al.* (1990)	Atlanta, Georgia	102	Abdominal aortic reconstruction	RCT; groups = CVC, PAC	No difference in morbidity, mortality, ICU or hospital stay	Possible type II error
Joyce *et al.* (1990)	Toronto, Canada	40	Abdominal aortic aneursym repair	RCT; groups = CVC, PAC. Comparison group of 11 high-risk patients	ICU stay longer in CVC and high-risk patients (combined) then PA catheter	Small sample size, comparison of CVC and PAC ICU stay not reported
Headorffer *et al.* (1987)	Johannesburg, South Africa	61/87	Abdominal aortic aneurysm repair	Obs-historical controls; 1983-1984 cohort vs. 1980-1982 cohort	Lower perioperative hypotensive episodes and mortality in study cohort than historical controls	Historical controls, nonrandom selection, does not compare PA catheter use, inconsistent data, uncertain attrition, statistical significance not reported

RCT=randomized controlled trial (composition of randomized groups described); Obs-historical=observational study with historical controls; PAC=patients monitored by pulmonary artery catheter; CVP=patients monitored by central venous pressure measurements.

* See text for results of uncontrolled studies and case series.

In observational studies with historical controls, sample size of study group and historical cohort reported.

Does not include outcomes for which no significant benefit observed.

in the control group, which was attributed to poor cardiac output. Postoperative morbidity and mortality otherwise did not differ between groups. The reported data do not support the authors' conclusion that postoperative morbidity was reduced. The study was limited by discrepancies in data reporting and by uncertain methods for group assignment.

iii. Abdominal Aortic Reconstruction:

Although some case series reports have noted that outcomes in patients monitored by PA catheter were better than adjusted rates for the general population, [29] the absence of control groups limits the value of the data. A study with historical controls found that mortality, perioperative hypotensive episodes, and renal failure were less common in patients who received an aggressive fluid management protocol that included PA catheterization than in previous patients who did not receive the protocol. [30] The study was limited by its historical design, inconsistent data reporting, unexplained attrition, and the fact that PA catheterization was only one component of the protocol. Two randomized controlled trials of patients undergoing abdominal aortic reconstruction found no difference in outcomes between patients monitored by PA catheter and CVC. [31] [32]

iv. Neurosurgery:

An uncontrolled case series and an observational study with a comparison group have examined the effectiveness of PA catheterization in patients undergoing neurosurgical procedures. [33] [34] The studies only addressed the ability of PA catheters to detect air embolism and did not measure clinical outcomes. An uncontrolled observational study of pediatric head trauma patients who underwent monitoring that included PA catheterization reported lower mortality rates than published rates for patients with similar trauma scores. [35] The study lacked internal controls, and PA catheterization was only one of multiple interventions that were offered.

d. Obstetric-Gynecologic Procedures:

Evidence regarding the effectiveness of PA catheterization in obstetrics and gynecology is lacking. It has been recommended for severe preeclampsia [36] and case reports have supported its value, [37] but controlled clinical outcome studies have not been reported. Case reports have also described PA catheter use in uncommon obstetric settings. [38] [39] Uncontrolled case series have examined mortality and other outcomes in series of obstetric and gynecologic surgical patients that underwent PA catheterization, but they did not include control groups for comparison. [40] [41]

e. Pediatric Catheterization:

PA catheterization is performed in critically ill new-borns, infants, and children, [14] but few studies have evaluated its effect on clinical outcomes. Uncontrolled case series reports have shown that it is useful in clarifying diagnoses, but these studies have not examined clinical outcomes or included unmonitored controls. [42] [43]

f. Hemodynamic Disorders:

Numerous studies have examined the benefits of PA catheterization in critically ill patients with severe hemodynamic disorders. Although the subjects in the studies were usually medical patients who did not undergo surgery, the studies were reviewed because the hemodynamic disorders that prompted PA catheter use

(*e.g.,* myocardial infarction, sepsis, pulmonary edema) include the principal risk factors for which surgical patients often undergo PA catheterization.

Uncontrolled studies have produced inconsistent findings. [44] [45] Studies with control groups have generally found that patients with myocardial infarction and other hemodynamic disorders who are monitored by PA catheters have higher in-hospital mortality, longer hospital stay, and shorter long-term survival than patients who do not undergo PA catheterization. [46] [47] [48] Although these studies have included large samples (300-6,000 patients), their designs were retrospective and failed to control adequately for differences in severity of illness, selection bias, and variation in catheter use. The data therefore do not clarify whether patients who underwent PA catheterization were sicker than unmonitored patients. A study with historical controls reported that mortality in patients with septic shock decreased during a period in which PA catheterization had increased, but the study design provided weak evidence that PA catheters had a causal role. [49]

2. Harms

Evidence regarding the adverse effects of PA catheterization comes from studies that examined multiple complications [50] [51] [52] [53] [54] [55] [56] [57] [58] [59] and from studies of specific complications. Only potentially life-threatening complications were considered by the task force. The reported incidence of complications is summarized in table 3 . The designs and complications rate of individual studies are provided in the full-length report.

In summary, complications from PA catheterization can occur with the establishment of central venous access, the catheterization procedure, and catheter residence. Complications of establishing central venous access include unintentional puncture of nearby arteries, (*e.g.,* carotid or subclavian artery), [60] bleeding, neuropathy, air embolism, and pneumothorax. [61]

Dysrhythmias are the primary complication of the catheterization procedure. Minor dysrhythmias, such as premature ventricular and atrial contractions, occur commonly with catheter insertion but usually resolve spontaneously after the catheter is advanced or withdrawn through the right ventricle. [62] [63] [64] Ventricular tachycardia or fibrillation occur occasionally and can usually be cardioverted with antiarrhythmic agents or electrical defibrillation. [65] [66] Catheter advancement can produce right bundle-branch block and, in patients with preexisting left bundle-branch block, can precipitate complete heart block. [67] [68] [69]

TABLE 3 -- Reported Incidence of Adverse Effects

Complication	Reported Incidence (%)
Central Venous Access	
Arterial puncture	1.1-13
Bleeding at cut down site (children)	5.3
Postoperative neuropathy	0.3-1.1
Pneumothorax	0.3-4.5
Air embolism	0.5
Catheterization	
Minor dysrhythmias *	4.7-68.9
Severe dysrhythmias (ventricular tachycardia or fibrillation) *	0.3-62.7
Right bundle-branch block *	0.1-4.3
Complete heart block (in patients with prior LBBB) *	0-8.5
Catheter Residence	
Pulmonary artery rupture *	0.1-1.5
Positive catheter-tip cultures	1.4-34.8
Catheter-related sepsis	0.7-11.4
Thrombophlebitis	6.5
Venous thrombosis	0.5-66.7
Pulmonary infarction *	0.1-5.6
Mural thrombus *	28-61
Valvular/endocardial vegetations or endocarditis *	2.2-100
Deaths (attributed to PA catheter) *	0.02-1.5

* Complications thought to be more common (or exclusively associated) with PA catherizaion than with central venous catheterization.

Complications of catheter residence include venous thrombosis, [70] thrombophlebitis, and pulmonary embolism and infarction. [71] Autopsy studies have revealed evidence of mural thrombi, endocarditis, and valvular injury in patients with indwelling PA catheters. [72] [73] [74] [75] [76] A serious complication of PA catheters is pulmonary artery rupture. [77] [78] [79] Mortality from this complication has been estimated to be 53%, [80] a rate that can be influenced by a variety of factors (*e.g.,* age, pulmonary hypertension, coagulopathy, heparinization).

Sepsis is a potential complication of PA catheter residence but its exact incidence is uncertain. Cultures of indwelling PA catheter tips are often positive, [81] [82] [83] [84] [85] but it is unclear whether these represent contamination, colonization from another source, or the primary nidus of infection. Incidence rates for culture-positive catheters, positive blood cultures, and catheter-related sepsis therefore vary considerably in the literature.

The rate of iatrogenic deaths from PA catheterization is uncertain. Patients who are monitored by PA catheter have high mortality rates, but in few cases is it possible to attribute their deaths specifically to PA catheterization and not the underlying illness.

B. Expert Opinion of Effectiveness

Currently available evidence from published research provides incomplete information about the effectiveness of PA catheter monitoring and the incidence of complications. Gaps in the evidence occur at several levels. First, surgical procedures that have been examined in studies of PA catheterization (*e.g.,* cardiac surgery, abdominal aortic reconstruction, neurosurgery) represent only a subset of clinical settings for which PA catheters are used. Second, available studies generally suffer from poor design and lack statistical power to demonstrate benefit. Third, available data generally do not control for differences in case mix and practitioner skill and therefore may not be generalizable to typical practice conditions.

Due to deficiencies in the evidence, it is difficult to draw meaningful conclusions about the effectiveness and safety of PA catheterization based on currently available data. There is a great need for additional research to provide this information (see "Research Agenda" below). In the meantime, important insights about the benefits and harms of PA catheterization can be obtained from clinical experience. The task force acknowledges the limitations of expert opinion, which include subjectivity, recall bias, nonuniformity of measures, and confounding.
With these caveats in mind, the following observations about the benefits and harms of PA catheterization are offered:

Clinical experience suggests that PA catheter monitoring of selected surgical patients can reduce the incidence of perioperative complications, primarily by providing immediate access to critical hemodynamic data. The expert opinion of the task force is that access to these data, coupled with accurate interpretation and appropriate treatment tailored to hemodynamic status, can reduce perioperative mortality and morbidity through reduced cardiac complications (*e.g.,* myocardial ischemia, congestive heart failure, arrhythmias), renal insufficiency, brain injury, and pulmonary complications. The task force also believes that PA catheter use may reduce length of stay in the hospital and intensive care unit, enhance postoperative functional status, and reduce the need for transfused blood products through optimization of fluid therapy. The task force believes the use of PA catheters in selected obstetric patients may reduce maternal and neonatal morbidity and mortality.

Although these benefits may not be realized in every surgical patient who is catheterized, the task force believes that having immediate access to PA catheter data allows important preemptive measures for that subset of patients who encounter hemodynamic disturbances that require immediate and precise decisions about fluid management and drug treatment. The exact proportion of patients for whom this applies and the magnitude of benefit from PA catheterization are uncertain. However, the task force believes that reliance on clinical assessment or alternative devices (*e.g.,* CVC monitoring) and the delay associated with PA catheter placement after complications have developed may endanger the patient and may increase the risk of complications from insertion. Emergency catheterization under hastily prepared sterile conditions may increase the risk of vascular injury and catheter-related sepsis. Prospective studies have found that the relative risk for catheter-related sepsis is 2.1 when PA catheters are inserted in the operating room under less stringent sterile technique. [86]

Numerous studies have shown that PA catheter data are more accurate than clinical assessment in evaluating the hemodynamic status of complicated patients. [8] [9] For postoperative patients, who have less immediate access to physicians after leaving the operating room, PA catheter data and trained nurses provide an important means of rapidly communicating precise information about hemodynamic status to physicians not at the bedside. This enables immediate execution of treatment decisions that are tailored to the patient's physiologic state.

The task force believes that these benefits have not been demonstrated in currently available research because most of these outcomes have not been properly evaluated. It is suggested that a properly designed randomized controlled trial with adequate sample size, well trained physicians and nurses, and meaningful outcome measures would reveal the benefits observed in practice. Meaningful outcome measures would include perioperative mortality and the incidence of cardiac, renal, and neurologic end-organ damage due to perioperative complications from hemodynamic changes. It is recognized that the performance of such a study might be difficult due to logistical and ethical considerations.

"Nonuniformity of measures" refers to lack of standardization and inconsistencies among experts in defining interventions and outcomes. "Confounding" refers to factors that may have a causal role in affecting outcomes that may not be consciously considered by experts in assessing effectiveness.

The generalizability of research findings to practice conditions is often limited. For example, the task force believes that outcomes for experienced clinicians may differ significantly from published rates, because catheterizations in clinical studies were often performed by less experienced physicians (*e.g.,* house staff) or in early years, when outmoded techniques and materials were used. The task force believes that experience and understanding are major determinants of PA catheter effectiveness. Experienced PA catheter users can achieve better outcomes and encounter fewer complications because of their enhanced skill in the interpretation of PA catheter data, in the prompt design of rational treatment strategies, and in the use of safe techniques of catheter insertion and balloon management. Characteristics of the practice setting, such as the skill of nurses and their attentiveness to PA catheter tracings, also influence significantly the outcome of PA catheter use.

There is compelling evidence that PA catheterization can result in serious and potentially fatal complications. Catheterization is therefore inappropriate as a routine practice in surgical patients and should be limited to cases in which the anticipated benefits of catheterization outweigh the potential risks. The actual complication rate is uncertain, in part because of variability in the designs and results of studies of complications and in part because only a subset of reported complications is attributable uniquely to PA catheters. Unintentional arteriotomy, pneumothorax, line sepsis, and similar complications also occur with the principal alternatives to PA catheterization (*ie.,* CVC monitoring). Published rates for certain complications are based on old studies that may not reflect recent advances. For example, venous thrombosis has been reduced by the use of heparin-bonded catheters. [87] The opinion of the task force based on clinical experience is that serious complications due specifically to PA catheterization (pulmonary artery rupture, serious ventricular dysrhythmias, endocardial lesions) occur in 0.1-0.5% of monitored surgical patients.

The task force believes that this risk is acceptable in selected surgical patients undergoing procedures associated with complications from hemodynamic changes (*e.g.,* cardiac surgery, aortic reconstruction) or entering surgery with preexisting risk factors for hemodynamic disturbances (*e.g.,* advanced cardiopulmonary disease). The role of PA catheterization in lowrisk patients is less certain, and there is less consensus within the panel as to whether the potential benefits outweigh the risks. Routine catheterization in low-risk surgical patients is often inappropriate. The decision to use PA catheters in this population should be based on individual circumstances and a careful assessment of the patient's risk factors and personal preferences.

/das/book/view/29494766/875/946.html

IV. Public Policy Issues

Although the recommendations in this report are based primarily on clinical benefits and harms, the following resource and implementation issues were considered by the task force in structuring its recommendations:

A. Costs

The costs of PA catheterization include the costs of equipment (*e.g.* PA catheters, pressure transducers, electronic monitoring devices, solutions) and personnel (*e.g.,* physician costs for insertion and interpretation, nurses, technicians). There is limited information from published literature about the actual costs of PA catheterization. It has been estimated that the procedure costs $ 300-500 per catheterization. [88] One study reported that mean total charges (monitoring catheter, physician charges for catheter insertion, hemodynamic measurements) were $ 855 per patient monitored by PA catheter and $ 1128 per patient for those who also received mixed venous O_2 measurements. [28] Another study found that the anesthesiologist's fee was an average of $ 188 higher for PA catheterization than for CVC monitoring. [32] On a national scale, it has been estimated that two billion dollars are spent each year on PA catheter use. [3] [4] There are no published cost-benefit or cost-effectiveness analyses of PA catheter monitoring.

B. Implementation Issues

In addition to clinical benefits, harms, and costs, the task force also considered patient and provider concerns that could influence implementation of the guideline:

1. Patient Concerns

1. *a. Access to Care:*
   Some disadvantaged patients who meet criteria for PA catheterization may lack access to hospitals with facilities and qualified personnel to perform the procedure.
2. *b. Personal Preferences:*
   Patients may have different preferences about the desirability of PA catheterization, depending on the relative importance they place on potential benefits and

   harms. Patients with the ability and desire to participate in the decision require information about the probability of potential outcomes and the potential impact on morbidity and mortality.
3. *c. Comfort:*
   Insertion of the PA catheter in the operating room may be more comfortable, less anxiety-provoking, and induce less physiologic stress than preoperative catheterization.

2. Provider Concerns

1. *a. Independent Decision-making:*
   Due to uncertainties in the scientific evidence, providers require flexible guidelines that do not interfere with the ability to make independent assessments in individual cases.
2. *b. Ease of Use:*
   Recommendations should be clear, specific, and rapidly interpretable to be useful in patient care. Conversely, recommendations that are too rigid in the absence of adequate evidence or that introduce restrictive administrative rules may interfere with the proper delivery of care.
3. *c. Competency and Training:*
   The appropriateness of PA catheterization and the determination of whether benefits exceed risks hinge on the competence of physicians and nurses in catheter use. This competence encompasses both technical and cognitive skills, which are first acquired in residency or post-residency training. Maintenance of skills following training often requires regular catheter use. Because PA catheterization by persons who have not maintained these skills is potentially harmful to patients and could threaten the acceptability of the procedure, it is important for the profession to periodically assess technical and cognitive performance. The best measure of competence is clinical outcome, but long periods of observation and careful data analysis may be necessary to obtain meaningful information. Surrogate measures such as the frequency of catheter use or the results of proficiency examinations may be the best alternative, but they are imperfect measures of competence.
4. *d. Reimbursement:*
   Although reimbursement for PA catheterization is important to providers, this document is not intended and should not be used as a basis for determining coverage policy. The task force is specifically opposed to the use of guidelines to require precertification for reimbursement for PA catheterization.
5. *e. Utilization Review and Medicolegal Liability:*
   Due to limitations in scientific evidence about the limits of appropriateness for PA catheterization, guidelines based on expert opinion should not be used as standards of care or to define cases of unnecessary catheterization.

V. Recommendations

The following recommendations are based on expert opinion, informed by scientific evidence.

Indications

A. Perioperative PA catheterization should be considered in surgical settings associated with an increased risk because of complications from hemodynamic changes. The risk of hemodynamic disturbance should be assessed as a function of three interrelated variables: the health status of the patient, the type of surgical procedure, and the characteristics of the practice setting. Consideration of the interrelationships between these three variables (fig. 2) aids in the accurate assessment of hemodynamic risk.

Patient

Patients at increased risk for hemodynamic disturbances are those with clinical evidence of significant cardiovascular disease, pulmonary dysfunction, hypoxia, renal insufficiency, or other conditions associated with hemodynamic instability (*e.g.,* advanced age, endocrine disorders, sepsis, trauma, burns). The assessment of risk should be based on a thorough analysis of the medical history and physical examination findings, rather than exclusive consideration of specific laboratory results or other quantitative criteria.

Procedure

Surgical procedures associated with an increased risk of complications from hemodynamic changes, including damage to the heart, kidneys, lungs, or brain, increase the chance of benefitting from PA catheterization. This report does not provide a list of indicated procedures and disease states for catheterization because the task force believes that catheterization decisions should be based on the hemodynamic risk characteristics of the individual case rather than on the type of procedure. Patients undergoing procedures that usually lack hemodynamic complications may need PA catheterization if circumstances pose a special risk. The clinician should therefore assess hemodynamic risks based on the case at hand and not on generic criteria.

Figure 2 Factors affecting risk of complications from hemodynamic changes.

/das/book/view/29494766/875/949.html

Practice Setting

The setting for the procedure may increase the risk of complications from hemodynamic changes. Factors that should be considered in assessing preoperative risk include physician skills, duration of procedure, and technical support. Factors affecting postoperative risk include the level of training and experience of nursing staff in the recovery room and intensive care unit, technical support for ancillary services, and the availability of specialists and equipment to manage potential complications detected by the PA catheter.

B. PA catheterization is not recommended when the patient, procedure, and practice setting each pose a low risk for hemodynamic complications, as defined above. The triangle in figure 2 defines the appropriate settings for PA catheterization. In certain cases, the alternative to PA catheterization should be CVC or noninvasive monitoring, rather than no hemodynamic monitoring.

Preoperative Catheterization

C. There is insufficient evidence to support preoperative PA catheter monitoring (*e.g.,* the evening before surgery) in patients who are hemodynamically stable. The risk of catheter-related sepsis and other complications appears to increase significantly if catheterization extends beyond 72 h in duration. [81] [82] [86] It is recognized that preoperative PA catheterization is often under the control of other medical specialists, such as cardiologists, pulmonologists, and surgeons.

Competency

D. Due to the risk of complications from PA catheterization, the procedure should not be performed by clinicians who lack competence in safe insertion or in the accurate interpretation of results. Competence in catheter placement is related to experience and is a function of the quality of the initial training and regular performance of the procedure after training.

1. All persons who use PA catheters should undergo high-quality, supervised training to establish competency.
2. A quality improvement program must be in place at all sites where PA catheters are used. Maintenance of knowledge and skills should be evaluated based on clinical outcomes. Proficiency examinations, simulation testing, and frequency of recent catheterizations may also aid in the evaluation process.
3. Competence in the interpretation of catheter data should be based on cognitive requirements, such as those outlined by the American College of Physicians/American College of Cardiology/American Heart Association Task Force on Clinical Privileges in Cardiology (table 4) (Table Not Available)
4. Nurses who provide care to patients who are monitored by PA catheter should be required to meet minimum training requirements for catheter maintenance and for the interpretation and communication of PA catheter data.

Note: These recommendations are intended as general guidelines. Departure from these guidelines should not necessarily be viewed as inappropriate care. The recommendations are intended for practitioners in the United States; elements of the recommendations and the principles on which they are based may also apply to practice settings in other countries. The recommendations are based on currently available evidence and should be updated as relevant new data become available.

VI. Research Agenda

Additional research is needed to demonstrate the effectiveness of PA catheterization. Deficiencies in current

(Not Available)

evidence suggest that future studies should emphasize certain design features to provide more meaningful evidence. Future studies should use relevant clinical outcome measures to judge effectiveness, including measures of morbidity (*e.g.,* Cardiac, pulmonary, renal, and neurologic disease; patient functional status after discharge) and mortality (*e.g.,* in-hospital fatality rates, 5-yr survival, quality-adjusted life years). Intermediate physiologic outcomes should not be used as measures of effectiveness.

Future studies should include adequate sample sizes to demonstrate statistically significant effects. Investigators should perform power calculations before initiating studies to confirm the adequacy of the sample size. Researchers should collect adequate information about severity of illness and comorbid variables to help separate the influence of these factors from the effects of PA catheterization on observed clinical outcomes. Studies must be clear about the endpoints of treatment, specifying the hemodynamic indices that clinicians use to make decisions based on PA catheter data. Published reports from studies should provide complete information about methodology and complete data reporting to minimize confusion about statistical calculations. Many authors have emphasized the need for well designed randomized controlled trials to test the effectiveness of PA catheterization. [89] The task force supports the need for such research but is concerned about logistical and ethical problems with randomizing the allocation of PA catheters in critically ill patients. Of particular concern is the potential contamination of control groups. This crossover effect has occurred frequently in past research when patients assigned to receive no monitoring or CVC monitoring were subsequently reassigned by their physicians to undergo PA catheterization because of clinical deterioration or because the physicians were uncomfortable with the group assignment.

The task force therefore recommends that future randomized controlled trials should use low-risk patients (*e.g.,* no renal or pulmonary disorders, ejection fraction greater than 50%) to minimize the potential for crossover and should restrict the analysis to a specific type of surgery (*e.g.,* coronary artery bypass graft surgery). Physicians participating in such studies should adhere closely to the protocol and should not violate the design by reassigning patients following randomization. Studies that use low-risk patients may require large sample sizes to demonstrate statistically significant results, depending on power calculations, and therefore multicenter involvement may be necessary. The study should be performed in a setting attuned to the management of postoperative hemodynamic status, and the control groups should be monitored by CVC or other appropriate alternate methods (*e.g.,* transesophageal echocardiography).

The optimal randomized controlled trial will provide evidence from only one class of patients and one type of surgery. To provide more comprehensive data about the effects of PA catheterization, the task force recommends the performance of a large-scale multicenter

observational study that (1) includes adequate numbers of patients for each indication; (2) collects adequate data to generate a comprehensive database regarding past medical history, comorbidity, severity of illness, hospital course, and immediate and long-term clinical outcomes; and (3) provides details about catheter insertion techniques, practitioner skills, and data interpretation. For example, rather than stating that PA catheter monitoring was performed for 48 h, the investigators should document the type of device, the specific hemodynamic variables that were measured, and the manner in which PA catheter data were used to make treatment decisions.

If properly designed randomized studies in low-risk patients do not demonstrate a potential benefit from PA catheter monitoring, the task force recommends the performance of similar studies in high-risk patients and would urge adherence to randomization (*e.g.,* not providing PA catheterization to patients in the control group). Ultimately, the state of knowledge will need to move beyond expert opinion to provide objective evidence about the benefits and harms of PA catheterization.

APPENDIX: Practice Guidelines for Perioperative Transesophageal Echocardiography[D]

A Report by the American Society of Anesthesiologists and the Society of Cardiovascular Anesthesiologists Task Force on Transesophageal Echocardiography

Echocardiography was introduced in the operating room in the 1970s, with its initial applications involving epicardial echocardiography (EE). The use of transesophageal echocardiography (TEE) during surgery was first described in 1980 and did not become commonplace until high-frequency transducers and color Doppler imaging became available in the mid1980s. The improved quality of the acoustic image enabled anesthesiologists and surgeons to use TEE intraoperatively to diagnose myocardial ischemia, confirm the adequacy of valve reconstruction and other surgical repairs, determine the cause of hemodynamic disorders and other intraoperative complications, and provide diagnostic information that could not be obtained preoperatively. Real-time access to this information has enabled surgeons to correct inadequate repairs before patients leave the operating room, has reduced the need for reoperation, and has facilitated the prevention and early treatment of perioperative complications.

Although other intraoperative monitoring devices can provide some of this information, TEE offers important advantages over other diagnostic monitoring techniques. For example, intraoperative echocardiograms can be obtained by transthoracic echocardiography (TTE) or, if the chest is open, by EE. However, the acoustic images of TTE are generally poorer than those of TEE, and monitoring must be discontinued if the chest is opened or if surgical equipment, drapes, or monitors block access to the chest. Epicardial echocardiographic images are equivalent and sometimes superior to TEE, but the probe must be placed in a sterile field, can disrupt surgical procedures, and must be removed once the chest is closed. In contrast, TEE can facilitate diagnosis, allow the institution of specific treatments, and monitor interventions throughout the operative course without disrupting surgical technique. Other devices, such as electrocardiography (ECG) and pulmonary artery catheters, can provide continuous monitoring of cardiac performance, but are often unable to provide important information (*e.g.,* wall motion abnormalities, perivalvular leakage) that can be provided readily and rapidly by TEE.

Anesthesiologists also have used TEE outside the operating room. Typical applications in this setting include the emergency assessment of patients preoperatively to determine whether surgery is indicated (*e.g.,* thoracic aortic disruption after blunt chest trauma), as well as the postoperative assessment and treatment of patients in the hours and days after surgery. Even in nonoperative settings, anesthesiologists engaged in critical care medicine increasingly use TEE to evaluate and treat unstable patients in the intensive care unit (ICU).

There are important limitations to TEE. Some regions of the heart and great vessels cannot be well visualized (although some of these limitations may be overcome by more advanced technology and new imaging planes). The procedure is generally safe, but insertion and manipulation of the TEE probe can produce pharyngeal and/or laryngeal trauma, dental injuries, esophageal trauma or bleeding, arrhythmias, respiratory

Developed by the Task Force on Perioperative Transesophageal Ecocardiography: Daniel M. Thys, M.D. (Chair), New York, New York; Martin Abel, M.B.B.Ch., Rochester, Minnesota; Bruce A. Bollen, M.D., Missoula, Montana; Michael K. Cahalan, M.D., San Francisco, California; Patrick Curling, M.D., Houston, Texas; Robert J. Dean, D.O., Grand Rapids, Michigan; David Paulus, M.D., Gainesville, Florida; Alan S. Pearlman, M.D., Seattle, Washington (American Society of Echocardiography); Michael F. Roizen, M.D., Chicago, Illinois; John Smith, M.D., Las Vegas, Nevada; William J. Stewart, M.D., Cleveland, Ohio (American College of Cardiology); and Steven H. Woolf, M.D., M.P.H. (Methodologist), Fairfax, Virginia.

distress, and hemodynamic effects. Case reports have attributed some perioperative deaths to TEE. The inaccurate interpretation of TEE images by inexperienced examiners can generate incorrect information, potentially resulting in improper clinical decisions by the anesthesiologist and surgeon and, hence, unnecessary perioperative complications. The performance of TEE can consume anesthesiologists' time and attention that they need to attend to other intraoperative responsibilities.

In recent years, the publication of practice guidelines has become a useful, and often necessary, means of establishing the scientific support for clinical procedures and for justifying their use in patient care. Although practice guidelines on TEE have been issued by the American College of Cardiology, American Society of Echocardiography, and Society of Pediatric Echocardiography, they include only brief comments on the use of TEE in the operating room. In 1993, the American Society of Anesthesiologists and the Society of Cardiovascular Anesthesiologists established the Ad Hoc Task Force on Practice Parameters for Transesophageal Echocardiography to develop evidence-based guidelines on the proper indications for performing TEE in the operative setting. The 12-member task force included 9 anesthesiologists (6 of whom hold academic appointments and 3 of whom are private practitioners), 2 cardiologists, and 1 methodologist.

Before developing its recommendations, the task force reviewed all evidence regarding the effectiveness of TEE in the perioperative setting. A computerized and manual literature search retrieved 1,844 studies, of which 558 were considered relevant to the perioperative setting. Evidence was considered relevant if it addressed the accuracy and reliability of perioperative TEE, its yield and predictive value, or the effect of perioperative TEE on therapeutic decisions or clinical outcomes. The role of TEE in the emergent preoperative assessment of potential surgical emergencies also was considered. Studies investigating TEE in nonoperative critical care patients were examined, but studies of TEE in the cardiac catheterization or echocardiography laboratory were not reviewed. Thus, a large body of indirect evidence of potential relevance to critical care and surgical patients is omitted from this report but is examined elsewhere. [1] [2] Further details about the literature review process are available on request.

A detailed summary of the studies examined by the task force is published in a separate monograph. This Executive Summary provides an overview of the evidence for each of the topic categories examined by the task force. Each section includes a summary discussing the evidence obtained directly from studies of perioperative TEE, and an "Expert Opinion" section, in which the task force cites other relevant data and documents its opinions regarding the benefits and harms of perioperative TEE. The recommendations of the task force address *indications,* the clinical settings in which TEE should be considered, and *proficiency,* the cognitive and technical skills expected of anesthesiologists who perform perioperative TEE. Guidelines on how to perform TEE examinations were considered beyond the scope of this report.

Recommendations for performing TEE in this report are intended for those anesthesiologists who use TEE, rather than for all anesthesiologists. The recommendations are divided into three categories based on the strength of supporting evidence or expert opinion that the technology improves clinical outcomes (table 1). *Category I* indications are supported by the strongest evidence or expert opinion; TEE frequently is useful in improving clinical outcomes in these settings and often is indicated, depending on individual circumstances (*e.g.,* patient risk and practice setting; fig. 1). *Category II* indications are supported by weaker evidence and expert consensus; TEE may be useful in improving clinical outcomes in these settings, depending on individual circumstances, but appropriate indications are less certain. *Category III* indications have little current scientific or expert support; TEE infrequently is useful in improving clinical outcomes in these settings, and appropriate indications are uncertain. The lack of supporting evidence for category III indications is often owing to the absence of relevant studies rather than to existing evidence of ineffectiveness. Thus, many category III indications are currently investigational, and future research and technological developments

may enhance their role in routine practice.

Recommendations in this report refer to clinical problems rather than to individual patients, who often have more than one potential reason for performing TEE. Thus, although patients may not necessarily require perioperative TEE because of a cardiomyopathy (category III), the same patients may need TEE because of coexisting hemodynamic problems (category I). Similarly, physicians must integrate multiple variables in assessing a patient's need for TEE. As illustrated in figure 1 , factors associated with the patient, procedure,

TABLE 1 -- Quick Reference Guide: Indications for Perioperative Transesophageal Echocardiography

Category I indications: Supported by the strongest evidence or expert opinion; TEE is frequently useful in improving clinical outcomes in these settings and is often indicated, depending on individual circumstances (*e.g.,* patient risk and practice setting; see fig. 1).
Intraoperative evaluation of acute, persistent, and life-threatening hemodynamic disturbances in which ventricular function and its determinants are uncertain and have not responded to treatment
Intraoperative use in valve repair
Intraoperative use in congential heart surgery for most lesions requiring cardiopulmonary bypass
Intraoperative use in repair of hypertrophic obstructive cardiomyopathy
Intraoperative use for endocarditis when preoperative testing was inadequate or extension of infection to perivalvular tissue is suspected
Preoperative use in unstable patients with suspected thoracic aortic aneurysms, dissection, or disruption who need to be evaluated quickly
Intraoperative assessment of aortic valve function in repair of aortic dissections with possible aortic valve involvement
Intraoperative evaluation of pericardial window procedures
Use in intensive care unit for unstable patients with unexplained hemodynamic disturbances, suspected valve disease, or thromboembolic problems (if other tests or monitoring techniques have not confirmed the diagnosis or patients are too unstable to undergo other tests)
Category II indications: Supported by weaker evidence and expert consensus; TEE may be useful in improving clinical outcomes in these settings, depending on individual circumstances, but appropriate indications are less certain.
Perioperative use in patients with increased risk of myocardial ischemia or infarction
Perioperative use in patients with increased risk of hemodynamic disturbances
Intraoperative assessment of valve replacement
Intraoperative assessment of repair of cardiac aneurysms
Intraoperative evaluation of removal of cardiac tumors
Intraoperative detection of foreign bodies
Intraoperative detection of air emboli during cardiotomy, heart transplant operations, and upright neurosurgical procedures
Intraoperative use during intracardiac thrombectomy
Intraoperative use during pulmonary embolectomy
Intraoperative use for suspected cardiac trauma
Preoperative assessment of patients with suspected acute thoracic aortic dissections, aneurysms, or disruption
Intraoperative use during repair of thoracic aortic dissections without suspected aortic valve involvement
Intraoperative detection of aortic atheromatous disease or other sources of aortic emboli
Intraoperative evaluation of pericardiectomy, pericardial effusions or evaluation of pericardial surgery
Intraoperative evaluation of anastomotic sites during heart and/or lung transplantation
Monitoring placement and function of assist devices
Category III indications: Little current scientific or expert support; TEE is infrequently useful in improving clinical outcomes in these settings, and appropriate indications are uncertain.
Intraoperative evaluation of myocardial perfusion, coronary artery anatomy, or graft patency
Intraoperative use during repair of cardiomyopathies other than hypertrophic obstructive cardiomyopathy
Intraoperative use for uncomplicated endocarditis during noncardiac surgery
Intraoperative monitoring for emboli during orthopedic procedures
Intraoperative assessment of repair of thoracic aortic injuries
Intraoperative use for uncomplicated pericarditis
Intraoperative evaluation of pleuropulmonary diseases
Monitoring placement of intraaortic balloon pumps, automatic implantable cardiac defibrillators, or pulmonary artery catheters
Intraoperative monitoring of cardioplegia administration
TEE = tranesophageal Echocardiography.

and clinical setting each contribute to the overall risk of perioperative complications and cumulatively alter the benefit-harm ratio of using TEE. Physicians should consider each of these variables when calculating the appropriateness of using TEE.

The recommendations in this report are intended as general guidelines. Guidelines differ from *standards,* which prohibit departure from recommended practices except under special circumstances. [3] Guidelines are intended to provide practitioners with sufficient flexibility to alter their practices based on important clinical considerations or differing interpretations of the evidence. Accordingly, deviation from the guidelines in this report is expected and should not necessarily be viewed as inappropriate care. Recommendations to perform TEE are not applicable when the procedure cannot be performed properly or safely, neither do they apply when TEE equipment or skilled examiners are

Figure 1 The three domains of risk in assessing the appropriateness of transesophageal echocardiography (TEE). Risk factors for perioperative complications associated with the *patient* include age, sex, coexisting medical disorders, and past medical history, which influence the risk of perioperative complications. Factors associated with the *procedure* include characteristics of the operation that increase the likelihood of complications. Factors associated with the clinical setting include hospital-specific variables (*e.g.,* complication rates, availability and skills of personnel, and access to equipment) and other special circumstances. A thoughtful examination of each of these variables is necessary to accurately assess a patient's risk of perioperative complications and to gauge whether the potential benefits of TEE in reducing these risks outweigh potential harms associated with TEE itself. The complex interactions among these variables makes it inappropriate to specify surgical procedures or clinical problems that uniformly do or do not require TEE. For example, a healthy

patient undergoing a simple procedure may require TEE if it occurs in a high-risk clinical setting; the overall risk of complications may exceed that of a high-risk patient undergoing surgery with skilled providers and excellent equipment. Only the overall magnitude of risk is useful in determining the potential utility and benefit-harm ratio of performing TEE.

unavailable. The recommendations in this report are based on consideration of clinical benefits and harms. The economic implications of providing TEE, although important, were not explicitly examined by the task force because available data are inadequate to properly evaluate cost-effectiveness. The recommendations are intended for practitioners in the United States; elements of the recommendations and the principles on which they are based also may apply to practice settings in other countries. The recommendations are based on currently available evidence and should be updated as relevant new data become available.

Recommendations regarding training, certification, credentialing, and quality assurance were based on the aforementioned scientific evidence, as well as on legal, regulatory, and scientific literature and expert opinion. The task force refers to two levels of training in perioperative TEE, basic and advanced. Both basic and advanced TEE training refer to specialized training that extends beyond the minimum exposure to TEE that occurs during normal anesthesia residency training. Anesthesiologists with basic training are considered able to use TEE for indications that lie within the customary practice of anesthesiology. Anesthesiologists with advanced training are considered, in addition to the above, to be able to exploit the full diagnostic potential of perioperative TEE. Further details about requirements for each level of training are discussed later.

In this report, evidence of effectiveness, recommendations, and proficiency levels are discussed relative to the specific conditions that TEE can detect (*e.g.,* hemodynamic disturbances, congenital heart disease, emboli). This reductionist approach to examining the evidence often understates the important ability of TEE to detect multiple problems at once. For example, although the ability of TEE to evaluate myocardial ischemia, ventricular dysfunction, valvular insufficiency, thrombi, and air emboli is discussed in separate sections of this report, these problems often occur together during surgery and can be detected simultaneously by TEE. The capacity to study the physiologic and anatomic interrelationships of these problems and to monitor response to treatment is one of the unique advantages that TEE offers over other methods of intraoperative monitoring or diagnosis, as discussed later.

Wall Motion, Myocardial Ischemia, and Coronary Artery Disease

Hemodynamic and other physiologic stresses during the perioperative period increase the risk of perioperative myocardial ischemia, especially among patients with coronary artery disease, multiple risk factors for coronary artery disease, and peripheral vascular disease. Traditional methods for monitoring myocardial ischemia during surgery, such as continuous ECG, have limited sensitivity in the early detection of tissue injury. A growing body of evidence therefore has examined the role of TEE in detecting ischemia during both cardiac and noncardiac surgery.

Summary of the Evidence.

There is good evidence that the development of regional ventricular dysfunction during surgery increases a patient's risk of developing perioperative myocardial infarction (MI) and sudden death. Transesophageal echocardiography can detect regional ventricular dysfunction, but there is

little evidence about its accuracy, because neither a reliable reference standard is available, nor is it certain that the wall motion abnormalities reflect true myocardial ischemia. Most studies have examined the accuracy of TEE relative to intraoperative ECG tracings, an imperfect reference standard, and find weak concordance. Intraoperative TEE evidence of regional ventricular dysfunction is reported to occur in 27-100% of cases in which there is ECG evidence of ischemia and in 56-85% of cases in which ECG evidence of ischemia is lacking. The reportedly high incidence of intraoperative regional ventricular dysfunction (21-30% of cardiac surgery cases, 10-52% of vascular cases, and 20-60% of noncardiovascular cases) and postoperative dysfunction (47-60% of cardiac surgery patients) raises important questions about the frequency of false-positive findings.

Moreover, there is little direct evidence that the detection of regional ventricular dysfunction or other TEE evidence of ischemia results in improved perioperative clinical outcomes or long-term survival. This lack of evidence is mainly due to the absence of studies examining these outcomes. Studies of cardiac surgery patients report that TEE findings were "valuable or essential" or resulted in a change in therapy (graft revision, hemodynamic support) in 2-12% of patients, but there is no direct evidence that patients experience better outcomes as a result of these changes. Intraoperative TEE also is capable of evaluating myocardial perfusion patterns, coronary artery anatomy, and graft patency, but few studies have examined whether this information improves clinical outcomes.

Expert Opinion.

Evidence from animal experiments and angioplasty studies suggests that wall motion abnormalities generally precede ECG changes during myocardial ischemia. [4] [5] [6] [7] The task force believes that TEE provides a more meaningful reference standard for ischemia than ECG. The limitations of TEE also are recognized, however. Interpretations of wall motion and thickening often are more subjective than quantifiable ECG changes (*e.g.,* ST-segment depression). Transesophageal echocardiography interpretations can be influenced by translational motion of the heart, bundle branch block, and ventricular pacing. A marked worsening of segmental wall motion and thickening is required (in the absence of similar global changes) to strongly suggest the diagnosis of ischemia; less pronounced changes are interpreted inconsistently, even by experts. Moreover, all segmental wall motion abnormalities are not indicative of myocardial ischemia. Segmental wall motion abnormalities not caused by ischemia can occur because of preexisting disease (*e.g.,* prior MI, myocarditis) or confounding intraoperative events (*e.g.,* myocardial stunning after cardiopulmonary bypass [CPB]). Protocols have recently been suggested for distinguishing intraoperatively between stunned and infarcted myocardium, but they require further evaluation to be validated. Because an automated system for analyzing wall motion and thickness is currently unavailable for TEE, only qualitative wall motion assessment is available in real time. Moreover, real-time assessment of segmental wall motion may be less accurate than off-line (laboratory) assessment. When TEE is used to evaluate wall motion, the yield will increase with the use of multiple planes and methods that facilitate temporal comparisons (*e.g.,* side-by- side cine loops).

Although there is little direct evidence that TEE detection of myocardial ischemia improves clinical outcome, the task force believes that indirect evidence can be extrapolated from non-TEE studies showing that early treatment of myocardial ischemia and MI improves survival. Intraoperative TEE detection of ischemia permits corrective interventions, including alterations in surgery, anesthetic management, and postoperative triage, which can prevent perioperative complications. For example, TEE detection of post-CPB myocardial ischemia during coronary artery bypass graft surgery permits, if indicated, immediate revascularization before the patient leaves the operating room, thereby reducing the risk of perioperative MI. Both indirect evidence and expert opinion suggest that these measures improve clinical outcomes.

Recommendations

Indications. An increased risk of myocardial ischemia or infarction during the perioperative period is a category II indication for perioperative TEE. An increased risk may occur when conditions associated with the *patient* (*e.g.,* history of prior MI or coronary artery disease, left ventricular dysfunction, dysrhythmias), *procedure* (*e.g.,* coronary artery bypass graft, operations on the great vessels or that involve aortic cross clamping, noncardiac intrathoracic surgery, upper abdominal procedures), or *clinical setting* (*e.g.,* anticipated duration of surgery, hospital-specific factors) predispose to myocardial ischemia or MI (fig. 1). Use of perioperative TEE to evaluate myocardial perfusion, coronary artery anatomy, or graft patency are category III indications. The argument for using TEE is strengthened

when ECG monitoring cannot provide accurate information, such as in patients with conduction disorders or in procedures that interfere with ECG lead placement. The argument for using TEE is weakened when clinical factors (*e.g.,* preexisting regional ventricular dysfunction) limit the accuracy of wall motion interpretations.

Proficiency. Anesthesiologists with basic TEE training should be able to use TEE to detect unequivocal changes in segmental wall thickening and motion (*e.g.,* from normal wall motion to akinesis) and should be able to distinguish these changes from artifacts (*e.g.,* translational motion of the heart, changing cross section, image dropout, abnormal ventricular activation). Subtle changes in segmental wall motion and thickening, however, are difficult to detect, even for experts. The ability to evaluate or quantify such changes in association with myocardial ischemia and MI requires advanced training.

Hemodynamic Function

Transesophageal echocardiography has been used extensively for the evaluation (monitoring of presence, followed by determination of etiology) of hemodynamic and global ventricular function. Some have used TEE to estimate standard hemodynamic variables (*e.g.,* filling pressures, cardiac output) that are normally obtained by other invasive techniques, such as pulmonary artery catheterization, whereas others have used it to quantify cardiac dimensions, intracardiac flow rates, and overall cardiac performance. Such measurements were previously not readily obtainable in the operating room or ICU.

Summary of the Evidence.

Current studies provide conflicting information about the correlation between TEE estimates of hemodynamic indexes (*e.g.,* cardiac output, filling pressure) and measurements obtained by more conventional tests (*e.g.,* thermodilution). Studies comparing TEE and thermodilution measurements of cardiac output report wide ranges in correlation coefficients (R = 0.72-0.97), bias estimates (0.03-1.01 1/min), and limits of agreement. The frequency with which TEE detects hemodynamic disturbances has not been studied. Moreover, there is little evidence beyond case reports to confirm that hemodynamic monitoring by TEE results in improved clinical outcomes.

Expert Opinion.

Quantitative analysis of TEE information may increase its sensitivity in detecting small changes in ventricular dimensions or ejection, a capacity that would dramatically enhance conventional hemodynamic monitoring, but it is time consuming and requires considerable skills. Until automated analysis systems overcome these limitations, intraoperative TEE will remain a largely qualitative tool for assessing hemodynamic function. Even with these limitations, however, the task force believes that TEE provides more accurate estimates of preload (end-diastolic volume) than the pulmonary artery catheter. Preload is physiologically determined by sarcomere length, a variable more accurately estimated by volume than by pressure measurements. When compared with the pulmonary artery catheter, TEE may be more expedient, because it can be inserted more quickly and without sterile technique; safer, because it does not enter the great vessels and heart; and more comprehensive, because it provides more global hemodynamic information about the performance and structure of the heart.

Although direct evidence is lacking, the task force believes that detecting acute hemodynamic disturbances during surgery improves clinical outcomes. These benefits are realized by using TEE to diagnose the hemodynamic problem (*e.g.,* hypovolemia, myocardial depression) and to suggest appropriate therapy (*e.g.,* volume expansion, inotropic therapy). The task force believes that failing to take action to correct or prevent hemodynamic disturbances increases the risk of end-organ damage and perioperative mortality.

Recommendations

Indications. An increased risk of hemodynamic disturbances during the perioperative period is a category II indication for perioperative TEE. Increased risk may occur when conditions associated with the *patient* (*e.g.,* congestive heart failure, valvular heart disease, abdominal aortic aneurysm, preeclampsia, trauma, burn injuries), *procedure* (*e.g.,* vascular surgery, CPB, extensive tumor resection, liver transplantation, total hip replacement), or *clinical setting* (*e.g.,* difficulties in inserting central venous pressure catheters, inability to estimate blood loss, poor hospital-specific conditions, such as complication rates for a specific procedure) predispose to hemodynamic disturbances (fig. 1.) The emergent use of perioperative TEE to determine the cause of acute, persistent, and life-threatening hemodynamic disturbances in which ventricular function and its determinants are uncertain and have not responded to treatment is a category I indication.

Proficiency. Anesthesiologists with basic TEE training should be able to make qualitative assessments of hemodynamic status and should have a cognitive understanding of more sophisticated TEE techniques for quantifying hemodynamic function.

Valvular Surgery

For patients requiring valve surgery, because of the potential for suboptimal results, it is preferable to recognize the need for further surgery in the operating room rather than waiting for postoperative complications to develop that necessitate a second operation. The unique ability of TEE to make these assessments during valve surgery accounts for its widespread application in this setting.

Summary of the Evidence.

Perioperative TEE can characterize valvular insufficiency and morphology. Studies report a fair correlation between intraoperative TEE estimates of valvular insufficiency and preoperative angiographic data (R = 0.83-0.88). Access to this information before and after valve repair appears to be useful. Pre-CPB TEE provides new information or prompts changes in valve surgery in 9-13% of cases. Its ability to reveal unanticipated valvular disease (*e.g.,* endocarditis, aortic valve tumor) is described in case reports. Post-CPB TEE identifies significant valve dysfunction in 6-11% of cases, prompting second pump runs in 3-10% of patients undergoing mitral valve repair. However, although there is evidence that post-CPB valve dysfunction is associated with increased postoperative complications and poorer survival, there is little evidence beyond case reports that perioperative interventions prompted by TEE improve clinical outcomes.

Expert Opinion.

Although direct evidence of benefit is lacking, the task force believes that indirect evidence can be extrapolated to infer effectiveness. Observational data from patients undergoing surgery for ischemic heart disease suggest that mitral regurgitation on post-CPB TEE is the most important predictor of postoperative mortality. Based in part on these data and on expert opinion, the task force believes that patients who are not evaluated by TEE during valve surgery may have longer ICU stays and a higher incidence of congestive heart failure, reoperation, and mortality than patients monitored by TEE. Transesophageal echocardiography evaluation appears to decrease the need for valve replacement, and observational data suggest that the latter increases the risk of mechanical dysfunction, perivalvular leakage, thromboembolic events, and anticoagulation therapy. Although observational data cannot prove effectiveness conclusively, the findings are consistent with the expert opinion of the task force. While most available evidence comes from patients undergoing valve repair, the task force believes that similar benefits (lower incidence of reoperation, congestive heart failure, and mortality) are also realized for patients undergoing valve replacement, albeit less frequently than for valve repair. After valve replacement, significant periprosthetic leaks are uncommon but may require immediate correction. At centers experienced with valve replacement, the yield of intraoperative TEE is likely to be low.

The task force recognizes that the effectiveness of TEE during valve surgery may be limited by inaccurate interpretation: "false-positive" or "false-negative" findings. Moreover, TEE evaluation of post-CPB valvular regurgitation can be confounded by the presence of abnormal loading conditions or myocardial ischemia. These conditions must be normalized or resolved before valvular insufficiency can be confirmed. Hemodynamic changes associated with the induction of anesthesia can alter valvular function and render comparisons between pre-CPB TEE and preoperative echocardiography problematic. Patients with evidence of tricuspid regurgitation on preoperative echocardiography, for example, may have normal examinations on pre-CPB TEE, prompting inappropriate revision of the surgical plan. The absence of regurgitation on post-CPB TEE also can be falsely negative when the patient is volume underloaded.

The potential benefits of TEE evaluation during valve surgery are not limited to valve assessment. Hemodynamic disturbances are common (see Hemodynamic Function), and TEE may be especially helpful in weaning the patient from CPB. Transesophageal echocardiography can detect entrapped air and facilitate venting procedures (see Air Emboli). Other potential benefits are discussed in separate sections.

Recommendations

Indications. Valve repair is a category I indication, and valve replacement is a category II indication, for the use of intraoperative TEE.

Proficiency. When valve surgery will be dictated by TEE assessment of valve function, TEE should be performed by, or in timely consultation with, a physician with advanced TEE training. Anesthesiologists with basic TEE training should have an understanding of the

anatomy and function of native and prosthetic valves, the hemodynamic changes that occur in valvular disease, and the echocardiographic tools (*e.g.,* continuous-wave Doppler) that are available for valve assessment. They should be able to obtain multiple views of all valves, recognize gross valvular dysfunction on two dimensional echocardiography, and appreciate the color patterns of antegrade and retrograde flow on color Doppler examinations. Quantitative echocardiographic measurements of valve function (*e.g.,* jet area, flow-velocity pattern, effective valve orifice area) require advanced training. Utilization of TEE to detect and diagnose the causes of hemodynamic disturbances and to detect the presence of air emboli during valve surgery can be performed by anesthesiologists with basic TEE training.

Congenital Heart Surgery

Although the acoustic window provided by TEE gives access to a variety of congenital heart lesions, especially in the atria and atrioventricular junction, its use in children was limited for many years because available probes were too large. As recently as 1989, available probe sizes limited the use of TEE to children older than 7 yr. Smaller probes that are now available measure 5.9 mm in diameter and enable examination of children as small as 2,400 g. Transesophageal echocardiography has special application in evaluating the adequacy of surgical repair of congenital heart lesions. New technologies (*e.g.,* biplane pediatric probes) and imaging techniques (*e.g.,* longitudinal planes) have enhanced further the information obtainable from TEE examinations of children.

Summary of the Evidence.

Intraoperative TEE has a reported sensitivity of 86-94% in detecting congenital heart lesions. Especially when performed with biplane probes, TEE can detect lesions not seen on preoperative TTE in as many as 30% of patients. The sensitivities of intraoperative TEE and EE are comparable, although each test may lack sensitivity in evaluating certain cardiac structures. In patients undergoing congenital heart surgery, pre-CPB findings prompt changes in treatment in 1-16% of patients, post-CPB TEE findings result in second pump runs or altered medical therapy in 3-45% of cases, and postoperative TEE detects information not available by TTE in 15-48% of patients. However, there is little direct evidence beyond case reports as to whether this information or the treatment changes that they prompt (*e.g.,* returning to CPB to correct residual defects) improve clinical outcomes.

Expert Opinion.

Most studies of TEE during congenital heart surgery, including those reporting poor visualization of the right ventricular outflow tract, pulmonary valve, and interventricular septum, lacked access to the enhanced imaging capabilities of recently introduced pediatric TEE technology (*e.g.,* biplane probes, continuous-wave Doppler) and techniques (*e.g.,* transgastric view of right ventricular outflow tract). When compared with EE, TEE offers the advantages of uninterrupted operation, decreased potential violation of the sterile field, and continuous hemodynamic evaluation. An important role of perioperative TEE during congenital heart surgery is the ability to detect previously unrecognized congenital anomalies.

The task force believes on the basis of indirect evidence [8] that the detection of residual defects improves outcomes by reducing the residual hemodynamic burden of these lesions and by decreasing the patient's risk of pulmonary hypertension and endocarditis. Despite these potential benefits, TEE may be inappropriate or infeasible in certain circumstances. Pre-CPB and post-CPB TEE examinations frequently are useful for patients undergoing repair of complex congenital heart lesions. In the repair of other defects (*e.g.,* patent ductus arteriosus, patent foramen ovale) where TEE may be useful, the physician must be especially careful in weighing the potential benefits of TEE against its potential risks. In addition to the usual potential adverse effects of TEE, small children may face the added risks of hemodynamic or respiratory compromise, which is more common among patients weighing less than 3 kg or when an appropriately sized probe is unavailable. For patients in whom esophageal intubation is difficult, repeated attempts at probe insertion may result in more harm than good. When TEE is not appropriate or small probes are not available, EE can be used to assess the repair of congenital heart defects.

Practical constraints related to the recent introduction of pediatric TEE technology also may limit the feasibility of its routine use during congenital heart surgery. Because pediatric TEE probes of appropriate size and imaging quality (*e.g.,* biplane) have become available only recently, practitioners currently face a temporary transition period during which some centers may lack access to appropriate equipment and expertise.

Recommendations

Indications. Congenital heart surgery for most lesions requiring CPB is a category I indication for intraoperative TEE, including pre-CPB and post-CPB imaging. Use of TEE is not recommended when available probes are too large for the child. Epicardial echocardiography can provide a useful alternative when TEE is inappropriate or small probes are unavailable.

Proficiency. When repair of congenital heart defects will be dictated by the results of intraoperative TEE assessment, TEE should be performed by, or in timely consultation with, a physician with advanced pediatric TEE training in complex congenital heart disease. Anesthesiologists with basic TEE training should have an understanding of how TEE is used during congenital heart surgery.

Cardiomyopathy

Hypertrophic, dilated, and restrictive cardiomyopathies are diagnosed accurately by echocardiography. The use of intraoperative TEE in patients with cardiomyopathy has centered on the detection and treatment of hypertrophic obstructive cardiomyopathy.

Summary of the Evidence.

There is little evidence regarding the accuracy or yield of intraoperative TEE relative to cardiomyopathy. One study reported that the detection of persistent outflow tract gradients aided surgical revision in 20% of patients undergoing hypertrophic obstructive cardiomyopathy repair, but otherwise there is little evidence that TEE alters therapy or improves outcome.

Expert Opinion.

Epicardial echocardiography may offer important advantages over TEE in evaluating hypertrophic cardiomyopathies. In addition to increased accuracy, EE can obtain outflow gradient measurements without the need for cardiac needle punctures. By either means, however, the task force believes that echocardiographic confirmation of the adequacy of hypertrophic obstructive cardiomyopathy repair improves clinical outcomes, based in part on natural history data suggesting poorer outcomes for patients with persistent hemodynamic compromise from hypertrophic obstructive cardiomyopathy. [9] Echocardiographic assessment also facilitates weaning from CPB, may offer improved myocardial protection during the procedure, and enables intraoperative detection of iatrogenic septal defects or systolic anterior motion resulting from the repair. The task force believes that these benefits improve clinical outcomes.

Recommendations

Indications. Hypertrophic obstructive cardiomyopathy repair is a category I indication for either EE or TEE assessments, but use of intraoperative TEE for other cardiomyopathies is a category III indication.

Proficiency. When hypertrophic obstructive cardiomyopathy repair will be dictated by intraoperative TEE assessment, TEE should be performed by, or in timely consultation with, a physician with advanced TEE training.

Cardiac Aneurysms

Summary of the Evidence.

Beyond case reports, there is little evidence that intraoperative TEE is accurate in detecting cardiac aneurysms or results in improved outcomes for patients undergoing aneurysmectomy.

Expert Opinion.

The task force believes that intraoperative TEE during aneurysmectomy can play an important role in evaluating the adequacy of repair and, occasionally, in detecting previously unsuspected abnormalities (*e.g.,* pseudoaneurysms). Patients with cardiac aneurysms typically have advanced ischemic heart disease and associated hemodynamic complications, and TEE often is useful in evaluating these problems (see "Wall Motion, Myocardial Ischemia, and Coronary Heart Disease" and "Hemodynamic Function"). Patients with cardiac aneurysms who undergo cardiac surgery often have difficulty weaning from CPB, and TEE monitoring of hemodynamic function often is helpful in withdrawing extracorporeal circulatory support.

Recommendations

Indications. Assessing surgical repair of cardiac aneurysms is a category II indication for intraoperative TEE.

Proficiency. When surgical repair of cardiac aneurysms will be dictated by the results of intraoperative TEE assessment, TEE should be performed by, or in timely consultation with, a physician with advanced TEE training.

Endocarditis

Summary of the Evidence.

Although its accuracy in detecting endocarditis outside the operating room is well established, there is little evidence beyond case

reports that the use of TEE during surgery is accurate in detecting endocarditis or achieves improved clinical outcomes.

Expert Opinion.

Beyond the accepted applications of intraoperative TEE during valve surgery (see "Valvular Heart Disease"), there is little role for TEE in evaluating endocarditis during surgery, unless preoperative testing was inadequate or the patient required urgent surgery. There are limitations to the sensitivity and specificity of TEE in detecting endocarditis. A negative TEE does not rule out endocarditis, and studies suggest that TEE evidence of vegetations may persist long after bacteriologic cure.

Recommendations

Indications. Noncardiac surgery involving patients with uncomplicated endocarditis is a category III indication for intraoperative TEE. A category I indication exists, however, when preoperative testing has been inadequate or extension of infection to perivalvular tissue is suspected.

Proficiency. When surgical exploration of endocarditic disease will be dictated by the results of intraoperative TEE assessment, TEE should be performed by, or in timely consultation with, a physician with advanced TEE training.

Cardiac Tumors

Summary of the Evidence.

There is some evidence that intraoperative TEE may be more accurate than preoperative testing in characterizing the anatomy of some cardiac tumors and intracardiac extensions of pulmonary or renal tumors, but there is little evidence beyond case reports that this information or the use of TEE during resection results in improved clinical outcomes.

Expert Opinion.

In many cases, the information that intraoperative TEE provides about the location and anatomy of intracardiac tumors to plan incision and excision techniques can be obtained before surgery by careful preoperative testing (including preoperative TEE). If preoperative testing is adequate, the most important role for intraoperative TEE is determining whether a mass has embolized and the new location of the mass, often preempting the need for further exploration or a change in surgical planning.

Recommendations

Indications. The removal of cardiac masses is a category II indication for intraoperative TEE.

Proficiency. Physicians with basic TEE training should be able to detect large, unequivocal cardiac masses. The use of TEE to accurately detect smaller or ill-defined masses, especially to distinguish potential masses from normal intracardiac structures, identify associated lesions, inspect the inferior vena cava, and rule out iatrogenic valve injury during resection of intracardiac masses, should be performed by, or in timely consultation with, a physician with advanced TEE training.

Foreign Bodies

Summary of the Evidence.

The ability of intraoperative TEE to locate bullet fragments and medical devices (*e.g.,* catheter fragments) is reported, but there is no evidence regarding its impact on clinical outcomes.

Expert Opinion.

The yield of intraoperative TEE in detecting foreign bodies is likely to be low in most settings, but it may have greater utility at centers with a high incidence of gunshot injuries.

Recommendations

Indications. The detection of foreign bodies is a category II indication for intraoperative TEE.

Proficiency. To accurately detect foreign bodies, TEE should be performed by, or in timely consultation with, a physician with advanced TEE training.

Air Emboli

Summary of the Evidence.

Intraoperative TEE can detect air bubbles in 8-60% of patients undergoing neurosurgery and 11-79% of patients undergoing cardiac surgery. Current evidence is inadequate, however, to determine whether these emboli increase the risk of neurologic complications or whether intraoperative TEE monitoring for air emboli improves clinical outcomes.

Expert Opinion.

Transesophageal echocardiography is an extremely sensitive test for air (emboli as small as 2 mum usually can be detected) but the clinical significance of these bubbles is unclear. Animal studies suggest that air entrainment greater than 1 cc/kg increase the risk of neurologic complications, but the threshold value for safe air volumes in humans is uncertain. The task force believes that patients benefit when TEE detects air during cardiotomy and neurosurgical

procedures. During cardiotomy, venting procedures before cessation of CPB can eliminate retained air, and the task force believes that such measures decrease the patient's risk of embolic neurologic events, right ventricular failure due to right coronary artery air embolism, and MI. [10] Transesophageal echocardiography offers similar benefits during sitting craniotomies, especially if the patient has not been screened preoperatively for patent foramen ovale. Patent foramen ovale appears to be a risk factor for stroke, and intraoperative maneuvers can induce intracardiac pressure changes that open probe-patent defects to permit paradoxical emboli. Transesophageal echocardiography is the only intraoperative tool for detecting these abnormalities; few other tests can detect air and sources of right-to-left shunts as accurately. The task force recognizes that the use of TEE during upright neurosurgical procedures may increase the risk of vocal cord injury, although these risks may be reduced by using proper technique and equipment.

Recommendations

Indications. The detection of air emboli during cardiotomy and heart transplant operations is a category II indication for using intraoperative TEE. It also should be considered on an individual basis for patients undergoing upright neurosurgical procedures (category II).

Proficiency. Anesthesiologists with basic TEE training should have an understanding of the physiologic effects of air emboli and should be technically capable of detecting air emboli intraoperatively, especially during upright neurosurgical procedures. The use of intraoperative TEE to accurately detect patent foramen ovale should be performed by, or in timely consultation with, a physician with advanced TEE training.

Intracardiac Thrombi

Summary of the Evidence.

Intraoperative TEE can detect intracardiac thrombi in 2-10% of patients undergoing cardiac surgery, often exposing thrombi that were inapparent on preoperative TTE, but there is little evidence beyond case reports that the detection or evacuation of these clots results in improved clinical outcomes.

Expert Opinion.

In patients undergoing thrombectomy, a preoperative echocardiographic examination can prevent an unnecessary operation if it determines that the thrombus has already embolized. If TTE was not performed in the immediate preoperative period, a pre-CPB TEE examination therefore is essential.

Recommendations

Indications. Intracardiac thrombectomy is a category II indication for pre-CPB TEE.

Proficiency. The use of intraoperative TEE to accurately detect intracardiac thrombi and to distinguish between true thrombi and artifacts should be performed by, or in timely consultation with, a physician with advanced TEE training.

Pulmonary Emboli

Summary of the Evidence.

Case reports describe the use of perioperative TEE to detect and evaluate treatment of pulmonary emboli, but there is little evidence regarding its impact on clinical outcomes.

Expert Opinion.

The task force believes that perioperative TEE is especially useful during pulmonary embolectomy to evaluate hemodynamic status and to detect residual emboli. The expert opinion of the task force, based on perioperative TEE monitoring, is that about 30% of embolectomy procedures fail to completely remove all emboli. The task force believes that these residual emboli are potentially harmful to the patient and that the use of TEE to detect them intraoperatively is therefore beneficial.

Recommendations

Indications. Transesophageal echocardiography may be useful to determine the cause of acute hemodynamic disturbances, such as those resulting from pulmonary emboli (see "Hemodynamic Function"), but it is not necessary for all patients with known or suspected pulmonary emboli. Pulmonary embolectomy is a category II indication for using TEE.

Proficiency. The use of perioperative TEE to accurately diagnose pulmonary emboli or to monitor embolectomy or thrombolysis should be performed by, or in timely consultation with, a physician with advanced TEE training.

Emboli during Orthopedic Procedures

Summary of the Evidence.

Intraoperative TEE can detect embolized air or medullary contents in as many as 30-62% of patients undergoing total hip replacement

and, after tourniquet deflation, in 27-100% of patients undergoing knee arthroplasty. There is little evidence, however, that this information results in improved clinical outcomes.

Expert Opinion.

In clinical practice, TEE detection of emboli during orthopedic procedures often prompts clinical interventions (*e.g.,* replacing tourniquets) but the ultimate benefit to the patient of these maneuvers is uncertain.

Recommendations

Indications. Monitoring for emboli during orthopedic procedures is a category III indication for intraoperative TEE.

Traumatic Cardiac Injuries

Summary of the Evidence.

Case reports describe the role of intraoperative TEE in detecting unrecognized traumatic injuries to the heart and of postoperative TEE in detecting injuries not seen on TTE, but there is otherwise little evidence that TEE improves the clinical outcome of cardiac trauma patients (see "Traumatic Aortic Disruption" and "Nonoperative Critical Care Medicine" later).

Expert Opinion.

Routine use of TEE for evaluating cardiac trauma is predicated on the availability of TEE equipment and qualified staff at trauma units. Although there have been no studies beyond case reports to determine whether intraoperative TEE inspections during trauma surgery improve outcomes, cohort studies of postoperative trauma patients have shown that TEE in this setting often discloses injuries that went undetected during surgery. This evidence suggests that unsuspected injuries could be detected during surgery if TEE was performed intraoperatively. The need to return for further surgery and the risk of complications might thereby be reduced by intraoperative TEE, but this hypothesis needs to be confirmed through further research.

Recommendations

Indications. Suspected cardiac trauma is a category II indication for perioperative TEE.

Proficiency. The use of TEE to accurately detect traumatic cardiac injuries should be performed by, or in timely consultation with, a physician with advanced TEE training.

Thoracic Aortic Aneurysms and Dissections

The mortality rate in the first 48 h of aortic dissection is about 1% per hour, and prompt diagnosis and surgical intervention therefore are critical. Angiography and other imaging studies are often impractical because of the patient's rapidly worsening hemodynamic instability. The ability of TEE to detect aortic dissection was first described in 1986 and its ease of application has expanded its role in both the emergent evaluation of suspected dissection and in the recognition of dissections that occur during surgery.

Summary of the Evidence.

With aortography, surgical findings, or necropsy as the reference standard, the use of TEE in the emergent preoperative assessment of aortic dissections has a reported sensitivity and specificity of 88-100% and 77-100%, respectively. Most of these studies, however, were unable to collect enough data to assess the true sensitivity and specificity of TEE. Transesophageal echocardiography in this setting appears to be more sensitive than TTE. However, beyond case reports and suggestive retrospective series, there is little direct evidence that the use of TEE for the emergent preoperative assessment of suspected aortic dissection results in improved clinical outcomes. In one series, its use during the repair of aortic dissections prompted a change in therapy in 14% of patients, but there is no direct evidence that the patients had better outcomes as a result of such interventions.

Expert Opinion.

Although direct evidence of improved clinical outcomes is lacking, there is evidence that delayed detection of acute aortic dissection increases mortality. The task force therefore believes that any method that enhances prompt detection of acute dissections is potentially beneficial. The principal benefits of perioperative TEE during aortic reconstruction are to assess hemodynamic status (*e.g.,* after cross-clamping), document entry and exit sites, confirm decompression of the false lumen, and determine whether valve surgery is needed.

Recommendations

Indications. The preoperative assessment of patients with suspected acute thoracic aortic dissections or aneurysms is a category II indication for TEE. Transesophageal echocardiography is among several accurate diagnostic tests, including angiography, computerized tomography, and magnetic resonance imaging. In unstable patients who should be evaluated quickly, there is a category I indication for TEE because it allows a

more expedient examination than other preoperative imaging procedures.

The intraoperative use of TEE for assessing aortic valve function when patients undergo repair of aortic dissections with possible aortic valve involvement is a category I indication. The repair of other types of thoracic aortic dissections is a category II indication for intraoperative TEE.

Proficiency. The use of TEE to diagnose thoracic aortic dissection or aortic aneurysms should be performed by, or in timely consultation with, a physician with advanced TEE training. See "Hemodynamic Function" for proficiency recommendations in assessing intraoperative hemodynamic status.

Traumatic Thoracic Aortic Disruption

In trauma patients with suspected aortic injuries, hemodynamic shock often precludes the performance of diagnostic tests before the patient is taken to surgery. Preoperative or intraoperative TEE therefore can play an important role in the early detection of aortic injuries.

Summary of the Evidence.

In most studies, the reported sensitivity and specificity of TEE in the emergent preoperative assessment of suspected aortic trauma is 100% and 94-100%, respectively, but limitations in study design make it difficult to determine the true sensitivity and specificity. There is little direct evidence that the use of TEE in this setting results in improved clinical outcomes.

Expert Opinion.

Although scientific evidence may currently be lacking, the task force believes that early detection of undiagnosed traumatic aortic disruption improves clinical outcomes, because of the life-threatening nature of such injuries, and that TEE is an important method for diagnosing aortic trauma.

Recommendations

Indications. The preoperative assessment of suspected thoracic aortic trauma is a category II indication for TEE. It is among several accurate diagnostic tests, including angiography, computerized tomography, and magnetic resonance imaging. In unstable patients who need to be evaluated quickly, there is a category I indication for preoperative TEE because it allows a more expedient examination than other preoperative imaging procedures. Assessing the repair of thoracic aortic injuries is a category III indication for intraoperative TEE.

Proficiency. The use of TEE to accurately diagnose traumatic thoracic aortic disruption should be performed by, or in timely consultation with, a physician with advanced TEE training. See "Hemodynamic Function" for proficiency recommendations in diagnosing the cause of intraoperative hemodynamic dysfunction.

Sources of Aortic Emboli

About 1-5% of patients suffer strokes during CPB, and embolization of atheromatous ulcers on the aorta is considered a major risk factor. Palpation of the aorta, the standard method for detecting atherosclerotic aortic disease, is known to be insensitive. Transesophageal echocardiography, which has been shown outside the operating room to be capable of detecting aortic atheromas, has been used intraoperatively to complement palpation.

Summary of the Evidence.

Intraoperative TEE may be less accurate than epivascular echocardiography in evaluating atheromatous disease in the ascending aorta. Atheromatous disease is noted on intraoperative TEE in 9% of elderly patients and result in a change in therapy in 8-17% of patients. However, although some studies suggest an association between TEE evidence of aortic atheroma and subsequent strokes, there is little direct evidence that the detection and treatment of such findings results in improved clinical outcomes.

Expert Opinion.

Intraoperative TEE and epivascular echocardiography are capable of detecting aortic atheromatous disease, but it is currently unclear whether its detection improves clinical outcomes. Some studies suggest that the risk of embolism and stroke may be reduced by altering patient treatment.

Recommendations

Indications. The detection of aortic artheromatous disease or other sources of aortic emboli is a category II indication for intraoperative TEE. Transesophageal echocardiography infrequently is useful when compared with epivascular echocardiography.

Pericarditis

Summary of the Evidence.

No studies have been performed to determine whether intraoperative TEE is accurate in detecting pericarditis or results in improved clinical outcomes.

Expert Opinion.

In clinical practice, TEE may be helpful in evaluating constrictive pericarditis and pericardiectomy procedures.

Recommendations

Indications. Evaluating the effectiveness of pericardiectomy is a category II indication for intraoperative TEE. Uncomplicated pericarditis is a category III indication.

Proficiency. Use of TEE to guide diagnosis or surgical treatment of pericarditis should be performed by, or in timely consultation with, a physician with advanced TEE training.

Pericardial Effusions and Tamponade

Summary of the Evidence.

There is some evidence suggesting that perioperative TEE is more sensitive than TTE in detecting pericardial effusions, but there is little evidence beyond case reports that such findings during or after surgery result in improved clinical outcomes.

Expert Opinion.

Although supporting scientific evidence is limited, the task force believes that perioperative TEE is clinically beneficial if it detects pericardial tamponade and avoids serious hemodynamic sequelae. This application is especially important when effusions cannot be detected easily by other means. For example, clinical experience suggests that posterior or loculated pericardial effusions that are easily missed by the surgeon may develop in patients receiving pericardial windows.

Recommendations

Indications. The detection of pericardial effusions or evaluation of pericardial surgery is a category II indication for intraoperative TEE. In patients undergoing pericardial window procedures, there is a category I indication for using TEE to evaluate the adequacy of treatment.

Proficiency. Anesthesiologists with basic TEE training should be able to detect large, pericardial effusions. Physicians with advanced TEE training should be able to detect and assess the hemodynamic significance of effusions. Transesophageal echocardiography that is used to guide pericardial surgery should be performed by, or in timely consultation with, a physician with advanced TEE training.

Pleuropulmonary Diseases

Summary of the Evidence.

There is no direct evidence that intraoperative TEE is accurate in detecting pleural or pulmonary parenchymal disease, or that such monitoring results in improved clinical outcomes.

Recommendations

Indications. The evaluation of pleuropulmonary diseases is a category III indication for perioperative TEE.

Transplant Surgery

Summary of the Evidence.

Some studies suggest that TEE is more sensitive than TTE in screening cardiac donor patients and more accurate than pulmonary capillary wedge pressure measurements in detecting hemodynamic disturbances during transplant surgery. Postoperative studies have demonstrated its ability to evaluate cardiac allograft function and detect thrombotic obstruction and stenoses in patients with lung transplants. However, its effect on clinical outcomes has not been evaluated systematically.

Expert Opinion.

Anastomotic integrity may be accurately assessed by TEE. The task force also believes that the hemodynamic benefits of TEE during major organ transplant surgery are especially important. In these patients, TEE is believed to be more accurate in diagnosing the cause of hemodynamic disturbances than is central venous pressure or pulmonary artery catheter monitoring.

Recommendations

Indications. Evaluating anastomotic sites during heart and/or lung transplantation is a category II indication for intraoperative TEE.

Proficiency. Perioperative TEE to evaluate the surgical results of transplant surgery, such as the integrity of anastomoses, should be performed by, or in timely consultation with, a physician with advanced TEE training. Anesthesiologists with basic training should be able to evaluate hemodynamic disturbances (see "Hemodynamic Function") and to detect entrapped air (see "Air Emboli") during transplant operations.

Mechanical Circulatory Support, Defibrillators, and Catheter Placement

Summary of the Evidence.

Case reports and small series have described the use of intraoperative TEE to aid placement and monitor function of intraaortic balloon pumps, ventricular assist devices, automatic implantable

cardiac defibrillators, pulmonary artery catheters, coronary sinus catheters, and ventriculoatrial shunts. There is little direct evidence, however, that TEE is necessary to insert and operate these devices safely or that its use results in improved clinical outcomes.

Expert Opinion.

Although there is no direct evidence regarding the clinical effectiveness of TEE monitoring of mechanical circulatory assist devices, patients receiving such devices usually are experiencing hemodynamic disturbances for which TEE is considered beneficial (see "Hemodynamic Function" earlier). The task force also believes that its use to confirm placement of such devices reduces the need for intraoperative radiography, thereby decreasing radiation exposure and operating room time.

Recommendations

Indications. Monitoring placement and function of assist devices is a category II indication for TEE. Monitoring placement of intraaortic balloon pumps, automatic implantable cardiac defibrillators, or pulmonary artery catheters is a category III indication.

Proficiency. The specific use of TEE to monitor placement and function of mechanical circulatory assistance devices should be performed by, or in timely consultation with, a physician with advanced TEE training. Anesthesiologists with basic training should be capable of evaluating accurately the mechanism of hemodynamic disturbances in patients receiving mechanical circulatory assistance (see "Hemodynamic Function").

Cardioplegia

Summary of the Evidence.

Studies have described the use of intraoperative TEE to evaluate the distribution of cardioplegia solution and to aid placement of cannulas for cardioplegia infusions, but there is little direct evidence that using TEE for this purpose results in improved clinical outcomes.

Expert Opinion.

The use of TEE for achieving cardioplegia is an emerging technology, and future research findings may warrant a more routine role for aiding cannula placement and confirming adequate distribution of the solution.

Recommendations

Indications. Monitoring the administration of cardioplegia solution is a category III indication for intraoperative TEE.

Nonoperative Critical Care Medicine

The increasing availability of TEE, along with recent technological advances, has resulted in its increased use in nonsurgical ICU patients. Many anesthesiologists engaged in critical care medicine encounter potential applications of TEE when caring for unstable ICU patients, and supporting scientific evidence is briefly reviewed below. As noted earlier, the methodology of the task force required it to limit its literature review to studies of TEE conducted specifically in the critical care or perioperative setting. Thus, evidence from echocardiographic and cardiac catheterization laboratories regarding the accuracy and effectiveness of TEE in evaluating valvular heart disease, hemodynamic disturbances, embolic sources, and a variety of other common problems in the ICU could not be included. Although an examination of this large body of indirect evidence was beyond the scope of the task force project and is omitted from this report, information about these studies is available in other reviews. [1] [2]

Summary of the Evidence.

Some studies report that TEE detects information not detected by TTE in 44-59% of ICU patients, but the studies did not compare both tests systematically. Information provided by TEE examinations is reported to change therapy in 17-48% of critical care patients. There is little direct evidence of clinical benefit, however, beyond case reports of the use of TEE to detect the cause of hemodynamic disturbances; to diagnose endocarditis, aortic disease, valvular insufficiency, embolic sources; or to aid ventilator management, thrombolytic therapy, and resuscitation. These studies provide little direct evidence that the diagnoses could not be made by other means or that patients diagnosed or monitored by TEE experience better clinical outcomes than those without it.

Expert Opinion.

Although there is little direct evidence that TEE affects clinical outcomes in the ICU, its effectiveness in correcting life-threatening problems can be inferred from its proven accuracy in detecting these problems and from evidence that early detection and treatment improves outcomes (*e.g.,* see earlier sections on acute aortic dissection, myocardial ischemia, and hemodynamic function). For those conditions that can be evaluated accurately by TEE, the task force believes its use in the ICU is appropriate when TTE or other tests are unable to make the diagnosis or when patients are too unstable to consider other tests. Transesophageal echocardiography may be the first choice in diagnosing certain problems. Its superiority

over other tests in detecting valve disease, hemodynamic disturbances, unsuspected traumatic cardiac injuries, embolic sources, and other problems has been reviewed already. The task force notes that, although the evidence reviewed in this section is limited to the nonoperative critical care patient, transophageal echocardiography has similar, if not greater, utility in the unstable postoperative patient being cared for in the postanesthesia care unit or ICU.

Recommendations

Indications. Unexplained hemodynamic disturbances, suspected valve disease, or thromboembolic problems in unstable ICU patients are category I indications for TEE if other tests or monitoring techniques have failed to confirm the diagnosis or if patients are too unstable to undergo other tests. Other reviews provide more detailed recommendations on the role of echocardiography and other diagnostic procedures in the critical care setting.

Proficiency. Transesophageal echocardiography examinations of nonoperative critical care patients for indications other than determining the cause of hemodynamic disturbances should be performed by, or in consultation with, a physician with advanced transophageal echocardiography training.

Adverse Effects

Summary of the Evidence.

In most studies, serious complications (*e.g.,* esophageal injury or bleeding, vocal cord paralysis, dysrhythmias, hypotension, seizures, cardiac arrest) occur in less than 3% of TEE examinations. Studies reporting a higher incidence of serious complications (8-13%) generally involve select study populations, outdated TEE techniques, or broader case definitions (e.g.,including atrial ectopy among dysrhythmias). The reported mortality rate associated with TEE is 0.01-0.03%, but in most cases a causal link with TEE has not been established. Minor complications from TEE (and their reported incidence) include lip injuries (13%), hoarseness (12%), dysphagia (1.8%), endotracheal intubation (0.3%), bradycardia (0.2%), and dental injuries (0.1%). The reported incidence of bacteremia in most studies is 0-4%, but there is little direct evidence that patients experience clinical consequences. Respiratory complications occur more frequently in awake examinations (0.1-4%) or in small children (2%), whose membranous trachea is easily compressed by the probe. Hemodynamic compromise also may be more common in small children. There is no scientific evidence that anticoagulation increases significantly the risk of bleeding during transophageal echocardiography examinations.

Expert Opinion.

Reported complication rates for TEE, although low, may overestimate true complication rates in the operating room, for several reasons. First, operator skill is an important determinant of complication rates, and reported rates from TEE studies involving inexperienced examiners may not be applicable to rates observed by experienced practitioners. (Conversely, rates reported by seasoned TEE examiners may underestimate the risk of complications among other practitioners). Second, reported incidence rates for adverse effects often originate from examinations of awake patients, in whom some complications are more common than in anesthetized surgical patients. For example, the task force believes that dysrhythmias may be less common in anesthetized than in awake patients. Inadvertent endotracheal insertion of the TEE probe is uncommon in the operating room, in part because endotracheal intubation precedes placement of the transophageal echocardiography probe. Third, confounding variables may have a more direct effect on observed complications than TEE. For example, endotracheal intubation, rather than TEE, may account for the high reported incidence (12-13%) of hoarseness and lip injuries. Comorbidity (*e.g.,* coronary artery disease, neoplasms), rather than TEE, may account for such observed outcomes as myocardial ischemia, dysrhythmias, and gastroesophageal bleeding.

Recommendations

Contraindications. The risk of esophageal injury can be minimized by avoiding TEE examination of patients with extensive esophageal or gastric disease. Relative contraindications include esophageal varices, Barrett's esophagus, Zenker's diverticulum, and postradiation therapy of the esophageal area. Attempts should be made to minimize the pressure exerted on the esophageal mucosa by the TEE probe, including avoiding the practice of keeping the probe in a locked, flexed position. An appropriate probe size should be selected for small children, and airway pressure monitoring should be emphasized during examinations. Most importantly, anesthesiologists performing TEE examinations should be careful that the procedure does not distract them from other intraoperative responsibilities.

Routine safety procedures also can reduce complication rates. Infectious complications can be reduced

by adhering to proper probe sterilization practices. Universal precautions to reduce transmission of infectious diseases should be followed. In patients with valve disease or congenital heart malformations, preoperative antibiotic prophylaxis should be prescribed according to current guidelines. Manufacturers' recommendations for ensuring electrical safety should also be followed.

Proficiency. All anesthesiologists who perform TEE should be familiar with the full range of potential complications of the procedure and with methods for minimizing their risk.

Certification, Credentialing, Quality Assurance, and Training

The incorporation of TEE in the practice of anesthesia has led to a number of challenging issues related to certification, credentialing, quality assurance and training. Using the available legal, regulatory, and scientific literatures, the task force has attempted to address some of these issues. In many instances, however, the task force has needed to rely on expert opinion in its efforts to formulate recommendations.

Certification

Certification of proficiency is not currently available for practitioners of TEE. While the authority and responsibility for certification of consultants in anesthesiology lies with the American Board of Anesthesiology, it has no precedent for certifying proficiency in technical procedures. The task force recommends that certification of special qualification in perioperative TEE be pursued through multispecialty collaboration.

Credentialing

Credentialing of health-care professionals is a volatile arena for physician-hospital and physician-physician relations, because the stakes for practitioners and institutions are so high. Physicians are credentialed for two reasons: first, to ensure that, at a given hospital, an even standard of care is delivered to patients; and second, to fulfill the legal responsibility of the hospital for the patient. Although these reasons are similar, the difference is crucial. Hospitals usually are corporations, legal entities established under state law, with authority and responsibilities provided by those laws. The law recognizes a corporate duty on the part of a hospital's board of directors (or trustees) that is much more specific than is the case for their broader responsibility for the provision of quality medical care. In the fulfillment of these duties, hospital boards rely on state-specific directives from statutory law as well as common law and Joint Commission for the Accreditation of Health Care Organizations guidelines. Although the hospital board passes the responsibility on to the medical staff for the specifics of appointment, reappointment and granting of privileges, which the medical staff codifies in the medical staff bylaws, the final authority for credentialing rests with the hospital board.

The Joint Commission for the Accreditation of Health Care Organizations requires that the medical staff be responsible to the hospital board for the quality of care provided to patients. This quality of care responsibility begins with the granting of clinical privileges and is hospital-specific. Thus, the hospital must have adequate facilities and support staff to provide the services for which privileges are granted. Furthermore, "Professional criteria specified in the medical staff bylaws and *uniformly* applied to all applicants for delineated clinical privileges constitute the basis for granting initial or continuing privileges." Each clinical department develops its own criteria for determining an applicant's ability to provide services within the scope of privileges requested. However, these department-specific criteria are in addition to the general medical staff criteria for clinical privileges.

These criteria must include evidence of relevant training and experience, and evidence of current competence. This evidence ideally includes at least proof of skill in performing invasive procedures and information on appropriateness and outcomes as well as the application of appropriate clinical judgment. Reappointment also must include information regarding the person's clinical and technical skills, as indicated in part by the results of quality assurance and improvement activities. The process should be most thorough when privileges are for complicated treatment or procedures.

Although many organizations, most notably the American College of Physicians, are attempting to develop guidelines to assist hospitals in the granting of clinical privileges, they are primarily based on the recommendations of postgraduate training programs with little supporting evidence. This problem is recognized by the Joint Commission for the Accreditation of Health Care Organizations, which requires that the granting of privileges take into account hospital-specific factors and, by inference, the local pool of specifically trained

---

professionals. In view of these considerations, the task force cannot justify the imposition of nationwide recommendations for the granting of initial clinical privileges in perioperative TEE. However, it strongly supports requirements of continuous assessment of an individual's clinical performance using objective evidence as the basis for the renewal of privileges.

Quality Assurance

Quality assurance programs employing total quality management concepts are used widely to improve medical services. [11] [12] [13] [14] [15] [16] [17] Quality management employs three basic, closely related activities: quality planning, quality control, and quality improvement. Quality planning involves developing definitions of quality as applied to the customer, designing products and services to meet customer needs, and designing processes capable of producing these products and services. Quality control involves developing and applying methods for ensuring that processes work as they are designed. Quality improvement focuses on improving the level of performance of key processes. Continuous quality improvement maintains periodic reviews of the quality assurance program to meet changing customer needs and improve the organization's efficiency. When applying total quality management concepts to perioperative TEE, the terms "products" and "customers" need to be employed in their broadest meaning. The major product of perioperative TEE is information,which is provided to customers. These customers can include other anesthesiologists, surgeons, cardiologists, other physicians, the patient, or the manufacturers of echocardiographic equipment.

Which process of a TEE program is the current "key process" that may benefit from improvement will vary from program to program. The following outline of "processes" was developed to assist in focusing on possible key processes within echocardiography programs.

1. Indications for performing TEE
2. Technical aspects of performing and recording the examination
3. Application of examination findings to physiologic condition
4. Documentation
5. Equipment
6. Professional Communications
7. Education
8. Billing

The application of quality management to an echocardiographic service need not be restricted to the areas mentioned earlier. Periodic updating of the quality assurance program as the TEE service evolves will facilitate meeting the goals originally set forth and defining new goals to meet clinical needs.

Training

General Principles.

While several guidelines for the training of physicians who wish to practice TEE have been developed, few have focused on the specifics of a perioperative TEE practice. [18] [19] [20] [21] The task force recommends that two levels of training in perioperative TEE, basic and advanced, be recognized for the anesthesiologist. Advanced training should be pursued only after basic training has been completed.

Anesthesiologists with basic training in perioperative TEE should be able to use TEE for indications that lie within the customary practice of anesthesiology. Examples of such indications include: the perioperative diagnosis of myocardial ischemia, the perioperative assessment of hemodynamics and ventricular function, the perioperative management of cardiovascular collapse, and others. The task force realizes, however, that anesthesiologists with basic training occasionally will encounter unanticipated diagnostic issues that require the assistance of a physician with advanced TEE training. Anesthesiologists with basic training must be able to recognize their limitations in this setting and request assistance, in a timely manner, from a physician with advanced training. Anesthesiologists with advanced training in perioperative TEE should,in addition to the above, be able to exploit the full diagnostic potential of TEE in the perioperative period. The task force recognizes that, once basic training has been completed, advanced training may occur along a continuum and in a gradual manner. Learning curves will vary from person to person, but are likely to be substantial for some of the TEE applications requiring advanced training. Because it is essential for many intraoperative applications to obtain a definitive interpretation of the TEE examination at the time of surgery, the task force strongly recommends that anesthesiologists actively pursue collaboration with surgeons, cardiologists, or other physicians involved in a patient's care. Specific objectives for basic and advanced training are defined in table 2.

TABLE 2 -- Specific Training Objectives

Basic training
Cognitive skills
1. Knowledge of the physical principles of echocardiographic image formation and blood flow velocity measurement
2. Understanding the operation of the ultrasonographic instrument, including the function of all controls affecting the quality of data displayed
3. Knowledge of the equipment handling, infection control, and electrical safety recommendations associated with the use of TEE
4. Knowledge of the indications and the absolute and relative contraindications to the use of TEE
5. General knowledge of appropriate alternative diagnostic modalities, especially transthoracic and epicardial echocardiography
6. Knowledge of the normal cardiovascular anatomy as visualized tomographically by TEE
7. Knowledge of commonly encountered blood flow velocity profiles as measured by Doppler echocardiography
8. Detailed knowledge of the echocardiographic presentations of myocardial ischemia and infarction
9. Detailed knowledge of the echocardiographic presentations of normal and abnormal ventricular function
10. Detailed knowledge of the physiology and TEE presentation of air embolization
11. Knowledge of native valvular anatomy and function as displayed by TEE knowledge of the major TEE manifestations of valve lesions and dysfunction and of the TEE techniques available for valve assessment
12. Knowledge of the principal TEE manifestations of cardiac masses, thrombi, and emboli; cardiomyopathies; pericardial effusions; and lesions of the great vessels
Technical skills
1. Ability to operate the ultrasonograph, including controls affecting the quality of the displayed data
2. Ability to perform safely a TEE-probe insertion in the anesthetized, tracheally intubated patient
3. Ability to perform a basic TEE examination
4. Ability to recognize major echocardiographic changes associated with myocardial ischemia and infarction
5. Ability to detect qualitative changes in ventricular function and hemodynamic status
6. Ability to recognize echocardiographic manifestations of air embolization
7. Ability to visualize cardiac valves in multiple views, ability to recognize gross valvular lesions and dysfunction
8. Ability to recognize large intracardiac masses and thrombi
9. Ability to detect large pericardial effusions
10. Ability to recognize common artifacts and pitfalls in TEE examination
11. Ability to communicate the results of a TEE examination to the patient and to other health care professionals and to summarize these results cogently in the medical record
Advanced training
Cognitive skills
1. All the cognitive skills defined under basic proficiency
2. Knowledge of the principles and methodology of quantitative echocardiography
3. Detailed knowledge of native valvular anatomy and function; knowledge of prosthetic valvular structure and function; detailed knowledge of the echocardiographic manifestations of valve lesions and dysfunction
4. Knowledge of the echocardiographic manifestations of congenital heart disease.

5. Detailed knowledge of echocardiographic manifestations of pathologic conditions of the heart and great vessels (such as cardiac aneurysms, HOCM, endocarditis, intracardiac masses, cardioembolic sources, aortic aneurysms and dissections, pericardial disorders, and postsurgical changes)

6. Detailed knowledge of other cardiovascular diagnostic methods for correlation with TEE findings

Technical skills

1. All the technical skills defined under basic proficiency

2. Ability to perform a complete TEE examination

3. Ability to quantify subtle echocardiographic changes associated with myocardial ischemia and infarction

4. Ability to utilize TEE to quantify ventricular function and hemodynamics

5. Ability to utilize TEE to evaluate and quantify the function of all cardiac valves (*e.g.,* measurement of gradient, regurgitant jet area, flow-velocity pattern, valve orifice area); ability to assess surgical intervention on cardiac valvular function

* 6. Ability to utilize TEE to evaluate congenital heart lesions; ability to assess surgical intervention in congenital heart disease

* 7. Ability to detect and assess the functional consequences of pathologic conditions of the heart and great vessels (such as cardiac aneurysms, HOCM, endocarditis, intracardiac masses, cardioembolic sources, aortic aneurysms and dissections, and pericardial disorders); ability to evaluate surgical intervention in these conditions if applicable

8. Ability to monitor placement and function of mechanical circulatory assistance devices

TEE = transesophageal echocardiography; HOCM = hypertrophic obstructive cardiomyopathy.

*Some of the technical skills may not apply, depending on practice setting.

Training Pathways

Anesthesiologists.

The anesthesiologist who wishes to attain basic or advanced training in perioperative TEE must undertake certain steps in the process. First, the anesthesiologist should begin to master the cognitive and some of the technical skills outlined in table 2 by studying standard texts and commercially available videotapes and by attending TEE workshops and training sessions. Second, the anesthesiologist should establish a collaborative relationship with a physician who is proficient in TEE to assist the anesthesiologist in acquiring additional technical skills in TEE. The nature of the collaborative relationship should be such that the anesthesiologist refers to the other physician in a timely manner when his/her expertise is exceeded. The collaboration should be an ongoing relationship rather than a brief period of assistance. Third, as with other clinical procedures, mastery of TEE requires time, practice, and repetition on the part of the anesthesiologist to achieve adequate proficiency. While training in perioperative echocardiography need not be restricted to a specific training pathway or protocol (*e.g.,* specified duration of echocardiography laboratory rotations, mandatory TTE training, videotape reviews, required number of examinations to be performed), the task force recommends that anesthesiologist training in TEE be one of the essential processes that are assessed objectively in a quality assurance program for perioperative TEE. Recognizing the importance of maintaining proficiency, the task force recommends that another essential quality assurance process should evaluate an anesthesiologist's ability to maintain skills after training is complete.

Residents in Anesthesiology.

Introductory Knowledge. The task force recommends that all residents in anesthesiology acquire introductory knowledge in perioperative TEE.Every resident who completes the continuum of education in anesthesiology should understand how TEE can be safely and effectively used in essential perioperative applications. The training should include knowledge on the physical principles of echocardiographic imaging and blood flow measurements, two-dimensional echocardiographic anatomy of the heart and great vessels, and the perioperative indications, limitations, diagnostic capabilities, and risks of TEE.

Basic Proficiency. Residents in anesthesiology who wish to pursue basic training in perioperative TEE should acquire the cognitive and technical skills outlined in table 2 for basic training. The training program should have an active perioperative TEE program. Although basic TEE skills can be taught by a physician with basic proficiency, the training program should be under the guidance of, or in close collaboration with, a physician with advanced training in perioperative TEE.

Advanced Proficiency. Residents in anesthesiology who wish to attain an advanced level of training in perioperative TEE should acquire the cognitive and technical skills defined in table 2 for advanced training. The training should occur in cooperation with an established echocardiography service and under the direct guidance of a physician with advanced proficiency in perioperative TEE.

The members of the task force thank all the reviewers for their constructive comments, without which the completion of the practice guidelines would not have been possible.

APPENDIX: Practice Guidelines for Management of the Difficult Airway[D]

A Report by the American Society of Anesthesiologists Task Force on Management of the Difficult Airway

Introduction

Practice guidelines are systematically developed recommendations that assist the practitioner and patient in making decisions about health care. These recommendations may be adopted, modified, or rejected according to clinical needs and constraints.

Practice guidelines are not intended as standards or absolute requirements. The use of practice guidelines cannot guarantee any specific outcome. Practice guidelines are subject to revision from time to time, as warranted by the evolution of medical knowledge, technology, and practice.

A. Purpose of Guidelines for Difficult Airway Management

The purpose of these guidelines is to facilitate the management of the difficult airway and to reduce the likelihood of adverse outcomes. The principal adverse outcomes associated with the difficult airway include (but are not limited to): death, brain injury, myocardial injury, and airway trauma.

B. Focus

The primary focus of the guidelines is the management of the difficult airway encountered during tracheal intubation. * Some aspects of the guidelines may be relevant in other clinical contexts. The guidelines do not represent an exhaustive consideration of all manifestations of the difficult airway or all possible approaches to management.

c. Application

The guidelines are intended for use by anesthesiologists and by individuals who deliver anesthetic care under the direct supervision of an anesthesiologist.

The guidelines apply to all types of anesthetic care delivered in anesthetizing locations.

The guidelines are intended for patients of all ages.

Guidelines

I. Evaluation of the Airway

History.

The literature and consultant opinion strongly support the conduct of an airway history. This support is based upon recognized associations between the difficult airway and a variety of congenital, acquired, and traumatic disease states. The predictive value of the airway history and its effect on outcome have not been clearly defined in the literature.

Recommendations: A. An airway history should be conducted, whenever feasible, prior to the initiation of anesthetic care in all patients. The intent of the airway history is to detect medical, surgical, and anesthetic factors that may indicate the presence of a difficult airway. Examination of previous anesthetic records, if available, may provide useful information.

Physical Examination.

The literature and consultant opinion strongly support the conduct of an airway

Developed by the Task Force on Guidelines for Management of the Difficult Airway: Robert A. Caplan, M.D. (Chairman); Jonathan L. Benumof, M.D.; Frederick A. Berry, M.D.; Casey D. Blitt, M.D.; Robert H. Bode, M.D.; Frederick W. Cheney, M.D.; Richard T. Connis, Ph.D. (Health Services Research Methodologist); Orin F. Guidry, M.D.; and Andranik Ovassapian, M.D. Approved by the House of Delegates, October 21, 1992. To become effective July 1, 1993.

physical examination. This support is based upon recognized associations between the difficult airway and physical findings. Specific features of the airway physical examination have been incorporated into rating systems that predict the likelihood of a difficult airway. These rating systems exhibit modest sensitivity and specificity. No current rating system is fail-safe. The specific effect of the airway physical examination on outcome has not been clearly defined in the literature.

Recommendations: B. An airway physical examination should be conducted, whenever feasible, prior to the initiation of anesthetic care in all patients. The intent of this examination is to detect physical characteristics that may indicate the presence of a difficult airway.

Additional Evaluation.

The airway history or physical examination may provide indications for additional diagnostic testing in some patients. The literature does not provide a basis for using specific diagnostic tests as routine screening tools in the evaluation of the difficult airway.

Recommendations: C. Additional evaluation may be indicated in some patients to characterize the likelihood or nature of the anticipated airway difficulty. The findings of the airway history and physical examination may be useful in guiding the selection of specific diagnostic tests and consultation.

II Basic Preparation for Difficult Airway Management

The literature has not rigorously addressed the effects of patient preparation and equipment preparation on outcome. However, there is strong agreement among consultants that preparatory efforts enhance success and minimize risk. The Task Force has identified several fundamental features of preparation that merit consideration.

Recommendations: A. At least one portable storage unit that contains specialized equipment for difficult airway management should be readily available. Specialized equipment suggested by the Task Force is listed in table 1.

B. If a difficult airway is known or suspected, the anesthesiologist should:

TABLE 1 -- Suggested Contents of the Portable Storage Unit for Difficult Airway Management

IMPORTANT: The items listed in this table represent suggestions. The contents of the portable storage unit should be customized to meet the specific needs, preferences, and skills of the practitioner and health-care facility.
1. Rigid laryngoscope blades of alternate design and size from those routinely used.
2. Endotracheal tubes of assorted size.
3. Endotracheal tube guides. Examples include (but are not limited to) semirigid stylets with or without a hollow core for jet ventilation, light wands, and forceps designed to manipulate the distal portion of the endotracheal tube.
4. Fiberoptic intubation equipment.
5. Retrograde intubation equipment.
6. At least one device suitable for emergency nonsurgical airway ventilation. Examples include (but are not limited to) a transtracheal jet ventilator, a hollow jet ventilation stylet, the laryngeal mask, and the esophageal-tracheal combitube.
7. Equipment suitable for emergency surgical airway access (e.g., cricothyrotomy).
8. An exhaled CO^2 detector.

1. Inform the patient (or responsible person) of the special risks and procedures pertaining to management of the difficult airway.
2. Ascertain that there is at least one additional individual who is immediately available to serve as an assistant in difficult airway management.
3. Consider the feasibility of supplemental oxygen administration during the process of difficult airway management. Opportunities for supplemental oxygen administration include (but are not limited to) mask preoxygenation before induction of anesthesia; oxygen delivery by mask, insufflation, or jet ventilation during intubation attempts; and oxygen delivery by mask, blow-by, or nasal cannulae after extubation of the trachea. The uncooperative patient may restrict the opportunities for supplemental oxygen administration, particularly options that involve the application of a mask.

Strategy for Intubation of the Difficult Airway

The literature provides strong evidence that specific strategies facilitate the management of the difficult airway. Although the degree of benefit cannot be determined from the literature, there is strong agreement among consultants that specific strategies lead to improved outcome. Specific strategies can be linked together to form more comprehensive treatment plans or *algorithms.* The cardiopulmonary resuscitation literature provides evidence for the beneficial effects of algorithms in the management of life-threatening cardiac events. The Task Force considers the technical and physiologic complexity of life-threatening airway events to be sufficiently similar to life-threatening cardiac events to

---

encourage the use of algorithms in difficult airway management.

Recommendations: A. The anesthesiologist should have a preformulated strategy for intubation of the difficult airway. This strategy will depend in part upon the anticipated surgery, the condition of the patient, and the skills and preferences of the anesthesiologist. An algorithm recommended by the Task Force is shown in figure 1.

B. The strategy for intubation of the difficult airway should include:

1. An assessment of the likelihood and anticipated clinical impact of three basic problems that may occur alone or in combination:
   a. Difficult intubation.
   b. Difficult ventilation.
   c. Difficulty with patient cooperation or consent.
2. A consideration of the relative clinical merits and feasibility of three basic management choices:
   a. Use of nonsurgical techniques for the initial approach to intubation *versus* use of surgical techniques for the initial approach to intubation.
   b. Preservation of spontaneous ventilation during intubation attempts *versus* ablation of spontaneous ventilation during intubation attempts.
   c. Awake intubation *versus* intubation attempts after induction of general anesthesia.
3. The identification of a primary or preferred approach to:
   a. Awake intubation.
   b. The patient who can be adequately ventilated but is difficult to intubate.
   c. The life-threatening situation in which the patient cannot be ventilated or intubated.
4. The identification of alternative approaches that can be employed if the primary approach fails or is not feasible:
   a. table 2 displays options for difficult airway management.
   b. The uncooperative patient may restrict the options for difficult airway management, particularly options that involve awake intubation. Airway management in the uncooperative patient may require an approach (*e.g.,* intubation attempts after induction of general anesthesia) that might not be regarded as a primary approach in a cooperative patient.
   c. The conduct of surgery using local anesthetic infiltration or regional nerve blockade may provide an alternative to the direct management of the difficult airway, but this approach does *not* represent a definitive solution to the presence of a difficult airway, *nor* does it obviate the need for a preformulated strategy for intubation of the difficult airway.
5. The use of exhaled CO2 to confirm tracheal intubation.

IV.Strategy for Extubation of the Difficult Airway

Although the literature does not provide a sufficient basis for evaluating the merits of an extubation strategy, the Task Force regards the concept of an extubation strategy as a logical extension of the intubation strategy. Consultant opinion strongly supports the use of an extubation strategy.

Recommendations: A. The anesthesiologist should have a preformulated strategy for extubation of the difficult airway. This strategy will depend in part upon the surgery, the condition of the patient, and the skills and preferences of the anesthesiologist.

B. The preformulated extubation strategy should include:

1. A consideration of the relative merits of awake extubation *versus* extubation before the return of consciousness.
2. An evaluation for general clinical factors that may produce an adverse impact on ventilation after the patient has been extubated.
3. The formulation of an airway management plan that can be implemented if the patient is not able to maintain adequate ventilation after extubation.
4. A consideration of the short-term use of a device that can serve as a guide for expedited reintubation. This type of device is usually inserted through the lumen of the endotracheal tube and into the trachea *before* the endotracheal tube is removed. The device may be rigid to facilitate intubation and/or hollow to facilitate ventilation.

Follow-Up Care

Although the literature does not provide a sufficient basis for evaluating the benefits of follow-up care, this

Figure 1

TABLE 2 -- Techniques for Difficult Airway Management

IMPORTANT: This table displays commonly cited techniques. It is not a comprehensive list. The order of presentation is alphabetical and does not imply preference for a given technique or sequence of use. Combinations of techniques may be employed. The techniques chosen by the practitioner in a particular case will depend upon specific needs, preferences, skills, and clinical constraints.

I Techniques for difficult intubation
Alternative laryngoscope blades
Awake intubation
Blind intubation (oral or nasal)
Fiberoptic intubation
Intubating stylet/tube changer
Light wand
Retrograde intubation
Surgical airway access
II Techniques for difficult ventilation
Esophageal-tracheal combitube
Intratracheal jet stylet
Laryngeal mask
Oral and nasopharyngeal airways
Rigid ventilating bronchoscope
Surgical airway access
Transtracheal jet ventilation
Two-person mask ventilation

activity is strongly supported by consultant opinion. The Task Force has identified several fundamental concepts that merit consideration.

Recommendations: A. The anesthesiologist should document the presence and nature of the airway difficulty in the medical record. The intent of this documentation is to guide and facilitate the delivery of future care. Aspects of documentation that may prove helpful include (but are not limited to):

1. A description of the airway difficulties that were encountered. If possible, the description should distinguish between difficulties encountered in mask ventilation and difficulties encountered in tracheal intubation.
2. A description of the various airway management techniques that were employed. The description should indicate the extent to which each of the techniques served a beneficial or detrimental role in management of the difficult airway.

B. The anesthesiologist should inform the patient (or responsible person) of the airway difficulty that was encountered. The intent of this communication is to provide the patient (or responsible person) with a role in guiding and facilitating the delivery of future care. The information conveyed may include (but is not limited to): the presence of a difficult airway, the apparent reasons for difficulty, and the implications for future care.

C. The anesthesiologist should evaluate and follow the patient for potential complications of difficult airway management. These complications include (but are not limited to): edema, bleeding, tracheal and esophageal perforation, pneumothorax, and aspiration.

Appendix

A. Definition of the Difficult Airway

A standard definition of the difficult airway cannot be identified in the available literature. The Task Force has not given preference to literature based upon any particular system of definition or classification. For these guidelines, *a difficult airway is defined as the clinical situation in which a conventionally trained anesthesiologist experiences difficulty with mask ventilation, difficulty with tracheal intubation, or both.*

The difficult airway represents a complex interaction between patient factors, the clinical setting, and the skills and preferences of the practitioner. Analysis of this interaction requires precise collection and communication of data. The Task Force urges clinicians and investigators to use explicit descriptions of the difficult airway. Descriptions that can be categorized or expressed as numerical values are particularly desirable, as this type of information lends itself to aggregate analysis and cross-study comparisons. Suggested descriptions include (but are not limited to):

1. Difficult Mask Ventilation.

1. It is *not* possible for the unassisted anesthesiologist to maintain the Sp_{o2} >90% using 100% oxygen and positive pressure mask ventilation in a patient whose Sp_{o2} was >90% before anesthetic intervention.
2. It is *not* possible for the unassisted anesthesiologist to prevent or reverse signs of inadequate ventilation during positive pressure mask ventilation.

Signs of inadequate mask ventilation include (but are not limited to): cyanosis, absence of exhaled CO_2, absence of spirometric measures of exhaled gas flow, absence of breath sounds, absence of chest movement, auscultatory signs of severe airway obstruction, gastric air entry or dilatation, and hemodynamic changes associated with hypoxemia or hypercarbia (*e.g.,* hypertension, tachycardia, arrhythmia).

2. Difficult Laryngoscopy.

It is *not* possible to visualize any portion of the vocal cords with conventional laryngoscopy.

3. Difficult Endotracheal Intubation.

1. Proper insertion of the tracheal tube with conventional laryngoscopy requires *more than three attempts.*
2. Proper insertion of the tracheal tube with conventional laryngoscopy requires *more than 10 min.*

B. Assessment of Scientific Evidence and Consultant Opinion

The assessment of scientific evidence focused on the following 10 statements or *linkages.* These linkages represent hypotheses about the relationships between clinical care and clinical outcome
in difficult airway management.

1. Preanesthetic evaluation predicts a difficult airway.
2. Preanesthetic evaluation leads to fewer adverse outcomes.
3. Preparation of the patient and equipment facilitates successful airway management.
4. Preparation of the patient and equipment leads to fewer adverse outcomes.
5. Use of a strategy or algorithm facilitates successful airway management.
6. Use of a strategy or algorithm leads to fewer adverse outcomes.
7. Confirmatory tests of endotracheal intubation facilitate successful management.
8. Confirmatory tests of endotracheal intubation lead to fewer adverse outcomes.
9. Use of an extubation strategy or algorithm leads to fewer adverse outcomes.
10. Follow-up care leads to fewer adverse outcomes.

Scientific support for the linkages was assessed by a structured literature search and meta-analysis. The bibliographic files of the National Library of Medicine and other large reference sources were searched for citations containing key words, subject headings, and text entries related to the 10 linkages. Task Force members provided supplemental citations. Several thousand citations were initially identified, of which 537 were associated with the specified linkages. Literature that could not be analyzed was eliminated. A total of 273 articles, published in the interval from 1973 to 1991, were available for consideration. Each article was reviewed, summarized, and coded by the research methodologist using a standardized rating instrument. Agreement between the Task Force members and the methodologist was established by interrater reliability testing.

Two approaches to meta-analysis were employed. First, the directional result of each study was classified as either 1) supporting a linkage, 2) refuting a linkage, or 3) neutral. These results were averaged to obtain an aggregate directional measure of support for each linkage. Second, the literature relating to linkages 1,5, and 6 contained enough studies with well defined experimental designs and statistical information to calculate significance levels for the direction of support. Using the Fisher combined test, the following results were obtained: linkage 1, $P < 0.001$; linkage 5, $P < 0.001$; linkage 6, $P < 0.01$. For this type of metaanalysis, $P < 0.01$ was considered significant. There were not enough data to assess the relative strength of the directional measures of support.

The findings of the literature analysis were supplemented by opinion from Task Force members and 50 consultant anesthesiologists with recognized interest in airway management and guidelines. The kappa statistic (k) was used to obtain a quantitative measure of agreement among consultants. Consultants exhibited strong agreement ($_k$
0.75) on the potential beneficial effects of the following activities: conduct of the airway history and physical examination, advance preparation of the patient and equipment, formulation of strategies for intubation and extubation of the difficult airway, and provision of follow-up care.

C. References

A list of the articles used to develop these guidelines is available by writing to the American Society of Anesthesiologists, 520 North Northwest Highway, Park Ridge, Illinois 60068-2573.

The process of guideline development was conducted according to the technique described by S.H. Woolf in the *Manual for Clinical Practice Guideline Development,* U.S. Department of Health and Human Services, March 1991, Agency for Health Care Policy and Research, publication number 91-0007.

See Introduction, Section A, for the principal adverse outcomes associated with difficult airway management.

The Task Force gratefully acknowledges the contributions of the members of the American Society of Anesthesiologists who responded to surveys on difficult airway management, reviewed guideline drafts, contributed oral and written testimony to the Open Forum, and participated in tests of clinical feasibility.

APPENDIX: Practice Guidelines for Blood Component Therapy[D]

A Report by the American Society of Anesthesiologists Task Force on Blood Component Therapy

In 1994, the American Society of Anesthesiologists established the Task Force on Blood Component Therapy to develop evidence-based indications for transfusing red blood cells, platelets, fresh-frozen plasma, and cryoprecipitate in perioperative and peripartum settings. The guidelines were developed according to an explicit methodology. The principal conclusions of the task force are that red blood cell transfusions should not be dictated by a single hemoglobin "trigger"but instead should be based on the patient's risks of developing complications of inadequate oxygenation. Red blood cell transfusion is rarely indicated when the hemoglobin concentration is greater than 10 g/dL and is almost always indicated when it is less than 6 g/dL. The indications for autologous transfusion may be more liberal than for allogeneic (homologous) transfusion. The risks of bleeding in surgical and obstetric patients are determined by the extent and type of surgery, the ability to control bleeding, the actual and anticipated rate of bleeding, and the consequences of uncontrolled bleeding. Prophylactic platelet transfusion is ineffective when thrombocytopenia is due to increased platelet destruction. Surgical and obstetric patients with microvascular bleeding usually require platelet transfusion if the platelet count is less than 50 × 109/1 and rarely require therapy if it is greater than 100 × 109/1. Fresh-frozen plasma is indicated for urgent reversal of warfarin therapy, correction of known coagulation factor deficiencies for which specific concentrates are unavailable, and correction of microvascular bleeding when prothrombin and partial thromboplastin times are >1.5 times normal. It is contraindicated for augmentation of plasma volume or albumin concentration. Cryoprecipitate should be considered for patients with von Willebrand's disease unresponsive to desmopressin, bleeding patients with fibrinogen levels below 80‐100 mg/dL. The task force recommends careful adherence to proper indications for blood component therapy to reduce the risks of transfusion. (Key words: Practice guidelines: anemia; blood component therapy; coagulopathy; cryoprecipitate; fresh-frozen plasma; red blood cells; transfusion.)

MORE than 22 million blood components are transfused each year in the United States [1] Many of these transfusions are administered to surgical and obstetric patients. The transfusion of red blood cells (RBCs), platelets, fresh-frozen plasma (FFP), and cryoprecipitate has the potential of improving clinical outcomes in perioperative and peripartum settings. These benefits include improved tissue oxygenation and decreased bleeding. However, transfusions are not without risks or costs. The transmission of infectious diseases (*e.g.,* hepatitis, human immunodeficiency virus (HIV) infection), hemolytic and nonhemolytic transfusion reactions, immunosuppression, alloimmunization, and other complications are potential sequelae of blood component therapy.

A number of groups have issued clinical practice guidelines for blood component therapy in an effort to improve transfusion practices, minimize the incidence of adverse transfusion reactions, and decrease costs. In the 1980s, the National Institutes of Health convened consensus conferences and published recommendations for RBC transfusion, platelet therapy, and the administration of FFP. [2] [3] [4] In 1984, the American College of Obstetricians and Gynecologists (ACOG) issued recommendations

Developed by the Task Force on Blood Component Therapy: Linda C. Stehling, M.D., (Chair), Scottsdale, Arizona; Dennis C. Doherty, D.O., Atlanta, Georgia; Ronald J. Faust, M.D., Rochester, Minnesota; A. Gerson Greenburg, M.D., Ph.D. (Representative, American College of Surgeons), Providence, Rhode Island; Chantal R. Harrison, M.D. (Representative, College of American Pathologists), San Antonio, Texas; Dennis F. Landers, M.D., Dallas, Texas; Russell K. Laros, Jr., M.D. (Representative, American College of Obstetricians and Gynecologists), San Francisco, California; Ellison C. Pierce, Jr., M.D., Boston, Massachusetts; Randall S. Prust, M.D., Tucson, Arizona; Andrew D. Rosenberg, M.D., New York, New York; Richard B. Weiskopf, M.D., San Francisco, California; Steven H. Woolf, M.D., M.P.H. (Methodologist), Fairfax, Virginia; and John F. Zeiger, M.D., Ft. Wayne, Indiana.

on blood component therapy. [5] In 1990, the Transfusion Practices Committee of the American Association of Blood Banks issued guidelines for transfusion of patients undergoing coronary artery bypass surgery. [6] In 1992, the American College of Physicians (ACP) issued recommendations for RBC transfusion. [7] In 1994, the College of American Pathologists (CAP) published a practice parameter for FFP, cryoprecipitate, and platelet transfusion. [8] Guidelines for blood utilization review were published in the same year by the American Association of Blood Banks. [9] Although these documents include sections on the use of blood components in the surgical setting, no group has issued current and comprehensive recommendations on perioperative and peripartum blood component therapy.

In 1994, the American Society of Anesthesiologists convened the Task Force on Blood Component Therapy to develop evidence-based guidelines on the proper indications for perioperative and peripartum administration of RBCs, platelets, FFP, and cryoprecipitate. The task force included nine anesthesiologists (in private and university-based practice); one physician representative from the American Pathologists, and ACOG; and a methodologist.

Before the guidelines were developed, the task force reviewed published evidence regarding the clinical effectiveness of perioperative and peripartum blood component therapy. A total of 1,417 articles were retrieved in a computerized and manual literature search conducted in mid-1994. The computerized search sought all English-language literature published in any country on the use of RBCs, platelets, FFP, or cryoprecipitate in the perioperative or peripartum setting. A total of 160 articles were considered relevant. Published evidence was considered relevant if it addressed the perioperative or peripartum use tof the above blood components and measured effectiveness in terms of clinical outcomes. The strength of evidence was classified by study design category, using the scale in table 1 (Table Not Available) . Further details about the literature review methodology are available on request. Input from practicing anesthesiologists was obtained at an open forum held in October 1994. The document was sent to members of the American Society of Anesthesiologists House of Delegates, Board of Directors, and Component Society Presidents for review. The overall guideline development process is reviewed elsewhere. [10] [11]

This article summarizes the results of the literature review and the recommendations of the task force. Recommendations apply to typical surgical and obstetric patients. Infants, children, and special clinical settings (*e.g.,* liver transplantation, sickle cell anemia) are beyond the scope of the report. Thus, the task force has not considered the transfusion of neonatal, infant, or pediatric patients or the recommendations on this topic that have been published by other groups. [12] [13] The recommended indications are based on scientific evidence and expert opinion regarding the effectiveness of the intervention. Effectiveness was judged by considering the potential clinical benefits, adverse effects, and costs of blood component therapy.

TABLE 2 -- Grading of Evidence

From U.S. Preventive Services Task Force: Guide to Clinical Preventive Services: An Assessment of the Effectiveness of 169 Interventions. Baltimore, Williams and Wilkins, 1989.

(Not Available)

Adverse Effects

Transfusion Reactions

Nonhemolytic transfusion reactions, often manifested in awake patients by fever, chills, or urticaria, are the most common adverse effects of RBC transfusion, but these signs may not be detectable during anesthesia. Nonhemolytic transfusion reactions occur in approximately 1-5% of all transfusions. [4] Hemolytic reactions due to administration of incompatible blood can be life-threatening. The estimated risk of ABO-incompatible transfusion is 1:33,000 RBC transfusions. [14] [15] As with nonhemolytic reactions, general anesthesia may mask the symptoms of hemolytic reactions, and many of the signs (hypotension, tachycardia, hemoglobinuria and microvascular bleeding) may be attributed erroneously to other causes. The probability of a fatal hemolytic transfusion reaction is uncertain with estimates ranging from 1:500,000 to 1:800,000. [15] Between 1976 and 1985, the U.S. Food and Drug Administration was notified of 131 fatal ABO-incompatible transfusions. [16]

Infectious Diseases

The incidence of post-transfusion hepatitis, more than 90% of which is due to hepatitis C virus, has decreased

since the introduction of testing for the virus in 1990. [17] The reported incidence of hepatitis C virus seroconversion is 0.03% per unit transfused. [18] However, the actual incidence is believed to be lower because of improved testing introduced in 1992. [19] The risk of transmission of hepatitis B is estimated to be 1:200,000 units. [20]

The risk of exposure to HIV through blood transfusion is uncertain. Although a range of incidence rates has been reported, [21] [22] [23] recent estimates suggest that the mean infectious window period (the period between viral infection and its detection by tests for the presence of antibodies) is approximately 22 days [24] and that the current risk of HIV infection in the United States is 1:450,000-1:660,000 per transfused unit of blood. [25] Implementation of donor screening tests for HIV-1 antigen is expected to prevent up to 25% of the window period cases, or five to ten cases per year. [25] Higher rates may occur in areas with increased HIV prevalence. [26] Perhaps the most common viral agent transmitted by blood transfusion is cytomegalovirus. Most infections are subclinical, although immunocompromised patients may develop severe morbidity. Parasitic and bacterial agents can be transmitted by blood components, but the incidence of clinically significant disease in the United States is low, possibly 1:1,000,000 units of blood. [27] Twenty-six deaths due to bacterial contamination of blood components were reported to the Food and Drug Administration between 1976 and 1985. [16]

Immunosuppression and Blood Transfusion

Some studies suggest that patients with colorectal, breast, prostate, and certain other cancers may experience earlier recurrence and lower survival rates if they receive allogeneic (homologous) blood transfusions in the perioperative period, [28] [29] but other data challenge the association [30] Higher rates of postoperative infections have been reported in patients who received perioperative allogeneic transfusions than in those who were not transfused or who received only autologous blood. [31] [32] [33] [34] Other studies, however, have not confirmed this relationship. [35] [36]

Costs

Although the costs of blood component therapy are substantial, exact figures are lacking. A study at one medical center estimated that the base cost for providing one unit of allogeneic RBCs was $114 and that the direct and indirect services involved in transfusing the unit increased the cost to $151. [37] A study at 18 hospitals estimated that average hospital costs were $155 per transfused unit of whole blood or RBCs, or $397 per patient for all blood components. [38] [39] With an estimated 12 million units transfused each year in the United States, this amounts to an annual cost of at least 2 billion dollars, with some estimating costs as high as 5-7 billion dollars for all transfused components. [40] Such estimates are of limited validity, because they do not include the cost of all blood components, administrative expenses, and indirect transfusion costs, [40] and they do not reflect the economic benefits of transfusion therapy. Nonetheless, the resource implications of blood component therapy must be recognized, and the role of improved transfusion practices in reducing costs must be considered. Almost 25% of the costs of RBC transfusions may be attributable to inappropriate transfusions. [39] These costs can be reduced through the adoption of more appropriate transfusion practices. For example, one large teaching hospital was able to reduce transfusion costs by $1.6 million over 3 yr by adopting new transfusion guidelines. [41]

Red blood cells

Approximately 12,000,000 units of RBCs are transfused each year in the United States. [1] Although most of these transfusions are performed for appropriate reasons, studies have documented substantial rates of unnecessary transfusions. Inappropriate rates of 18-57% have been reported. [42] [43] [44] [45] [46] [47] [48] [49] [50] . The proper objective of RBC transfusion is the improvement of inadequate oxygen delivery. The scientific argument for perioperative RBC transfusion therefore rests on two principal assumptions: (1) surgical patients experience adverse outcomes as a result of diminished oxygen-carrying capacity, and (2) RBC transfusions, by enhancing oxygen-carrying capacity, can prevent these adverse outcomes. Evidence to support these assumptions is reviewed below.

Adverse Effects of Diminished Oxygen-carrying Capacity

Diminished oxygenation due to inadequate oxygen-carrying capacity can have serious clinical implications, primarily because of ischemic effects on the myocardium and brain. Oxygen delivery (Do2) is defined as

---

the product of cardiac output (Qt) and arterial oxygen content (Ca_{o2}). The latter is a function of hemoglobin saturation (Sa_{o2}), hemoglobin concentration (Hb), and the amount of oxygen physically dissolved in arterial blood:

DO2 =; (CaO2).(Qt),

CaO2 =; (SaO2/100).(1.39.Hb) + (0.003.PaO2).

Although an increase in cardiac output is the primary compensation for reduced oxygen-carrying capacity, changes in the microcirculation can affect oxygen transport at the tissue level. For example, during periods of blood loss, the autonomic nervous system can restrict blood flow and oxygen delivery to skin, muscle, and the abdominal viscera to preserve oxygen delivery to the central nervous system and heart.

The effects of anemia must be separated from those of hypovolemia, although both can interfere with oxygen transport. The clinical manifestations of hypovolemia are well known, and a classification based on blood loss has been established by the American College of Surgeons. [51] A loss of up to 15% of total blood volume (class I hemorrhage) usually has little hemodynamic effect other than vasoconstriction and mild tachycardia. A loss of 15-30% of blood volume (class II hemorrhage) produces tachycardia and decreased pulse pressure; unanesthetized patients may also exhibit anxiety or restlessness. A loss of 30-40% (class III hemorrhage) produces increasing signs of hypovolemia, including marked tachycardia, tachypnea, and systolic hypotension; unanesthetized patients demonstrate altered mental status. Experience has shown that, in young healthy patients, losses of up to 30-40% of blood volume usually can be treated adequately with crystalloid therapy. Loss of more than 40% of total blood volume (class IV hemorrhage) is life-threatening and accompanied by marked tachycardia and hypotension, very narrow pulse pressure, and low urine output; mental status is markedly depressed.

The lower limit of human tolerance to acute normovolemic anemia has not been established. It is believed that oxygen delivery is adequate in most individuals at hemoglobin concentrations as low as 7 g/dL. [4] In healthy, normovolemic individuals, tissue oxygenation is maintained and anemia tolerated at hematocrit values as low as 18-25%. [52] [53] The heart does not begin producing lactic acid until a hematocrit of 15-20% is reached. [54] [55] Myocardial lactate flux does not appear to be affected at hemoglobin concentrations as low as 6 g/dL. [56] Heart failure usually does not occur until the hematocrit reaches 10%. [57] [58]

Chronic anemia is better tolerated than acute anemia. Oxygen delivery is facilitated through increases in 2,3-diphosphoglycerate levels in RBCs. In patients with chronic anemia, cardiac output usually does not change until the hemoglobin concentration falls below 7 g/dL. Significant symptoms are unusual unless the RBC mass is decreased by approximately 50%. [58] Chronic anemia has special implications for pregnant women. Obstetric patients usually tolerate chronic anemia without significant adverse maternal or fetal effects. A review of 17 studies of obstetric patients revealed no effect of hemoglobin concentration on the incidence of stillbirth or intrauterine growth retardation, [59] whereas another found increased complications of pregnancy associated with both low (<10.4 g/dL) and high (>13.2 g/dL) hemoglobin concentrations. [60] Studies of acute isovolemic anemia in animals suggest that fetal oxygen extraction is maintained until the maternal hematocrit is reduced by more than 50%. [61] In a study of pregnant sheep with chronic anemia (hematocrit less than 14% for 6 days), decreased oxygen delivery to the placenta did not reduce fetal oxygen consumption. [62]

In acute anemia, reductions in arterial oxygen content usually are well tolerated because of compensatory increases in cardiac output. This compensatory mechanism may be affected by several factors, however, such as left ventricular, dysfunction and vasoactive pharmacologic agents (*e.g.,* beta adrenergic or calcium channel blockade), necessitating a higher hemoglobin concentration for adequate oxygen delivery. Human tolerance of acute anemia is further affected by certain pharmacologic agents, such as anesthetics, hypnotics, and neuromuscular blocking drugs, and by intraoperative conditions (*e.g.,* hypothermia). Anesthetics have important cardiovascular and endocrine actions that influence oxygen transport and consumption and the physiologic response to acute anemia. Most anesthetics cause myocardial depression and decrease arterial blood pressure, cardiac output, stroke volume, peripheral vascular resistance, total-body oxygen consumption, and cerebral and myocardial oxygen demands. [63] The magnitude of these effects varies among anesthetics and as a function of anesthetic depth. In addition, anesthetics differ in their effects on hepatic blood flow, and thus they may differ in how they influence the development of systemic lactic acidosis and base-deficit in patients with anemia or impaired oxygen transport.

The physiologic limit of oxygen transport is not known in either awake humans or those under general anesthesia. Case reports suggest that humans may tolerate lower hemoglobin concentration and oxygen transport during anesthesia than when awake. [64] This may be due to an anesthetic-and neuromuscular block-ade-induced reduction of oxygen consumption. However, there are no controlled prospective studies addressing this important issue. The impact of regional anesthesia on oxygen transport is also unclear.

These physiologic principles have been reinforced by clinical studies demonstrating inconsistent associations between anemia and adverse perioperative or peripartum outcomes. Case series reports of Jehovah's Witnesses indicate that some patients tolerate very low hemoglobin concentrations (less than 6-8 g/dL) in the perioperative period without an increase in mortality. [65] [66] [67] A review of 16 series published between 1983 and 1990, involving 1,404 operations on Jehovah's Witnesses, found that lack of blood was implicated as the primary cause of death in only 8 (0.6%) patients and as a contributor to death in an additional 12 (0.9%) patients. [68] Another review of 61 reports of 4,722 Jehovah's Witnesses identified 23 deaths due to anemia, all but 2 of which occurred at hemoglobin concentrations

less than 5 g/dL. [64] A stastistical analysis of one series of Jehovah's Witnesses found that hemoglobin alone was not a statistically significant predictor of outcome unless it was less than 3 g/dL. [69] Both hemoglobin and intraoperative blood loss must be taken into consideration. [65] This body of literature represents self-selected reports, however, in which clinicians are more likely to report survivors than nonsurvivors. The information provided in most reports is insufficient to allow for independent conclusions regarding the degree to which profound anemia contributed to morbidity or mortality.

Decisions regarding perioperative transfusion are often difficult, necessitating clinical judgment. There is little scientific support for relying on a specific hemoglobin or hematocrit value as a "transfusion trigger," such as the outdated "10/30 rule" that transfusion is necessary in patients with a hemoglobin concentration less than 10 g/dL or an hematocrit less than 30%. [70] Estimates of blood volume are also unreliable, because of inaccuracies of intraoperative blood loss measurement, intercompartmental fluid shifts during surgery, and the dilutional effects of crystalloid therapy. Although often useful, intraoperative hemoglobin determinations can be misleading. Alterations of intravascular volume due to the concomitant administration of colloids and crystalloids can produce artificially lowered or elevated hemoglobin concentrations.

Intraoperative estimates of blood volume are indirect, being inferred from pressure measurements obtained at various locations (arterial, central venous, or pulmonary capillary wedge pressures). Whole-body oxygen consumption, oxygen extraction ratio, and oxygen delivery have been used to estimate the need for RBC transfusion. [71] [72] [73] These measurements require invasive monitoring (*e.g.,* arterial, pulmonary artery), have not been independently verified, and are global (not organ-specific) measures of oxygen utilization. In the clinical setting, it is not possible to directly measure the adequacy of oxygen transport to specific organs or to regions within these organs.

The perioperative decision-making process regarding transfusion is complicated by knowledge that myocardial ischemia is often silent and most frequent in the postoperative period, when monitoring is less intense. [74] [75] A patient's oxygen transport needs can increase at any time during the postoperative period because of pain, fever, shivering, or physical activity.

Aside from the more obvious potential benefits of RBC transfusion in improving oxygen-carrying capacity, other unsubstantiated claims of benefit have been made, including effects on wound-healing. However, in healing tissue, collagen deposition is dependent on oxygen tension and perfusion and not on blood hemoglobin concentration. [76]

Effectiveness of Red Blood Cell Transfusion

The transfusion of one unit of whole blood or RBCs increases the hematocrit by approximately 3%, or the hemoglobin concentration by 1 g/dL, in a 70-kg nonbleeding adult. [77] Controlled studies have not been performed to determine the hemoglobin concentration at which RBC transfusion improves clinical outcome. Indirect evidence suggests that many RBC transfusions are unnecessary, because mild to moderate blood loss does not appear to be associated with increased perioperative morbidity or mortality. [78] [79] [80] [81] [82] [83] [84] and reduced transfusions brought about by concerns over transfusion-related infections have not been associated with poorer perioperative outcomes. [85] [86] [87] However, most of these studies were uncontrolled and lacked long-term follow-up.

A relationship between perioperative anemia and myocardial ischemia or infarction has been proposed. A controlled observational study of 27 high-risk patients

undergoing infrainguinal arterial bypass surgery found that the incidence of postoperative myocardial ischemia and morbid cardiac events was significantly higher among the 14 patients with hematocrits less than 28% than among patients with higher hematocrits. [88] However, the anemic group was significantly older and underwent longer procedures, the results were not adjusted for confounding variables that increase ischemic risk, and the study did not examine the effectiveness of RBC transfusions. A study of 30 postoperative critical care patients with hemoglobin concentrations less than 10 g/dL found that RBC transfusions had little impact on oxygen consumption, [89] a finding consistent with other studies of critical care patients. [90] [91] [92] [93]

Strength of Evidence: Category II-2 and II-3 (Controlled and Uncontrolled Observational Studies)

Expert Opinion.

Recommendations of Other Groups. In 1988, the National Institutes of Health Consensus Conference on Perioperative Red Blood Cell Transfusion concluded that evidence did not support the use of a single criterion for transfusion, such as a hemoglobin concentration less than 10 g/dL, nor was there evidence that mild to moderate anemia contributed to perioperative morbidity. [64] In 1992, the ACP recommended distinguishing between stable and unstable vital signs in determining whether to transfuse anesthetized patients. The ACP concluded that patients with stable vital signs and no risk of myocardial or cerebral ischemia do not require RBC transfusion, independent of hemoglobin level, and recommended transfusing patients with unstable vital signs only if risks of myocardial or cerebral ischemia were present. [67] A consensus conference convened by the Royal College of Physicians of Edinburgh concluded that RBC transfusion is indicated only to increase oxygen-carrying capacity, the transfusion decision should be made by a qualified practitioner as part of the overall management of the illness, patients should be offered information about RBC transfusion and available alternatives, and the indication for transfusion should be documented in the medical record. [94]

Expert Opinion of Task Force. The task force believes that any uniform "transfusion trigger" (*e.g.,* an absolute hemoglobin or hematocrit value) provides an inappropriate basis for determining the need for perioperative or peripartum RBC transfusion. Hemoglobin concentration alone is an inadequate measure of oxygen delivery. The ACP recommendation to rely solely on vital signs [67] is inappropriate for anesthetized patients. The decision to transfuse often is affected by the dynamic nature of surgical hemorrhage. [95] Patients with hypovolemia and anemia may be transfused more aggressively when rapid blood loss is anticipated (*e.g.,* aortic unclamping). Changes in vital signs often are masked by anesthetics and other drugs and are frequently a late sign of cardiovascular decompensation. Moreover, silent ischemia of the myocardium, cerebrum, liver, kidney, and other tissues can occur in the presence of stable vital signs. Intraoperative myocardial ischemia, a predictor of cardiac morbidity and mortality, [74] is associated with tachycardia in only 26% of patients and with blood pressure changes in less than 10% of patients. [75]

Factors affecting the surgical patient's response to decreased hemoglobin concentration, and thus the factors that should influence the physician's decision to transfuse, include the patient's cardiopulmonary reserve (determined by the presence or absence of cardiac and/or pulmonary disease and hemodynamic indexes, and affected by drugs and anesthetics), the rate and magnitude of blood loss (actual and anticipated), oxygen consumption (affected by body temperature, drugs/anesthetics, sepsis, muscular activity), and atherosclerotic disease (cerebrovascular, cardiovascular, peripheral, renal).

Recommendations. The task force bases its recommendations on available category II-2 and II-3 evidence and expert opinion. The task force concludes that (1) transfusion is rarely indicated when the hemoglobin concentration is greater than 10 g/dL and is almost always indicated when it is less than 6 g/dL, especially when the anemia is acute; (2) the determination of whether intermediate hemoglobin concentrations (6-10 g/dL) justify or require RBC transfusion should be based on the patient's risk for complications of inadequate oxygenation; (3) the use of a single hemoglobin "trigger" for all patients and other approaches that fail to consider all important physiologic and surgical factors affecting oxygenation are not recommended; (4) when appropriate, preoperative autologous blood donation, intraoperative and postoperative blood recovery, acute normovolemic hemodilution, and measures to decrease blood loss (deliberate hypotension and pharmacologic agents) may be beneficial; and (5) the indications for transfusion of autologous RBCs may be more liberal than for allogenic RBCs because of the lower (but still significant) risks associated with the former.

Platelets

More than 7,000,000 units of platelets are transfused each year in the United States. [1] Platelets are used in the perioperative and peripartum setting when a quantitative or qualitative platelet defect is the suspected cause of bleeding. The scientific rationale rests on two principal arguments: (1) surgical patients experience adverse outcomes as a result of thrombocytopenia and/or platelet dysfunction, and (2) platelet transfusion can correct platelet defects and thereby reduce, minimize, or prevent bleeding. Evidence to support these arguments follows.

Adverse Effects of Thrombocytopenia and Platelet Dysfunction

Patients with thrombocytopenia or platelet dysfunction may experience morbidity and mortality from severe surgical hemorrhage. The platelet count at which surgical and obstetric patients are likely to experience increased bleeding is unknown. In nonsurgical patients, spontaneous bleeding is uncommon with platelet counts greater than 20 × 109/1, [96] and some studies suggest low complication rates in surgical patients with thrombocytopenia. [97] Performance of paracentesis and thoracentesis was not associated with increased bleeding in patients with platelet counts of 50-99 × 109/1. [98]

Coexisting clinical conditions influence the value of platelet counts in predicting the occurrence of bleeding in surgical and obstetric patients, but the probability of clinically significant thrombocytopenia increases in proportion to the number of units of blood transfused. [99] [100] [101] [102] In a study of 39 massively transfused patients, platelet counts less than 50 × 109/1 were found in 75% of patients who received 20 or more units of RBCs and in no patients who received less than 20 units. [103] Consumption of platelets, as well as simple dilution, can lead to microvascular bleeding (*e.g.,* diffuse bleeding from wound edges, mucous membranes, insertion sites of vascular cannulae). [102]

Gestational thrombocytopenia is usually a benign phenomenon during pregnancy. [104] There is little evidence of bleeding complications from anesthetic procedures (*e.g.,* epidural placement) performed in pregnant women with thrombocytopenia. [105] Because hemostasis after placental separation is largely mechanical, thrombocytopenia has virtually no effect on the incidence of postpartum uterine bleeding. [106] Mild thrombocytopenia is detected in approximately 15% of women with preeclampsia. [107] With the HELLP (hemolysis, elevated liver enzymes, and low platelet count) syndrome associated with preeclampsia, the thrombocytopenia is more severe, but spontaneous resolution usually occurs by the 4th postpartum day. [108] [109]

In some circumstances, platelet dysfunction (*e.g.,* secondary to preoperative aspirin therapy) may be more important than platelet count in explaining a bleeding disorder. Although preoperative platelet aggregation studies may be helpful in predicting bleeding in some surgical patients, [110] the bleeding time is a poor predictor. [111] [112] [113] Neither test is useful in the operating room. The bleeding time, which assesses both platelet function and the vascular component of hemostasis, lacks specificity, is affected by technique and body temperature, and is subject to individual interpretation.

Effectiveness of Platelet Transfusion

It is well established that platelet transfusion can increase platelet counts. The magnitude of effect is variable and is influenced by the release of stored platelets from the spleen and peripheral platelet destruction. Transfusion of one platelet concentrate will increase the platelet count by approximately 5-10 × 109/1 in the average adult. The usual therapeutic dose is one platelet concentrate per 10 kg body weight. Singledonor platelets obtained by apheresis are the equivalent of approximately six platelet concentrates. Patients repeatedly transfused over a prolonged period may become alloimmunized and refractory to platelet transfusion. In such patients, human leukocyte antigenmatched or crossmatched platelets may be required. [114]

There is indirect evidence from nonsurgical settings regarding the effectiveness of platelets in controlling bleeding. Studies of leukemic patients with platelet counts of 30 × 109/1 or less have suggested that the incidence of spontaneous bleeding can be decreased by platelet transfusions. [115] [116] However, similar studies in surgical patients are lacking. Controlled trials of prophylactic platelet transfusion have not demonstrated benefit for patients undergoing cardiopulmonary bypass [117] or massive transfusion. [101]

Strength of Evidence: Category II-2 and II-3 (Controlled and Uncontrolled Observational Studies)

Expert Opinion.

Recommendations of Other Groups. In 1987, the National Institutes of Health Consensus Conference on

Platelet Transfusion Therapy recommended prophylactic platelet transfusion for patients with platelet counts less than 10-20 × 109/1, noting that patients with platelet counts above 50 × 109/1 were unlikely to benefit. It added that platelet transfusions at higher platelet counts may be indicated for patients with systemic bleeding or those at increased risk of bleeding because of coagulation defects, sepsis, or platelet dysfunction. [3] In 1994, the CAP recommended platelet transfusion in patients with decreased platelet production and platelet counts below 5 × 109/1. The CAP also recommended considering prophylactic platelet transfusions in patients with platelet counts between 5 × 109/1 and 30 × 109/1. For major surgery with life-threatening bleeding, they concluded that transfusions may be indicated at higher platelet counts to maintain a concentration greater than 50 × 109/1. The CAP recommended transfusing patients with enhanced platelet destruction and platelet counts below 50 × 109/1 in the presence of microvascular bleeding. [8] It indicated that some experts recommend platelet transfusion after cardiopulmonary bypass in patients with normal coagulation values and platelet counts below 100 × 109/1 I when major unexplained bleeding occurs. Similar guidelines may be appropriate for patients undergoing neurosurgical procedures, in part because of concerns about local tissue damage from extravasation. The ACOG recommends platelet transfusion in certain patients with hereditary or acquired thrombocytopenia. [5] A 1992 survey of 630 hospitals caring for hematology and oncology patients reported that prophylactic platelets transfusions usually were ordered for patients with platelet counts of 20 × 109/1 or less; for patients undergoing minor invasive procedures (*e.g.,* biopsy, central line placement, lumbar puncture), the most commonly cited criteria was 50 × 109/1 or less. [18]

Expert Opinion of Task Force. The task force believes that the need for platelet transfusion is dependent on multiple risk factors and not a single laboratory value (*e.g.,* platelet count, bleeding time). The risk in surgical and obstetric patients is defined by the type and extent of surgery, the ability to control bleeding, the consequences of uncontrolled bleeding, the actual and anticipated rate of bleeding, and the presence of factors that adversely affect platelet function (*e.g.,* extracorporeal circulation, renal failure, medications).

There is inadequate scientific evidence to determine the platelet count below which the risk of surgical bleeding is increased. Some recommendations of other groups (*e.g.,* CAP) regarding safe platelet counts are based on evidence that may not be applicable to all surgical patients. In the absence of evidence, the opinion of the task force is that platelet transfusion is justified in bleeding patients at higher platelet counts than recommended for nonbleeding patients because of the increased risk of complications due to bleeding in the surgical patient. The task force believes that intraoperative platelet counts are beneficial in bleeding patients who are massively transfused. Under normal circumstances, platelet counts should be obtained to determine the need for platelet transfusion. In unusual situations, massively transfused patients with microvascular bleeding suspected to be secondary to platelet deficiency may benefit from empirical platelet therapy.

Recommendations. The task force bases its recommendations on available category II-2 and II-3 evidence and expert opinion. The task force concludes that (1) prophylactic platelet transfusion is ineffective and rarely indicated when thrombocytopenia is due to increased platelet destruction (*e.g.,* idiopathic thrombocytopenic purpura); (2) prophylactic platelet transfusion is rarely indicated in surgical patients with thrombocytopenia due to decreased platelet production when the platelet count is greater than 100 × 109/1 and is usually indicated when the count is below 50 × 109/1. The determination of whether patients with intermediate platelet counts (50-100 × 109/1) require therapy should be based on the risk of bleeding; (3) surgical and obstetric patients with microvascular bleeding usually require platelet transfusion if the platelet count is less than 50 × 109/1 and rarely require therapy if it is greater than 100 × 109/1. With intermediate platelet counts (50-100 × 109/1), the determination should be based on the patient's risk for more significant bleeding; (4) vaginal deliveries or operative procedures ordinarily associated with insignificant blood loss may be undertaken in patients with platelet counts less than 50 × 109/1; and (5) platelet transfusion may be indicated despite an apparently adequate platelet count if there is known platelet dysfunction and microvascular bleeding.

Fresh-frozen Plasma

Approximately 2,000,000 units of FFP are transfused each year in the United States. [1] A significant portion of FFP is transfused inappropriately. [119] [120] The scientific rationale for administering FFP rests on the assumptions that (1) patients are at risk of adverse effects from inadequate coagulation factors, and (2) FFP transfusions

can decrease those risks. Evidence to support these assumptions is reviewed below.

Adverse Effects of Inadequate Plasma Coagulation Factors

Evidence that coagulation factors can be depleted sufficiently to produce perioperative bleeding due to dilutional coagulopathy is limited. Blood usually coagulates appropriately when coagulation factor concentrations are at least 20-30% of normal and when fibrinogen levels are greater than 75 mg/dL. [101] [102] [121] Replacement of an entire blood volume leaves the patient with approximately one-third of the original concentration of coagulation factors. [122] [123] Although laboratory values such as prothrombin time (PT) and partial thromboplastin time (PTT) may be abnormal, clinical coagulopathy from dilution does not usually occur until replacement exceeds one blood volume or when the PT and PTT exceed 1.5-1.8 times control values. [99] [100] [101] [102] [121] [124] [125] [126] [127] In a study of 39 massively transfused patients, Leslie and Toy reported PT values greater than 1.5 times normal in all patients who received 12 or more units of RBCs and in 36% of patients who received less than 12 units. [103] In a series of 12 patients who received RBCs for massive blood loss, Murray *et al.* reported that PT and PTT were increased in nine patients before replacement of one blood volume but that there was no clinical evidence of abnormal bleeding. Abnormal bleeding occurred primarily in patients with PT or PTT values greater than 1.5 times normal. [121] In a subsequent study of 32 patients who lost more than 50% of their blood volume during elective spinal surgery, Murray *et al.* found once again that patients with PT or PTT values greater than 1.5 times normal were more likely to have evidence of abnormal hemostasis during surgery. Abnormal PT or PTT, which occurred in 30 of the 32 patients, was not predictive of intraoperative bleeding due to inadequate hemostasis, which occurred in only 17 patients. [127]

Shock, independent of blood loss, may be associated with a consumptive coagulopathy, leading to microvascular bleeding. A study of 36 massively transfused patients found that approximately 150 min of shock was required before significant prolongation of PTT or decreases in factor V activity were noted. [128] A retrospective review of 64 massively transfused patients found that prolongation of PTT during the first 3-4 hcorrelated with the volume of electrolyte solution administered. Thereafter, the prolongation of PTT corresponded with the duration of the preceding hypotension. [129] A retrospective study of 44 trauma patients found that 33% of those with blunt trauma and brain injuries and 55% of those with penetrating trauma and no brain injuries had a PT greater than 18 s and a PTT greater than 55 s on arrival in the emergency department, after having received only electrolyte solution as prehospital therapy. [130]

In the preoperative patient with no history of bleeding, retrospective studies show that abnormal PT and PTT are poor predictors of surgical bleeding. [131] [132] Friedman and Sussman reported no cases of significant bleeding in 71 invasive procedures performed on patients with chronic liver disease and a PT greater than 15 s. [133] McVay and Toy reported that paracentesis and thoracentesis were not associated with increased bleeding in patients with a PT or PTT of up to 2 times control values, [98] Ewe found no association between clotting indexes and bleeding in 200 patients undergoing percutaneous liver biopsy, [134] and Foster *et al.* reported no complications from coagulopathies in 259 central venous catheterizations. [135] However, outcomes from these noninvasive procedures may not be relevant to the surgical setting.

Prolongation of the PT and/or PTT rarely is seen in association with preeclampsia. However, evidence of increased fibrinolysis without clinically significant hypofibrinogenemia is found in approximately one-third of patients when a D-dimer assay is used. [136] ; these abnormalities generally do not require treatment.

Effectiveness of Fresh-frozen Plasma Transfusions

Few Studies have been performed to determine whether perioperative administration of FFP improves clinical outcome. Although Miller *et al.* reported correction of PT and PTT with FFP administration in patients massively transfused with whole blood, no change in bleeding occurred until thrombocytopenia was corrected. [124] Spector *et al.* reported that 600-1,800 ml of FFP was required to reduce the PT to within 3 s of control values in patients with liver disease and that the responses were generally transient (a finding possibly related to hepatic dysfunction and not to normal surgical conditions). [137] A retrospective review of 100 sequential patients having coronary artery bypass surgery and given either albumin or an average of six units of FFP did not demonstrate any differences in blood loss or transfusion requirements. [138] In 17 patients with abnormal intraoperative bleeding due to dilutional coagulopathy, Murray *et al.* reported that hemostasis improved after FFP administration in 14 patients.

Coagulation studies in this group were comparable after FFP transfusion to those of massively transfused patients undergoing the same procedure with no evidence of abnormal hemostasis. [127]

Strength of Evidence: Category II-2 and II-3 (Controlled and Uncontrolled Observational Studies)

Expert Opinion.

Recommendations of Other Groups. In 1985, the National Institutes of Health Consensus Conference on Fresh-Frozen Plasma concluded that FFP is indicated for the following conditions that may occur in the perioperative or peripartum setting: certain coagulation factor deficiencies, selected cases of massive transfusion, and multiple coagulation defects (*e.g.,* liver disease). [2] In 1994, the CAP recommended FFP transfusions for the following indications: massive blood transfusion (more than one blood volume) with active bleeding, urgent reversal of warfarin therapy, and a history or clinical course suggestive of an inherited or acquired coagulopathy (with active bleeding or before an operative procedure). The CAP indicated that the use of FFP as a volume expander or for wound healing was contraindicated. [8] Similar guidelines for FFP transfusion have been issued by the ACOG [5] and the British Committee for Standards in Hematology; the Committee noted that at least four units of FFP usually will promote coagulation in adults. [139]

Expert Opinion of Task Force. The task force believes that few clinical circumstances in the perioperative or peripartum setting result in coagulopathies that require replacement of coagulation factors with FFP. The special clinical circumstances that might warrant FFP in the nonbleeding patient include the urgent reversal of warfarin therapy and the treatment of known coagulation factor deficiencies for which specific factor concentrates are unavailable.

In the patient with microvascular bleeding, there is adequate scientific evidence to suggest that coagulation studies (PT/PTT) obtained in the operating room are useful in detecting a coagulopathy that may respond to FFP transfusion. Although massive blood replacement can produce prolongation of PT and/or PTT, the task force believes that a true dilutional coagulopathy does not ordinarily occur until more than 100% of the patient's blood volume has been replaced. The task force believes that FFP is beneficial in patients with microvascular bleeding or hemorrhage who are massively transfused if the PT/PTT values exceed 1.5 times the laboratory's normal values. If PT and PTT cannot be obtained in a timely fashion, the task force believes that massively transfused patients with microvascular bleeding that is believed to be secondary to coagulation factor deficiency may benefit from empirical FFP therapy.

Recommendations. The task force bases its recommendations on available category II-2 and II-3 evidence and expert opinion. The task force recommends the administration of FFP with the following guidelines: (1) for urgent reversal of warfarin therapy; (2) for correction of known coagulation factor deficiencies for which specific concentrates are unavailable; (3) for correction of microvascular bleeding in the presence of elevated (>1.5 times normal) PT or PTT; (4) for correction of microvascular bleeding secondary to coagulation factor deficiency in patients transfused with more than one blood volume and when PT and PTT cannot be obtained in a timely fashion; (5) FFP should be given in does calculated to achieve a minimum of 30% of plasma factor concentration (usually achieved with administration of 10-15 m1/kg of FFP), except for urgent reversal of warfarin anticoagulation, for which 5-8 m1/kg of FFP usually will suffice. Four to five platelet concentrates, one unit of single-donor apheresis platelets, or one unit of whole blood provide a quantity of coagulation factors similar to that contained in one unit of FFP (except for decreased, but still hemostatic, concentrations of factors V and VIII in whole blood); and (6) FFP is contraindicated for augmentation of plasma volume or albumin concentration.

Cryoprecipitate

Almost 1,000,000 units of cryoprecipitate are transfused each year in the United States. [1] Cryoprecipitate, which contains factor VIII, fibrinogen, fibronectin, von Willebrand's factor, and factor XIII, is used for the correction of inherited and acquired coagulopathies. Its use in the operative setting is based on the assumptions that (1) patients with these coagulation factor deficiencies are at increased risk of hemorrhagic complications, and (2) replacement of coagulation factors is effective in decreasing these risks. Evidence to support these assumptions is reviewed below.

Adverse Effects of Coagulation Factor Deficiencies

There is limited evidence from observational studies that patients with certain inherited or acquired coagulopathies

---

(*e.g.,* hemophilia A, von Willebrand's disease, hypofibrinogenemia, disseminated intravascular coagulation, hepatic insufficiency) are at increased risk of perioperative or peripartum bleeding. [95] [140]

Effectiveness of Cryoprecipitate Transfusion

One unit of cryoprecipitate per 10 kg body weight raises plasma fibrinogen concentration by approximately 50 mg/dL in the absence of continued consumption or massive bleeding. No studies have been performed to determine whether perioperative or peripartum administration of cryoprecipitate improves clinical outcome. Indirect observational evidence suggests a beneficial effect for patients with factor VIII deficiency and certain subtypes of von Willebrand's disease. [141] [142] However, most patients with factor VIII deficiency are treated with factor VIII concentrates, and patients with some subtypes of von Willebrand's disease respond to administration of desmopressin acetate (DDAVP). [143] [144] [145] [146] Similarly, coagulopathy associated with uremia can be treated with cryoprecipitate, but DDAVP is usually the first-line therapy.

Severe placental abruption frequently is associated with disseminated intravascular coagulation, in which thrombocytopenia, hypofibrinogenemia, and increased fibrinolytic activity are the most consistent findings. Indirect evidence suggests that administration of cryoprecipitate in these settings increases the plasma fibrinogen concentration. The hypofibrinogenemia responds well to treatment with cryoprecipitate once delivery has been accomplished. [140] [147]

Strength of Evidence: Category II-3 and III (uncontrolled Observational and Descriptive Studies)

Expert Opinion.

Recommendations of Other Groups. In 1994, the CAP recommended cryoprecipitate transfusions in bleeding patients with hypofibrinogenemia, von Willebrand's disease, and patients with hemophilia A (When factor VIII concentrate is not available) [8] Similar recommendations have been issued by the ACOG. [5] The British Committee for Standards in Haematology recommended the administration of cryoprecipitate for massively transfused patients with microvascular bleeding when the fibrinogen level is less than 80 mg/dL. [114]

Expert Opinion of Task Force. There is little scientific evidence regarding the effectiveness of cryoprecipitate in improving clinical outcomes, and therefore, the task force believes that its perioperative and peripartum use should be limited to selected indications. Based on clinical experience, the task force believes that cryoprecipitate is likely to be effective in patients with von Willebrand's disease unresponsive to DDAVP, congenital fibrinogen deficiencies, and consumptive coagulopathies when fibrinogen levels are below 80-100 mg/dL.

Recommendations. The task force bases its recommendations on available category II-3 evidence and expert opinion. The task force recommends considering the administration of cryoprecipitate for (1) prophylaxis in nonbleeding perioperative or peripartum patients with congenital fibrinogen deficiencies or von Willebrand's disease unresponsive to DDAVP (whenever possible, these decisions should be made in consultation with the patient's hematologist), (2) bleeding patients with von Willebrand's disease, and (3) correction of microvascular bleeding in massively transfused patients with fibrinogen concentrations less than 80-100 mg/dL (or when fibrinogen concentrations cannot be measured in a timely fashion).

Conclusions

Adherence to proper indications for blood component therapy is essential because of the potential adverse effects and costs of transfusion. These risks can be reduced further by other effective measures, the most important being efforts to minimize exposure to allogeneic blood through use of autologous transfusion and other blood conservation techniques, but the costeffectiveness of these practices requires further study. [148] The unnecessary complications of incompatible blood transfusions can be minimized by careful specimen, unit, and patient identification before blood sampling and transfusion and by maintaining a high index of suspicion for transfusion reactions. Most importantly, transfusion decisions should be based on sound physiologic principles and a comprehensive assessment of the patient's risk factors.

A variety of comprehensive intervention strategies and transfusion algorithms have been associated with reductions in inappropriate blood component therapy. [9] [41] [87] [149] [150] [151] [152] [153] Inappropriate RBC use has been decreased by audits, discussions with ordering physicians, ward rounds, computer-based decision-support systems, and comprehensive educational outreach programs. [47] [154] [155] [156] Studies have suggested that FFP transfusions can be reduced by programs that include chart

audits and the review of results with ordering physicians, dissemination of practice guidelines, case presentations, house staff education and review by pathologists of transfusion orders. [157] [158] [159] [160] Similar results have been achieved for platelet use. [161] [162]

All available evidence regarding the effectiveness of blood component therapy qualifies as category II-2, II-3, or III evidence. The lack of data from prospective, randomized studies with adequate sample size, control groups, clinical outcome measurements, and other features of well designed clinical effectiveness research impedes development of evidence-based clinical practice guidelines for blood component therapy. To establish a stronger scientific basis for transfusion practice, future research is essential to provide meaningful evidence regarding the indications and effectiveness of blood component therapy. As these data become available, guidelines for blood component therapy are likely to change.

APPENDIX: Practice Guidelines for Sedation and Analgesia by Non-Anesthesiologists[D]

A Report by the American Society of Anesthesiologists Task Force on Sedation and Analgesia by Non-Anesthesiologists

ANESTHESIOLOGISTS possess specific expertise in the pharmacology, physiology, and clinical management of patients receiving sedation and analgesia. For this reason, they are frequently called on to participate in the development of institutional policies and procedures for sedation and analgesia in nonoperating-room settings. To assist in this process, the American Society of Anesthesiologists developed these Guidelines for Sedation and Analgesia by Non-Anesthesiologists. Practice guidelines are systematically developed recommendations that assist practitioners in making decisions about health care. These recommendations may be adopted, modified, exceeded, or rejected according to clinical needs and constraints, and they are subject to periodic revision as warranted by the evolution of medical knowledge, technology, and practice. Practice guidelines are not intended as standards or absolute requirements, and their use cannot guarantee any specific outcome.

The practice guidelines enumerated below have been developed using systematic literature summarization techniques. Results of the literature analyses have been supplemented by the opinions of the Task Force members and a panel of more than 60 consultants, drawn from a variety of medical specialties in which sedation and analgesia are commonly provided. In those instances when the literature does not provide conclusive data, there is an explicit statement that the guidelines are based on the opinion of the consultants or the consensus of the Task Force members. A detailed description of the analytic methods is included in appendix 1.

A. Definition

"Sedation and analgesia" describes a state that allows patients to tolerate unpleasant procedures while maintaining adequate cardiorespiratory function and the ability to respond purposefully to verbal command and/or tactile stimulation. The Task Force decided that the term "sedation and analgesia" (sedation/analgesia) more accurately defines this therapeutic goal than does the commonly used but imprecise term "conscious sedation." Note that patients whose only response is reflex withdrawal from a painful stimulus are sedated to a greater degree than encompassed by "sedation/analgesia."

B. Purpose

The purpose of these guidelines is to allow clinicians to provide their patients with the benefits of sedation/analgesia while minimizing the associated risks. Sedation/analgesia provides two general types of benefit: First, sedation/analgesia allows patients to tolerate unpleasant procedures by relieving anxiety, discomfort, or pain. Second, in children and uncooperative adults, sedation/analgesia may expedite the conduct of procedures that are not particularly uncomfortable but require that the patient not move. Excessive sedation/analgesia may result in cardiac or respiratory depression that must be rapidly recognized and appropriately

Developed by the Task Force on Sedation and Analgesia by Non-Anesthesiologists: Jeffrey B. Gross, M.D. (Chair), Farmington, Connecticut; Peter L. Bailey, M.D., Salt Lake City, Utah; Robert A. Caplan, M.D., Seattle, Washington; Richard T. Connis, Ph.D. (Methodologist), Woodinville, Washington; Charles J. Cote, M.D., Chicago, Illinois; Fred G. Davis, M.D., Burlington, Massachusetts; Burton S. Epstein, M.D., Washington, D.C.; Patricia A. Kapur, M.D., Los Angeles, California; John M. Zerwas, M.D., Houston, Texas; and Gregory Zuccaro, Jr., M.D., Cleveland, Ohio.

managed to avoid the risk of hypoxic brain damage, cardiac arrest, or death. Conversely, inadequate sedation/analgesia may result in undue patient discomfort or patient injury because of lack of cooperation or adverse physiologic response to stress.

C. Focus

These guidelines have been designed to be applicable to procedures performed in a variety of settings (*e.g.,* hospitals, free-standing clinics, physicians' offices) by practitioners who are not specialists in anesthesiology. The guidelines specifically exclude the following: (1) patients who are not undergoing a diagnostic or therapeutic procedure (*e.g.,* postoperative analgesia, sedation for treatment of insomnia); (2) otherwise healthy patients receiving peripheral nerve blocks, local or topical anesthesia, and/or no more than 50% N_2O with oxygen and no other sedative or analgesic agents administered by any route; (3) situations when it is anticipated that the required sedation will eradicate the purposeful response to verbal commands or tactile stimulation (as distinct from reflex withdrawal from a painful stimulus); such patients require a greater level of care than recommended by these guidelines; and (4) perioperative management of patients undergoing general anesthesia or major conduction anesthesia (spinal or epidural/caudal blockade).

D. Application

These guidelines are intended to be general in their application and broad in scope. The appropriate choice of agents and techniques for sedation/analgesia is dependent on the experience and preference of the individual practitioner, requirements or constraints imposed by the patient or procedure, and the likelihood of producing unintended loss of consciousness. Templates are provided as examples to illustrate principles; clinicians and their institutions have ultimate responsibility for selecting patients, procedures, medications, and equipment.

Guidelines

I. Patient Evaluation

Published data suggest and consultant opinion strongly supports the contention that appropriate preprocedure evaluation of patients' histories and physical findings reduces the risk of adverse outcomes. Additionally, consultant opinion supports the contention that an appropriate history, physical examination, and laboratory evaluation leads to improved patient satisfaction.

Recommendations: Clinicians administering sedation/analgesia should be familiar with relevant aspects of the patient's medical history including: (1) abnormalities of the major organ systems, (2) previous adverse experience with sedation/analgesia, as well as regional and general anesthesia, (3) current medications and drug allergies, (4) time and nature of last oral intake, and (5) history of tobacco, alcohol, or substance use or abuse. Patients presenting for sedation/analgesia should undergo a focused physical examination including auscultation of the heart and lungs and evaluation of the airway (template 1). Preprocedure laboratory testing should be guided by the patient's underlying medical condition and the likelihood that the results will affect the management of sedation/analgesia.

Preprocedure Preparation

Patient Counseling: There is insufficient evidence in the literature to establish the benefit of providing the patient (or her/his guardian, in the case of a child or impaired adult) with preprocedure information about sedation/analgesia. However, the consultants strongly support the contention that appropriate preprocedure counseling improves patient satisfaction and reduces risks; they also support the view that costs may be reduced. The Task Force members concur that patients undergoing sedation/analgesia should be informed of the benefits, risks, and limitations associated with this therapy, as well as possible alternatives.

Preprocedure Fasting: Because sedatives and analgesics tend to impair airway reflexes in proportion to the degree of sedation/analgesia achieved, members of the Task Force support the concept of preprocedure fasting before sedation/analgesia for elective procedures. However, the literature provides insufficient data to test the hypothesis that preprocedure fasting results in a decreased incidence of adverse outcomes in patients undergoing sedation/analgesia (as distinct from patients undergoing general anesthesia).

Recommendations: Patients (or their legal guardians in the case of minors or legally incompetent adults) should be informed of and agree to the administration of sedation/analgesia before the procedure begins. Patients undergoing sedation/analgesia for elective procedures should not drink fluids or eat solid foods for a sufficient period of time to allow for gastric emptying

---

Template 1. Example of Airway Assessment Procedures for Sedation and Analgesia

Positive pressure ventilation, with or without endotracheal intubation, may be necessary if respiratory compromise develops during sedation/analgesia. This may be more difficult in patients with atypical airway anatomy. Also, some airway abnormalities may increase the likelihood of airway obstruction during spontaneous ventilation. Factors that may be associated with difficulty in airway management are:
History
Previous problems with anesthesia or sedation
Stridor, snoring, or sleep apnea
Dysmorphic facial features (e.g., Pierre-Robin syndrome, trisomy 21)
Advanced rheumatoid arthritis
Physical examination
Habitus
Significant obesity (especially involving the neck and facial structures)
Head and neck
Short neck, limited neck extension, decreased hyoid-mental distance (<3 cm in an adult), neck mass, cervical spine disease or trauma, tracheal deviation
Mouth
Small opening (<3 cm in an adult); edentulous; protruding incisors; loose or capped teeth; high arched palate; macroglossia; tonsillar hypertrophy; nonvisible uvula
Jaw
Micrognathia, retrognathia, trismus, significant malocclusion

before their procedure (template 2). In urgent, emergent, or other situations when gastric emptying is impaired, the potential for pulmonary aspiration of gastric contents must be considered in determining the timing of the intervention and the degree of sedation/analgesia.

III. Monitoring

Level of Consciousness: The response of patients to commands during procedures performed with sedation

Template 2. Example of Fasting Protocol for Sedation and Analgesia for Elective Procedures

Gastric emptying may be influenced by many factors, including anxiety, pain, abnormal autonomicfunction (e.g., diabetes), pregnancy, and mechanical obstruction. Therefore, the suggestions listeddo not guarantee that complete gastric emptying has occurred. Unless contraindicated, pediatricpatients should be offered clear liquids until 2-3 h before sedation to minimize the risk ofdehydration.

	Solids and Nonclear Liquids *	Clear Liquids
Adults	6-8 h or none after midnight	2-3 h
Children older than 36 months	6-8 h	2-3 h
Children aged 6-36 months	6 h	2-3 h
Children younger than 6 months	4-6 h	2 h

* This includes milk, formula, and breast milk (high fat content maydelay gastric emptying).

There are no data to establish whether a 6-8 hfast is equivalent to an overnight fast before sedation/analgesia.

/analgesia serves as a guide to their level of consciousness. Spoken responses also provide an indication that the patients are breathing. Patients whose only response is reflex withdrawal from painful stimuli are likely to be deeply sedated, approaching a state of general anesthesia, and should be treated accordingly. The consultants strongly support the contention that monitoring level of consciousness reduces risks and support the concept that overall costs may be reduced. The members of the Task Force believe that many of the complications associated with sedation/analgesia can be avoided if adverse drug responses are detected and treated in a timely manner (*i.e.,* before the development of cardiovascular decompensation or cerebral hypoxia); this may pose a special risk to patients given sedatives/analgesics in unmonitored settings in anticipation of a subsequent procedure.

Pulmonary Ventilation: It is the opinion of the Task Force that a primary cause of morbidity associated with sedation/analgesia is drug-induced respiratory depression. The literature suggests and consultant opinion strongly supports the observation that monitoring of ventilatory function reduces the risk of adverse outcomes associated with sedation/analgesia. Ventilatory function usually can be effectively monitored by observation of spontaneous respiratory activity or auscultation of breath sounds. In circumstances where patients are physically separated from the caregiver, the consultants support and the Task Force members concur

that automated apnea monitoring (by detection of exhaled carbon dioxide or other means) may decrease risks; the consultants suggest that such monitoring will not reduce overall costs. The Task Force cautions practitioners that impedance plethysmography may fail to detect airway obstruction.

Oxygenation: Published data suggest and the consultants strongly support the view that early detection of hypoxemia through the use of oximetry during sedation/analgesia decreases the likelihood of adverse outcomes, such as cardiac arrest and death. The literature suggests, the consultants strongly support, and Task Force members agree that hypoxemia during sedation and analgesia is more likely to be detected by oximetry than by clinical assessment alone. The Task Force emphasizes that oximetry is not a substitute for monitoring ventilatory function.

Hemodynamics: Although there is insufficient published data to reach a conclusion, it is the opinion of the Task Force that sedative and analgesic agents may blunt the appropriate autonomic compensation for hypovolemia and procedure-related stresses. Early detection of changes in patients' heart rate and blood pressure may enable practitioners to detect problems and intervene in a timely fashion, reducing the risk of cardiovascular collapse. The consultants support the concept that regular monitoring of vital signs reduces risks and suggest that it decreases costs. Although the literature provides no guidance, the consultants suggest the use of continuous electrocardiographic monitoring in patients with hypertension and strongly support its use in patients with significant cardiovascular disease or dysrhythmias; the consultants suggest that electrocardiographic monitoring is not required in patients without cardiovascular disease.

Recommendations: Monitoring of patient response to verbal commands should be routine, except in patients who are unable to respond appropriately (*e.g.,* young children, mentally impaired or uncooperative patients) or during procedures in which facial movement could be detrimental. During procedures in which a verbal response is not possible (*e.g.,* oral surgery, upper endoscopy), the ability to give a "thumbs up" or other indication of consciousness in response to verbal or tactile (light tap) stimulation suggests that the patient will be able to control his airway and take deep breaths if necessary. Note that a response limited to reflex withdrawal from a painful stimulus represents a greater degree of sedation/analgesia than addressed by this document.

Ventilatory function should be continually monitored by observation and/or auscultation. When ventilation cannot be directly observed, exhaled carbon dioxide detection is a useful adjunct to these modalities. All patients undergoing sedation/analgesia should be monitored by pulse oximetry with appropriate alarms. If available, the variable pitch "beep," which gives a continuous audible indication of the oxygen saturation reading, may be helpful. When possible, blood pressure should be determined before sedation/analgesia is initiated. Once sedation/analgesia is established, blood pressure should be measured at regular intervals during the procedure, as well as during the recovery period. Electrocardiographic monitoring should be used in patients with significant cardiovascular disease as well as during procedures in which dysrhythmias are anticipated.

/das/book/view/29494766/875/1043.html

IV. Recording of Monitored Parameters

Both the literature and consultant opinion suggest that contemporaneous recording of patients' level of consciousness, respiratory function, and hemodynamics reduces the risk of adverse outcomes.Although consultant opinion suggests that recording of this information may not improve patient comfort or satisfaction, the consultants suggest that it may reduce costs resulting from adverse events. The consultants strongly support recording of vital signs and respiratory variables before initiating sedation/analgesia, after administration of sedative/analgesic medications, at regular intervals during the procedure, on initiation of recovery, and immediately before discharge. It is the opinion of the Task Force that contemporaneous recording (either automatic or manual) of patient data provides information that could prove critical in determining the cause of any adverse events that might occur. Additionally, manual recording ensures that an individual caring for the patient is aware of changes in patient status in a timely fashion.

Recommendations: Patients' ventilatory and oxygenation status and hemodynamic variables should be recorded at a frequency to be determined by the type and amount of medication administered as well as the length of the procedure and the general condition of the patient. At a minimum, this should be: (1) before the beginning of the procedure, (2) after administration of sedative/analgesic agents, (3) on completion of the procedure, (4) during initial recovery, and (5) at the time of discharge. If recording is performed automatically,

device alarms should be set to alert the care team to critical changes in patient status.

V. Availability of a Staff Person Dedicated Solely to Patient Monitoring and Safety

Although there are insufficient data in the literature to provide guidance on this issue, the Task Force recognizes that it is difficult for the individual performing a procedure to be fully cognizant of the patient's condition during sedation/analgesia. The consultants support the contention that the availability of an individual other than the person performing the procedure to monitor the patient's status improves patient comfort and satisfaction; they also strongly support the view that risks are reduced. The consultants support the observation that this would not decrease overall costs. It is the consensus of the Task Force members that the individual monitoring the patient may assist the practitioner with interruptible ancillary tasks of short duration once the patient's level of sedation/analgesia and vital signs have stabilized, provided that adequate monitoring is maintained.

Recommendations: A designated individual, other than the practitioner performing the procedure, should be present to monitor the patient throughout procedures performed with sedation/analgesia. This individual may assist with minor, interruptible tasks.

VI. Training of Personnel

Although there is insufficient literature to determine the effectiveness of training on patient outcomes, the consultants strongly support the observation that providing appropriate training in clinical pharmacology for individuals administering sedative/analgesic medications reduces the risk of adverse outcomes; they also support the views that patient comfort is improved and overall costs are reduced. Specific concerns include: (1) potentiation of sedative-induced respiratory depression by concomitantly administered opioids; (2) inadequate time intervals between doses of sedative or analgesic agents, resulting in a cumulative overdose; and (3) inadequate familiarity with the role of pharmacologic antagonists for sedative and analgesic agents.

Because the primary complications of sedation/analgesia are related to respiratory or cardiovascular depression, it is the consensus of the Task Force that the individual responsible for monitoring the patient should be trained in the recognition of complications associated with sedation/analgesia. In addition, at least one qualified individual, capable of establishing a patent airway and maintaining ventilation and oxygenation, should be present during the procedure.

Recommendations: Individuals responsible for patients receiving sedation/analgesia should understand the pharmacology of the agents that are administered, as well as the role of pharmacologic antagonists for opioids and benzodiazepines. Individuals monitoring patients receiving sedation/analgesia should be able to recognize the associated complications. At least one individual capable of establishing a patent airway and positive pressure ventilation, as well as a means for summoning additional assistance, should be present whenever sedation/analgesia is administered. It is recommended that an individual with advanced life-support skills be immediately available.

VII. Availability of Emergency Equipment

The literature suggests and the consultants strongly support the view that the ready availability of appropriately sized emergency equipment reduces the risk of sedation and analgesia. The consultants also support the contention that overall costs, including those associated with adverse outcomes, may be reduced. The literature does not address the need for cardiac defibrillators during sedation/analgesia. The consultants strongly support the availability of a defibrillator whenever sedation/analgesia is administered.

Recommendations: Pharmacologic antagonists as well as appropriately sized equipment for establishing a patent airway and providing positive pressure ventilation with supplemental oxygen should be present whenever sedation/analgesia is administered. Advanced airway equipment and resuscitation medications should be immediately available (template 3). A defibrillator should be immediately available when sedation/analgesia is administered to patients with significant cardiovascular disease.

VIII. Use of Supplemental Oxygen

The literature supports the use of supplemental oxygen during sedation/analgesia: There is a decreased incidence and severity of hypoxemia among sedation/analgesia patients given oxygen as compared to those breathing room air. However, it must be appreciated that, by delaying the onset of hypoxemia, supplemental oxygen will delay the detection of apnea by pulse oximetry, emphasizing the importance of monitoring pulmonary ventilation by other means (see above). Consultant opinion supports the view that supplemental oxygen decreases patient

Template 3. Example of Emergency Equipment for Sedation and Analgesia

Appropriate emergency equipment should be available whenever sedative or analgesic drugscapable of causing cardiorespiratory depression are administered. The table below should be used as a guide, which should be modified depending on the individual practice circumstances. Items inbrackets are recommended when infants or children are sedated.

- Intravenous equipment
  - Gloves
  - Tourniquets
  - Alcohol wipes
  - Sterile gauze pads
  - Intravenous catheters [24- or 22-G]
  - Intravenous tubing [pediatric "microdrip" (60 drops/ml)]
  - Intravenous fluid
  - Three-way stopcocks
  - Assorted needles for drug aspiration, intramuscular injection [intraosseous bone marrow needle]
  - Appropriately sized syringes
  - Tape
- Basic airway management equipment
  - Source of compressed oxygen (tank with regulator or pipeline supply with flowmeter)
  - Source of suction
  - Suction catheters [pediatric suction catheters]
  - Yankauer-type suction
  - Face masks [infant/child]
  - Self-inflating breathing bag-valve set [pediatric]
  - Oral and nasal airways [infant/child-sized airways]
  - Lubricant
- Advanced airway management equipment (for practitioners with intubation skills)
  - Laryngoscope handles (tested)
  - Laryngoscope blades [pediatric]
  - Endotracheal tubes
    - Cuffed; 6.0, 7.0, or 8.0 mm ID [Uncuffed; 2.5, 3.0, 3.5, 4.0, 4.5, 5.0, 5.5, or 6.0 mm ID]
  - Stylet (appropriately sized for endotracheal tubes)
- Pharmacologic antagonists
  - Naloxone
  - Flumazenil
- Emergency medications
  - Epinephrine
  - Ephedrine
  - Atropine
  - Lidocaine
  - Glucose, 50% [10% or 25%]
  - Diphenhydramine
  - Hydrocortisone, methylprednisolone, or dexamethasone
  - Diazepam or midazolam
  - Ammonia pirits

risk, while suggesting that routine use of supplemental oxygen may increase costs.

Recommendations: Equipment to administer supplemental oxygen should be present when sedation/analgesia is administered. If hypoxemia is anticipated or develops during sedation/analgesia, supplemental oxygen should be administered.

IX. Use of Multiple Sedative/Analgesic Agents

The literature supports the observation that combinations of agents may be more effective than single agents in certain circumstances. However, the published data also suggest and consultant opinion supports the observation that combinations of sedatives and opioids may increase the likelihood of adverse outcomes,

including ventilatory depression and hypoxemia. Although not evaluated in the literature, it is the consensus of the Task Force that fixed combinations of sedative and analgesic agents may not allow the individual components of sedation/analgesia to be appropriately titrated to meet the individual requirements of the patient and procedure.

Recommendations: Combinations of sedative and analgesic agents should be administered as appropriate for the procedure being performed and the condition of the patient. Ideally, each component should be administered individually to achieve the desired effect (*e.g.,* additional analgesic medication to relieve pain, additional sedative medication to decrease awareness or anxiety). The propensity for combinations of sedative and analgesic agents to potentiate respiratory depression emphasizes the need to appropriately reduce the dose of each component as well as the need to continually monitor respiratory function.

X. Titration of Sedative/Analgesic Medications to Achieve the Desired Effect

The literature suggests that the administration of small, incremental doses of intravenous sedative/analgesic drugs until the desired level of sedation and/or analgesia is achieved is preferable to a single dose based on patient size, weight, or age. The consultants support the concept that incremental drug administration improves patient comfort and decreases costs; they strongly support the contention that the potential risks associated with excessive doses are reduced.

Recommendations: Intravenous sedative/analgesic drugs should be given in small, incremental doses that are titrated to the desired endpoints of analgesia and sedation. Sufficient time must elapse between doses to allow the effect of each dose to be assessed before subsequent drug administration. When drugs are administered by nonintravenous routes (*e.g.,* oral, rectal, intramuscular), allowance should be made for the time required for drug absorption before supplementation is considered.

XI. Intravenous Access

Published data suggest that, in cooperative patients, administration of sedative/analgesic agents by the intravenous route improves patient comfort and satisfaction. The consultants strongly support the importance of intravenous access in reducing patient risks. In situations when sedative/analgesic medications are to be administered intravenously, it is the consensus of the Task Force that maintaining intravenous access until the patient is no longer at risk for cardiorespiratory depression improves patient safety. In those situations when sedation is begun by nonintravenous routes (*e.g.,* oral, rectal, intramuscular), the need for intravenous access is not sufficiently addressed in the literature. However, initiation of intravenous access after the initial sedation takes effect allows additional sedative/analgesic and resuscitation drugs to be administered if necessary.

Recommendations: In patients receiving intravenous medications for sedation/analgesia, vascular access should be maintained throughout the procedure and until the patient is no longer at risk for cardiorespiratory depression. In patients who have received sedation/analgesia by nonintravenous routes or whose intravenous line has become dislodged or blocked, practitioners should determine the advisability of establishing or reestablishing intravenous access on a case-by-case basis. In all instances, an individual with the skills to establish intravenous access should be immediately available.

XII. Reversal Agents

Specific antagonist agents are available for the opioids (*e.g.,* naloxone) and benzodiazepines (*e.g.,* flumazenil). The literature supports the ability of naloxone to reverse opioid-induced sedation and ventilatory depression during sedation/analgesia. However, the Task Force reminds practitioners that acute reversal of opioid-induced analgesia may result in pain, hypertension, tachycardia, or pulmonary edema. The literature supports the ability of flumazenil to reverse benzodiazepine-induced sedation and its effectiveness in reversing ventilatory depression in patients who have received benzodiazepines alone. In patients who have received both benzodiazepines and opioids, published data support the ability of flumazenil to reverse sedation; however, there are insufficient data to establish the effectiveness of flumazenil in reversing ventilatory depression under these circumstances. The consultants strongly support the contention that the availability of reversal agents is associated with decreased risk. It is the consensus of the Task Force that respiratory depression should be initially treated with supplemental oxygen and, if necessary, positive pressure ventilation by mask.

Recommendations: Specific antagonists should be available whenever opioid analgesics or benzodiazepines are administered for sedation/analgesia. Naloxone and/or flumazenil may be administered to improve

Template 4. Example of Recovery and Discharge Criteria after Sedation and Analgesia

Each patient-care facility in which sedation/analgesia is administered should develop recovery and discharge criteria that are suitable for its specific patients and procedures. Some of the basic principles that might be incorporated in these criteria are enumerated.

General principles

1. All patients receiving sedation/analgesia should be monitored until appropriate discharge criteria are satisfied. The duration of monitoring must be individualized depending on the level of sedation achieved, overall condition of the patient, and nature of the intervention for which sedation/analgesia was administered.

2. The recovery area should be equipped with appropriate monitoring and resuscitation equipment.

3. A nurse or other trained individual should be in attendance until discharge criteria are fulfilled. An individual capable of establishing a patent airway and providing positive pressure ventilation should be immediately available.

4. Level of consciousness and vital signs (including frequency and depth of respiration in the absence of stimulation) should be recorded at regular intervals during recovery. The responsible practitioner should be notified if vital signs fall outside of the limits previously established for each patient.

Guidelines for discharge

1. Patients should be alert and oriented; infants and patients whose mental status was initially abnormal should have returned to their baseline. Practitioners must be aware that pediatric patients are at risk for airway obstruction should the head fall forward while the child is secured in a car seat.

2. Vital signs should be stable and within acceptable limits.

3. Sufficient time (up to 2 h) should have elapsed after the last administration of reversal agents (naloxone, flumazenil) to ensure that patients do not become resedated after reversal effects have abated.

4. Outpatients should be discharged in the presence of a responsible adult who will accompany them home and be able to report any post-procedure complications.

5. Outpatients should be provided with written instructions regarding post-procedure diet, medications, and activities and a phone number to use in case of emergency.

spontaneous ventilatory efforts in patients who have received opioids or benzodiazepines, respectively. This may be especially helpful in cases in which airway control and positive pressure ventilation are difficult. Before or concomitantly with pharmacologic reversal, patients who become hypoxemic or apneic during sedation/analgesia should: (1) be encouraged or stimulated to breathe deeply, (2) receive positive pressure ventilation if spontaneous ventilation is inadequate, and (3) receive supplemental oxygen. After pharmacologic reversal, patients should be observed long enough to ensure that cardiorespiratory depression does not recur.

XIII. Recovery Care

Patients may continue to be at significant risk for complications after their procedure is completed. Decreased procedural stimulation, prolonged drug absorption after oral or rectal administration, and postprocedure hemorrhage may contribute to cardiorespiratory depression. When sedation/analgesia is administered to outpatients, one must assume there will be no medical supervision once the patient leaves the medical facility. Although there is not sufficient literature to examine the effects of post-procedure monitoring on patient outcomes, the consultants suggest that appropriate monitoring of patients during the recovery period will improve patient comfort and strongly support the view that adverse outcomes may be reduced. It is the consensus of the Task Force that discharge criteria should be established that minimize the risk for cardiorespiratory depression after patients are released from observation by trained personnel.

Recommendations: After sedation/analgesia, patients should be observed until they are no longer at increased risk for cardiorespiratory depression. Vital signs and respiratory function should be monitored at regular intervals until patients are suitable for discharge. Discharge criteria should be designed to minimize the risk of central nervous system or cardiorespiratory depression after discharge from observation by trained personnel (template 4.)

XIV. Special Situations

The literature suggests, the consultants strongly support, and the Task Force members concur that certain classes of patients (*e.g.,* uncooperative patients; extremes of age; severe cardiac, pulmonary, hepatic, renal, or central nervous system disease; morbid obesity; sleep apnea; pregnancy; drug or alcohol abuse) are at increased risk for developing complications related to sedation/analgesia unless special precautions are taken. However, the consultants support the view

that risks may be reduced by preprocedure consultation with appropriate specialists (*e.g.,* cardiologist, pulmonologist, nephrologist, obstetrician, pediatrician, anesthesiologist) before administration of sedation/analgesia to these individuals. The consultants support the concept that patient comfort is improved and risks are reduced by consultation with an anesthesiologist before administering sedation/analgesia to patients who are likely to develop complications (*e.g.,* inadequate spontaneous ventilation, loss of airway control, cardiovascular compromise) or in whom sedation/analgesia alone is not expected to provide adequate conditions (*e.g.,* young children, uncooperative patients). However, the consultants also support the contention that such consultation will not reduce costs.

Recommendations: Whenever possible, appropriate medical specialists should be consulted before administration of sedation/analgesia to patients with significant underlying conditions. The choice of specialists depends on the nature of the underlying condition and the urgency of the situation. For significantly compromised patients (*e.g.,* severe obstructive pulmonary disease, coronary artery disease, congestive heart failure) or if it appears likely that sedation to the point of unresponsiveness or general anesthesia will be necessary to obtain adequate conditions, practitioners who are not specifically qualified to provide these modalities should consult an anesthesiologist.

Appendix 1: Methods and Analyses

The scientific assessment of these guidelines was based on the following statements or evidence linkages. These linkages represent directional hypotheses about relationships between sedation/analgesia by non-anesthesiologists and clinical outcomes.

1. A preprocedure patient evaluation (*i.e.,* history, physical examination, laboratory evaluation) improves patient satisfaction, increases clinical benefits, and reduces adverse outcomes.
2. Preprocedure preparation of the patient (*e.g.,* counseling, fasting) improves patient satisfaction, increases clinical benefits, and reduces adverse outcomes.
3. Patient monitoring (*i.e.,* level of consciousness, pulmonary ventilation, oxygenation, hemodynamics) improves patient satisfaction, increases clinical benefits, and reduces adverse outcomes.
4. Contemporaneous recording of monitored parameters (*e.g.,* level of consciousness, respiratory function, hemodynamics) improves patient satisfaction, increases clinical benefits, and reduces adverse outcomes.
5. Availability of a staff person dedicated solely to patient monitoring and safety improves patient satisfaction, increases clinical benefits, and reduces adverse outcomes.
6. Education and training of (sedation/analgesia) providers improves patient satisfaction, increases clinical benefits, and reduces adverse outcomes.
7. Availability of appropriately sized emergency and airway equipment, including trained staff, improves patient satisfaction, increases clinical benefits, and reduces adverse outcomes.
8. Use of supplemental oxygen improves patient satisfaction, increases clinical benefits, and reduces adverse outcomes.
9. Use of multiple sedative/analgesic agents improves patient satisfaction, increases clinical benefits, and reduces adverse outcomes.
10. Titration of sedative/analgesic medications to achieve the desired effect improves patient satisfaction, increases clinical benefits, and reduces adverse outcomes.
11. Administration of sedative/analgesic agents by the intravenous route improves patient satisfaction, increases clinical benefits, and reduces adverse outcomes.
12. Availability of reversal agents (*e.g.,* naloxone, flumazenil) improves patient satisfaction, increases clinical benefits, and reduces adverse outcomes.
13. Post-procedure monitoring (*e.g.,* during duration of recovery stay, postdischarge) improves patient satisfaction, increases clinical benefits, and reduces adverse outcomes.
14. Special regimens for patients with special problems (*e.g.,* uncooperative patients; extremes of age; severe cardiac, pulmonary, hepatic, renal, or central nervous system disease; morbid obesity; sleep apnea; pregnancy; drug or alcohol abuse; emergency/unprepared patients; metabolic and airway difficulties) improves patient satisfaction, increases clinical benefits, and reduces adverse outcomes.

Scientific evidence was derived from multiple sources, including aggregated research literature (with metaanalyses when appropriate), surveys, open presentations, and other consensus-oriented activities. For purposes of literature aggregation, potentially relevant clinical studies were identified *via* electronic and manual searches of the literature. The electronic search covered a 29 yr, from 1966 through 1994. Manual searches covered 48 yr, from 1947 through 1994. More than 3,000 citations were initially identified, yielding 1,315 nonoverlapping articles that addressed topics related to the 14 evidence linkages. After review of the articles, 1,046 studies did not provide direct evidence and were subsequently eliminated, yielding 269 articles containing direct linkage-related evidence. Journals represented by the 269 articles included the following disciplines: anesthesiology, 59; oncology, 5; cardiology, 12; oral/maxillofacial/dental, 71; emergency medicine, 19; gastroenterology, 50; lithotripsy, 4; obstetrics/gynecology, 5; pediatrics, 4; pharmacology, 7; pulmonary medicine, 4; radiology, 17; surgery, 8; and urology, 4.

A directional result for each study was initially determined by classifying the outcome as: (1) supporting a linkage, (2) refuting a linkage, or (3) neutral. The results were averaged to obtain a directional assessment of support for each linkage. The literature relating to linkages 8 (supplemental oxygen); 9 (multiple agents); and 12a, 12b, and 12c (naloxone to reverse opioids, flumazenil to reverse benzodiazepines, and flumazenil to reverse benzodiazepines combined with opioids, respectively) contained enough studies with well defined experimental designs and statistical information to conduct formal metaanalyses. Combined probability tests were applied when studies reported continuous data, and an odds-ratio procedure was applied to dichotomous study results.

Two combined probability tests were employed as follows: (1) the Fisher combined test, producing chi-square values based on logarithmic transformations of the reported *P* values from the independent studies, and (2) the Stouffer combined test, providing representation of the studies by weighting each of the standard normal deviates by the size of the sample. A procedure based on the Mantel-Haenszel method for combining study results using 2 × 2 tables was used when sufficient outcome frequency information was available. An acceptable significance level was set at $P < 0.01$ (one-tailed), and effect size estimates were calculated. Interobserver agreement was established through assessment of interrater reliability testing. Tests for heterogeneity of the independent samples were conducted to ensure consistency among the study results. To control for potential publishing bias, a "failsafe" N value was calculated for each combined probability test. No search for unpublished studies was conducted, and no reliability tests for locating research results were done.

Results of the combined probability tests are reported in table 1. Significance levels from the weighted Stouffer combined tests for clinical efficacy were $P < 0.001$ for four linkages: 9 (multiple agents), 12a (naloxone for opioid reversal), 12b (flumazenil for benzodiazepine reversal), and 12c (flumazenil for benzodiazepine-opioid combinations). Weighted effect size estimates ranged from r = 0.20 to r = 0.42, demonstrating small-to-moderate effect size estimates. Significance levels from the weighted Stouffer combined tests for beneficial outcomes were $P < 0.001$ for two linkages, 8 (supplemental oxygen) and 12a (naloxone). Significance levels for adverse outcomes ($P < 0.001$) were found for linkage 9 (multiple agents). Linkage 12b was not significant. Weighted effect size estimates ranged from r = 0.30 to r = 0.36. Sufficient data were available to conduct Mantel-Haenszel analyses for linkages 8 (supplemental oxygen) and 9 (multiple agents). Significant differences in the odds of hypoxemia (assessed by Spo2 levels) were found between patients breathing supplemental oxygen versus those breathing room air (odds ratio 4.68, 99% confidence limits 4.13-5.23, Z = 6.51, $P < 0.001$). The odds of an adverse outcome for multiple agents were found to be nonsignificant.

Tests for heterogeneity of statistical tests and effect size were nonsignificant in all cases ($P > 0.01$) except linkage 9 (multiple agents) and 12c (flumazenil to reverse benzodiazepines combined with opioids), indicating that the majority of pooled studies provided common estimates of significance and population effect sizes for the linkages. The two significant effect size estimates for heterogencity may be due to a variety of factors (*e.g.,* methodologic differences among the various studies), dissimilar outcome measures, or other mediating effects.

Agreement among Task Force members and two methodologists was established by interrater reliability testing. Agreement levels using a kappa statistic for two-rater agreement pairs were as follows: (1) type of study design, $k = 0.69\text{-}0.95$; (2) type of analysis, $k = 0.48\text{-}0.81$; (3) evidence linkage assignment, $k = 0.65\text{-}0.90$; and (4) literature inclusion for database, $k = 0.35\text{-}1.00$. Three-rater chance-corrected agreement values were: (1) design, $S_{a\backslash} = 0.79$, Var (S_{av}) = 0.06; (2) analysis, $S_{a\backslash} = 0.61$, Var ($S_{a\backslash}$) = 0.06; (3) linkage identification, $S_{av} = 0.74$, Var ($S_{a\backslash}$) = 0.01; and (4) literature inclusion, $S_{av} = 0.53$, Var ($S_{a\backslash}$) = 0.02. These values represent moderate to high levels of agreement.

The findings of the literature analyses were supplemented by the opinions of Task Force members and surveys of the opinions of a panel of consultants drawn from the following specialties in which sedation/analgesia are commonly administered: anesthesiology, 9; cardiology, 5; dental anesthesiology, 3; dermatology, 1; emergency medicine, 3; gastroenterology, 6; hematology/oncology; 2; intensive care, 2; oral and maxillofacial surgery, 5; pediatric dentistry, 2; pediatric oncology, 1; pharmacology, 2; plastic surgery, 1; pulmonary medicine, 5; radiology, 8; surgery, 4; and urology, 2. Consultants, in general, were highly supportive of the linkage(*i.e.,* agreed that they resulted in improvement of patient comfort/satisfaction, reduced risk of adverse outcomes, reduced overall costs, and were important issues for the guidelines to address). Responses were given on a 5-point scale, ranging from 1, strongly disagree, to 5, strongly agree; support for a linkage was defined as the fraction of consultants responding "4" or "5" to a given linkage. The percentage of consultants reporting support for each linkage is reported in table 2. Additional responses from consultants are listed as follows: (1) percentage of consultants supporting continuous electrocardiographic monitoring of different classes of patients was, for all patients, 23%; patients with hypertension, 51%; patients with cardiovascular disease, 91%; and patients with cardiac dysrhythmias, 94%; (2) percentage of consultants supporting the immediate availability of a defibrillator for different classes of patients was: for all patients, 64%; patients with hypertension, 68%; patients with cardiovascular disease, 83%; and patients with dysrhythmias, 85%; and (3) percentage of consultants supporting determination of vital signs and respiratory variables at the following times was: before sedation, 91%; immediately after sedation initiated, 79%; at regular intervals during procedure, 83%; at beginning of recovery, 89%; at intervals during recovery, 81%; and just before discharge, 87%.

The feasibility of implementing these guidelines into clinical practice was assessed by an opinion survey of those respondents from the consultant panel who were non-anesthesiologists (N = 37). Responses for feasibility of implementation of the guidelines were as follows: Seventy-five percent of these consultants indicated that implementation of the guidelines would not result in the need to purchase new equipment, supplies, or pharmaceuticals. Among the 25% who stated that purchases would be required, the median anticipated cost was $ 3,750 (mean $ 6,167; range $ 1,500-$ 20,000). Anticipated new costs included: hiring and training (*e.g.,* ACLS) personnel, the presence of a nurse during procedures, establishing intravenous access as a routine procedure, exhaled carbon dioxide monitoring equipment, defibrillator, more attention to preprocedure needs (*e.g.,* NPO status), and additional personnel time during recovery.

The non-anesthesiologist consultants were asked to indicate which, if any, of the evidence linkages would change their clinical practices if the guidelines were instituted. Percentages of consultants expecting no change associated with each linkage were as follows: preprocedure history, 81%; preparation of the patient, 76%; direct monitoring of respiration, 89%; automated ventilatory monitoring, 38%; pulse oximetry, 95%; cardiovascular monitoring, 95%; patient-dedicated staff, 89%; education and training, 95%; emergency equipment, 95%; supplemental oxygen, 95%; multiple classes of agents, 95%; titration, 92%; i.v. access, 89%; reversal agents, 92%; post-procedure monitoring, 89%; and preprocedure consultation with an anesthesiologist, 84%.

Sixty-six percent of the respondents indicated that the guidelines would have no effect on the amount of time spent on a typical case. None reported that the guidelines would reduce the amount of time spent per case. For all respondents, the mean increase in the amount of time spent on a typical case was 4.8 min. Of the 32% of respondents who reported an anticipated increase in time spent on a typical case, the mean was 14.0 min (range 5.0-30.0 min).

TABLE 1 -- Statistical Summary

Combined Test Results		*P*	df
Sedation efficacy			
Linkage 9: Multiple agents			
Fisher's combined test	chi^2 = 92.54	<0.001	38
Stouffer combined test	Zc (weighted) = 5.270	<0.001	
Effect size estimate	r (weighted) = 0.20		
Failsafe n value	Nfs 0.01 = 117.9		
Reversal efficacy			
Linkage 12a: Naloxone to reverse opioids			
Fisher's combined test	chi^2 = 50.66	<0.001	10
Stouffer combined test	Zc (weighted) = 3.894	<0.001	
Effect size estimate	r (weighted) = 0.36		
Failsafe n value	Nfs 0.01 = 24.6		
Linkage 12b: Flumazenil to reverse benzodiazepines			
Fisher's combined test	chi^2 = 220.54	<0.001	46
Stouffer combined test	Zc (weighted) = 6.450	<0.001	
Effect size estimate	r (weighted) = 0.32		
Failsafe n value	Nfs 0.01 =628.4		
Linkage 12c: Flumazenil to reverse benzodiazepines + opioids			
Fisher's combined test	chi^2 = 80.39	<0.001	12
Stouffer combined test	Zc (weighted) = 3.183	<0.001	
Effect size estimate	r (weighted) = 0.42		
Failsafe n value	Nfs 0.01 = 79.4		
Adverse outcomes			
Linkage 9: Multiple agents			
Fisher's combined test	chi^2 = 86.17	<0.001	28
Stouffer combined test	Zc (weighted) = 3.716	<0.001	
Effect size estimate	r (weighted) = 0.32		
Failsafe n value	Nfs 0.01 = 127.9		
Beneficial respiratory outcomes			
Linkage 8: Supplemental oxygen			
Fisher's combined test	chi^2 = 73.95	<0.001	14
Stouffer combined test	Zc (weighted) = 7.227	<0.001	
Effect size estimate	r (weighted) = 0.30		
Failsafe n value	Nfs 0.01 = 61.3		
Linkage 12a: Naloxone to reverse opioids			
Fisher's combined test	chi^2 = 45.94	<0.001	10
Stouffer combined test	Zc (weighted) = 4.487	<0.001	

Effect size estimate	r (weighted) = 0.36		
Failsafe n value	Nfs 0.01 = 24.7		
Linkage 12b: Flumazenil to reverse benzodiazepines			
Fisher's combined test	chi^2 = 29.07	<0.001	10
Stouffer combined test	Zc (weighted) = 0.740	>0.010	NS
Effect size estimate	r (weighted) = 0.35		
Failsafe n value	Nfs 0.01 = 9.8		

Readers with special interest in the statistical analyses used in establishing these guidelines can receive further information by writing to: Jeffrey B. Gross, M.D., Department of Anesthesiology (M/C 2015), University of Connecticut School of Medicine, Farmington, Connecticut 06030-2015.

Appendix 2: Definition of Terms

In these guidelines, the following terms are used to express the strength of the evidence relating various interventions and the associated outcomes.

TABLE 2 -- Proportion of Consultants Indicating Support for Linkages (%)

Linkage	Patient Comfort/Satisfaction	Reduced Risk	Reduced Costs	Important Topic
1. Patient evaluation	57	92	63	62
2. Preprocedure preparation	92	85	63	65
3a. Level of consciousness	70	87	52	71
3b. Ventilation monitoring, observation/auscultation	45	85	43	70
3c. Automated apnea monitoring	32	74	30	72
3d. Pulse oximetry	77	96	56	81
3e. Heart rate, blood pressure	55	83	45	66
4. Contemporaneous recording of monitored parameters	23	67	38	67
5. Staff availability	58	65	31	75
6. Training of personnel	69	94	67	77
7. Availability of emergency equipment	42	96	54	63
8. Supplemental oxygen	35	50	19	67
9. Multiple agents	48	13	7	71
10. Titration	87	81	55	70
11. Intravenous access	42	85	33	67
12. Reversal agents	35	85	29	71
13. Post-procedure monitoring	67	92	52	81
14a. Special regimens	71	88	37	67
14b. Anesthesia consultation	70	74	34	68

Literature review

Insufficient data: There are insufficient published data to provide an indication of the relationship between intervention and outcome.

Suggests: There is qualitative evidence in the form of case reports or descriptive studies, but there is insufficient quantitative evidence to establish a statistical relationship between intervention and outcome.

Supports: Quantitative data indicate a significant relationship between intervention and outcome ($P < 0.01$), and qualitative data are supportive.

Consultant opinion

The consultants' questionnaire was based on a 5-point scale ranging from "1" (strongly disagree) to "5" (strongly agree), with a score of "3" being neutral.

Suggests: The number of individuals responding "4" or "5" exceeds the number responding "1" or "2".

Supports: 50% or more of the responses were "4" or "5".

Strongly supports: 50% or more of the responses were "5".

Appendix 3: Summary of Guidelines*

- Preprocedure evaluation
  - Relevant history
    - Focused physical examination (to include heart, lungs, airway)
    - Laboratory testing when indicated
  - Patient counseling
    - Risks, benefits, limitations, and alternatives
  - Preprocedure fasting
    - Elective procedures
      - Sufficient time for gastric emptying
    - Urgent or emergent situations
      - Benefits of sedation/analgesia must be weighed against the potential risk of regurgitation and aspiration of gastric contents
  - Monitoring
    - Data to be recorded at appropriate intervals before, during, and after procedure
    - Pulse oximetry
    - Response to verbal commands when practical
    - Pulmonary ventilation (observation, auscultation, other means)
    - Blood pressure and heart rate at appropriate intervals
    - Electrocardiograph for patients with significant cardiovascular disease
- Personnel
  - Designated individual, other than the practitioner performing the procedure, present to monitor the patient throughout the procedure
- Training
  - Pharmacology of sedative and analgesic agents
  - Pharmacology of available antagonists
  - Basic life support skills present
  - Advanced life support skills immediately available
- Emergency equipment
  - Suction, appropriately sized airway equipment, means of positive-pressure ventilation
  - Intravenous equipment, pharmacologic antagonists, and basic resuscitative medications
  - Supplemental oxygen
    - Oxygen delivery equipment available
    - Oxygen administered if hypoxemia occurs
- Choice of agents
  - Sedatives to decrease anxiety, promote somnolence
  - Analgesics to relieve pain
- Dose titration
  - Medications given incrementally with sufficient time between doses to assess effects
  - Appropriate does reduction if both sedatives and analgesics are used

Intravenous access

Sedatives administered ntravenously, maintain intravenous access

Sedatives administered by other routes, case-by-case decision

Recovery

Observation until patients are no longer at risk for cardiorespiratory depression

Appropriate discharge criteria

Special situations

Severe underlying medical problems, consult with appropriate specialist

Risk of severe cardiovascular or respiratory compromise or need for deep sedation/general anesthesia to obtain adequate operating conditions, consult anesthesiologist

*This is a summary of the guidelines. The body of the document should be consulted for complete details.

GUIDELINES FOR AMBULATORY SURGICAL FACILITIES
(Approved by House of Delegates on October 11, 1973 and last amended on October 12, 1988)

ASA endorses and supports the concept of Ambulatory Surgery and Anesthesia and encourages the anesthesiologist to play a role of leadership in both the hospital and freestanding setting.

I. An ambulatory surgical facility may be hospital-affiliated or freestanding. The facility is established, equipped and operated primarily for the purpose of performing outpatient surgical procedures.
II. ASA Standards, Guidelines and Policies should be adhered to in all areas except where they are not applicable to outpatient care.
III. A licensed physician, preferably an anesthesiologist, must be in attendance in the facility at all times during patient treatment, recovery and until medically discharged.
IV. The facility must be established, equipped, constructed and operated in accordance with applicable local, state and federal laws.
V. Staff shall be adequate to meet patient and facility needs, and consist of:
    A. Professional Staff
        1. Physicians and other practitioners who are duly licensed and qualified.
        2. Nurses who are duly licensed and qualified.
    B. Administration Staff
    C. Housekeeping and Maintenance Staff
VI. Physicians providing medical care in the facility should be organized into a Medical Staff which assumes responsibility for credentials review, delineation of privileges, quality assurance and peer review.
VII. Personnel and equipment shall be on hand to manage emergencies. The facility must have an established policy and procedure concerning unanticipated patient transfer to an acute care hospital.
VIII. Minimal patient care shall include:
    A. Preoperative instructions and preparation.
    B. An appropriate history and physical exam by a physician prior to anesthesia and surgery.
    C. Preoperative studies as medically indicated.
    D. Anesthesia shall be administered by anesthesiologists, other qualified physicians or medically directed nonphysician anesthetists.
    E. Discharge of the patient is a physician responsibility.
    F. Patients who receive other than unsupplemented local anesthesia must be discharged to the company of a responsible adult.
    G. Written postoperative and follow-up care instructions.
    H. Accurate, confidential and current medical records.

APPENDIX: Practice Guidelines for Acute Pain Management in the Perioperative Setting

A Report by the American Society of Anesthesiologists Task Force on Pain Management, Acute Pain Section

Introduction

Developed by the Task Force on Pain Management, Acute Pain Section: L. Brain Ready, M.D. (Chair), Seattle, Washington; Michael Ashburn, M.D., Salt Lake City, Utah; Robert A. Caplan, M.D., Seattle, Washington; Daniel B. Carr, M.D., Boston, Massachusetts; Richard T. Connis, Ph.D., Woodinville, Washington; Cheryl L. Dixon, M.D., Jacksonville, Florida; Lex Hubbard, M.D., Shreveport, Louisiana; and Linda Jo Rice, M.D., Hartford, Connecticut.

Practice guidelines are systematically developed recommendations that assist the practitioner and patient in making decisions about health care. These recommendations may be adopted, modified, or rejected according to clinical needs and constraints.

Practice guidelines are not intended as standards or absolute requirements. The use of practice guidelines cannot guarantee any specific outcome. Practice guidelines are subject to revision from time to time, as warranted by the evolution of medical knowledge, technology, and practice. The guidelines provide basic recommendations that are supported by analysis of the current literature and by a synthesis of expert opinion, open forum commentary, and clinical feasibility data (Appendix).

A. Definition of Acute Pain in the Perioperative Setting

Acute pain in the perioperative setting has not been specifically defined in the available literature. The Task Force has not given preference to literature based on any particular system of definition or classification. For these guidelines, acute pain in the perioperative setting is defined as pain that is present in a surgical patient because of preexisting disease, the surgical procedure (*e.g.,* associated drains, chest or nasogastric tubes, complications), or a combination of disease-related and procedure-related sources.

B. Purpose of Guidelines for Acute Pain Management in the Perioperative Setting

The purpose of these guidelines is to facilitate the efficacy and safety of acute pain management in the perioperative setting and to reduce the risk of adverse outcomes. A number of adverse outcomes can result from undertreatment of postoperative pain. These include (but are not limited to) thromboembolic and pulmonary complications, extension of time spent in an intensive care unit and/or in a hospital, and reduced patient satisfaction. The principal adverse outcomes associated with management of perioperative pain include (but are not limited to) respiratory depression, brain injury, other neurologic injury, sedation, circulatory depression, nausea and/or vomiting, impairment of bowel function, pruritus, and urinary retention.

C. Focus

These guidelines focus on modalities of perioperative pain management that require a higher level of expertise and organizational structure than "as needed" intramuscular or intravenous injections of opioids and that generally provide more effective relief of pain. Examples include (but are not limited to) epidural (and intrathecal) analgesia (EA), intravenous patient-controlled analgesia (Patient-controlled analgesia), and a number of regional analgesic (RA) techniques. The guidelines are not intended as an exhaustive or detailed consideration of specific techniques or all possible approaches.

The specialty of anesthesiology brings an exceptional level of interest and expertise to the area of perioperative

---

pain management. As a consequence, the anesthesiologist is in a unique position to provide leadership in integrating pain management into other aspects of perioperative care and thus improve this area of practice. In this leadership role, the anesthesiologist can contribute further to quality of care by developing and directing institution-wide perioperative analgesia programs that include collaboration with and participation by others, when appropriate.

The role of anesthesiologists in managing acute pain extends beyond the perioperative setting. Patients with severe or concurrent medical illness such as sickle cell crisis, pancreatitis, or acute pain related to cancer or cancer treatment also benefit from aggressive pain control. Labor pain is another condition of interest to anesthesiologists. However, the complex interactions of concurrent medical therapies and physiologic alterations make it impractical to address pain management for these populations within the context of this document.

D. Application

These guidelines focus on management of acute pain in the perioperative setting for adult (including geriatric) and pediatric patients. The guidelines apply to inpatient and outpatient surgery. These guidelines are intended for use by anesthesiologists or by individuals who deliver care under the supervision of anesthesiologists.

Evidence to support each guideline was carefully sought. The search included a comprehensive review of the published literature, surveys of the opinions of a large panel of consultants with expertise in acute pain management, and the opinions of the members of the Task Force. An indication of the strength of the evidence supporting each guideline is provided.

Guidelines

1. Proactive Planning

The Task Force defines proactive planning as a process of integrating pain management into the perioperative care of patients. The literature, the panel of consultants, and the Task Force members strongly support the use of proactive planning for postoperative pain management. This support is based on recognized associations between preoperative and intraoperative analgesic techniques for the reduction of pain in the postoperative period.

Recommendations: An individualized proactive plan (*e.g.,* a predetermined strategy for postoperative analgesia) should be considered for all surgical patients. Factors that may influence the formulation of a proactive plan include (but are not limited to) type of surgery and expected severity of postoperative pain, underlying medical conditions (*e.g.,* presence of respiratory or cardiac disease, allergies), the risk-benefit ratio of the techniques available, and patients' preferences and/or previous experience with pain. Proactive planning of perioperative pain should be part of the preoperative evaluation by the anesthesiologist and, in collaboration with others (*e.g.,* nurses, surgeons, pharmacists), should be part of an institution's general plan for patient care.

Activities that are commonly encompassed by proactive planning include (but are not limited to) (1) obtaining a pain history based on patients' experiences, (2) preoperative pain therapy when appropriate and feasible, (3) intraoperative procedures (*e.g.,* wound infiltration) when appropriate and feasible, and (4) intraoperative or postincisional preparation of patients for postoperative pain management (*e.g.,* initiating EA administration before the completion of surgery). Any treatment plan requires regular assessment and refinement based on the changing responses of individual patients.

II. Education and Training of Hospital Personnel

The available literature suggests that training and experience of hospital personnel (*e.g.,* nurses, house-officers, pharmacists, psychologists) may be helpful in reduction of risk. There is strong agreement among the panel of consultants and the Task Force members that such education, training, and experience also contribute to improved quality of care.

Recommendations: Anesthesiologists offering perioperative analgesia services should provide, in collaboration with others as appropriate, ongoing education and training to ensure that hospital personnel are knowledgeable and skilled with regard to the effective and safe use of the available treatment options within the institution. The scope of education should include topics ranging from basic bedside skills for evaluation of acute pain to an understanding of sophisticated pharmacologic techniques (*e.g.,* PCA, EA, and various RA techniques) and nonpharmacologic techniques (*e.g.,* relaxation, imagery, hypnotic methods). The need for education and training is ongoing as new personnel enter an institution and as modifications in therapeutic approaches are made.

TABLE 1 -- Template 1. Information Recorded on a Bedside Pain Management Flow Sheet

1. Patient assessment at regular intervals
According to institutional protocols (*e.g* ., pain levels, respiratory evaluation, sedation) *
2. Medication administration
Intravenous PCA
Incremental dose
Lockout interval
1 or 4 h limit
Rate of continuous infusion (if applicable)
Supplemental doses for breakthrough pain
Total drug use per unit of time (*e.g* ., nursing shift end total)
Epidural analgesia
Bolus dose and time (if applicable)
Infusion rate (if applicable)
Supplemental doses for breakthrough pain

PCA = patient-controlled analgesia.

*These and other observations may be documented on a separate Vital Signs Flow Sheet.

4. Maintain iv route and access to drugs for immediate use
5. A statement to eliminate the ordering of CNS depressants by others
6. Monitoring instruction
   - For effects of opioids
   - For effects of local anesthetics
     - Bradycardia
     - Hypotension
     - Extensive sensory or motor block
7. Observations that should be communicated to the anesthesiologist (*e.g* ., systolic blood pressure less than --mmHg)
8. Instructions for treatment of side effects
   - Respiratory depression
   - Nausea and/or vomiting
   - Pruritus
   - Urinary retention
9. Instructions about concurrent use of other CNS depressants
10. Instructions for whom to contact if problems occur
11. Date, time, signature

CNS = central nervous system.

III. Education and Participation of Patients and Families in Perioperative Pain Control

The panel of consultants and the Task Force members regard the concept of education of patients and families in planning and participation in perioperative pain control as being important to their comfort and wellbeing.

Recommendations: Anesthesiologists offering perioperative analgesia services should provide, in collaboration with others as appropriate, education to patients and families regarding their roles in achieving comfort, reporting pain, and using the recommended analgesic methods to optimal benefit. Common misconceptions about the risk of side effects and addiction should be dispelled. Educational methods that facilitate optimal care of patients using PCA and other sophisticated methods might include (but are not limited to) discussion of analgesic methods at the time of the preanesthetic evaluation, brochures and video tapes to educate

TABLE 4 -- Template 4. Elements of Intravenous PCA Care by Anesthesiologists

The following items should be included during a bedside evaluation at least once a day while iv PCA is administered.

1. Note the dose of analgesic medication given in the past 24 h, and parameters of PCA settings (PCA bolus dose, lockout interval, basal infusion [if applicable], hourly or other interval limit).
2. Evaluate pain intensity both at rest and with operation-specific convalescent activity (*e.g.,* passive continuous movement for knee replacement or chest physical therapy for thoracotomy). If pain is out of proportion to the surgical procedure, the number of days elapsed postoperatively, and analgesic therapy given, consider whether another cause is present (*e.g.,* surgical complication, personality disorder, opioid tolerance) and initiate appropriate evaluation, including communication with the surgeon and/or other consultant physicians.
3. Determine whether side effects are present. Assess each side effect in the context of the type of operation and days elapsed since the operation. Decide whether the side effect is in proportion to the operation, the number of days postoperatively, and the amount of opioid and other medications given. For sedation, as an example, note other concurrent drug therapy and decide whether to undertake additional workup (*e.g.,* glucose, electrolytes, arterial blood gas, calcium, magnesium, electrocardiogram).
4. Perform a problem-oriented physical examination (*e.g.,* surgical site, presence of rales, venous thrombosis). Note the current vital signs (HR, RR, BP) and compare them with the last evaluation. If these are unstable or unsatisfactory (*e.g.,* low BP or irregular pulse), consider suitable diagnostic workup (*e.g.,* hematocrit, electrocardiogram).
5. Consider whether the patient would benefit from changing the PCA pump settings or the PCA opioid.
6. Note concurrent medications and consider whether the patient would benefit from changing the overall regimen (*e.g.,* simplifying to avert drug interactions), or employing adjuvant analgesic medication or nonpharmacologic therapies, and if so, order these.
7. Evaluate overall patient satisfaction with current care.
8. Evaluate patient's response(s) to prior adjustments of pain therapy or addition of adjuvants (*e.g.,* for nausea or anxiety).
9. Evaluate patient's suitability for making the transition to simpler alternatives (*e.g.,* oral analgesics). *
10. Discuss the assessment and plan with the patient and the patient's nurse and/or surgeon, when appropriate.
11. Document findings, impression, and plan in the hospital chart.
12. Ensure availability of personnel with appropriate expertise to deal with questions or problems at any time.

PCA = patient-controlled analgesia; HR = heart rate; RR = respiratory rate; BP = blood pressure.

*See template 7 on transition from sophisticated techniques to simpler analgesic methods.

See template 6 for an example of a preprinted daily clinical note form.

patients about therapeutic options, and discussion at the bedside during postoperative visits.

IV. Assessment and Documentation of Perioperative Pain Management

The panel of consultants and the Task Force members strongly support the concept of assessment and documentation of response to perioperative pain therapy as important to effective care. Unless the response to pain therapy is regularly evaluated, there is no basis for rational, individualized therapy.

Recommendations: Anesthesiologists offering perioperative analgesia services should use, in collaboration with others as appropriate, pain assessment instruments to facilitate the regular evaluation and documentation of pain, the effects of pain therapy, and side effects caused by the therapy (templates 1 and 6) .

V. 24-Hour Availability of Anesthesiologists

The panel of consultants and the Task Force members support the concept of 24-hour availability of anesthesiologists providing perioperative pain management as being important for maximizing patient comfort and safety. The condition of patients after surgery is frequently dynamic, and analgesic needs may change at any time.

Recommendations: Most analgesic techniques place patients at some risk for side effects or complications that require prompt medical evaluation. Anesthesiologists responsible for perioperative analgesia, in collaboration with others as appropriate, should be available at all times to consult with ward nurses, surgeons, or other involved physicians and assist in evaluating patients who are experiencing problems with any aspect of postoperative pain relief.

VI. Use of Standardized Institutional Policies and Procedures for Ordering, Administering, Discontinuing, and Transferring Responsibility for Perioperative Pain Management

The available literature suggests that institutional protocols and procedures for ordering, administering, discontinuing, and transferring responsibility for pain management are helpful in providing effective and

TABLE 5 -- Template 5. Elements of Epidural Analgesia Daily Care by Anesthesiologists

The following items should be included during a bedside evaluation at least once a day while epidural analgesia is administered.

1. Note the dose of analgesic medication given in the past 24 h, and present parameters of bolus administration or infusion pump settings (if used).
2. Evaluate pain intensity both at rest and with operation-specific convalescent activity (*e.g.,* passive continuous movement for knee replacement or chest physical therapy for thoracotomy). If pain is out of proportion to the surgical procedure, the number of days elapsed postoperatively, and analgesic therapy given, consider whether another cause is present (*e.g.,* surgical complication, personality disorder, opioid tolerance) and initiate appropriate evaluation, including communication with the surgeon and/or consultant physicians.
3. Determine whether side effects are present. Assess each side effect in the context of the type of operation and days elapsed since the operation. Decide whether the side effect is in proportion to the operation, the number of days postoperatively, and amount of opioid and other medications given. For sedation, as an example, note other concurrent drug therapy, as well as the patient's physical status, and decide whether to undertake other workup (*e.g.,* glucose, electrolytes, arterial blood gas, calcium, magnesium, electrocardiogram).
4. Perform a problem-oriented physical examination (*e.g.,* surgical site, presence of rales, venous thrombosis, sensory/motor function). Included in the physical examination should be an examination of the catheter site and brief neurologic evaluation for evidence of catheter-related complications (*e.g.,* change in position, infection, hematoma), as well as an evaluation for cardiovascular stability (especially in patients receiving local anesthetics). Note the current vital signs (HR, RR, BP) and compare them with the last evaluation. If these are unstable or unsatisfactory, consider suitable diagnostic workup (*e.g.,* hematocrit, electrocardiogram).
5. Adjust drug doses, administration interval, infusion pump settings, or change to a different analgesic, as appropriate.
6. Note concurrent medications and consider whether the patient would benefit from changing the overall regimen (*e.g.,* simplifying to avert drug interactions), or employing adjuvant analgesic medications or nonpharmacologic therapies, and if so, order these.
7. Evaluate overall patient satisfaction with current care.
8. Evaluate the patient's response(s) to prior adjustments of pain therapy or addition of adjuvants (*e.g.,* for nausea or anxiety). Make changes in pain and adjuvant therapy as indicated.
9. Evaluate the patient's suitability for making the transition to simpler alternatives (*e.g.,* oral analgesics). *
10. Discuss the assessment and plan with the patient's nurse and/or surgeon, when appropriate.
11. Document findings, impression, and plan in the hospital chart.
12. Ensure availability of personnel with appropriate expertise to deal with questions or problems at any time.

HR = heart rate; RR = respiratory rate; BP = blood pressure.

*See template 7 on transition from sophisticated techniques to simpler analgesic methods.

See template 6 for an example of a preprinted daily clinical note form.

continuous pain control. The Task Force regards the use of institutional policies and procedures as a logical part of interdisciplinary management of perioperative pain, and there is strong agreement from the panel of consultants that this approach is beneficial. The development of hospital-wide policies and procedures helps standardize clinical practice using techniques such as PCA, EA, and various RA techniques (templates 2 and 3). Standardization promotes safety and creates a framework for customization of care. Routine use of bedside documentation encourages caregivers to continually reevaluate pain treatment and respond to inadequate therapy in a timely manner. Daily evaluation, planning, and written documentation by those who are medically responsible for pain relief help establish the importance of a formal and structured approach to pain management (templates 4 - 7).

Recommendations: Anesthesiologists offering perioperative analgesia services should participate in developing, in collaboration with others as appropriate (especially nurses), standardized institutional policies and procedures for ordering, administering, discontinuing, and transferring responsibility for postoperative pain management. Policies (the foundation or "ground rules" for practice) and procedures (outlining the "how to" aspects of applying policies to patient care) should be readily available on each patient care unit. The polices and procedures also serve as ongoing educational and informational references.

VII. Use of Three Specific Techniques for Perioperative Pain Management

The literature strongly supports the efficacy and safety of three techniques used by anesthesiologists for the control of pain in the perioperative setting: (1) PCA with systemic opioids, (2) EA with opioids or opioid/local anesthetic mixtures (or intrathecal opioids), and (3) RA techniques, including (but not limited to) intercostal blocks, plexus infusions, and local anesthetic infiltration of incisions. The literature

indicates that these three techniques used by anesthesiologists have no higher incidence of side effects than less effective techniques for perioperative pain management. The panel of consultants and the Task Force members strongly support the use of PCA, EA, and RA by anesthesiologists when appropriate and feasible.

Recommendations: To meet the diverse needs of individual patients, anesthesiologists who manage perioperative pain should make available as appropriate a variety of effective therapeutic options such as PCA, EA, and RA.

VIII. A Multimodality Approach to Perioperative Pain Management

During the administration of anesthetics for surgery, the needs of many patients may best be met by taking advantage of the combined effects of a number of

TABLE 7 -- Template 7. Considerations in Making the Transition of Pain Therapy from More Sophisticated Techniques (*e.g.,* PCA, EA, RA) to Less Sophisticated Techniques (*e.g.,* oral analgesics)

1. Review the efficacy and dose requirement of the sophisticated technique.
2. Consider the pain expected following the transition: type of procedure, level of activity (including physical therapy), and other sources of discomfort (*e.g.,* nasogastric tube).
3. Review the patient's past experience with oral analgesics. What has been effective? What has caused side effects?
4. Based on the above information, use the simple technique with an analgesic drug and dose calculated to provide adequate analgesia. Adjust the dose as needed based on regular assessment.
5. Overlap therapy during the transition, *i.e.*, do not discontinue the original therapy until the replacement has reached a therapeutic effect.
6. Provide for treatment of "breakthrough" pain during use of the simpler method.
7. If there is to be a change in responsibility for prescribing an analgesic (*e.g.,* the surgeon assumes responsibility for an oral analgesic), be sure the change is clearly understood and that orders are available from the new therapist.
PCA = patient-controlled analgesia; EA = epidural analgesia; RA = regional analgesic techniques.

agents. Similarly, there is growing conviction that a multimodality approach (*i.e.,* two or more analgesic agents or techniques used in combination) to providing postoperative analgesia has advantages over the use of a single modality.

The literature supports the efficacy of two or more analgesic techniques (including nonpharmacologic methods) used in combination for the control of perioperative pain, especially when different sites and/or mechanisms of action are involved and/or when synergy of effect is achieved. In addition, the literature indicates that multimodality approaches are associated with side effects no greater than those resulting from single analgesic techniques for perioperative pain management. The panel of consultants and the Task Force members support the use of multimodality techniques when appropriate and feasible.

Recommendations: Anesthesiologists managing perioperative pain should make available as appropriate a variety of analgesic techniques and should consider their use in combination under appropriate circumstances.

IX. An Organized Interdisciplinary Approach to Perioperative Pain Management

Although dedicated individuals can improve perioperative pain control for the individual patients they treat, comprehensive programs provide optimal analgesia throughout an institution. Such programs have been advocated by national and international pain specialty societies [1] [2] and the Federal government. * The Task Force strongly believes that, based on training, knowledge, skills, interest, and historical innovation, anesthesiologists are uniquely qualified to provide leadership within their institutions in developing and managing perioperative pain management programs.

*Clinical Practice Guideline--Acute Pain Management: Operative or Medical Procedures and Trauma, Agency for Health Care Policy and Research. Co-chairs Carr DB. Jacox AK. Washington, D.C., U.S. Department of Health and Human Services, 1992. Available by calling 1-800-358-9295.

The panel of consultants and the Task Force members regard organized interdisciplinary activities (*e.g.,* anesthesiologists in collaboration with nurses, surgeons, and pharmacists) as important and optimal in providing effective, safe, and continuous perioperative pain control (template 8) . An essential feature of such an approach should be an ongoing strong working relationship between anesthesiologists and nurses.

Recommendations: Anesthesiologists who manage perioperative pain should develop (in collaboration with nurses, surgeons, pharmacists, and others) an organized, interdisciplinary approach to perioperative pain management within their institutions.

/das/book/view/29494766/875/1071.html

X. Recognition and Management of Special Features of Pediatric Perioperative Pain Management.

Pediatric patients (infants and children) present unique problems regarding perioperative pain management for reasons that include differences in the perception of care-givers regarding the need for analgesia, differences in the pharmacology of analgesic medications when used in this group, and the strong emotional components of pain in children. In the past, safe methods for providing analgesia have been underused in pediatric patients because of fear of opioid-induced respiratory depression.

The emotional component of pain is very strong in children. Absence of parents, security objects, and familiar surroundings may be perceived by the child to be as painful as the surgical incision. When clear evidence of physical pain is not seen, the tendency of health-care providers is to assume pain is not present and therefore defer treatment. In addition, young childrens' fear of injections makes intramuscular opioids or other methods, which themselves cause discomfort, less acceptable to this group than to adults. Many children will choose to suffer in silence knowing that an expression of pain will result in a dreaded injection.

Pain assessment is more difficult in children because, as they grow and develop, cognitive and emotional responses are different from adults and are constantly changing. Special instruments are available to assist young children in self-reporting of pain, and behavioral and physiologic parameters can be employed to assess preverbal children or in those who cannot self-report.

The literature strongly supports the effectiveness of a variety of techniques in providing analgesia in pediatric patients. Many of these are the same techniques used in adults, although some techniques (*e.g.,* caudal analgesia) are more commonly used in children. There is strong agreement among the panel of consultants and the Task Force members that it is important to recognize that pediatric patients represent a unique population with special features when planning and providing perioperative analgesia.

Recommendations: Anesthesiologists who treat perioperative pain in pediatric patients should be familiar with the special features of this group. Based on that knowledge, pharmacologic and nonpharmacologic strategies for perioperative analgesia appropriate for the age of the child should be offered in a manner that promotes efficacy and safety.

XI. Recognition and Management of Special Features of Geriatric Perioperative Pain Management

Elderly patients are a unique population facing surgery. They may experience physical and mental limitation and may have different attitudes than younger patients with regard to expressing pain and appropriate therapy for it. Altered physiology with aging changes the way analgesic drugs and local anesthetics are distributed and metabolized, frequently necessitating alterations in dosing. There is strong agreement from the panel of consultants and the Task Force members on the importance of recognizing the unique features of geriatric patients in planning and providing perioperative analgesia.

The literature indicates that single and multimodality techniques that have been shown to be effective in younger adult patients are also effective (often with reduced drug dose requirements) in geriatric patients without increasing side effects.

Recommendations: Anesthesiologists who treat perioperative pain in geriatric patients should be familiar with the special features of this group. In particular, dose reduction for drugs that may cause central nervous system depression should be considered.

XII. Recognition of Special Features of Perioperative Pain Management in Ambulatory Surgery Patients

The increasing trend toward ambulatory surgery poses special problems in perioperative pain management. One of the most common reasons for unanticipated hospital admission in this population is inadequate pain control. Analgesic techniques must provide safe, ade-quate

pain relief for patients who quickly leave the supervised hospital environment. Techniques such as EA and intravenous PCA, which require special nursing and monitoring, are not suitable for such patients, but others such as local anesthetic wound infiltration and oral nonsteroidal antiinflammatory drugs may be very effective.

The panel of consultants and the Task Force members strongly agree that the provision of effective analgesia to ambulatory surgery patients is important and beneficial. A limited search of this evolving literature suggests that planning of perioperative analgesia for ambulatory patients including the use of certain procedures (*e.g.,* local anesthetic wound infiltration and certain RA techniques) may improve analgesia without increasing the risk of side effects.

Recommendations: Anesthesiologists who care for ambulatory surgery patients should proactively plan therapeutic strategies appropriate for them, recognizing that they are expected to leave the surgical facility within a few hours after the completion of surgery.

The Task Force thanks those who responded to surveys on acute pain in the perioperative setting, reviewed guideline drafts, contributed oral and written testimony to the Open Forum, and participated in tests of clinical feasibility.

The development of these guidelines included methods recommended in the following publications: (1) Clinical Practice Guidelines--Directions for a New Program, Committee to Advise the Public Health Service on Clinical Practice Guidelines, Division of Health Care Services, Institute of Medicine. Edited by Field MJ, Lohr KN. Washington, D.C., National Academy Press, original document 1990, summary document 1992; and (2) Woolf SH: Manual for Clinical Practice Guideline Development. Washington, D.C., U.S. Department of Health and Human Services, Agency for Health Care Policy and Research, publication number 91-0007, March 1991.

Appendix: Assessment of Scientific Evidence and Consultant Opinion

The scientific assessment was based on the following statements or evidence linkages. These linkages represent directional hypotheses about relationships between perioperative pain management and clinical outcomes.

1. Proactive planning for perioperative pain management improves pain control and reduces adverse outcomes.
2. Education and training of hospital personnel improve pain control and reduce adverse outcomes.
3. Education and participation of patients and families improve pain control and reduce adverse outcomes.
4. Monitoring and documentation activities improve pain control and reduces adverse outcomes.
5. Availability of anesthesiologists providing perioperative pain management improves pain control and reduces adverse outcomes.
6. Standardized institutional policies and procedures for perioperative pain management improve pain control and reduce adverse outcomes.
7. Use of PCA, EA, or RA techniques improves pain control and reduces adverse outcomes.
8. Use of multimodality techniques improves pain control and reduces adverse outcomes.
9. Organizational characteristics related to perioperative pain management improve pain control and reduce adverse outcomes.
10. Pediatric perioperative pain management techniques improve pain control and reduce adverse outcomes.
11. Geriatric perioperative management techniques improve pain control and reduce adverse outcomes.
12. Ambulatory surgery acute pain management techniques improve pain control and reduce adverse outcomes.

Scientific evidence was derived from aggregated research findings, including metaanalyses, and from surveys, open forum presentations, and other consensusoriented activities. For purposes of literature aggregation, potentially relevant clinical studies were identified *via* electronic and manual searches of the literature. The search covered a 27-yr period from 1966 through 1993. More than 4,000 articles were identified initially, yielding 465 nonoverlapping articles that addressed the 12 evidence linkages. Studies that could not be analyzed statistically were reviewed and eliminated, yielding 233 articles used in the formal metaanalyses.

A directional result for each study was determined initially by classifying the outcome as (1) supporting a linkage, (2) refuting a linkage, or (3) neutral. The results were averaged to obtain a directional assessment of support for each linkage. The literature relating to linkages 1, 7 (PCA, EA, and RA as separate assessments), 8, 10, and 11 contained enough studies with well defined experimental designs and statistical information for formal metaanalysis. Combined probability tests were applied to continuous data, and an odds-ratio procedure was applied to dichotomous study results.

Two combined probability tests were employed as follows: (1) the Fisher combined test, producing chisquare values based on logarithmic transformations of the reported *P* values from the independent studies, and (2) the Stouffer combined test, providing representation of the studies by weighting each of the standard normal deviates by the sample size. A procedure based on the Mantel-Haenszel method for combining study results using 2 × 2 tables was used when sufficient outcome frequency information was available. An acceptable significance level was set at $P < 0.01$ (onetailed), and effect-size estimates were calculated. Interobserver agreement was established through assessment of interrater reliability testing. Tests for heterogeneity of the independent samples were conducted to ensure consistency among the study results. To control for potential publishing bias, a "fail-safe N" value was calculated for each combined probability test. No search for unpublished studies was conducted, and no reliability tests for locating research results were done.

Significance levels from the weighted Stouffer combined tests for pain reduction were as follows: linkage 1 ($P < 0.001$, linkage 7 (PCA $P < 0.001$), EA ($P < 0.001$), and RA ($P < 0.001$)), and linkage 8 ($P < 0.003$), linkage 10 ($P < 0.004$), and linkage 11 ($P < 0.001$). Weighted effect size estimates ranged from r = 0.14 to r = 0.35, demonstrating small-to-moderate effect size estimates. Significance levels for all beneficial/adverse outcomes were $P > 0.01$ (*i.e.,* not significant). Tests for heterogeneity/homogeneity of statistical tests and of effect size estimates were nonsignificant in all cases ($P > 0.01$), indicating that the various studies provided common estimates of the population effect sizes for the linkages. Agreement among the Task Force members and two methodologists was established by interrater reliability testing. Agreement levels using a Kappa statistic for two-rater agreement pairs were as follows: (1) type of study design, kappa = 0.61-0.65; (2) type of analysis, kappa = 0.65-0.87; (3) evidence linkage assignment, kappa = 0.60-0.74; and (4) literature inclusion for database, kappa = 0.22-0.64. Three-rater chance-corrected agreement values were: (1) design, $S_{av} = 0.62$, Var (S_{av}) = 0.16; (2) analysis, $S_{av} = 0.76$, Var (S_{av}) = 0.15; and (3) linkage, $S_{av} = 0.65$, Var (S_{av}) = 0.12. These values represent moderate to high levels of agreement.

The findings of the literature analyses were supplemented by survey of opinions from a panel of 65 consultant anesthesiologists with expertise in acute pain in the perioperative setting and from the opinions of the Task Force members. Consultants were highly supportive of the linkages (*i.e.,* agreed that they resulted in improvement in pain control, reduced adverse side effects, and were important issues for the guidelines to address). The percentage of consultants supporting each linkage based on these criteria were 1 (86%), 2 (98%), 3 (71%), 4 (78%), 5 (79%), 6 (75%), 7 (74%), 8 (60%), 9 (78%), 10 (86%), and 11 (81%). Linkage 12 was added to the guidelines after completion of the consultant survey.

The feasibility of implementing these guidelines into clinical practice was assessed using a survey of opinions from a panel of 61 consultant anesthesiologists with expertise in acute pain in the perioperative setting. Analysis of the responses indicated that these guidelines can be implemented in a large majority of institutions with minimal additional cost.

Eighty-nine percent of the consultant anesthesiologists indicated that implementation of the guidelines would not result in the need to purchase new equipment, supplies, or pharmaceuticals. Mean estimate of guideline implementation costs for all respondents was $ 3,705 (range 0 to $ 100,000). Among the 11% who stated that purchases would be required, the median anticipated cost was $ 15,000 (mean $ 32,286, range = $ 6,000-100,000). Anticipated new equipment consisted of PCA pumps, epidural pumps, and PCA/epidural disposable equipment.

The consultant anesthesiologists were asked to indicate which, if any, of the evidence linkages would change their clinical practices if the guidelines were instituted. The percent of consultants expecting no change associated with each linkage were as follows: proactive planning 82%; education and training 89%; education and participation of patients and families 80%; monitoring and documentation 77%; availability

---

of anesthesiologist 90%; institutional policies and procedures 87%; use of PCA, EA, and RA techniques 90%; use of multimodality techniques 89%; organizational characteristics 90%; pediatric techniques 95%; geriatric techniques 92%; and ambulatory surgery techniques 85%.

Sixty-four percent of the respondents indicated that the guidelines would have no effect on the amount of time spent on a typical case. None reported that the guidelines would reduce the amount of time spent per case. For all respondents, the mean increase in the amount of time spent on a typical case was 3.4 min. Of the 36% of respondents who reported an anticipated increase in time spent on a typical case, the mean was 9.7 min (range 3.0-30.0 min).

APPENDIX: Practice Guidelines for Chronic Pain Management[D]

A Report by the American Society of Anesthesiologists Task Force on Pain Management, Chronic Pain Section

PRACTICE guidelines are systematically developed recommendations that assist the practitioner and patient in making decisions about health care. These recommendations may be adopted, modified, or rejected according to clinical needs and constraints.

Practice guidelines are not intended as standards or absolute requirements. The use of practice guidelines cannot guarantee any specific outcome. Practice guidelines are subject to periodic revision as warranted by the evolution of medical knowledge, technology, and practice. The Guidelines provide basic recommendations that are supported by analysis of the current literature and by a synthesis of expert opinion, open forum commentary, and clinical feasibility data (appendix).

A. Definition of Chronic Pain

For these Guidelines, *chronic pain* is defined as persistent or episodic pain of a duration or intensity that adversely affects the function or well-being of the patient, attributable to any nonmalignant etiology. The Task Force has not given preference to literature based on any particular system of definition or classification of chronic pain.

B. Purpose of Guidelines for Chronic Pain Management

The purpose of these Guidelines is to 1) optimize pain control, recognizing that a pain-free state may not be achievable, 2) minimize adverse outcomes and costs, 3) enhance functional abilities and physical and psychological well-being, and 4) enhance the quality of life for patients with chronic pain.

C. Focus

These Guidelines focus on the knowledge base, skills, and range of interventions that are the essential elements of effective management of chronic pain and pain-related problems. The Guidelines recognize that the management of chronic pain occurs within the broader context of health care, including psychosocial function and quality of life.

The Guidelines recognize that all anesthesiologists may not have access to the same knowledge base, skills, or range of modalities. However, aspects of these Guidelines may be helpful to anesthesiologists who manage patients with chronic pain in a variety of practice settings.

The decision to implement a particular management approach should be based on a comprehensive assessment of the patient's overall health. The Guidelines recognize that accurate diagnosis and appropriate therapies used to modify the underlying causes of pain may improve analgesia and outcome. The risks and benefits of therapies designed to modify or correct the underlying cause(s) of pain is outside the scope of these Guidelines. Although headache is included in the definition of chronic pain, these Guidelines are not specifically intended for the management of headache. The literature search was not comprehensive with respect to headache, but the general principles of these Guidelines may be applied to the management of headache.

D. Application

These Guidelines are intended for use by anesthesiologists and health care personnel who deliver care under the direct supervision of anesthesiologists. The Guidelines

Developed by the Task Force on Pain Management, Chronic Pain Section: Peter R. Wilson, M.B.B.S., Ph.D. (Chair), Rochester, Minnesota; Robert A. Caplan, M.D., Seattle, Washington; Richard T. Connis, Ph.D., Woodinville, Washington; Hugh C. Gilbert, M.D., Chicago, Illinois; Eric J. Grigsby, M.D., Napa, California; J. David Haddox, D.D.S., M.D., Atlanta, Georgia; Alan M. Harvey, M.D., M.B.A., Springfield, Massachusetts; Wilhelmina C. Korevaar, M.D., Bala Cynwyd, Pennsylvania; Timothy R. Lubenow, M.D., Chicago, Illinois; and Dana L. Simon, M.D., West Des Moines, Iowa.

do not compare the relative effectiveness of different interventions. They are not intended to provide treatment algorithms for specific pain syndromes. Complementary therapies are beyond the scope of these Guidelines.

Guidelines

I. A Comprehensive History and Physical Examination of the Patient with Chronic Pain

The literature suggests that a comprehensive history and physical examination be conducted. The Task Force and panel of consultants support the conduct of a comprehensive pain-related history and physical examination.

Recommendations: General Constructs. The Task Force identifies four fundamental issues that should guide a comprehensive history and physical examination of the patient with chronic pain.

1. The patient's general medical condition and extent of concurrent medical and surgical diagnoses.
2. Knowledge of chronic pain syndromes is a necessary prerequisite for conducting a chronic pain evaluation. Chronic pain syndromes may be related to pathology or dysfunction in one or more organ systems or to psychological conditions. In addition, knowledge of other medical or surgical conditions that may present with pain and may mimic chronic pain syndromes also is necessary.
3. Knowledge of the diagnosis and management of painful crises.
4. Knowledge of the diagnosis and management of medical emergencies and complications arising from the underlying cause or treatment.

Elements. The Task Force identifies five essential features of a comprehensive evaluation and treatment plan (template 1).

Figure Template 1. Algorithm for Comprehensive Evaluation and Longitudinal Assessment of Chronic Pain.

1. History. A complete pain history includes a general medical history with emphasis on the chronology and symptomatology of the presenting complaint. The data should include information about the onset, quality, intensity, distribution, duration, course and affective components of the pain, and details about exacerbating and relieving factors. Additional symptoms (*e.g.,* motor, sensory, and autonomic changes) should be noted. Information regarding previous diagnostic tests, results of previous therapies, and current therapies should be reviewed by the anesthesiologist (template 2).
2. Physical examination. The physical examination should include an appropriate, directed neurologic and musculoskeletal evaluation, with attention to other systems as indicated. Not only the cause(s) of the pain, but also the effects of the pain, such as physical deconditioning, should be evaluated and recorded.
3. Psychosocial evaluation. The psychosocial evaluation should include information about the presence of psychological symptoms (*e.g.,* anxiety, depression, or ranger), psychiatric disorders, personality traits or states, coping mechanisms, and the meaning of the pain. Evidence of family, vocational, or legal issues and involvement of rehabilitation agencies should be noted. The expectations of the patient, significant others, employer, attorney, and other agencies (*e.g.,* Workers' compensation, Social Security Administration) also should be determined.
4. Impression and differential diagnosis. The previous findings should be used to determine the possible etiologies and effects of the pain (template 3 (Table Not Available)).
5. Treatment plan. Once a working diagnosis has been determined, a treatment plan is formulated with input from the patient, other involved professionals, and other involved persons (e.g., significant others

or qualified rehabilitation counselors). Treatment and outcome goals should be discussed with the patient.

Template 2. History Review--Sample Form

Patient:		Physician:	
Date:	Referred:	Time in:	Time out:
Chief complaint:			
History of present illness	Pain from onset to present:		
	Location	Past medical history	
	Quality	Illnesses

	Genitourinary		
	Musculoskeletal	Drug reactions	

/das/book/view/29494766/875/1081.html

II. Diagnostic Evaluation

The literature is supportive of the conduct of a diagnostic evaluation for chronic pain. The panel of consultants and Task Force members also support diagnostic evaluation for purposes of determining potential etiologies of chronic pain and for identification of pain sites for treatment. The use of diagnostic local anesthetic blockade is suggested by the literature and supported by the Task Force.

Recommendations: Anesthesiologists treating chronic pain should have a working knowledge of the utility and interpretation of diagnostic evaluations, including diagnostic neural blockade, imaging modalities, pharmacodiagnosis, electrodiagnosis, and laboratory studies. Diagnostic evaluation is an essential addition to the history and physical examination in the evaluation of patients with chronic pain. The treatment plan, contingencies, and plan for reassessment should be formulated based on these sources of clinical data.

Neural blockade with local anesthetic, including somatic and autonomic blocks, may be useful in determining the site and etiology of chronic pain. Anesthesiologists have unique skills in this area that may benefit carefully selected patients. Anesthesiologists should personally review and interpret diagnostic data when clinically indicated.

III. Counseling and Coordination of Care

There is insufficient literature to suggest that the anesthesiologist's role in counseling and coordination of care is associated with improved analgesia or other health effects. The Task Force and consultants are supportive of the effectiveness of counseling and appropriate coordination of care in improving analgesia and quality of life.

Recommendations: Anesthesiologists should provide appropriate counseling of the patient regarding the pain syndrome diagnosis, treatment options, rehabilitation, and follow-up goals. In addition, the anesthesiologist should coordinate care with other health professionals, rehabilitation and vocational agencies, and social and legal entities. Longitudinal assessments of outcome should be maintained.

IV. Periodic Monitoring and Measurement of Clinical Outcomes

There is insufficient literature to evaluate the effectiveness of periodic pain assessment in chronic pain management. Multiple times of measurements, fluctuating patient and disease status, and variable interventions over time are confounding factors that make useful analysis difficult. The Task Force and consultants support the contention that periodic monitoring of the effects of therapy and patient status will result in improved

Template 3. Elements of Medical Decision-making for Treatment of Chronic Pain*

(Not Available)

* *Adapted from the Physician's Current Procedural Terminology (CPT), American Medical Association, 1996 Edition.*

pain management and reduced adverse health effects from therapy.

Recommendations: Accurate and complete records of pain therapies should be maintained. Reports of pain made by the patient should be the primary source of pain assessment (template 4) and should be obtained at periodic intervals. Periodic monitoring may include, but is not limited to, a patient's verbal report of treatment efficacy, other pain records (*e.g.,* pain diaries), and reports of side effects associated with pain management. Analyses of aggregate outcomes are essential to continuous quality improvement of chronic pain management in the clinical setting.

V. Multidisciplinary Pain Management

For these Guidelines, multidisciplinary care includes, but is not limited to 1) contributions to patient pain care by more than one health care discipline, 2) a process or program of pain care by more than one health care discipline, or 3) a combination of 1 and 2.

The literature does not provide a standard definition for multidisciplinary care. The available literature was only sufficient to address multidisciplinary care on a programmatic basis. This literature is supportive of the efficacy of multidisciplinary programs in providing analgesia and improvement of health status (*e.g.,* functional status, quality of life). The panel of consultants and Task Force members endorse multidisciplinary chronic pain management.

The literature, Task Force, and consultants also support programs that emphasize the reduction or elimination of pain medications as a primary objective of therapy (*i.e.,* through use of physical therapy, biofeedback, behavior modification, or other psychosocial techniques).

Recommendations: Anesthesiologists offer a unique contribution to patient care in the context of multidisciplinary chronic pain management. Anesthesiologists should be involved in patient evaluation, provision and interpretation of diagnostic procedures, clinical pharmacology, provision of alternative drug delivery methods, provision of temporary or long-term neural blockade, and provision of neuromodulatory techniques.

Figure Template 4. Pain Intensity Scales.

VI. Multimodality Pain Management

For these Guidelines, *multimodal therapy* is defined as concomitant use of separate therapeutic interventions under the direction of a single practitioner to obtain additive beneficial effects or reduction of adverse effects. Examples include, but are not limited to 1) the use of neural blockade with medications, 2) rehabilitative therapies (*e.g.,* physical therapy) with neural blockade or medications, and 3) medications of different categories (template 5).The literature suggests that concomitant application of separate therapeutic interventions in chronic pain management provides effective analgesia. The literature on other health effects is equivocal. The panel of consultants and Task Force members also are supportive of the efficacy of multimodality techniques for the management of chronic pain.

Recommendations: Multiple modalities, such as the combined use of neural blockade, medications, or rehabilitative therapies should be considered when analgesia with acceptable adverse effects is no longer attained with single modalities. Ideally, each modality should be administered as appropriate to achieve the desired therapeutic effect. A multimodal approach may reduce the potential for adverse effects arising from either escalating frequency or dosage levels of a single modality.

VII. Adjuvant Analgesics: Antidepressants, Membrane Stabilizing Agents, and Nonsteroidal Antiinflammatory Drugs (NSAIDs)

The literature supports the use of antidepressants for reducing chronic pain without notable adverse effects. The literature also supports the use of antidepressants for providing overall health benefits and for improving mood. The literature supports the benefits of membrane

Template 5. Elements of Multimodality Pain Management and Therapeutic Options for Treatment

Elements
1. Comprehensive speciality pain history and physical examination.
2. Personal review of previous consultations, examinations, and diagnostic studies (e.g., radiographs, scans, laboratory data).
3. Discussion or communication with patient's other physicians and allied health care professionals (e.g., rehabilitation counselor).
4. Indicated laboratory or radiologic diagnostic testing procedures (e.g., radiograph, CT scan, MRI, three-phase bone scan, sedimentation rate, ANA).
5. Indicated diagnostic, clinical interventions, procedures, surgical consultation, psychosocial evaluation.
6. Formulation of an appropriate and specific diagnosis.
Options
Physical therapies
Active and passive range of motion
Tone and strengthening
Desensitization
Other
Medications
NSAIDs
Antidepressants
alpha-adrenergic antagonist
Membrane stabilizing drugs
Opioids
Neural blockade
Somatic, sympathetic, neuraxial
Local single injection technique
Continuous infusion-catheter techniques
Local anesthetic, opioid, steroid, other
Neuroablation (chemical, thermal)
Neuroaugmentation
Transcutaneous electrical nerve stimulation (TENS)
Peripheral nerve stimulation (PNS)
Spinal cord stimulation (SCS)
Biofeedback-relaxation technique

stabilizing agents (*i.e.,* anticonvulsants) and NSAIDs for providing analgesia but is equivocal regarding other health effects. The Task Force and consultants are supportive of the use of antidepressants, membrane stabilizing agents, and NSAIDs for providing analgesic and health benefits.

Recommendations: Antidepressants are useful medications for the reduction of pain and improvement of sleep. The specific agent and the dosage should be optimized for each patient. The beneficial and adverse effects should be monitored. NSAIDS and membrane stabilizing agents (*e.g.,* anticonvulsants) also may be used for the reduction of pain. As with antidepressants, the specific agent and dosage should be optimized for each patient, with periodic monitoring of beneficial and undersirable health effects.

VIII. Regional Sympathetic Blockade

The literature suggests that regional sympathetic blockade (*e.g.,* lumbar sympathetic block, stellate ganglion block, intravenous regional block) is effective in providing analgesia and is equivocal regarding beneficial or adverse health effects. The Task Force and panel of consultants are supportive of the analgesic benefits of regional sympathetic blockade. The Task Force and panel of consultants are equivocal regarding potentially beneficial or adverse health effects (*e.g.,* hypotension, hyperalgesia, sensory and motor deficit).

Recommendations: The adequacy of sympathetic blockade should be objectively assessed and recorded. Appropriate sympathetic blockade by the anesthesiologist should be provided within the context of the patient's overall treatment plan. To ensure the judicious use of sympathetic blockade, periodic monitoring should be conducted to assess analgesic benefit and adverse effects (*e.g.,* sensory or motor block; failed blockade of sympathetic outflow, especially to the upper extremity; local anesthetic toxicity; site infections).

IX. Corticosteroid Injection Therapy

The literature suggests that locally injected corticosteroids are effective in providing analgesia. The literature is equivocal regarding other health effects. The panel of consultants support the importance of locally injected corticosteroids in improving analgesia and enhancing patient functioning and quality of life. The consultants are equivocal regarding the adverse effects of corticosteroids.

Recommendations: Local injection of corticosteroids by the anesthesiologist should be provided within the context of the patient's overall treatment plan. A directed neurologic evaluation should precede the local injection of corticosteroids. Appropriate follow-up evaluation is necessary to monitor health effects, including analgesia, function, and adverse effects on local tissues and the hypothalamic-pituitary-adrenal axis.

X. Neurostimulation Therapy

The literature is supportive of transcutaneous electrical nerve stimulation (TENS) and spinal cord stimulation (SCS) techniques in providing analgesia and is suggestive of the analgesic benefit of peripheral nerve stimulation (PNS) techniques. The literature is equivocal regarding the beneficial or adverse health effects of TENS, PNS, and SCS. The Task Force and panel of consultants are supportive of neurostimulation therapy for analgesia.

Recommendations: An office or home trial of TENS should be considered as an early management option because of its low complexity and low risk. TENS also may be considered as adjunctive therapy.

Peripheral nerve stimulation should be reserved for patients with a peripheral monoeuropathy who have responded to a diagnostic sequence of local neural blockade and a stimulation trial.

Spinal cord stimulation should not be a first-line treatment but may be considered after failure of oral medications. SCS may be effective in the management of patients with peripheral neuropathic pain or with pain arising from the spinal cord (*e.g.,* arachnoiditis, syringomyelia, spinal cord injury, multiple sclerosis). It should be preceded by a trial with a percutaneous electrode system.

XI. Opioid Therapy

Opioid therapy for chronic pain management may be administered by several routes, the most common being systemic delivery (*e.g.,* oral, transdermal, or intravenous). Opioids also may be delivered directly to the neuraxis (*e.g.,* epidural, intrathecal). The relative merit of systemic versus neuraxial opioid administration for chronic pain management was not addressed in the these guidelines.

The literature supports the analgesic efficacy of systemic opioids. However, the literature suggests that systemic use of opioids may be associated with increased risk of adverse sequelae (*e.g.,* tolerance, dependence, pruritus, nausea, and respiratory depression).

The literature suggests that neuraxial delivery of opioids for chronic pain is associated with effective analgesia

---

and is equivocal regarding adverse effects. The consultants are supportive of the analgesic benefits of opioid therapies and are equivocal regarding adverse effects.

Recommendations: Opioid therapy may be considered when analgesia provided by other modalities (*e.g.,* NSAIDs, TENS) is no longer adequate to manage chronic pain. Systemic or neuraxial opioids should be administered on the basis of patient need. Delivery of opioids should occur within the context of a logistic system that provides the resources and availability of personnel to respond to patient needs and according to applicable local, state, and federal regulations. The analgesic benefits of opioids should be balanced against the potential adverse sequelae of long-term opioid use. Patients treated with opioids for chronic pain may require frequent follow-up evaluation. A controlled substance agreement or a second opinion from another provider with expertise in pain management may be considered.

XII. Neuroablative Techniques

Neuroablative techniques destroy neural tissue using chemicals (e.g., alcohol or phenol) or thermal lesions (e.g., radiofrequency or cryoneurolysis). The literature suggests that chemical and thermal neuroablative techniques can provide some control of chronic pain and reduction in regional sympathetic overactivity. Severe adverse health effects from treatment are possible but reported rarely. There is insufficient literature regarding the value of prognostic neural blockade before neuroablative techniques. The Task Force and consultants are supportive of the value of neurolytic techniques in symptom management and are neutral regarding other health effects.

Recommendations: Neuroblation should be preceded by confirmation of needle placement using local anesthetic, imaging, or electrical stimulation. Successful temporary blockade does not guarantee the success of subsequent neuroablation. Although the reported incidence of adverse effects of neuroblative techniques is very low, the impact on the patient may be catastrophic. Reported adverse effects include motor, sensory, and autonomic dysfunction (*e.g.,* paralysis, deafferentation pain, loss of sphincter control, or impotence), regeneration pain, and neuralgias. Neuroablative techniques should be used as part of a comprehensive approach to managing pain and applied only as a last resort after failure of other therapies. Follow-up assessments of pain and other health effects should be conducted periodically.

Appendix: Methods and Analyses

The scientific assessment of these Guidelines was based on the following statements, or *evidence linkages.* These linkages represent directional hypotheses about relationships between chronic pain, symptom management, and clinical outcomes.

1. A comprehensive history and physical examination: a) reduces pain or suffering, b) reduces adverse effects from pain therapy, c) improves function and quality of life, d) provides optimal utilization and cost of services.
2. Diagnostic evaluation (*e.g.,* neural blockade, imaging, pharmacodiagnosis, epiduroscopy, electrodiagnostics) a) reduces pain or suffering, b) reduces adverse effects from pain therapy, c) improves function and quality of life, d) provides optimal utilization and cost of services.
3. Counseling and coordination of care (*i.e.,* within-practice) a) reduces pain or suffering, b) reduces adverse effects from pain therapy, c) improves function and quality of life, d) provides optimal utilization and cost of services.
4. Monitoring and measurement of clinical outcomes a) reduces pain or suffering, b) reduces adverse effects from pain therapy, c) improves function and quality of life, d) provides optimal utilization and cost of services.
5. Multidisciplinary pain management a) reduces pain or suffering, b) reduces adverse effects from pain therapy, c) improves function and quality of life, d) provides optimal utilization and cost of services.
6. Multimodality pain management a) reduces pain or suffering, b) reduces adverse effects from pain therapy, c) improves function and quality of life, d) provides optimal utilization and cost of services.
7. Adjuvant analgesics (*e.g.,* antidepressants, membrane stabilizing agents, and nonsteroidal antiinflammatory drugs [NSAIDs]) a) reduce pain or suffering, b) reduce adverse effects from pain therapy, c) improve function and quality of life, d) provide optimal utilization and cost of services.
8. Regional sympathetic blockade (*e.g.,* lumbar sympathetic block, stellate ganglion block, intravenous regional block) a) reduces pain or suffering, b) reduces adverse effects from pain therapy, c) improves function and quality of life, d) provide optimal utilization and cost of services.
9. Corticosteroid injection therapy a) reduces pain or suffering, b) reduces adverse effects from pain therapy, c) improves function and quality of life, d) provides optimal utilization and cost of services.
10. Neurostimulation therapy (*i.e.,* transcutaneous electrical nerve stimulation [TENS], peripheral nerve stimulation [PNS], spinal cord stimulation [SCS]) a) reduces pain or suffering, b) reduces adverse effects from pain therapy, c) improves function and quality of life, d) provides optimal utilization and cost of services.
11. Opioid therapy (*i.e.,* systemic drug delivery and neuraxial drug delivery) a) reduces pain or suffering, b) reduces adverse effects from pain therapy, c) improves function and quality of life, d) provides optimal utilization and cost of services.
12. Neuroablative techniques (*i.e.,* chemical and thermal) a) reduce pain or suffering, b) reduce adverse effects from pain therapy, c) improve function and quality of life, d) provide optimal utilization and cost of services.

Scientific evidence was derived from aggregated research literature,

with meta-analyses used when appropriate, and from surveys, open presentations, and other consensus-oriented activities. For purposes of literature aggregation, potentially relevant clinical studies were identified via electronic and manual searches of the literature. The electronic search covered a 30-yr period from 1966 through 1995. The manual search covered a 52-yr period from 1944 through 1995. More than 3,000 citations were initially identified, yielding 1,450 nonoverlapping articles that addressed topics related to the 12 evidence linkages. After review of the articles, 1,074 studies did not provide direct evidence and were subsequently eliminated. A total of 376 articles (from 153 journals) contained direct linkage-related evidence.

A directional result for each study was initially determined by classifying the outcome as either supporting a linkage, refuting a linkage, or neutral. The results were then summarized to obtain a directional assessment of support for each linkage. The literature relating to five evidence linkages contained enough studies with well-defined experimental designs and statistical information to conduct formal meta-analyses. These five linkages were linkage 2 (diagnostic evaluation), 5a (multidisciplinary pain management programs), 5b (multidisciplinary pain management programs that emphasize the reduction or elimination of pain medications as a primary objective of therapy), 7a (antidepressants), and 7b (anticonvulsants and NSAIDS), 10a (TENS), 10b (SCS), and 11b (opioid therapy, systemic drug delivery).

The following terms were used in the Guidelines to express the strength of the evidence relating to various interventions and their associated outcomes.

1. *Insufficient data* : there are insufficient published data to provide an indication of the relationship between the intervention and outcome.
2. *Suggestive data* : there is qualitative evidence in the form of case reports or descriptive studies, but there is insufficient quantitative evidence to establish a statistical relationship between intervention and outcome.
3. *Supportive data* : quantitative data indicate a significant relationship between intervention and outcome ($P < 0.01$), and qualitative data are supportive.

Combined probability tests were applied to continuous data, and an odds-ratio procedure was applied to dichotomous study results. Two combined probability tests were used as follows: 1) The Fisher Combined Test, producing chi-square, values based on logarithmic transformations of the reported P values from the independent studies, and 2) the Stouffer Combined Test, providing weighted representation of the studies by weighting each of the standard normal deviates by the size of the sample. A procedure based on the MantelHaenszel method for combining study results using 2 × 2 tables was available for use with outcome frequency information. An acceptable significance level was set at $P < 0.01$ (one-tailed), and effect size estimates were calculated. Interobserver agreement was established through assessment of interrater reliability testing. Tests for heterogeneity of the independent samples were conducted to assure consistency among the study results. To control for potential publishing bias, a "fail-safe N" value was calculated for each combined probability test. No search for unpublished studies was conducted, and no reliability tests for locating research results were done.

Results of the combined probability tests are reported in Table 1 . Significance levels from the weighted Stouffer combined tests for analgesic efficacy were significant for linkages 2 (diagnostic evaluation), 5a (multidisciplinary pain management programs), 5b (multidisciplinary pain management programs with emphasis on pain medication reduction or elimination), 7a (antidepressants), 7b (anticonvulsants and NSAIDs), 10a (TENS), 10b (SCS), and 11a (systemic opioid therapy. Weighted effect size estimates ranged from r = 0.10 to r = 0.28, demonstrating small-to-moderate effect size estimates. Significance levels from the weighted Stouffer combined tests for beneficial effects were significant for linkages 5a (multidisciplinary pain management programs), 5b (multidisciplinary pain management programs, pain medication reduction), and 7a (antidepressants). Weighted effect size estimates for beneficial effects ranged from r = 0.19 to r = 0.22. For linkage 7a, a separate analysis was conducted excluding mood state findings to determine if there were any nonmood state effects associated with the use of these medications. Significance levels for this linkage were not significant ($Z_c = 0.113$, $P > 0.10$). Sufficient data were not available in the literature to conduct Mantel-Haenszel analyses on these linkages.

Tests for heterogeneity of statistical tests and effect size were non-significant for linkages 2, 10a, and 10b, indicating that the pooled studies provided common

estimates of significance and population effect sizes. Tests for heterogeneity of statistical tests were significant for linkages 5a (health effects) and 5b (analgesia and health effects). Tests for heterogeneity of effect size were significant for linkages 5a (health effects), 5b (analgesia and health effects), 7a (analgesia), 7b (analgesia), and 11b (analgesia). Significant findings for analgesic efficacy for linkage 11b may reflect the small number of studies used in the pooled analysis (N = 5). Significant findings for analgesic efficacy of 7a and 7b may reflect either the differential influence of the various adjuvant medications or that the pooled analysis used adjuvant medications whose primary purpose was not specifically intended for pain management. Significant findings for linkages 5a and 5b suggest that the findings be further examined for commonalities in therapeutic approaches, medications, personnel, or targeted patient populations in multidisciplinary pain programs.

Agreement among Task Force members and two methodologists was established by interrater reliability testing. Agreement levels using a kappa statistic for two-rater agreement pairs were 1) type of study design, kappa = 0.77-0.89;2) type of analysis, kappa = 0.41-0.88; 3) evidence linkage assignment, kappa = 0.65-0.80; and 4) literature inclusion for database, kappa = 0.30-0.71. Three-rater chance-corrected agreement values were 1) design, Sav = 0.85, Var (Sav) = 0.005; 2) analysis, Sav = 0.59, Var (Sav) = 0.008; 3) linkage identification, Sav = 0.74, Var (Sav) = 0.006; and 4) literature database inclusion, Sav = 0.46, Var (Sav) = 0.043. These values represent moderate levels of agreement.

The findings of the literature analyses were supplemented by the opinions of Task Force members and by surveys of the opinions of a panel of consultants with expertise in chronic pain management (N = 96). The rate of return was 60% (N = 58 of 96). The percentage of consultants supporting each linkage is reported in Table 2 (Table Not Available) . Consultants, in general, were highly supportive of the linkages (*i.e.,* a] agreed that they provided analgesic benefit, b] reduced risk of adverse outcomes, c] improved function and quality of life, and d] were important issues for the Guidelines to address).

The feasibility of implementing these Guidelines into clinical practice was assessed by an opinion survey of the chronic pain consultant panel. The rate of return was 54% (N = 51). The mean number of patients treated annually by the consultants was reported to be 1,636 (min/max = 10--9,000). Responses for feasibility of implementation of the Guidelines were as follows: 96% (N = 50) of these consultants indicated that implementation of the Guidelines would not result in the need to purchase new equipment, supplies, or pharmaceuticals.

TABLE 1 -- Statistical Summary: Combined Test Results

Analgesic Efficacy			
Linkage #2: Diagnostic evaluation			
Fisher Combined Test	X^2 = 69.23	$P < 0.001$	df = 12
Stouffer Combined Test	Z_c (weighted) = 3.886	$P < 0.001$	
Effect Size Estimate	r (weighted) = 0.28

TABLE 2 -- Consultant Survey of Evidence Linkages: Percentage Agreement (N = 58)

(Not Available)

The two respondents who stated that purchases would be required estimated cost of initial implementation of the Guidelines to be $ 20,000-30,000 for the purchase of improved nerve stimulators, cryotherapy, and radiofrequency equipment.

The consultants were asked to indicate which, if any, of the evidence linkages would change their clinical practices if the Guidelines were instituted. The percentage of consultants expecting no change associated with each linkage was as follows: comprehensive history and physical examination, 92%; diagnostic evaluation, 98%; counseling and coordination of care, 92%; monitoring and measurement of outcomes, 83%; multidisciplinary pain management, 96%; multimodality pain management, 100%; adjuvant analgesics, 100%; regional sympathetic blockade, 100%; corticosteroid therapy, 100%; neurostimulation therapy, 96%; opioid therapy, 98%; and neuroablative techniques, 94%.

Ninety-two percent of the respondents indicated that the Guidelines would have no effect on the time spent on a typical case. None reported that the Guidelines would reduce the amount of time spent per case. For all respondents, the mean increase in the amount of time spent on a typical case was 2.1 min. Of the 8% of respondents who reported an anticipated increase in time spent on a typical case, the mean was 18.0 min (range, 4-60 min). [*] ["]

*Readers with special interest in the statistical analyses used in establishing these Guidelines can receive further information by writing to: Peter R. Wilson, MBBS, PhD, Anesthesia Department, Mayo Clinic, 200 First Street, Rochester, Minnesota 55905.

APPENDIX: Practice Guidelines for Cancer Pain Management[D]

A Report by the American Society of Anesthesiologists Task Force on Pain Management, Cancer Pain Section

Practice guidelines are systematically developed recommendations that assist the practitioner and patient in making decisions about health care. These recommendations may be adopted, modified, or rejected according to clinical needs and constraints.

Practice guidelines are not intended as standards or absolute requirements. The use of practice guidelines cannot guarantee any specific outcome. Practice guidelines are subject to revision from time to time as warranted by the evolution of medical knowledge, technology, and practice. The guidelines provide basic recommendations that are supported by analysis of the current literature and by a synthesis of expert opinion, open forum commentary, and clinical feasibility data (Appendix 1).

A. Definition of Cancer Pain.

For these guidelines, cancer pain is defined as pain that is attributable to cancer or its therapy. The Task Force has not given preference to literature based on any particular system of definition or classification of cancer pain.

B. Purpose of Guidelines for Cancer Pain Management.

The purpose of these guidelines is to: (1) optimize pain control; (2) minimize side effects, adverse outcomes, and costs; (3) enhance functional abilities and physical and psychological well-being; and (4) enhance the quality of life for cancer patients.

C. Focus.

These guidelines focus on the knowledge base, skills, and range of interventions that are the essential elements of effective management of pain and pain-related problems in patients with cancer. The guidelines recognize that the management of cancer pain occurs within the broader context of supportive care which also encompasses other quality of life concerns (*e.g.,* functional status, psychosocial well-being).

The guidelines recognize that comprehensive pain management by anesthesiologists may not be feasible in every clinical setting. However, aspects of these guidelines may be useful when comprehensive pain management cannot be offered.

The Task Force recognizes that therapies used to modify the underlying cause of pain may improve analgesia and outcome. Commonly used approaches include radiotherapy, surgery, and chemotherapy. The decision to implement primary therapy should be based on a comprehensive assessment of risks and benefits and are outside the scope of these guidelines.

D. Application.

The guidelines are intended for use by anesthesiologists and individuals who deliver care under the direct supervision of anesthesiologists. The guidelines apply to patients of all ages and with all types of cancer.

I. Comprehensive Evaluation and Assessment of the Patient with Cancer Pain

The literature suggests that a comprehensive cancer pain evaluation is associated with improved analgesia. The Task Force and panel of consultants support the conduct of a comprehensive pain evaluation. In the opinion of the Task Force and consultants, effective cancer pain management requires a clear understanding of the etiology and pathophysiology of the pain.

Developed by the Task Force on Pain Management, Cancer Pain Section: F. Michael Ferrante, M.D., F.A.B.P.M. (Chair), Philadelphia, Pennsylvania; Marshall Bedder, M.D., F.R.C.P.(C), Portland, Oregon; Robert A. Caplan, M.D., Seattle, Washington; Hui-Ming Chang, M.D. Houston, Texas; Richard T. Connis, Ph.D. (Methodologist), Woodinville, Washington; Patricia Harrison, M.D., Buffalo, New York; Robert N. Jamison, Ph.D, Boston, Massachusetts; Elliot J. Krane, M.D., Stanford, California; Srdjan Nedeljkovic, M.D., Boston, Massachusetts; Richard Patt, M.D., Houston, Texas; and Russell K. Portenoy, M.D., New York, New York.

Recommendations:

1. General Constructs.

The Task Force identifies four fundamental features that should guide the comprehensive evaluation of the patient with cancer pain.

a. The patient's general medical condition and the extent of disease must be assessed.
b. A knowledge of common pain syndromes is a prerequisite for conducting a cancer pain evaluation. Common pain syndromes include but are not limited to bone metastases, abdominal (visceral) pain, neuropathic pain (*e.g.,* peripheral neuropathies, acute herpes zoster and postherpetic neuralgia, plexopathies), and mucositis.
c. A knowledge of oncologic emergencies (*e.g.,* hypercalcemia, spinal cord compression, cardiac tamponade, superior vena cava syndrome) is also required to conduct a comprehensive cancer pain evaluation.
d. A thorough knowledge of the modalities that car be employed in the treatment of painful crisis (*i.e.* pain emergency) is also necessary.

2. Elements.

The Task Force identifies six essentia features of a comprehensive evaluation and treatment plan. These features are outlined below (template 1)

a. History: A complete history includes a general medical and oncologic history with a description of the extent of disease and prognosis. A pain history should include: (1) the quality of the pain *e.g.,* "burning", "aching"), (2) pain intensity (*i.e.,* numeric, categorical, or visual analog scales), (3) spatial relationships of the pain (*i.e.,* location, areas of radiation), (4) factors that palliate or provoke pain, (5) temporal characteristics of the pain (*i.e.,* continuous, episodic), (6) duration of the pain, (7) course of the pain (*e.g.,* stable, progressive, "crescendo"), and (8) associated features of the pain (*e.g.,* numbness, weakness, vasomotor changes).
b. Psychosocial evaluation: A psychosocial evaluation should include: (1) the presence of psychological symptoms (*e.g.,* anxiety, depression), (2) indicators of psychiatric disorder (*e.g.,* delirium, major depression), (3) investigation of the "meaning" of the pain to the patient and his or her significant others, (4) changes in mood state, (5) premorbid and current coping mechanisms, (6) family function, (7) the availability of psychosocial support systems, and (8) assessment of the patient's expectations and preconceptions regarding pain management (*e.g.,* fear of addiction surrounding opioids, psychostimulants).
c. Physical examination: A physical examination should include general medical and neurologic examinations and a specific examination of the site of pain and surrounding anatomic regions.
d. Impression and differential diagnosis: The findings of the history and physical examination should be used to determine the probable etiology and pathophysiology of the pain.
e. Diagnostic evaluations: Additional diagnostic tests may be required to ascertain or confirm the etiology of the pain and its relationships to underlying disease processes.
f. Treatment plan: Once a definitive diagnosis has been made, a treatment plan should be formulated and discussed with the patient. The treatment plan should characterize the expected outcome, define contingencies, and outline a plan for reassessment.

Figure Template 1. Algorithm for comprehensive evaluation and longitudinal assessment of cancer pain.

II. Longitudinal Monitoring of Pain

There is insufficient literature to evaluate the efficacy of the longitudinal monitoring of pain. The Task Force

and consultants support the contention that the longitudinal monitoring of pain will result in improved pain management and reduced adverse effects from therapy (template 1) .

Recommendations:

The Task Force identifies three fundamental concepts in the longitudinal monitoring of pain.

1. Patient Self-report.

Reports of pain made by the patient should be the primary source of pain assessment and should take precedence, whenever possible, over inferences and observations made by others. Continuous assessment over time (*e.g.,* pain diaries) is appropriate for outpatients. For some age groups and populations (*e.g.,* the cognitively or developmentally impaired), external observation may be preferable. Age-appropriate instruments should be used in children.

2. Rating Scale.

The longitudinal monitoring of pain intensity should be based on rating scales that are easy to use and interpret. Typical examples of rating scales include discrete numeric scales (*e.g.,* 0-10), categorical scales (none, mild, moderate, severe, worst possible), and continuous visual analog scales of pain or pain relief (template 2) .

3. Frequency of Pain Ratings.

Self-report should be obtained at regular intervals. Increased frequency and evaluation of self-reports may be indicated: (1) at the onset of new pain, (2) when established pain exhibits changes in pattern and/or intensity, or (3) when a major therapeutic intervention is performed.

III. Involvement of Specialists from Multiple Disciplines

The literature supports the concept that involvement of specialists from multiple disciplines results in effective analgesia and suggests that such involvement improves other health outcomes. The panel of consultants and Task Force members endorse the importance of collaboration between anesthesiologists and other health-care providers in the management of cancer pain.

Recommendations:

Anesthesiologists who engage in cancer pain management should avail themselves of interdisciplinary expertise in their clinical environments. It is important to note that the patient's primary physician must be a part of the coordination of pain management. The Task Force recognizes that full interdisciplinary coordination of cancer pain treatment is not feasible in every clinical setting.

Figure Template 2. Pain intensity scales.

IV. Paradigm for the Management of Cancer Pain

The guidelines conceptualize the--pharmacologic management of cancer pain as a continuum from indirect drug delivery (*i.e.,* systemic analgesia) to direct drug delivery (*i.e.,* neuraxial drug administration and neuroablation; template 3) . *Indirect* drug delivery systems rely on blood-borne carriage of analgesic to receptors after (1) systemic absorption, (2) formation of a depot for sustained and continuous release, or (3) administration into the blood stream. *Direct* drug delivery systems involve administration of an agent to the neuraxis or in the vicinity of "target" neural tissue.

Recommendations for the oral administration of analgesics are provided by the World Health Organization (WHO) analgesic ladder (template 4) . These American Society of Anesthesiologists guidelines provide evidence and recommendations for cancer pain management involving the oral and other routes of administration. The literature provides supportive evidence for specific elements of the paradigm (template 5) .

A. Indirect Delivery Systems: Systemic Analgesia

a. Oral pharmacologic interventions: The literature suggests and consultant opinion supports the view that oral pharmacologic interventions applied according to the WHO analgesic ladder are associated with adequate analgesia. The literature indicates an

increased risk of adverse sequelae with the use of oral opioids (Appendix 2).
b. Rectal and transdermal analgesia: The literature suggests that rectal and transdermal modes of analgesia are effective alternatives to oral analgesics. The Task Force supports the use of these analgesic modalities, when appropriate, before employment of more invasive systemic therapies.
c. Subcutaneous and intravenous drug delivery: The literature suggests that subcutaneous or intravenous administration of opioids is effective for patients requiring continuous infusions and does not increase the risk of adverse effects. Subcutaneous administration provides blood levels similar to intravenous infusion, and the comparative risks and benefits of the continuous parenteral techniques have not been evaluated.

Template 3. Drug Delivery Systems

Method of Access to the "Receptor" *	
Indirect (*via* blood-borne carriage, *i.e* ., systemic analgesia)	**Direct**
Via systemic absorption	Neuraxial drug delivery
Oral, bucchal	Epidural
Sublingual, intranasal	Subarachnoid
Rectal	Intraventricular
Via depot formation	Neuroablation
Transdermal	Chemical
Intramuscular	Thermal
Subcutaneous	Surgical
Intravenous administration	

*Neural tissue.

Indirect (systemic) delivery systems rely on the transport of an analgesic to the receptor site in neural tissue by the blood. Access to the blood may be achieved by systemic absorption, formation of a depot with sustained release, and instillation into the blood.

Direct drug delivery systems involve administration of an agent to the neuraxis (*i.e.,* in proximity to the receptor) or in the vicinity of "target" neural tissue.

Recommendations:

1. General Recommendations.

Oral medications should be used as the first line approach in most patients when initiating analgesic therapy. Because it is not effective in all patients and may not be optimal therapy in painful crisis (*i.e.,* the pain emergency), the indications, risks, and potential benefits of alternative interventions must be understood and assessed.

Any proposed systemic regimen must be individualized for the patient, and inflexible reliance should not be placed on any "standard" mixture of medications and/or dosing regimens. For patients with moderate or severe pain, opioid therapy is recommended. Once an opioid and a route of administration are chosen, the dose should be increased until a favorable response occurs or when unmanageable or intolerable adverse effects ensue. There is no predetermined maximum dose of an opioid. Dose titration may be required periodically because of the natural history of the primary

Figure Template 4. The World Health Organization (WHO) analgesic ladder consists of a hierarchy of oral pharmacologic interventions designed to effectively treat pain of increasing magnitude. The ladder presents a framework for the rational use of oral medication before application of other techniques of drug administration. Opioid therapy is considered the mainstay approach for patients with moderate or severe pain. The type of medication administered is sequentially escalated from nonopioids (*e.g.,* nonsteroidal antiinflammatory drugs (NSAIDs) ± adjuvants to opioids used for mild to moderate pain (codeine, dihydrocodeine, oxycodone (compounded with a coanalgesic), hydrocodone, dihydrocodone) ± adjuvants to opioids commonly used for severe pain (morphine, hydromorphone, methadone, oxycodone (without compounding), fentanyl or levorphanol). Adjuvant medications are listed in template 7 . *(Modified with permission from WHO: Cancer pain relief and palliative care: Report of a WHO expert committee. Geneva, World Health Organization, 1990 (technical report series, no. 804).)*

Figure Template 5. Paradigm for the management of cancer pain.

disease or the development of tolerance. When pain is continuous or occurs frequently, medication generally should be administered around-the-clock with additional "rescue" doses available for breakthrough pain. The practitioner should be aware of the potential adverse sequelae of opioids and their appropriate treatment.

When considering changing opioids or routes of administration, dose adjustments should be made to correct for differences in potency. Apparent differences in potency among opioids are the result of physicochemical and pharmacokinetic differences rather than pharmacodynamic distinctions (template 6) . When tolerance to a particular opioid develops, another opioid may be substituted at approximately 50-75% of the equianalgesic dose, because cross-tolerance is incomplete. The size of the reduction should be based on the severity of pain, the presence of adverse effects, and the medical status of the patient. Based on clinical observation, a switch to methadone should be done with a reduction of 75% of the equianalgesic dose.

Adjuvant agents should be used as coanalgesics (*e.g.,* corticosteroids, antidepressants) or to treat adverse drug effects. These agents may be added at any stage (template 7) .

2. Specific Recommendations.

Template 6. Opioid Analgesics Commonly Used to Manage Cancer Pain*

Generic Name	Proprietary Name	Route	Dose Equivalence (mg)	Comments
Opioids conventionally used to manage mild to moderate pain				
Codeine	Various	Oral	200	With the exception of codeine, these opioids are compounded with aspirin or acetaminophen, which imposes a dosage ceiling.
Dihydrocodeine	Various	Oral		
Hydrocodone	Vicodin, Lortab, various	Oral		
Oxycodone	Various	Oral		
Opioids conventionally used to manage moderate to severe pain				
"Immediate release" morphine	MSIR	Oral	30	Especially useful for initial dose titration and prn supplementation with long-acting opioids
Controlled release morphine	MS Contin, Oramorph	Oral	30	Used around-the-clock for basal pain (Do not break, crush, or chew.)
Morphine	Various	Parenteral	10	Usual standard for comparison
Hydromorphone	Dilaudid	Oral	7.5	Especially useful for initial dose titration and prn supplementation with long-acting opioids
Hydromorphone	Dilaudid	Parenteral	1.5	Often used subcutaneously

Oxycodone	Various	Oral	20-30	Often compounded with adjuvants for moderate pain Used as single entity for severe pain Sustained release form is available
Fentanyl	Sublimaze	Intravenous	0.1	Minimal experience outside the hospital setting
Fentanyl	Duragesic	Transdermal	45-134 mg oral morphine ~25 mug/h fentanyl	Used around-the-clock for stable pain, especially with GI dysfunction
Methadone	Dolophine	Oral	20	Inexpensive, but long, variable half-life may complicate titration and predispose to toxicity
Methadone	Dolophine	Parenteral	10	Inexpensive, but long, variable half-life may complicate titration and predispose to toxicity
Levorphanol	Levodromoran	Oral	4	Long half-life with much shorter dosing interval
Levorphanol	Levodromoran	Parenteral	2	Long half-life with much shorter dosing interval

*This list is partial and based on commonly used U.S. formulations. Meperidine and the agonist-antagonist opioids are not included in the table. Meperidine may produce seizures because of accumulation of the normeperidine breakdown product during chronic administration. This is of particular importance in the elderly and in patients with abnormal renal function. The agonist-antagonist opioids have ceiling and dysphoric effects and may precipitate withdrawal in patients chronically receiving pure agonist opioids.

Dose equivalencies are approximate.

When converting between drugs or routes of administration, it is recommended to reduce the calculated dose by 25-50% to account for incomplete cross-tolerance. (Based on clinical observation, methadone dose should be reduced by 75%.) Appropriate titration of dosage should then be performed as clinically indicated.

a. Oral medications: Oral medications such as acetaminophen, acetylsalicylic acid or other nonsteroidal antiinflammatory drugs (NSAIDs) should be employed first for mild to moderate pain. (Note: the simultaneous use of more than one NSAID or the concomitant use of an NSAID with a glucocorticoid is not recommended because the risk of toxicity is increased, and additional analgesia is not achieved.) If pain is not relieved or increases or if moderate pain is present at presentation, an opioid conventionally used for moderate pain (*e.g.,* codeine, dihydrocodeine, oxycodone (compounded with a coanalgesic), or hydrocodone) should be used, usually combined with a nonopioid analgesic. When increasing opioid dose, an increment of 25-50% is usually the minimum required to observe effect. If pain is not relieved, increases, or is severe at presentation, an opioid conventionally used for severe pain (*e.g.,* morphine, hydromorphone, methadone, oxycodone (not compounded with a coanalgesic), fentanyl, or levorphanol) should be selected. (Note: Besides consideration of a change in opioid, an increase in pain intensity should prompt a reevaluation of the cause of pain.)
b. When analgesia with acceptable adverse effects is no longer attained with the oral route of administration or when oral administration is no longer viable (inability to swallow and/or absorb medication), an alternate systemic route of administration should be chosen. (Note: The enteral route should be used in patients with percutaneous feeding tubes and inability to swallow, as long as absorption still

occurs.) If dose-limiting toxicity precludes effective therapy, a trial of a different opioid, a reduction of adverse effects by optimization of adjuvants, neuraxial drug delivery, or neuroablative therapy should be considered.
c. Rectal and transdermal: Use of an alternative route of administration, specifically rectal or transdermal, should be chosen before use of invasive therapies. Rectal administration usually is considered when oral therapy is temporarily unavailable (*e.g.,* nausea and vomiting refractory to therapy), although long-term use is effective in some patients. Transdermal

fentanyl should be used in patients with stable pain states who are (1) noncompliant with oral medication, (2) unable to swallow or absorb, or (3) may benefit from a trial of fentanyl.
d. Subcutaneous and intravenous administration: The subcutaneous route of administration should be used in (1) patients unable to swallow or absorb opioids who may benefit from a continuous infusion of opioid and (2) similar patients with dynamic pain states requiring frequent "rescue" doses for break-through pain. Subcutaneous administration of opioids may be used in the home setting. The recommendations for intravenous administration are the same as for subcutaneous administration. Intravenous administration may be preferred when the patient has permanent venous access. (Note: Intramuscular injection is not recommended as either short- or long-term therapy for cancer pain management because of the attendant discomfort, variable blood concentrations, and fluctuating levels of analgesia.)

Template 7. Commonly Used Adjuvant Analgesics

Class (examples)	Usual Indications
Anticonvulsants	
Phenytoin	Neuropathic pain, particularly lancinating or paroxysmal pain
Carbamazepine	
Clonazepam	
Valproate	
Antidepressants	
Amitriptyline	Neuropathic pain
Nortriptyline	
Imipramine	
Desipramine	
Trazodone	
Local anesthetics	
Lidocaine	Neuropathic pain
Mexiletine	
Corticosteroids	
Dexamethasone	Tumor invasion of neural tissue, elevated intracranial pressure, spinal cord compression, additional effects (mood elevation, antiemesis, appetite stimulation)
Antihistaminics	
Hydroxyzine	Coanalgesic, antiemetic
Muscle relaxants	
Orphenadrine	Occasionally useful for musculoskeletal pain
Carisoprodol	

Methocarbamol	
Chlorzoxazone	
Cyclobenzaprine	
Neuroleptics	
Methotrimeprazine	Neuropathic pain
Fluphenazine	
Other drugs for neuropathic pain	
Baclofen	Neuropathic pain
Clonidine	
Calcitonin	
Capsaicin, topical	
Drug action on bone	
Biphosphonates (pamidronate)	Bone pain
Calcitonin	
Radiopharmaceuticals (Strontium 89)	
Anticholinergics	
Scopalamine	Visceral pain due to bowel obstruction
Glycopyrrolate	
Psychostimulants	
Caffeine	Decrease sedation due to opioid analgesia
Methylphenidate	
Dextroamphetamine	

B. Direct Delivery Systems: Neuraxial Drug Delivery and Neuroablation

Opioids and local anesthetics can be delivered directly to the vicinity of neural tissue, obviating the need for systemic absorption as a means to reach receptor sites. Other potential agents for neuraxial drug delivery are under development. Neuroablation refers to the chemical, thermal, or surgical destruction of neural tissue.

Neuroablation is preceded by diagnostic neural blockade. Regional analgesic techniques are referred to in these guidelines as neural blockade (*e.g.,* intercostal blocks, celiac plexus blocks) and are distinct from neurolytic blocks. Neural blockade is used alone for short-term pain management with specific indications (see below). The Task Force is supportive of the efficacy of neural blockade for prognostic purposes. (Note: Sufficient literature is not available to assess the effectiveness of neural blockade as either a prognostic procedure or a long-term analgesic modality for the treatment of cancer pain.)

a. Neuraxial drug delivery: The literature is supportive of the efficacy of neuraxial analgesic delivery (*i.e.,* epidural, subarachnoid, intraventricular). Epidural or subarachnoid drug administration may be performed by either percutaneous catheterization, reservoir, or implantation of a catheter and pump. Although

the literature suggests that neuraxial techniques are not associated with an increased incidence of adverse effects, the Task Force and consultants suggest that adverse effects may be possible (*e.g.,* catheter-site infections).

b. Neuroablation: The literature suggests and consultants and Task Force members support the view that neuroablation by chemical and thermal neurolysis or surgery can provide long-term control of severe cancer pain without a substantial incidence of adverse effects. Examples of chemical neuroablative procedures include but are not limited to intercostal neurolysis, neurolytic celiac plexus block, neurolytic superior hypogastric plexus block, neurolytic ganglion impar (ganglion of Walther) block, craniofacial neurolytic techniques, and subarachnoid rhizolysis. Examples of thermal neuroablative techniques include radiofrequency ablation (heat) and cryoanalgesia (cold).

Recommendations:

1. General Recommendations.

When adequate analgesia cannot be achieved or intolerable side effects occur with indirect methods of drug delivery, direct drug delivery systems should be considered. In certain specific circumstances, neuraxial drug delivery or neuroablative therapies should be considered at the initiation of therapy or early in the natural history of the pain (see below). Neuraxial drug delivery and neuroablative therapies should not be used: (1) in individuals who are unmotivated or noncompliant or do not possess the cognitive functioning necessary to understand the risks and benefits and (2) when an appropriate logistical system does not exist. Patients must have access to a logistical system that provides the resources and availability of personnel to respond to patient needs on an around-the-clock basis. The establishment of an office or network with professional support may be necessary. For long-term therapies, appropriate home care must be available and functionally integrated into the office, hospital, and community.

2. Specific Recommendations.

a. Neuraxial drug delivery: Neuraxial drug delivery should be used: (1) when severe pain cannot be controlled with systemic drugs because of doselimiting toxicity, (2) when there is immediate need for local anesthetic (some neuropathic pains), (3) after failed neuroablation, or (4) patient preference indicates its use. The choice between epidural or subarachnoid catheterization is determined in part by patient life expectancy. When extended life expectancy is anticipated, subarachnoid catheter placement should be considered because epidural catheters may become obstructed. The presence of epidural metastases necessitates subarachnoid catheterization.
   Before insertion of an indwelling neuraxial drug delivery system, efficacy and appropriate dose range should be ascertained by trial injection or use of a temporary delivery system. Patients should have access to "rescue" doses for breakthrough pain. "Rescue" doses may be given by any route of administration as deemed appropriate by the practitioner.
   Intraventricular administration of opioids may be considered in patients with head and neck cancer and Ommaya reservoirs. (Note: Neural blockade should be used before neuraxial drug delivery because of (1) the presence of pain therapeutically amenable to neural blockade (*e.g.,* myofascial pain, sympathetically-maintained pain, pain of acute herpes zoster); or (2) patient preference, when appropriate.)
b. Neuroablation: Neuroablative techniques should be initiated (1) when systemic therapies have failed to provide adequate pain control or when adverse side effects from systemic therapies are unacceptable; (2) after failure of neuraxial drug administration; (3) early in the natural history of the cancer pain in the presence of selected focal somatic lesions (*e.g.,* rib metastases), visceral (*e.g.,* cancer of the pancreas), or neuropathic (*e.g.,* craniofacial) pain that is believed to be highly responsive to neuroablation with limited risk; or (4) patient preference indicates use of neuroablative techniques, if appropriate. Except for the aforementioned specific indications, chemical, radiofrequency (thermal), and surgical neuroablation should be deferred until anticipated life expectancy is short-term, thereby minimizing the potential for deafferentation pain. On the other hand, consideration of life expectancy is moot with cryoanalgesia because of the potential for nerve regeneration associated with the technique. The cryoanalgesia procedure often must be repeated because the endoneurium is spared, allowing regrowth over time. After performance of successful chemical, thermal, or surgical neurolysis, opioid administration should not be immediately curtailed to avoid precipitation of withdrawal. Dosage

---

should be immediately reduced, and opioids should be weaned to avoid respiratory depression, which may occur in the setting of abrupt pain relief.
c. Neural blockade should be used prognostically to determine the possible efficacy of neuroablation. However, even with proper needle placement under fluoroscopic guidance, successful neural blockade does not ensure the subsequent success of a neurodestructive procedure. Neural blockade should be performed at the time of potential neuroablation and should not be performed as a separate procedure. If analgesia is not achieved with neural blockade or significant adverse sequelae result, neuroablation should be reconsidered.
   Definitive neuroablation should be performed with the aid of imaging techniques when feasible or with direct visualization of the intended neural target in the case of open surgical ablation.

V. Management of Cancer-related Symptoms and Adverse Effects of Pain Therapy

The literature supports the efficacy of interventions designed to manage symptoms related to primary disease and its treatment. In addition, the literature suggests that specific interventions used to treat the adverse effects of pain therapy are efficacious. Adverse drug effects directly resulting from cancer pain therapies include but are not limited to sedation, nausea and vomiting, pruritus, constipation, urinary retention, and respiratory depression. (Note: Respiratory depression is rare in the cancer patient receiving chronic opioid therapy (Appendix 2)).

The literature does not suggest that management of symptoms or adverse effects has an effect on analgesia.

The Task Force and consultants are supportive of the value of managing cancer-related symptoms and adverse drug effects as part of the comprehensive management of cancer pain.

Recommendations:

1. General Recommendations.

Adverse effects should be promptly identified and assessed, and appropriate remedies should be offered. Opioids should not be withheld from cancer patients for fear of producing respiratory depression, tolerance, physical dependence, or addiction.

2. Specific Recommendations.

a. Constipation: All patients with an increased risk for constipation should receive prophylaxis (Appendix 2). Prophylactic or symptomatic therapy should involve the use of bulk agents, osmotic laxatives (*e.g.,* magnesium or sodium salts, lactulose or sorbitol), and/or stimulant cathartics (*e.g.,* senna or bisacody1). A stool softener may be concomitantly used with the aforementioned agents. Occasionally, patients require enemas.
b. Sedation: Sedation should be treated by (1) eliminating contributory factors such as nonessential drugs and metabolic disturbances, (2) reducing the dose of an opioid by 25-50% if analgesia is satisfactory, (3) lowering the requirement for opioids by the addition of a nonopioid analgesic or adjuvant analgesic, (4) switching to another opioid, (5) the use of psychostimulants, or (6) considering more invasive modalities if sedation is refractory to therapy.
c. Nausea and vomiting: Persistent nausea is rare, and prophylactic therapy is not indicated. Transitory nausea and vomiting should be treated initially with standard antiemetics, such as promethazine, prochlorperazine, haloperidol, metoclopramide, or hydroxyzine. In some cases, ondansetron or meclizine can be helpful. Some patients may benefit from the use of low-dose corticosteroid, alternative treatment for gastroparesis (*i.e.,* cisapride), or a benzodiazepine (*i.e.,* lorazepam). Treatment of factors contributing to nausea (*e.g.,* constipation) should be considered when appropriate.
d. Mental clouding: The treatment of cognitive impairment should mirror the management of sedation. The addition of low-dose haloperidol occasionally may be necessary for confusional states induced by opioids. Psychostimulants can be administered to reverse mental clouding in the absence of sedation but should not be administered to agitated patients.
e. Myoclonus: Myoclonus is not usually a clinical problem, and reassurance should be given to patients regarding its benign nature. However, if myoclonus impairs function, prevents sleep, or increases pain, clonazepam or valproate should be administered. A reduction in opioid dose or a switch to a different opioid should be considered in the face of refractory or severe myoclonus.

f. Pruritus: Pruritus is rarely a problem with chronic opioid administration, and consideration should be given to an initial trial of diphenhydramine if it occurs.
g. Urinary retention: Urinary retention is also rare with chronic opioid administration and should be treated by administration of a direct cholinomimetic agent, such as bethanecol.
h. Respiratory depression: The least amount of naloxone should be administered to preserve analgesia and avoid withdrawal (Appendix 2). Because of the short half-life of naloxone, a continuous infusion may be necessary.

VI. Recognition, Assessment, and Management of Psychosocial Factors

The literature suggests that psychosocial interventions are effective in improving analgesia and the quality of life for cancer pain patients. The Task Force and panel of consultants offer similar support. Psychosocial interventions for the management of cancer pain include pain diaries, hypnosis, biofeedback, relaxation training, psychotherapy, and behavior management. Recognition is given to the nonspecific effects of listening and showing concern for the welfare of the patient. Management of the psychosocial consequences of cancer pain includes the use of nonpharmacologic interventions (*e.g.,* psychotherapy and pastoral counseling), psychotropic medications, and antidepressants.

Recommendations:

A psychosocial assessment should be conducted initially as an integral part of the comprehensive pain evaluation. Results of the psychosocial assessment should be considered when formulating a pain treatment plan. Pain diaries and counseling should be considered to enhance medication compliance, if needed. The anesthesiologist should recognize that pharmacologic and neurolytic techniques may not be fully effective in controlling pain and that relaxation training, hypnosis, biofeedback, and behavior therapy are important adjuncts. The anesthesiologist should collaborate with psychologists and other health professionals when psychosocial interventions are indicated. The anesthesiologist should recognize that psychosocial manifestations related to cancer (but not to cancer pain) may require referral to appropriate mental health professionals.

VII. Home Parenteral Therapy

The literature suggests that home parenteral therapy is effective for analgesia without notable risk of adverse effects. The panel of consultants and Task Force members support the importance of home parenteral therapy in increasing analgesia and enhancing patient quality of life. Home parenteral therapy provides an infrastructure for the logistical support and clinical management of complex drug delivery systems in a nonhospital setting. Home parenteral therapy includes subcutaneous, intravenous, and neuraxial drug delivery techniques, either on an outpatient basis or with the assistance of a home health-care provider. The coordination of home parenteral therapy may be accomplished by various providers (*e.g.,* hospitals, clinics, or home health-care professionals).

Recommendations:

Before changing from the oral route of administration, the anesthesiologist should ascertain the availability of family and professional support systems. The patient and family must be educated in the use of the home therapy system. The anesthesiologist should determine whether the patient and/or significant others are motivated and competent to care for sophisticated delivery systems. An assessment must be made as to whether appropriate professional services and supplies are obtainable in specific locales, because special planning may be required in rural areas. Communication among the patient, the home health-care professional, and the prescribing physician must be maintained at all times.

VII. End-of-Life Care

The need for supportive care intensifies for patients and their families at the end of life. The literature, Task Force members, and consultants are supportive of the efficacy of palliative therapies for cancer patients approaching the end of life. End-of-life care is intended to improve patient comfort and quality of life by means of palliative therapies, including but not limited to anxiolytics, skin care, mouth care, massage, and appetite stimulants. Palliative therapies may be provided in the form of comprehensive programs, such as hospice or nursing-care outreach programs.

Recommendations:

The management of cancer pain must be integrated into a comprehensive care system that may include hospice and psychosocial support for patients and their families. Assessing and monitoring a patient's palliative care needs are essential parts of the

evaluative/therapeutic process. When cancer patients are approaching the end of life, the anesthesiologist should integrate pain management with palliative care needs. Collaboration with palliative care providers is recommended to maximize patient comfort and improve patient and family quality of life.

IX. Recognition and Management of Special Features of Pediatric Cancer Pain Management

The literature suggests that child-specific interventions are associated with improved analgesia and health outcomes. The Task Force and consultants are supportive of the effectiveness of pediatric cancer pain therapies in improving analgesia and quality of life. Age-appropriate assessment includes behavioral observation (*e.g.,* facial expressions, crying) and self-reports using age-appropriate scales (*e.g.,* visual analog scale, facial pain scale). Pharmacologic interventions designed for children's use include but are not limited to (1) adjustment of dosage to those levels specific for children and (2) interventions designed to be less invasive or to alleviate patient fears or anxieties about their pain therapy (*e.g.,* topical anesthetics as premedication). Psychological and other nonpharmacologic interventions include those designed specifically for children or adult interventions modified to be applicable to children.

Recommendations:

The anesthesiologist should give special attention to the assessment of pain in pediatric patients. For children unable to communicate verbally, observation of patient behavior should be the primary assessment tool. For children who can communicate verbally, age-appropriate pain scales are the recommended self-report instruments when evaluating the efficacy of pain therapy. Observation should be used as an adjunct to self-report.

Administration of oral medications to children should follow the schema of the WHO analgesic ladder, with particular attention paid to age-appropriate dosing regimens. Liquids or suspensions should be employed whenever possible, because many children find them more palatable than pills. (Note: Continuous-release morphine preparations cannot be crushed and still maintain their continuous release properties.) Every attempt should be made to minimize repetitive exposure to needles, if possible. Patient-controlled analgesia (intravenous or subcutaneous) is a viable alternative when children are of sufficient cognitive age. Invasive systemic therapies and direct delivery systems should be used when oral and noninvasive analgesic deliveries do not achieve sufficient analgesia, or side effects make their continued use untenable. Psychological and other nonpharmacologic methods of pain management should be considered as adjuvants.

The Task Force thanks those who responded to surveys on cancer pain management, reviewed guideline drafts, contributed oral and written testimony to the Open Forum, and participated in tests of clinical feasibility.

The development of these guidelines included methods recommended in the following publications: (1) Committee to Advise the Public Health Service on Clinical Practice Guidelines, Division of Health Care Services, Institute of Medicine: Clinical Practice Guidelines: Directions for a New Program. Edited by Field MJ, Lohr KN. Washington, DC, National Academy, 1990, 1992; and (2) Woolf SH: Manual for Clinical Practice Guidelines Development. Washington, DC, US Department of Health and Human Services, Agency for Health Care Policy and Research, publication number 91-0007, March 1991.

Appendix 1. Assessment of Scientific Evidence and Consultant Opinion

The scientific assessment of these guidelines was based on the following statements or evidence linkages. These linkages represent directional hypotheses about relationships between cancer pain, symptom management, and clinical outcomes.

1. Comprehensive evaluation and assessment of pain (*i.e.,* history, physical examination, laboratory evaluation) improve analgesia, reduce adverse effects of pain therapy, and improve quality of life.
2. Longitudinal monitoring of pain (*e.g.,* patient self-report, rating scales, and frequency of pain ratings) improves analgesia, reduces adverse effects of pain therapy, and improves quality of life.
3. Involvement of specialists in multiple disciplines improves analgesia, reduces adverse effects of pain therapy, and improves quality of life.
4. Indirect drug delivery systems (*i.e.,* systemic analgesia: oral medications administered by application of the WHO pain ladder, rectal and transdermal analgesia, subcutaneous drug delivery, and intravenous drug delivery) improve analgesia, reduce adverse effects of pain therapy, and improve quality of life.
5. Direct drug delivery systems (*i.e.,* neuraxial drug delivery (epidural, subarachnoid, intraventricular), neural blockade (diagnostic blockade, neural blockade for pain management), and neuroablation

(chemical, thermal, and surgical neurolysis)) improve analgesia, reduce adverse effects of pain therapy, and improve quality of life.
6. Management of cancer-related symptoms, side effects of cancer treatment, and adverse effects from pain therapy (*e.g.,* use of antiemetics and laxatives) improves analgesia, reduces adverse effects of pain therapy, and improves quality of life.
7. Psychosocial interventions for pain management and interventions to treat psychosocial consequences from cancer pain and pain management improve analgesia, reduce adverse effects of pain therapy, and improve quality of life.
8. Home parenteral therapy improves analgesia, reduces adverse effects of pain therapy, and improves quality of life.
9. End-of-life care improves analgesia, reduces adverse effects of pain therapy, and improves quality of life.
10. Special features of pediatric cancer pain management (*i.e.,* age-appropriate assessments and dosage levels, interventions to alleviate fears and anxieties about pain therapy, less invasive routes of pharmacologic administration) improve analgesia, reduce adverse effects of pain therapy, and improve quality of life.

Scientific evidence was derived from aggregated research literature with metaanalyses when appropriate, surveys, open presentations, and other consensus-oriented activities. For purposes of literature aggregation, potentially relevant clinical studies were identified *via* electronic and manual searches of the literature. The electronic search covered a 30-yr period from 1966 through 1995. The manual search covered a 48-yr period from 1948 through 1995. More than 3,000 citations were identified initially, yielding 953 non-overlapping articles that addressed topics related to the 10 evidence linkages. After review of the articles, 603 studies did not provide direct evidence and were subsequently eliminated, yielding 350 articles containing direct evidence. Journals (n = 116) represented by the 350 articles included the following disciplines: anesthesiology, 205; oncology, 36; internal medicine, 3; neurology, 4; neurosurgery, 34; nursing, 8; palliative care, 27; pediatrics, 6; pharmacology, 9; psychology, 14; and radiology, 4.

A directional result for each study was determined initially by classifying the outcome as either supporting a linkage, refuting a linkage, or neutral. The results were summarized to obtain a directional assessment of support for each linkage. The literature relating to linkages 3 (involvement of specialists from multiple disciplines), 5a (neuraxial, *i.e.,* epidural and subarachnoid drug delivery), 6 (management of symptoms or adverse effects), and 9 (end-of-life care) contained enough studies with well defined experimental designs and statistical information to conduct formal metaanalyses.

The following terms were used in the guidelines to express the strength of the evidence relating to various interventions and their associated outcomes: (1) *insufficient* data: There is insufficient published data to provide an indication of the relationship between intervention and outcome; (2) *suggestive* data: There is qualitative evidence in the form of case reports or descriptive studies, but there is insufficient quantitative evidence to establish a statistical relationship between intervention and outcome; (3) *supportive* data: Quantitative data indicate a significant relationship between intervention and outcome ($P < 0.01$), and qualitative data are suggestive.

Combined probability tests were applied to continuous data, and an odds-ratio procedure was applied to dichotomous study results. Two combined probability tests were employed as follows: (1) Fisher's combined test, producing chi-square values based on logarithmic transformations of the reported P values from the independent studies, and (2) the Stouffer combined test, providing representation of the studies by weighting each of the standard normal deviates by the size of the sample. A procedure based on the Mantel-Haenszel method for combining study results using 2 × 2 tables was used when sufficient outcome frequency information was available. An acceptable significance level was set at $P < 0.01$ (one-tailed), and effect-size estimates were calculated. Interobserver agreement was established through assessment of interrater reliability testing. Tests for heterogeneity of the independent samples were conducted to assure consistency among the study results. To control for potential publishing bias, a "fail-safe n" value was calculated for each combined probability test. No search for unpublished studies was conducted, and no reliability tests for locating research results were done.

Results of the combined probability tests are reported in table A1 . Significance levels from the weighted Stouffer combined test for clinical efficacy were significant for linkages 3 (multiple disciplines) and 5a (neuraxial drug delivery). The weighted Stouffer test for linkage

TABLE 1 -- Staistical Summary: Combined Test Results

Analgesic efficacy			
Linkage 3. Involvement of specialists in multiple disciplines			
Fisher combined test:	Chi-square = 35.83	$P < 0.001$	$df = 12$
Stouffer combined test:	Z_c (weighted) = 3.025	$P < 0.010$	
Effect size estimate:	r (weighted) = 0.13		
Fail-safe N value:	Nfs .01 = 15.7		
Linkage 5a. Epidural and subarachnoid drug delivery			
Fisher combined test:	Chi-square = 34.45	$P < 0.001$	$df = 12$

Stouffer combined test:	Z_c (weighted) = 3.742	*P* = 0.001	
Effect size estimate:	r (weighted) = 0.34		
Fail-safe N value:	Nfs .01 = 20.2		
Linkage 9. End-of-life care			
Fisher combined test:	Chi-square = 48.39	*P* < 0.001	*df* = 10
Stouffer combined test:	Z_c (weighted) = 2.286	*P* < 0.011 (NS)	
Effect size estimate:	*r* (weighted) = 0.20		
Fail-safe N value:	Nfs .01 = 23.1		
Beneficial outcomes			
Linkage 3. Involvement of specialists from multiple disciplines			
Fisher combined test:	Chi-square = 40.06	*P* < 0.001	*df* = 10
Stouffer combined test:	Z_c (weighted) = 3.442	*P* < 0.010	
Effect size estimate:	*r* (weighted) = 0.17		
Fail-safe N value:	Nfs .01 = 19.1		
Linkage 6. Management of side effects (primary disease and treatment)			
Fisher combined test:	Chi-square = 80.21	*P* < 0.001	*df* = 16
Stouffer combined test:	Z_c (weighted) = 3.650	*P* < 0.001	
Effect size estimate:	*r* (weighted) = 0.34		
Fail-safe N value:	Nfs .01 = 83.7		
Linkage 9. End-of-life care			
Fisher combined test:	Chi-square = 47.34	*P* < 0.001	*df* = 14
Stouffer combined test:	Z_c (weighted) = 4.147	*P* < 0.001	
Effect size estimate:	*r* (weighted) = 0.18		
Fail-safe N value:	Nfs .01 = 28.8		

9 (end-of-life care) was not significant. Weighted effect size estimates ranged from r = 0.13 to r = 0.34, demonstrating small-to-moderate effect size estimates. Significance levels from the weighted Stouffer combined tests for beneficial outcomes were significant for linkages 3 (multiple disciplines), 6 (symptoms or adverse effects), and 9 (end-of-life care). Weighted effect size estimates for beneficial outcomes ranged from r = 0.17 to r = 0.34. Tests for heterogeneity of statistical tests and effect size were nonsignificant in all cases, indicating that the pooled studies provided common estimates of significance and population effect sizes. Sufficient data were not available in the literature to conduct Mantel-Haenszel analyses on these linkages.

Metaanalysis was not performed on linkage 4 (indirect drug delivery systems) for either efficacy or outcomes because literature was not conducive to an appropriate assessment. The literature did not consistently report analgesic requirements of the patients studied, which may vary over time as a function of the natural history of the disease. Lack of concurrent analytical control for time-of-measurement and cohort effects preclude valid comparisons. However, subgroup analyses indicated that mild adverse outcomes were associated with the use of weak opioids in comparison to NSAID administration. Weighted Stouffer combined test results were: Zc = 4.69, *P* < 0.001; the weighted effect size estimate (r = 0.32) indicated a moderate effect size. The odds of adverse effects (*e.g.,* sedation, nausea, vomiting) were greater for weak opioids *versus* NSAID groups (odds ratio 1.95, 99% confidence limits 1.45-2.46, Z = 3.10, *P* < 0.001).

Agreement among Task Force members and two methodologists was established by interrater reliability testing. Agreement levels using a Kappa statistic for two-rater agreement pairs were as follows: (1) type of study design, k = 0.37-0.67; (2) type of analysis, k = 0.47-0.72; (3) evidence linkage assignment, k =

0.47-0.96; and (4) literature inclusion for database, k = 0.35-1.00. Three-rater chance-corrected agreement values were: (1) design, Sav = 0.46, Var (Sav) = 0.008; (2) analysis, Sav = 0.63, Var (Sav) = 0.006; (3) linkage identification, Sav = 0.64, Var (Sav) = 0.005; and (4) literature database inclusion, Sav = 0.53, Var (Sav) = 0.030. These values represent moderate to high levels of agreement.

The findings of the literature analyses were supplemented by the opinions of Task Force members as well as by surveys of the opinions of a panel of consultants with expertise in cancer pain management (n = 72). The rate of return of the surveys was 81% (n = 58 of 72). The percentage of consultants supporting each linkage is reported in table A2 . Consultants, in general, were highly supportive of the linkages (*i.e.,* agreed that they provided analgesic benefit, reduced risk of adverse outcomes, improved other cancer-related symptoms, improved quality of life, and were important issues for the guidelines to address).

The feasibility of implementing these guidelines into clinical practice was assessed by an opinion survey of the cancer pain consultant panel (n = 71). Rate of return of the survey was 65% (n = 46 of 71). The mean number of patients treated annually by the consultants was reported to be 557.5 (min/max = 10/5,000). Responses for feasibility of implementation of the guidelines were as follows: (1) Ninety-one percent (n = 42 of 46) of these consultants indicated that implementation of the guidelines would not result in the need to purchase new equipment, supplies, or pharmaceuticals. (2) Among the four respondents who stated that purchases would be required, the median anticipated cost was $ 25,000 (mean $ 24,625; range $ 13,500-35,000).

The consultants were asked to indicate which, if any, of the evidence linkages would change their clinical practices if the guidelines were instituted. The percent of consultants expecting no change associated with each linkage were as follows: comprehensive evaluation, 76%; longitudinal monitoring, 78%; multiple disciplines, 89%; administration of systemic opioids, 100%; neuraxial drug delivery, 87%; neurolytic techniques, 87%; management of symptoms/adverse effects, 89%; psychosocial factors, 89%, use of parenteral therapy, 94%, end-of-life care, 80%, and pediatric pain management, 83%.

Eighty percent of the respondents indicated that the guidelines would have no effect on the amount of time spent on a typical case. None reported that the guidelines would reduce the amount of time spent per case. For all respondents, the mean increase in the amount of time spent on a typical case was 7.1 min (range 0-120 min). Of the 20% of respondents who reported an anticipated increase in time spent on a typical case, the mean was 36.1 min (range 10-120 min).

Readers with special interest in the statistical analyses used in establishing these guidelines can receive further information by writing to the American Society of Anesthesiologists: 520 North Northwest Highway, Park Ridge, Illinois 60068-2573.

TABLE 2 -- Consultant Responses to Evidence Linkages Survey (n = 58)

Linkages	Analgesic Benefit (% Supportive)	Reduced Risk (% Supportive)	Improved Symptoms (% Supportive)	Improved Quality of Life (% Supportive)	Important Topic (% Supportive)
1. Comprehensive evaluation	98	93	90	91	98
2. Longitudinal monitoring	98	100	85	100	100
3. Involvement of specialists in multiple disciplines	83	64	90	83	79

4. Administration of systemic opioids	71	66	38	74	91
5. Neuraxial drug administration	83	64	41	69	91
6a. Management of cancer-related symptoms or side effects of cancer	81	91	--	98	93

7. Psychosocial interventions	83	71	79	95	98
8. Parenteral therapy	81	62	53	81	41
9. End-of-life care	85	86	97	97	95
10. Pediatric cancer pain management	93	83	67	91	98

Appendix 2. Adverse Drug Effects from Opioid Therapies

Tolerance, physical dependence, and addiction are concerns expressed by patients and physicians and must be understood to optimize therapy.

1. Tolerance refers to the progressive decline in the potency of an opioid with continued use, such that increasingly greater doses are needed to achieve the same degree of analgesia. The phenomenon is characteristic of opioids as a class of analgesics and is receptor-mediated. Clinical observations confirm that most patients with stable pain do not require dose escalation to maintain relief. Hence, tolerance is seldom the "driving force" for dose escalation.
   When tolerance to an opioid develops, incomplete cross-tolerance to other opioids concomitantly develops. In such cases, another opioid can be substituted to provide better analgesia.
2. Physical dependence does not imply addiction. Physical dependence is a physiologic state characterized by withdrawal (abstinence syndrome) after abrupt discontinuation of an opioid.
3. Addiction is a psychological and behavioral syndrome characterized by compulsive drug-seeking behavior (among other behaviors), loss of control over drug use, and continued use despite harm. Addiction implies compulsive behavior and psychological dependence. This is exceedingly rare among cancer patients who are given opioids. Tolerance (a pharmacologic property of a class of drugs) and physical dependence (a physiologic effect characteristic of this class of drugs) are conceptually and phenomenologically distinct from addiction.
4. Constipation is highly prevalent among patients receiving chronic treatment with opioids. All patients with an increased risk for constipation should receive prophylactic therapy. Clinical scenarios or syndromes with an increased risk for the development of constipation include: (1) cachexia and/or debilitation, (2) poor performance status (especially the bedridden patient), (3) intraabdominal neoplasm, (4) a history of prior abdominal radiation, (5) autonomic neuropathy, (6) poor fluid intake, and (7) the concurrent use of constipating agents. A stool softener (*e.g.,* docusate) often is used in combination with bulk, osmotic, or stimulant cathartics.
5. Sedation is a common adverse effect associated with the analgesic therapy of cancer pain.
6. Nausea and vomiting are usually uncommon and transitory in patients undergoing opioid titration. Persistent nausea is rare, and prophylaxis is not indicated.
7. Mental clouding or cognitive impairment can vary from mild mental clouding to frank delirium. Mental clouding may occur without sedation.
8. Myoclonus, pruritus, and urinary retention occur infrequently in patients receiving chronic opioid therapy.
9. Respiratory depression is rare in the cancer patient receiving chronic opioid therapy and occurs in association with obtundation and bradypnea. Respiratory depression can occur with abrupt resolution of pain and inadequate reduction of opioid dosage after successful neuroablation. If respiratory depression occurs in a patient taking stable opioid doses without abrupt resolution of pain due to a major therapeutic maneuver, an explanation other than opioid toxicity should be sought (*e.g.,* pulmonary embolism). Reversal of respiratory problems with naloxone only signifies that an opioid was contributing to the respiratory problem. Reversal of respiratory depression with naloxone does not obviate the need to consider other possible etiologies or pursue further evaluation.

APPENDIX: Practice Guidelines for Preoperative Fasting and the Use of Pharmacologic Agents to Reduce the Risk of Pulmonary Aspiration: Application to Healthy Patients Undergoing Elective Procedures[D]

A Report by the American Society of Anesthesiologists Task Force on Preoperative Fasting

PRACTICE guidelines are systematically developed recommendations that assist the practitioner and patient in making decisions about health care. These recommendations may be adopted, modified, or rejected according to clinical needs and constraints.

Practice guidelines are not intended as standards or absolute requirements. The use of practice guidelines cannot guarantee any specific outcome. Practice guidelines are subject to periodic revision as warranted by the evolution of medical knowledge, technology, and practice. The guidelines provide basic recommendations that are supported by analysis of the current literature and by a synthesis of expert opinion, open forum commentary, and clinical feasibility data (Appendix).

A. Purposes of the Guidelines for Preoperative Fasting

The purposes of these Guidelines are to enhance the quality and efficiency of anesthesia care, stimulate evaluation of individual practices, and reduce the severity of complications related to pulmonary aspiration of gastric contents, should it occur. Enhancements in the quality and efficiency of anesthesia care include, but are not limited to, the cost-effective utilization of perioperative preventive medication, increased patient satisfaction, avoidance of delays and cancellations, decreased risk of dehydration or hypoglycemia from prolonged fasting, and the minimization of perioperative morbidity. Complications of aspiration include, but are not limited to, aspiration pneumonia, respiratory disabilities, and related morbidities.

B. Focus

Prevention of pulmonary aspiration is part of the larger process of preoperative evaluation and preparation of the patient. The Guidelines specifically focus on preoperative fasting recommendations, as well as recommendations regarding the administration of pharmacologic agents to modify the volume and acidity of gastric contents during procedures in which upper airway protective reflexes may be impaired.

Airway management techniques that are intended to reduce the occurrence of pulmonary aspiration are not the focus of these Guidelines. For example, a rapid-sequence induction/endotracheal intubation technique or awake endotracheal intubation technique may be useful to prevent this problem during the delivery of

Developed by the Task Force on Preoperative Fasting and the Use of Pharmacologic Agents to Reduce the Risk of Pulmonary Aspiration: Mark A. Warner, M.D. (Chair), Rochester, Minnesota; Robert A. Caplan, M.D., Seattle, Washington; Burton S. Epstein, M.D., Washington, DC; Charles P. Gibbs, M.D., Denver, Colorado; Candace E. Keller, M.D., M.P.H., Hattiesburg, Mississippi; Jessie A. Leak, M.D., Fayetteville, North Carolina; Roger Maltby, M.B.B.S., Calgary, Alberta, Canada; David G. Nickinovich, Ph.D., Bellevue, Washington; Mark S. Schreiner, M.D., Philadelphia, Pennsylvania; Chris M.Weinlander, M.D., Appleton, Wisconsin.

anesthesia care. The Guidelines do not address the selection of anesthetic technique.

The intended patient population is limited to healthy patients of all ages undergoing elective procedures. The Guidelines do not apply to patients who undergo procedures with no anesthesia or only local anesthesia when upper airway protective reflexes are not impaired, and no risk factors for pulmonary aspiration are apparent. The Guidelines are not intended for women in labor.

The Guidelines may not apply to or may need to be modified for patients with co-existing diseases or conditions that might affect gastric emptying or fluid volume (*e.g.,* pregnancy, obesity, diabetes, hiatal hernia, gastroesophageal reflux disease, ileus or bowel obstruction, emergency care, or enteral tube feeding) and patients in whom airway management might be difficult. Anesthesiologists and other anesthesia providers should recognize these conditions and minimize the opportunity for regurgitation and pulmonary aspiration.

C. Application

The Guidelines are intended for use by anesthesiologists and other anesthesia providers. They also may serve as a resource for other health care professionals who advise or care for patients who will receive anesthesia care during procedures. Anesthesia care during procedures is defined as general anesthesia, regional anesthesia, or sedation/analgesia (*i.e.,* monitored anesthesia care). Throughout these Guidelines, the term "preoperative" should be considered synonymous with "preprocedural", as the latter term relates to procedures commonly not considered to be operations.

D. Task Force Members and Consultants

The ASA appointed a Task Force of 10 members to (a) review the published evidence; (b) obtain consultant opinion from a representative body of anesthesiologists, nurse anesthetists, anesthesiology assistants, perioperative nurses, surgeons, gastroenterologists and other internists, dentists and oral surgeons, ophthalmologists, psychiatrists, emergency medicine physicians, and practice management staff personnel; and (c) build consensus within the Task Force. The Task Force members consisted of anesthesiologists in both private and academic practices from various geographic areas of the United States and Canada and methodologists from the ASA Ad-Hoc Committee on Practice Parameters.

The Task Force met its objective in a five-step process. First, original published research studies relevant to these issues were reviewed and analyzed. Second, Consultants from around the world who practice or work in various settings (*e.g.,* academic and private practice) were asked to (a) participate in a survey of their impressions of the effectiveness of various fasting and pharmacologic interventions to decrease the risks of perioperative pulmonary aspiration, and (b) review and comment on the initial draft report of the Task Force. Third, the Task Force held an open forum at a major national anesthesia meeting to solicit input on its draft recommendations from attendees of the meeting. Fourth, all available information was used to build consensus within the Task Force on the recommended guidelines that follow. Finally, the Consultants were surveyed to assess their opinions on the feasibility of implementing the Guidelines.

E. Availability and Strength of Evidence

Evidence-based guidelines are developed by a rigorous analytic process. To assist the reader, the Guidelines make use of several descriptive terms that are easier to understand than the technical terms and data that are used in the actual analyses. These descriptive terms are defined below: The following terms describe the availability of scientific evidence in the literature.

Insufficient:

There are too few published studies to investigate a relationship between a clinical intervention and clinical outcome.

Inconclusive:

Published studies are available, but they cannot be used to assess the relationship between a clinical intervention and a clinical outcome because the studies either do not meet predefined criteria for content as defined in the "Focus of the Guidelines," or do not meet research design or analytic standards.

Silent:

There are no available studies in the literature that address a relationship of interest.

The following terms describe the strength of scientific data when sufficient literature is available.

Supportive:

There is sufficient quantitative information from adequately designed studies to describe a statistically significant relationship (P<0.01) between a clinical intervention and a clinical outcome, using the technique of meta-analysis.

Suggestive:

There is enough information from case reports

and descriptive studies to provide a directional assessment of the relationship between a clinical intervention and a clinical outcome. This type of qualitative information does not permit a statistical assessment of significance.

Equivocal: Qualitative data have not provided a clear direction for clinical outcomes related to a clinical intervention and (1) there is insufficient quantitative information or (2) aggregated comparative studies have found no quantitatively significant differences among groups or conditions.

The following terms describe survey responses from Consultants for any specified issue. Responses are weighted as agree = +1, undecided = 0 or disagree = -1.

Agree: The average weighted responses must be equal to or greater than +0.30 (on a scale of -1 to 1) to indicate agreement.

Equivocal: The average weighted responses must be between -0.30 and
0.30 (on a scale of -1 to 1) to indicate an equivocal response.

Disagree: The average weighted responses must be equal to or less than -0.30 (on a scale of -1 to 1) to indicate disagreement.

Guidelines

I. Preoperative Assessment

There is insufficient published evidence to evaluate the effect of a preoperative assessment (e.g., history, physical examination, survey/interview) on the frequency or severity of pulmonary aspiration of gastric contents during the perioperative period. The Consultants and the Task Force agree that a preoperative assessment may be associated with improved outcome related to the prevention of perioperative pulmonary aspiration of gastric contents.

Recommendations:

A review of pertinent medical records, a physical examination, and patient survey or interview should be performed as part of the preoperative evaluation. The history, examination, and interview should include pertinent assessment of gastroesophageal reflux disease, dysphagia symptoms, or other gastrointestinal motility disorders, potential for difficult airway management, and metabolic disorders (e.g., diabetes mellitus) that may increase the risk of regurgitation and pulmonary aspiration. Patients should be informed of fasting requirements and the reasons for them sufficiently in advance of their procedures. Verification of their compliance with the fasting requirements should be assessed at the time of their procedures. When the following fasting guidelines are not followed, the practitioner should compare the risks and benefits of proceeding, with consideration given to the amount and type of liquids or solids ingested.

II. Preoperative Fasting Status (Clear Liquids)

Published evidence is silent on the relationship between fasting times, gastric volume, or gastric acidity and the risk of emesis/reflux or pulmonary aspiration in humans. Studies comparing fasting times of between 2 and 4 hours versus more than 4 hours found smaller gastric volumes in adult patients who fasted 2 to 4 hours, although the effect size was small. No differences in gastric volume were found for children who fasted 2 to 4 hours versus more than four hours. In studies that examine the ingestion of clear liquids between 2 and 4 hours before procedures and in which ingested liquid volumes were recorded, participants received volumes of clear liquids ranging widely from 2 ml/kg to unrestricted amounts. Published evidence is equivocal regarding the effect of clear liquid ingestion on gastric acidity for both adults and children.

The Consultants are equivocal regarding a fasting period for clear liquids of between 2 and 4 hours for adults, but they support a fasting period of 2 hours for infants and children. The Task Force supports a fasting period for clear liquids of 2 hours for all patients.

Recommendations:

It is appropriate to fast from intake of clear liquids for 2 or more hours before procedures requiring general anesthesia, regional anesthesia, or sedation/analgesia (i.e., monitored anesthesia care) [*Table 1*]. Examples of clear liquids include, but are not limited to, water, fruit juices without pulp, carbonated beverages, clear tea, and black coffee. These liquids should not include alcohol. The volume of liquid ingested is less important than the type of liquid ingested.

III. Preoperative Fasting Status (Breast Milk)

There is insufficient published evidence to evaluate the relationship of the timing of breast milk intake before procedures to the incidence of emesis/reflux or pulmonary aspiration. The Consultants and Task Force support a fasting period for breast milk of 4 hours for both neonates and infants.

Recommendations:

It is appropriate to fast from intake of breast milk for 4 or more hours before procedures requiring general anesthesia, regional anesthesia,

TABLE 1 -- Summary of Fasting Recommendations to Reduce the Risk of Pulmonary Aspiration*

Ingested Material	Minimum Fasting Period (h)
Clear liquids	2
Breast milk	4
Infant formula	6
Non-human milk	6
Light meal	6

*These recommendations apply to healthy patients who are undergoing elective procedures. They are not intended for women in labor. Following the Guidelines does not guarantee complete gastric emptying.
The fasting periods noted above apply to all ages.
Examples of clear liquids include water, fruit juices without pulp, carbonatedbeverages, clear tea, and black coffee.
Since non-human milk is similar to solids in gastric emptying time, the amount ingested must be considered when determining an appropriate fasting period.
A light meal typically consists of toast and clear liquids. Meals that include fried or fatty foods or meat may prolong gastric emptying time. Both the amount and type of foods ingested must be considered when determining an appropriate fasting period.

or sedation/analgesia (i.e., monitored anesthesia care) *[Table 1].*

IV. Preoperative Fasting Status (Infant Formula)

There is insufficient published evidence to address the safety of any preoperative fasting period for infant formula. For infants and children, the Consultants and Task Force support a fasting period of 6 hours. For neonates, the Consultants support a fasting period of 4 hours, and the Task Force supports a fasting period of 6 hours.

Recommendations:

It is appropriate to fast from intake of infant formula for 6 or more hours before elective procedures requiring general anesthesia, regional anesthesia, or sedation/analgesia (i.e., monitored anesthesia care) *[Table 1]* .

V. Preoperative Fasting Status (Solids and Non-human Milk)

There is insufficient published evidence to address the safety of any preoperative fasting period for solids or non-human milk. For patients of all ages, the Consultants and Task Force support a fasting period for a light meal (e.g., toast and a clear liquid) of 6 hours before elective procedures requiring general anesthesia, regional anesthesia, or sedation/analgesia (i.e., monitored anesthesia care). They also support a fasting period for a meal that includes fried or fatty foods or meat of 8 or more hours before elective procedures. For infants and children, the Consultants and Task Force support a fasting period of 6 hours for non-human milk.

Recommendations:

It is appropriate to fast from intake of a light meal or non-human milk for 6 or more hours before elective procedures requiring general anesthesia, regional anesthesia, or sedation/analgesia (i.e., monitored anesthesia care) *[Table 1]* .The Task Force notes that intake of fried or fatty foods or meat may prolong gastric emptying time. Both the amount and type of foods ingested must be considered when determining an appropriate fasting period. Since non-human milk is similar to solids in gastric emptying time, the amount ingested must be considered when determining an appropriate fasting period.

VI. Preoperative Gastrointestinal Stimulants

Published evidence supports the efficacy of gastroin-testinal stimulants (e.g., metoclopramide) for reducing gastric volume during the perioperative period. It is equivocal regarding the relationship between gastroin-testinal stimulants and gastric acidity. There is insufficient published evidence to examine the relationship between gastrointestinal stimulants and the frequency of pulmonary aspiration. The Consultants and Task Force are equivocal regarding the preoperative use of gastrointestinal stimulants to reduce the risks of pulmonary aspiration.

Recommendations:

The routine preoperative use of gastrointestinal stimulants to decrease the risks of pulmonary aspiration in patients who have no apparent increased risk for pulmonary aspiration is not recommended *(Table 2).*

VII. Preoperative Pharmacologic Blockade of Gastric Acid Secretion

Published evidence supports the efficacy of histamine-2 receptor antagonist agents (e.g., cimetidine, famotidine, or ranitidine) to reduce gastric acidity and volume during the perioperative period and also suggests that proton pump inhibitors (e.g., omeprazole or lansoprazole) are effective for these same purposes. However, it does not sufficiently examine the relationship between reduced gastric acid secretion and the frequency of pulmonary aspiration in humans, and it is silent on the relationship between agents that block gastric acid secretion and the frequency of pulmonary aspiration. There is not sufficient published evidence to evaluate whether reduced gastric acid secretion is associated with decreased morbidity or mortality in patients who have aspirated gastric contents. The Consultants

TABLE 2 -- Summary of Pharmacologic Recommendations to Reduce the Risk of Pulmonary Aspiration

Medication Type and Common Examples	Recommendation
Gastrointestinal stimulants	No routine use
Metoclopramide	
Gastric acid secretion blockers	No routine use
Cimetidine	
Famotidine	
Ranitidine	
Omeprazole	
Lansoprazole	
Antacids	No routine use
Sodium citrate	
Sodium bicarbonate	
Magnesium trisilicate	
Antiemetics	No routine use
Droperidol	
Ondansetron	
Anticholinergics	No use
Atropine	
Scopolamine	
Glycopyrrolate	
Combinations of the medications above	No routine use

and Task Force are equivocal regarding the use of agents that block preoperative gastric acid secretion to reduce the risks of pulmonary aspiration.

Recommendations:

The routine preoperative use of medications that block gastric acid secretion to decrease the risks of pulmonary aspiration in patients who have no apparent increased risk for pulmonary aspiration is not recommended.

VIII. Preoperative Antacids

Published evidence supports the efficacy of preoperative antacids (e.g., sodium citrate, sodium bicarbonate; or magnesium trisilicate) for decreasing gastric acidity during the perioperative period, but it does not support their efficacy in reducing gastric volume. It does not sufficiently examine the relationship between reduced gastric acidity and the frequency of pulmonary aspiration in humans. It also does not examine the relationship between the preoperative use of antacids and the frequency of emesis. There is insufficient published evidence to evaluate whether reduced gastric acidity or volume is associated with decreased morbidity or mortality in patients who have aspirated gastric contents. The Task Force agrees that the pulmonary aspiration of antacids that contain particulates, compared with those that do not, may increase the risk of pulmonary damage. The Consultants and Task Force are equivocal regarding the preoperative use of antacids.

Recommendations:

The routine preoperative use of antacids to decrease the risks of pulmonary aspiration in patients who have no apparent increased risk for pulmonary aspiration is not recommended. Only nonparticulate antacids should be used when antacids are indicated for selected patients for purposes other than reducing the risk of pulmonary aspiration.

IX. Preoperative Antiemetics

Published evidence suggests that preoperative antiemetics (e.g., droperidol, ondansetron) reduce nausea and vomiting during the perioperative period, but statistical significance was not obtained. The literature does not sufficiently examine the relationship between nausea or vomiting and the frequency of pulmonary aspiration in humans during the perioperative period, nor does it sufficiently examine the relationship between preoperative antiemetics and the frequency of pulmonary aspiration. The Consultants and Task Force are equivocal regarding the preoperative use of antiemetics. These Guidelines do not address the use of antiemetics during the extended postoperative period after upper airway protective reflexes are no longer impaired.

Recommendations:

The routine preoperative use of antiemetics to reduce the risks of pulmonary aspiration in patients who have no apparent increased risk for pulmonary aspiration is not recommended.

X. Preoperative Anticholinergics

Published evidence is equivocal regarding the use of anticholinergics (e.g., atropine, scopolamine, or glycopyrrolate) to decrease gastric volume or acidity. The Consultants and Task Force agree that the preoperative use of anticholinergics is not associated with improved outcomes related to pulmonary aspiration.

Recommendations:

The use of anticholinergics to decrease the risks of pulmonary aspiration is not recommended.

XI. Preoperative Multiple Agents

Published evidence supports the preoperative effectiveness of multiple agents, such as histamine-2 receptor antagonists, gastrointestinal stimulants, and antacids, to decrease gastric volume and acidity. However, it is equivocal regarding the added benefit of multiple agents when compared with single agents. It also does not sufficiently examine the relationship between reduced gastric volume or acidity and the frequency of pulmonary aspiration in humans, and it is silent on the relationship between multiple pharmacologic agents and the

frequency of pulmonary aspiration. There is not sufficient published evidence to evaluate whether reduced gastric volume or acidity is associated with decreased morbidity or mortality in patients who have aspirated gastric contents. The Consultants and Task Force are equivocal regarding the use of multiple pharmacologic agents to reduce the frequency or severity of complications associated with pulmonary aspiration.

Recommendations:

The routine preoperative use of multiple agents in patients who have no apparent increased risk for pulmonary aspiration is not recommended.

Appendix: Methods and Analyses*

The scientific assessment of these Guidelines was based on the following statements, or evidence linkages. These linkages represent directional statements about relationships between preoperative fasting and pharmacologic prophylaxis of pulmonary aspiration and clinical outcomes.

1. A preoperative assessment (e.g.,history, physical exam, survey/interview): a) increases patient comfort, b) reduces adverse outcomes, c) improves patient satisfaction, and d) improves cost/utilization of services.
2. For adults, preoperative fasting status of solids between 4 and 8 hours: a) increases patient comfort, b) reduces adverse outcomes, c) improves patient satisfaction, and d) improves cost/utilization of services.
3. For adults, preoperative fasting status of liquids between 2 and 4 hours: a) increases patient comfort, b) reduces adverse outcomes, c) improves patient satisfaction, and d) improves cost/utilization of services.
4. For children, infants and neonates, preoperative fasting status of milk, breast milk or formula between 2 and 4 hours: a) increases patient comfort, b) reduces adverse outcomes, c) improves patient satisfaction, and d) improves cost/utilization of services.
5. Preoperative gastrointestinal stimulants: a) increases patient comfort, b) reduces adverse outcomes, c) improves patient satisfaction, and d) improves cost/utilization of services.
6. Preoperative pharmacologic blockage of gastric acid secretion (i.e., histamine-2 receptor antagonists and proton pump inhibitors): a) increases patient comfort, b) reduces adverse outcomes, c) improves patient satisfaction, and d) improves cost/utilization of services.
7. Preoperative antacids: a) increase patient comfort, b) reduce adverse outcomes, c) improve patient satisfaction, and d) improve cost/utilization of services.
8. Preoperative antiemetics: a) increase patient comfort, b) reduce adverse outcomes, c) improve patient satisfaction, and d) improve cost/utilization of services.
9. Preoperative anticholinergics: a) increase patient comfort, b) reduce adverse outcomes, c) improve patient satisfaction, and d) improve cost/utilization of services.
10. Preoperative multiple agents (e.g., triple prophylaxis): a) increase patient comfort, b) reduce adverse outcomes, c) improve patient satisfaction, and d) improve cost/utilization of services.

TABLE 3 -- Summary of First-, Second-, Third- and Fourth-order Comparisons of Outcomes Related to Fasting and Pharmaceutical Interventions

Fasting of Pharmaceutical Intervention	Number of Studies
First-order comparison

Third-order comparisons	
Intervention--pulmonary aspiration	4
Gastric volume or *p* H--adverse outcomes	0
Fourth-order comparisons	
Intervention--adverse outcomes	0

Scientific evidence was derived from aggregated human research literature, with meta-analyses utilized when appropriate, and from surveys, open presentations and other consensus-oriented activities. For purposes of literature aggregation, potentially relevant clinical studies were identified via electronic and manual searches of the literature. The electronic search covered a 31-year period from 1966 through 1996. The manual search covered a 57-year period of time from 1940 through 1996. Over 3000 citations were initially identified, yielding a total of 1156 non-overlapping articles that addressed topics related to the 10 evidence linkages. Following review of the articles, 924 studies did not provide direct evidence, and were subsequently eliminated. A total of 232 articles (from 48 journals) contained direct linkage-related evidence.

The literature was first categorized according to the proximity or directness of the outcome to the intervention. Generally, a study should either evaluate a direct comparison or institute methodologic controls (e.g., control for intervening variables) in order to appropriately evaluate an outcome. For these Guidelines, the primary outcome of interest was either pulmonary aspiration or the adverse consequences from aspiration. Therefore, comparison of an intervention with pulmonary aspiration or comparison of an intervention with an adverse consequence from aspiration (e.g.,pneumonitis) was the focus of these Guidelines. However, the literature was generally not sufficient to evaluate such relationships. The literature revealed four types of analytic relationships between interventions and outcomes of interest. These types of relationships are referred to as first, second, third, or fourth-order comparisons (Table 3)

A first-order comparison represents a direct comparison either between an intervention (e.g., antacid administration) and a clinical outcome, or between two

outcomes. In the studies reviewed with first-order comparisons, the relationship between one of the identified

*Readers with special interest in the statistical analyses used in establishing these Guidelines can receive further information by writing to the American Society of Anesthesiologists: 520 North Northwest Highway, Park Ridge, Illinois 60068-2573.

Effect size estimate:	r (weighted) = 0.14		

interventions in the Guidelines and the incidence of pulmonary aspiration (i.e., the primary outcome) was not assessed. Therefore, cause-and-effect relationships between the intervention of interest and pulmonary aspiration cannot be shown. Although some outcomes (e.g., gastric volume or pH) were considered by the authors to be representative of a predicted "risk" of pulmonary aspiration, results of such comparisons were not sufficient to provide methodologically acceptable evidence.

Levels 2 through 4 represent comparisons that must first control for an intermediate outcome. For example, in order to examine the effectiveness of a histamine-2 receptor antagonist on pulmonary aspiration, the effect of the histamine-2 receptor antagonist on gastric content as well as the occurrence of emesis must be methodologically controlled. The gastric content and emesis "outcomes" are intervening steps between the intervention and pulmonary aspiration. This example would be considered a "third-order" comparison.

Level 2 represents a comparison in which one step, or intermediate outcome, exists between the intervention and the outcome of interest. However, level 2 relationships do not examine the association between an intervention of interest and the occurrence of pulmonary aspiration.

Level 3 contains one relationship of interest to the Guidelines (i.e., intervention/pulmonary aspiration), and Level 4 contains the other relationship of interest to the Guidelines (i.e., the association between an intervention and clinical consequences from pulmonary aspiration).

Table 3 indicates that outcomes related to preoperative fasting and the administration of pharmacologic agents were insufficient to evaluate cause-and-effect relationships that link the interventions of interest in these Guidelines with the occurrence of pulmonary aspiration or the clinical consequences from pulmonary aspiration.

Although the literature was not sufficient for casual assessment related to pulmonary aspiration, the efficacy of the interventions of interest regarding intermediate outcomes are reported below. For these purposes, a directional result for each study was initially determined by classifying the outcome as either supporting a linkage, refuting a linkage, or neutral. The results were then summarized to obtain a directional assessment of support for each linkage. The literature relating to eight evidence linkages contained enough studies with well-defined experimental designs and statistical information to conduct formal meta-analyses. These eight linkages were: linkage 3a [preoperative fasting status of liquids between 2 and 4 hours for adults], 3b [preoperative fasting status of liquids between 2 and 4 hours for children], 5 [preoperative gastrointestinal stimulants], 6 [preoperative histamine-2 receptor antagonists], 7 [preoperative antacids], 8 [preoperative antiemetics], 9 [preoperative anticholinergics], and 10 [preoperative multiple agents versus single agents]. Outcomes for all of the above linkages consisted of gastric volume, pH, gastric secretions, or nausea and vomiting.

Combined probability tests were applied to continuous data, and an odds-ratio procedure was applied to dichotomous study results. Two combined probability tests were employed as follows: (1) The Fisher Combined Test, producing chi-square values based on logarithmic transformations of the reported p-values from the independent studies, and (2) the Stouffer Combined Test, providing weighted representation of the studies by weighting each of the standard normal deviates by the size of the sample. A procedure based on the Mantel-Haenszel method for combining study results using 2 × 2 tables was available for use with outcome frequency information. An acceptable significance level was set at $p < 0.01$ (one-tailed) and effect size estimates were calculated. Interobserver agreement was established through assessment of interrater reliability testing. Tests for heterogeneity of the independent samples were conducted to assure consistency among the study results. To control for potential publishing bias, a "fail-safe N" value was calculated for each combined probability test. No search for unpublished studies was conducted, and no reliability tests for locating research results were done.

Results of the combined probability tests are reported in Table 4. Significance levels from the Fisher and weighted Stouffer Combined Tests for gastric volume were significant for linkages 3a (preoperative fasting status of liquids between 2 and 4 hours for adults), and 6 (preoperative histamine-2 receptor antagonists). Significance levels for gastric pH were significant for linkages 6 (preoperative histamine-2 receptor antagonists) and 7 (preoperative antacids). Significance levels for gastric volume and airway/salivary secretions were significant for linkage 9 (preoperative anticholinergics). Weighted effect size estimates for these linkages ranged from r = 0.17 to r = 0.40, demonstrating moderate effect size estimates.

Tests for heterogeneity of statistical tests and effect size were non-significant for: a) gastric volume outcomes; linkages 3a, 3b, 5, 7, and 10; b) gastric pH outcomes, linkages 3a, 3b, 5, 6, 7, 9, and 10; for gastric volume and airway/salivary secretions; linkage 9; for nausea and vomiting: linkage 8. These findings indicate that the pooled studies provided common estimates of significance and population effect sizes. Tests for heterogeneity of statistical tests and for effect size were

TABLE 5 -- Consultant Survey of Evidence Linkages: Weighted Responses (N = 77)

Linkages	Reduces Adverse Outcomes	Increases Patient Comfort	Improves Patient Satisfaction	Improves Cost/Utilization
1. A preoperative assessment	0.83	0.92	0.97	0.66
2. 4-8 h fasting of solids for adults	-0.49	0.42	0.45	-0.43
3a. 2-4 h fasting of liquids for adults	0.16	0.92	0.89	0.15
3b. 2-4 h fasting of clear liquids for children	0.55	1.00	0.99	0.22
4. 2-4 h fasting of milk for infants	-0.12	0.88	0.73	-0.07
5. Preoperative gastrointestinal stimulants	-0.03	-0.32	-0.27	-0.27
6. Preoperative gastric acid secretion blockage	0.26	-0.19	-0.22	-0.19
7. Preoperative antacids	0.12	-0.53	-0.54	-0.22
8. Preoperative antiemetics	0.29	0.14	0.34	-0.11
9. Preoperative anticholinergics	-0.45	-0.89	-0.84	-0.57
10. Preoperative multiple drugs	-0.07	-0.14	-0.14	-0.29

significant for linkage 6 (gastric volume). These findings may reflect the differential influence of the various types of histamine-2 receptor antagonists (e.g.,

cimetidine,ranitidine, famotidine), and further analysis may need to separate the distinct influence on gastric volume of each agent.

Agreement among Task Force members and two methodologists was established by interrater reliability testing. Agreement levels using a Kappa statistic for two-rater agreement pairs were as follows: (1) type of study design, k = 0.75 to 0.95; (2) type of analysis, k = 0.54 to 0.85; (3) evidence linkage assignment, k = 0.68 to 0.82; and (4) literature inclusion for database, k = 0.64 to 0.78. Three-rater chance-corrected agreement values were: (1) design, Sav = 0.81, Var (Sav) = 0.006; (2) analysis, Sav = 0.66, Var (Sav) = 0.014; (3) linkage identification, Sav = 0.75, Var (Sav) = 0.005; (4) literature database inclusion, Sav = 0.67, Var (Sav) = 0.050. These values represent moderate to high levels of agreement.

The findings of the literature analyses were supplemented by the opinions of Task Force members as well as by surveys of the opinions of a panel of Consultants as described in the text of the Guidelines (N = 92). The rate of return was 84% (N = 77/92). The percentage of Consultants supporting each linkage is reported in Table 5. Consultants, in general, were highly supportive (i.e., they agreed that the specified linkage reduced the risk of adverse outcomes) of linkage 1 (preoperative assessment) and linkage 3b (2-4 hour fasting of clear liquids for children). Consultants believed that each of the 10 linkages were important issues for the Guidelines to address. Consultants generally did not agree with linkage 2 (4-8 hour fasting of solids for adults), linkage 4 (2-4 hour fasting of milk for infants), and linkage 9 (preoperative anticholinergics).

A second survey addressing fasting periods for liquids, breast milk, infant formula, non-human milk and solids was conducted. The rate of return was 76% (N = 84/110). The percentage of Consultants indicating a specific number of fasting hours is reported in Table 6. For clear liquids, the Consultants indicated support for a 2-hour fasting period for both infants and children. For breast milk, the Consultants indicated support for a 4-hour fasting period for both neonates and infants. For infant formula, the Consultants indicated support for a 4-hour fasting period for neonates, and a 6-hour fasting period for infants. For non-human milk, a 6-hour fasting period was supported for both infants and children. For solids, a 6-hour fasting period was supported for infants and children. For a light meal, the Consultants indicated

TABLE 6 -- Consultant Fasting Survey: Percentage Agreement (N = 84)

	Number of Hours								
	1	**2**	**3**	**4**	**5**	**6**	**7**	**8**	**>8**
Clear liquids--infants	11%	83%	3%	3%	0%	0%	0%	0%	0%
Clear liquids--children	12%	78%	5%	5%	0%	0%	0%	0%	0%
Breast milk--neonates	0%	22%	20%	54%	0%	4%	0%	0%	0%
Breast milk--infants	0%	19%	12%	56%	0%	13%	0%	0%	0%
Formula--neonates	0%	4%	9%	48%	1%	38%	0%	0%	0%
Formula--infants	0%	1%	9%	39%	1%	48%	0%	1%	0%
Non-human milk--infants	0%	1%	7%	36%	1%	49%	0%	6%	0%
Non-human milk--children	0%	0%	3%	38%	0%	50%	0%	9%	0%
Solids--infants	0%	0%	0%	8%	1%	71%	0%	19%	0%

Light meal--adults	1%	8%	1%	14%	1%	65%	0%	10%	0%
Meat, milk, fried food--adults	0%	1%	0%	3%	1%	15%	1%	75%	4%

support for a 6-hour fasting period for adults. For a meal of meat, milk, or fried foods, an 8-hour fasting period was supported for adults.

The Consultants were asked to indicate which, if any, of the evidence linkages would change their clinical practices if the Guidelines were instituted. The percent of Consultants expecting no change associated with each linkage were as follows: preoperative assessment--95%; preoperative fasting of solids--75%; preoperative fasting of liquids--67%; preoperative fasting of breast milk--78%; gastrointestinal stimulants--95%; pharmacologic blockage of gastric secretion--91%; antacids--100%; antiemetics--98%, anticholinergics--100%, and multiple agents--98%.

Ninety-six percent of the respondents indicated that the Guidelines would have no effect on the amount of time spent on a typical case. For all respondents, the mean increase in the amount of time spent on a typical case was 2.4 minutes. Two respondents reported that the Guidelines would increase the amount of time spent per case. The anticipated increase for these two respondents was 5 and 120 minutes.

APPENDIX: Practice Guidelines for Obstetrical Anesthesia[D]

A Report by the American Society of Anesthesiologists Task Force on Obstetrical Anesthesia

PRACTICE guidelines are systematically developed recommendations that assist the practitioner and patient in making decisions about health care. These recommendations may be adopted, modified, or rejected according to clinical needs and constraints.

Practice guidelines are not intended as standards or absolute requirements. The use of practice guidelines cannot guarantee any specific outcome. Practice guidelines are subject to periodic revision as warranted by the evolution of medical knowledge, technology, and practice. The guidelines provide basic recommendations that are supported by analysis of the current literature and by a synthesis of expert opinion, open forum commentary, and clinical feasibility data (Appendix).

A. Purposes of the Guidelines for Obstetrical Anesthesia

The purposes of these Guidelines are to enhance the quality of anesthesia care for obstetric patients, reduce the incidence and severity of anesthesia-related complications, and increase patient satisfaction.

B. Focus

The Guidelines focus on the anesthetic management of pregnant patients during labor, non-operative delivery, operative delivery, and selected aspects of postpartum care. The intended patient population includes, but is not limited to intrapartum and postpartum patients with uncomplicated pregnancies or with common obstetric problems. The Guidelines do not apply to patients undergoing surgery during pregnancy, gynecological patients or parturients with chronic medical disease (*e.g.,* severe heart, renal or neurological disease).

C. Application

The Guidelines are intended for use by anesthesiologists. They also may serve as a resource for other anesthesia providers and health care professionals who advise or care for patients who will receive anesthesia care during labor, delivery and the immediate postpartum period.

D. Task Force Members and Consultants

The ASA appointed a Task Force of 11 members to review the published evidence and obtain consultant opinion from a representative body of anesthesiologists and obstetricians. The Task Force members consisted of anesthesiologists in both private and academic practices from various geographic areas of the United States.

The Task Force met its objective in a five-step process. First, original published research studies relevant to these issues were reviewed and analyzed. Second, Consultants from various geographic areas of the United States who practice or work in various settings (*e.g.,* academic and private practice) were asked to participate

Developed by the Task Force on Obstetrical: Anesthesia: Joy L. Hawkins, M.D. (Chair), Denver, Colorado; James F. Arens, M.D., Galveston, Texas; Brenda A. Bucklin, M.D., Omaha, Nebraska; Robert A. Caplan, M.D., Seattle, Washington; David H. Chestnut, M.D., Birmingham, Alabama; Richard T. Connis, Ph.D., Woodinville, Washington: Patricia A. Dailey, M.D., Hillsborough, California; Larry C. Gilstrap, M.D., Houston, Texas; Stephen C. Grice, M.D., Alpharetta, Georgia; Nancy E. Oriol, M.D., Boston, Massachusetts; Kathryn J. Zuspan, M.D., Edina, Minnesota.

in opinion surveys and review and comment on drafts of the Guidelines. Third, the Task Force held two open forums at major national meetings to solicit input from attendees on its draft recommendations. Fourth, all available information was used by the Task Force in developing the Guideline recommendations. Finally, the Consultants were surveyed to assess their opinions on the feasibility of implementing the Guidelines.

E. Availability and Strength of Evidence

Evidence-based guidelines are developed by a rigorous analytic process. To assist the reader, the Guidelines make use of several descriptive terms that are easier to understand that the technical terms and data that are used in the actual analyses. These descriptive terms are defined below:

The following terms describe the availability of scientific evidence in the literature.

Insufficient: There are too few published studies to investigate a relationship between a clinical intervention and clinical outcome.

Inconclusive: Published studies are available, but they cannot be used to assess the relationship between a clinical intervention and a clinical outcome because the studies either do not meet predefined criteria for content as defined in the "Focus of the Guidelines," or do not meet research design or analytic standards.

Silent: There are no available studies in the literature that address a relationship of interest.

The following terms describe the strength of scientific data.

Supportive: There is sufficient quantitative information from adequately designed studies to describe a statistically significant relationship ($p < 0.01$) between a clinical intervention and a clinical outcome, using the technique of meta-analysis.

Suggestive: There is enough information from case reports and descriptive studies to provide a directional assessment of the relationship between a clinical intervention and a clinical outcome. This type of qualitative information does not permit a statistical assessment of significance.

Equivocal: Qualitative data have not provided a clear direction for clinical outcomes related to a clinical intervention and (1) there is insufficient quantitative information or (2) aggregated comparative studies have found no quantitatively significant differences among groups or conditions.

The following terms describe survey responses from Consultants for any specified issue. Responses are weighted as agree = +1, undecided = 0 or disagree = -1.

Agree: The average weighted responses must be equal to or greater than +0.30 (on a scale of -1 to 1) to indicate agreement.

Equivocal: The average weighted responses must be between -0.30 and +0.30 (on a scale of -1 to 1) to indicate an equivocal response.

Disagree: The average weighted responses must be equal to or less than -0.30 (on a scale of -1 to 1) to indicate disagreement.

Guidelines

I. Perianesthetic Evaluation.

History and Physical Examination.

The literature is silent regarding the relationship between anesthesia-related obstetric outcomes and the performance of a focused history and physical examination. However, there is suggestive data that a patient's medical history and/or findings from a physical exam may be related to anesthetic outcomes. The Consultants and Task Force agree that a focused history and physical examination may be associated with reduced maternal, fetal and neonatal complications. The Task Force agrees that the obstetric patient benefits from communication between the anesthesiologist and the obstetrician.

Recommendations: The anesthesiologist should do a focused history and physical examination when consulted to deliver anesthesia care. This should include a maternal health history, an anesthesia-related obstetric history, an airway examination, and a baseline blood pressure measurement. When a regional anesthetic is planned, the back should be examined. Recognition of significant anesthetic risk factors should encourage consultation with the obstetrician.

Intrapartum Platelet Count.

A platelet count may indicate the severity of a patient's pregnancy-induced hypertension. However, the literature is insufficient to assess the predictive value of a platelet count for anesthesia-related complications in either uncomplicated parturients or those with pregnancy-induced hypertension. The Consultants and Task Force both agree that a routine platelet count in the healthy parturient is not

---

necessary. However, in the patient with pregnancy-induced hypertension, the Consultants and Task Force both agree that the use of a platelet count may reduce the risk of anesthesia-related complications.

Recommendations: A specific platelet count predictive of regional anesthetic complications has not been determined. The anesthesiologist's decision to order or require a platelet count should be individualized and based upon a patient's history, physical examination and clinical signs of a coagulopathy.

3. Blood Type and Screen.

The literature is silent regarding whether obtaining a blood type and screen is associated with fewer maternal anesthetic complications. The Consultants and Task Force are equivocal regarding the routine use of a blood type and screen to reduce the risk of anesthesia-related complications.

Recommendations: The anesthesiologist's decision to order or require a blood type and screen or cross-match should be individualized and based on anticipated hemorrhagic complications (e.g., placenta previa in a patient with previous uterine surgery).

4. Perianesthetic Recording of the Fetal Heart Rate.

The literature suggests that analgesic/anesthetic agents may influence the fetal heart rate pattern. There is insufficient literature to demonstrate that perianesthetic recording of the fetal heart rate prevents fetal complications. However, both the Task Force and Consultants agree that perianesthetic recording of the fetal heart rate reduces fetal and neonatal complications.

Recommendations: The fetal heart rate should be monitored by a qualified individual before and after administration of regional analgesia for labor. The Task Force recognizes that continuous electronic recording of the fetal heart rate may not be necessary in every clinical setting [1] and may not be possible during placement of a regional anesthetic.

Fasting in the Obstetric Patient.

Clear Liquids.

Published evidence is insufficient regarding the relationship between fasting times for clear liquids and the risk of emesis/reflux or pulmonary aspiration during labor. The Task Force and Consultants agree that oral intake of clear liquids during labor improves maternal comfort and satisfaction. The Task Force and Consultants are equivocal whether oral intake of clear liquids increases maternal risk of pulmonary aspiration.

Recommendations: The oral intake of modest amounts of clear liquids may be allowed for uncomplicated laboring patients. Examples of clear liquids include, but are not limited to, water, fruit juices without pulp, carbonated beverages, clear tea, and black coffee. The volume of liquid ingested is less important than the type of liquid ingested. However, patients with additional risk factors of aspiration (e.g., morbid obesity, diabetes, difficult airway), or patients at increased risk for operative delivery (e.g., nonreassuring fetal heart rate pattern) may have further restrictions of oral intake, determined on a case-by-case basis.

2. Solids.

A specific fasting time for solids that is predictive of maternal anesthetic complications has not been determined. There is insufficient published evidence to address the safety of *any* particular fasting period for solids for obstetric patients. The Consultants agree that a fasting period for solids of 8 hours or more is preferable for uncomplicated parturients undergoing *elective* cesarean delivery. The Task Force recognizes that in laboring patients the timing of delivery is uncertain; therefore compliance with a predetermined fasting period is not always possible. The Task Force supports a fasting period of at least 6 hours before elective cesarean delivery.

Recommendations: Solid foods should be avoided in laboring patients. The patient undergoing elective cesarean delivery should undergo a fasting period for solids consistent with the hospital's policy for nonobstetric patients undergoing elective surgery. Both the amount and type of food ingested must be considered when determining the timing of surgery.

III. Anesthesia Care for Labor and Vaginal Delivery

A. Overview of Recommendations.

Anesthesia care is not necessary for all women for labor and/or delivery. For women who request pain relief for labor and/or delivery, there are many effective analgesic techniques available. Maternal request represents sufficient justification for pain relief, but the selected analgesia technique depends on the medical status of the patient, the progress of the labor, and the resources of the facility. When sufficient resources (e.g., anesthesia and nursing staff) are available, epidural catheter techniques should be one of the analgesic options offered. The primary goal is to provide adequate maternal analgesia with as little motor block as possible when regional analgesia is used for uncomplicated labor and/or vaginal delivery. This can be achieved by the administration of local anesthetic at low concentrations. The concentration of the local anesthetic may be further reduced by the addition of narcotics and still provide adequate analgesia.

B. Specific Recommendations.

1. Epidural anesthetics:

a. Epidural local anesthetics.

The literature supports the use of single-bolus epidural local anesthetics for providing greater quality of analgesia compared to *parenteral opioids.* However, the literature indicates a reduced incidence of spontaneous vaginal delivery associated with single-bolus epidural local anesthetics. The literature is insufficient to indicate causation. Compared to *single-injection spinal opioids* the literature is equivocal regarding the analgesic efficacy of single-bolus epidural local anesthetics. The literature suggests that epidural local anesthetics compared to spinal opioids are associated with a lower incidence of pruritus. The literature is insufficient to compare the incidence of other side-effects.

b. Addition of opioids to epidural local anesthetics. The literature supports the use of epidural local anesthetics with opioids, when compared with equal concentrations of epidural local anesthetics without opioids for providing greater quality and duration of analgesia. The former is associated with reduced motor block and an increased likelihood of spontaneous delivery, possibly as a result of a reduced total dose of local anesthetic administered over time. [N]

The literature is equivocal regarding the analgesic efficacy of *low* concentrations of epidural local anesthetics with opioids compared to *higher* concentrations of epidural local anesthetics without opioids. The literature indicates that low concentrations of epidural local anesthetics with opioids compared to higher concentrations of epidural local anesthetics are associated with reduced motor block.

No differences in the incidence of nausea, hypotension, duration of labor, or neonatal outcomes are found when epidural local anesthetics with opioids were compared to epidural local anesthetics without opioids. However, the literature indicates that the addition of opioids to epidural local anesthetics results in a higher incidence of pruritus. The literature is insufficient to determine the effects of epidural local anesthetics with opioids on other maternal outcomes (e.g., respiratory depression, urinary retention).

The Task Force and majority of Consultants are supportive of the case-by-case selection of an analgesic technique for labor. The subgroup of Consultants reporting a preferred technique, when all choices are available, selected an epidural local anesthetic technique. When a low concentration of epidural local anesthetic is used, the Consultants and Task Force agree that the addition of an opioid(s) improves analgesia and maternal satisfaction without increasing maternal, fetal or neonatal complications.

Recommendations: The selected analgesic/anesthetic technique should reflect patient needs and preferences, practitioner preferences or skills, and available resources. When an epidural local anesthetic is selected for labor and delivery, the addition of an opioid may allow the use of a lower concentration of local anesthetic and prolong the duration of analgesia. Appropriate resources for the treatment of complications related to epidural local anesthetics (e.g., hypotension, systemic toxicity, high spinal anesthesia) should be available. If opioids are added, treatments for related complications (e.g., pruritus, nausea, respiratory depression) should be available.

c. Continuous infusion epidural techniques (CIE) The literature indicates that effective analgesia can be maintained with a low concentration of local anesthetic with an epidural infusion technique. In addition, when an opioid is added to a local anesthetic infusion, an even lower concentration of local anesthetic provides effective analgesia. For example, comparable analgesia is found, with a reduced incidence of motor block, using bupivacaine infusion concentrations of *less than* 0.125% with an opioid compared to bupivacaine concentrations *equal to* 0.125% without an opioid. [R] No comparative differences are noted for incidence of instrumental delivery.

The literature is equivocal regarding the relationship between different local anesthetic infusion regimens and the incidence of nausea or neonatal outcome. However, the literature suggests that local anesthetic infusions with opioids are associated with a higher incidence of pruritus.

The Task Force and Consultants agree that infusions using low concentrations of local anesthetics with or without opioids provide equivalent analgesia, reduced motor block, and improved maternal satisfaction when compared to higher concentrations of local anesthetic.

No meta-analytic differences in the likelihood of spontaneous delivery were found when studies using morphine or meperidine were added to studies using only fentanyl or sufentanil.
References to bupivacaine are included for illustrative purposes only, and because bupivacaine is the most extensively studied local anesthetic for CIE. The Task Force recognizes that other local anesthetic agents are equally appropriate for CIE.

Recommendations: Adequate analgesia for uncomplicated labor and delivery should be provided with the secondary goal of producing as little motor block as possible. The lowest concentration of local anesthetic infusion that provides adequate maternal analgesia and satisfaction should be used. For example, an infusion concentration of bupivacaine equal to or greater than 0.25% is unnecessary for labor analgesia for most patients. The addition of an opioid(s) to a low concentration of local anesthetic may improve analgesia and minimize motor block. Resources for the treatment of potential complications should be available.

2. Spinal Opioids with or without Local Anesthetics.

The literature suggests that spinal opioids with or without local anesthetics provide effective labor analgesia without significantly altering the incidence of neonatal complications. There is insufficient literature to compare spinal opioids with parenteral opioids. However, the Consultants and Task Force agree that spinal opioids provide improved maternal analgesia compared to parenteral opioids.

The literature is equivocal regarding analgesic efficacy of spinal opioids compared to epidural local anesthetics. The Consultants and Task Force agree that spinal opioids provide equivalent analgesia compared to epidural local anesthetics. The Task Force agrees that the rapid onset of analgesia provided by single-injection spinal techniques may be advantageous for selected patients (e.g., those in advanced labor).

Recommendations: Spinal opioids with or without local anesthetics may be used to provide effective, although time-limited, analgesia for labor. Resources for the treatment of potential complications (e.g., pruritus, nausea, hypotension, respiratory depression) should be available.

3. Combined spinal-epidural techniques.

Although the literature suggests that combined spinal-epidural techniques (CSE) provide effective analgesia, the literature is insufficient to evaluate the analgesic efficacy of CSE compared to epidural local anesthetics. The literature indicates that use of CSE techniques with opioids when compared to epidural local anesthetics with or without opioids results in a higher incidence of pruritus and nausea. The Task Force and Consultants are equivocal regarding improved analgesia or maternal benefit of CSE versus epidural techniques. Although the literature is insufficient to evaluate fetal and neonatal outcomes of CSE techniques, the Task Force and Consultants agree that CSE does not increase the risk of fetal or neonatal complications.

Recommendations: Combined spinal-epidural techniques may be used to provide rapid and effective analgesia for labor. Resources for the treatment of potential complications (e.g., pruritus, nausea, hypotension, respiratory depression) should be available.

4. Regional Analgesia and Progress of Labor.

There is insufficient literature to indicate whether timing of analgesia related to cervical dilation affects labor and delivery outcomes. Both the Task Force and Consultants agree that cervical dilation at the time of epidural analgesia administration does not impact the outcome of labor.

The literature indicates that epidural analgesia may be used in a trial of labor for previous cesarean section patients without adversely affecting the incidence of vaginal delivery. However, randomized comparisons of epidural versus other specific anesthetic techniques were not found, and comparison groups were often confounded.

Recommendations: Cervical dilation is not a reliable means of determining when regional analgesia should be initiated. Regional analgesia should be administered on an individualized basis.

5. Monitored or Stand-by Anesthesia Care for Complicated Vaginal Delivery.

Monitored anesthesia care refers to instances in which an anesthesiologist has been called upon to provide specific anesthesia services to a particular patient undergoing a planned procedure. [2] For these Guidelines, stand-by anesthesia care refers to the availability of the anesthesiologist in the facility, in the event of obstetric complications. The literature is silent regarding the subject of monitored or stand-by anesthesia care in obstetrics. However, the Task Force and Consultants agree that monitored or stand-by anesthesia care for complicated vaginal delivery reduces maternal, fetal, and neonatal complications.

Recommendations: Either monitored or stand-by anesthesia care, determined on a case-by-case basis for complicated vaginal delivery (e.g., breech presentation, twins, and trial of instrumental delivery), should be made available when requested by the obstetrician.

IV. Removal of Retained Placenta

1. Anesthetic Choices.

The literature is insufficient to indicate whether a particular type of anesthetic is more effective than another for removal of retained placenta. The literature is also insufficient to assess the relationship between a particular type of anesthetic and maternal complications. The Task Force and Consultants agree that spinal or epidural anesthesia (i.e., regional anesthesia)

---

is associated with reduced maternal complications and improved satisfaction when compared to general anesthesia or sedation/analgesia. The Task Force recognizes that circumstances may occur when general anesthesia or sedation/analgesia may be the more appropriate anesthetic choice (e.g., significant hemorrhage).

Recommendations: Regional anesthesia, general endotracheal anesthesia, or sedation/analgesia may be used for removal of retained placenta. Hemodynamic status should be assessed before giving regional anesthesia to a parturient who has experienced significant bleeding. In cases involving significant maternal hemorrhage, a general anesthetic may be preferable to initiating regional anesthesia. Sedation/analgesia should be titrated carefully due to the potential risk of pulmonary aspiration in the recently delivered parturient with an unprotected airway.

2. Nitroglycerin for Uterine Relaxation.

The literature suggests and the Task Force and Consultants agree that the administration of nitroglycerin is effective for uterine relaxation during removal of retained placental tissue.

Recommendations: Nitroglycerin is an alternative to terbutaline sulfate or general endotracheal anesthesia with halogenated agents for uterine relaxation during removal of retained placental tissue. Initiating treatment with a low dose of nitroglycerin may relax the uterus sufficiently while minimizing potential complications (e.g., hypotension).

V. Anesthetic Choices for Cesarean Delivery

The literature suggests that spinal, epidural or CSE anesthetic techniques can be used effectively for cesarean delivery. When compared to regional techniques, the literature indicates that general anesthetics can be administered with shorter induction-to-delivery times. The literature is insufficient to determine the relative risk of maternal death associated with general anesthesia compared to other anesthetic techniques. However, the literature suggests that a greater number of maternal deaths occur when general anesthesia is administered. The literature indicates that a larger proportion of neonates in the general anesthesia groups, compared to those in the regional anesthesia groups, are assigned Apgar scores of less than 7 at one and five minutes. However, few studies have utilized randomized comparisons of general versus regional anesthesia, resulting in potential selection bias in the reporting of outcomes.

The literature suggests that maternal side effects associated with regional techniques may include hypotension, nausea, vomiting, pruritus and postdural puncture headache. The literature is insufficient to examine the comparative merits of various regional anesthetic techniques.

The Consultants agree that regional anesthesia can be administered with fewer maternal and neonatal complications and improved maternal satisfaction when compared to general anesthesia. The consultants are equivocal about the possibility of increased maternal complications when comparing spinal or epidural anesthesia with CSE techniques. They agree that neonatal complications are not increased with CSE techniques.

Recommendations: The decision to use a particular anesthetic technique should be individualized based on several factors. These include anesthetic, obstetric and/or fetal risk factors (e.g., elective versus emergency) and the preferences of the patient and anesthesiologist. Resources for the treatment of potential complications (e.g., airway management, inadequate analgesia, hypotension, pruritus, nausea) should be available.

VI. Postpartum Tubal Ligation

There is insufficient literature to evaluate the comparative benefits of local, spinal, epidural or general anesthesia for postpartum tubal ligation. Both the Task Force and Consultants agree that epidural, spinal and general anesthesia can be effectively provided without affecting maternal complications. Neither the Task Force nor the Consultants agree that local anesthetic techniques provide effective anesthesia, and they are equivocal regarding the impact of local anesthesia on maternal complications. Although the literature is insufficient, the Task Force and Consultants agree that a postpartum tubal ligation can be performed safely within eight hours of delivery in many patients.

Recommendations. Evaluation of the patient for postpartum tubal ligation should include assessment of hemodynamic status (e.g., blood loss) and consideration of anesthetic risks. The patient planning to have an elective postpartum tubal ligation within 8 hours of delivery should have no oral intake of solid foods during labor, and postpartum until the time of surgery. Both the timing of the procedure and the decision to use a particular anesthetic technique (i.e., regional versus general) should be individualized, based on anesthetic and/or obstetric risk factors and patient preferences. The anesthesiologist should be aware that an epidural catheter placed for labor may be more likely to fail with longer postdelivery time intervals. If a postpartum tubal ligation is to be done before the patient is discharged

TABLE 1 -- Suggested Resources for Obstetric Hemorrhagic Emergencies*

1. Large bore iv catheters
2. Fluid warmer
3. Forced air body warmer
4. Availability of blood bank resources
5. Equipment for infusing iv fluids and/or blood products rapidly. Examples include (but are not limited to) hand squeezed fluid chambers, hand inflated pressure bags, and automatic infusion devices.

* The items listed represent suggestions. The items should be customized to meet the specific needs, preferences, and skills of the practitioner and health-care facility.

from the hospital, the procedure should not be attempted at a time when it might compromise other aspects of patient care in the labor and delivery area.

VII. Management of Complications

1. Resources for Management of Hemorrhagic Emergencies.

The literature suggests that the availability of resources for hemorrhagic emergencies is associated with reduced maternal complications. The Task Force and Consultants agree that the availability of resources for managing hemorrhagic emergencies is associated with reduced maternal, fetal and neonatal complications.

Recommendations: Institutions providing obstetric care should have resources available to manage hemorrhagic emergencies *(Table 1).* In an emergency, the use of type-specific or O negative blood is acceptable in the parturient.

2. Equipment for Management of Airway Emergencies.

The literature suggests, and the Task Force and Consultants agree that the availability of equipment for the management of airway emergencies is associated with reduced maternal complications.

Recommendations: Labor and delivery units should have equipment and personnel readily available to manage airway emergencies. Basic airway management equipment should be immediately available during the initial provision of regional analgesia (Table 2) In addition, portable equipment for difficult airway management should be readily available in the operative area of labor and delivery units (Table 3) (Table Not Available) .

3. Central Invasive Hemodynamic Monitoring.

There is insufficient literature to indicate whether pulmonary artery catheterization is associated with improved maternal, fetal or neonatal outcomes in patients with pregnancy-related hypertensive disorders. The literature is silent regarding the management of obstetric

TABLE 2 -- Suggested Resources for Airway Management During Initial Provision of Regional Anesthesia *

1. Laryngoscope and assorted blades
2. Endotracheal tubes, with stylets
3. Oxygen source
4. Suction source with tubing and catheters
5. Self-inflating bag and mask for positive pressure ventilation
6. Medications for blood pressure support, muscle relaxation, and hypnosis

*The items listed represent suggestions. The items should be customized to meet the specific needs, preferences, and skills of the practitioner and health-care facility.

Recommendations: The decision to perform invasive hemodynamic monitoring should be individualized and based on clinical indications that include the patient's medical history and cardiovascular risk factors. The Task Force recognizes that not all practitioners have access to resources for utilization of central venous or pulmonary artery catheters in obstetric units.

TABLE 3 -- Suggested Contents of a Portable Unit for Difficult Airway Management for Cesarean Section Rooms *

(Not Available)

* The items listed represent suggestions. The items should be customized to meet the specific needs, preferences, and skills of the practitioner and health-care facility.

patients with central venous catheterization alone. The literature suggests that pulmonary artery catheterization has been used safely in obstetric patients; however, the literature is insufficient to examine specific obstetric outcomes. The Task Force and Consultants agree that it is not necessary to use central invasive hemodynamic monitoring routinely for parturients with severe preeclampsia.

4. Cardiopulmonary Resuscitation.

The literature is insufficient to evaluate the efficacy of CPR in the obstetric patient during labor and delivery. The Task Force is supportive of the immediate availability of basic and advanced life-support equipment in the operative area of labor and delivery units.

Recommendations: Basic and advanced life-support equipment should be immediately available in the operative area of labor and delivery units. If cardiac arrest occurs during labor and delivery, standard resuscitative measures and procedures, including left uterine displacement, should be taken. In cases of cardiac arrest, the American Heart Association has stated the following: "Several authors now recommend that the decision to perform a perimortem cesarean section should be made rapidly, with delivery effected within 4 to 5 minutes of the arrest." [3]

/das/book/view/29494766/875/1145.html

Appendix: Methods and Analyses.

The scientific assessment of these Guidelines was based on the following statements, or evidence linkages. These linkages represent directional statements about relationships between obstetrical anesthetic interventions and clinical outcomes.

I. Perianesthetic Evaluation

1. A directed history and physical examination reduces maternal, fetal & neonatal complications.

2a. A routine intrapartum platelet count reduces maternal anesthetic complications.

2b. For pregnancy-induced hypertension, an intrapartum platelet count reduces maternal anesthetic complications.

3. For all parturients, an intrapartum blood type & screen reduces maternal, fetal & neonatal complications.

4. Perianesthetic recording of the fetal heart rate reduces fetal & neonatal complications.

II. Fasting for Labor and Delivery

5a. Oral intake of clear liquids during labor improves patient comfort and satisfaction, and does not increase maternal complications.

5b. Oral intake of solids during labor increases maternal complications.

III. Anesthetic Choices for Labor and Delivery

6a. Epidural techniques versus parenteral opioids: (a) improve maternal analgesia, (b) decrease maternal anesthetic complications, and (c) decrease fetal and neonatal complications.

6b. Epidural techniques versus spinal techniques: (a) improve maternal analgesia and (b) decrease maternal anesthetic complications.

6c. Epidural local anesthetics with opioids versus equal concentrations of epidural local anesthetics without opioids: (a) improve maternal analgesia, but (b) increase maternal, fetal & neonatal anesthetic complications.

6d. Epidural local anesthetics with opioids versus higher concentrations of epidural local anesthetics without opioids: (a) improve maternal analgesia, and (b) reduce maternal, fetal & neonatal anesthetic complications.

6e. Epidural infusion of lower concentrations of local anesthetics with opioids (i.e., bupivacaine concentrations less than 0.125% with opioids versus concentrations equal to 0.125%): (a) provides equivalent maternal analgesia, (b) reduces maternal motor block, but (c) increases opioid-related maternal anesthetic complications.

6f. Epidural infusion of lower concentrations of local anesthetics with opioids (i.e., bupivacaine concentrations less than 0.25% with opioids versus bupivacaine equal to or greater than 0.25%): (a) provides equivalent maternal analgesia, (b) reduces maternal motor block, but (c) increases opioid-related maternal anesthetic complications.

6g. Spinal opioids (with or without local anesthetic) versus parenteral opioids: (a) improve maternal analgesia, (b) reduce maternal, fetal & neonatal anesthetic complications, and (c) improve maternal satisfaction.

6h. Combined spinal-epidural techniques versus epidural local anesthetics: (a) improve maternal analgesia, but (b) increase maternal, fetal & neonatal anesthetic complications.

6i. Administering epidural analgesia at cervical dilatations of 3 to 5 centimeters (versus <3 cm) (a) improves maternal analgesia, (b) reduces maternal, fetal & neonatal obstetric complications, and (c) improves maternal satisfaction.

6j. Administering epidural analgesia at cervical dilatations of 3 to 5 centimeters (versus >5 cm) (a) improves maternal analgesia, (b) reduces maternal, fetal & neonatal anesthetic complications, and (c) improves maternal satisfaction.

6k. Epidural techniques for trial of labor patients: (a) reduces the incidence of cesarean delivery, (b) reduces maternal, fetal & neonatal obstetric complications, and (c) improves maternal satisfaction.

6l. Monitored or stand-by anesthesia care for complicated vaginal delivery reduces maternal, fetal & neonatal complications.

IV. Removal of Retained Placenta

7. Regional anesthesia [versus general anesthesia or sedation] for pain management during removal of retained placenta reduces maternal anesthetic complications and improves patient satisfaction.

8. Administration of nitroglycerin for uterine relaxation improves success at removing retained placenta.

V. Anesthetic Choices for Cesarean Delivery

9a. Spinal anesthesia for cesarean section provides maternal comfort & satisfaction without clinically significant maternal, fetal & neonatal anesthetic

complications.

9b. Epidural anesthesia for cesarean section provides maternal comfort & satisfaction without clinically significant maternal, fetal & neonatal anesthetic complications.

9c. General anesthesia for cesarean section provides maternal comfort & satisfaction without clinically significant maternal, fetal & neonatal anesthetic complications.

9d. Combined spinal-epidural techniques versus epidural or spinal techniques alone for cesarean section provide maternal comfort & satisfaction without clinically significant maternal, fetal & neonatal anesthetic complications.

VI. Postpartum Tubal Ligation

10a. Local anesthesia for postpartum tubal ligation without preexisting anesthesia (a) improves maternal analgesia, (b) reduces maternal anesthetic complications, and (c) improves maternal satisfaction.

10b. Spinal anesthesia for postpartum tubal ligation without preexisting anesthesia (a) improves maternal analgesia, (b) reduces maternal anesthetic complications, and (c) improves maternal satisfaction.

10c. Epidural anesthesia for postpartum tubal ligation without preexisting anesthesia (a) improves maternal analgesia, (b) reduces maternal anesthetic complications, and (c) improves maternal satisfaction.

10d. General anesthesia for postpartum tubal ligation without preexisting anesthesia (a) improves maternal analgesia, (b) reduces maternal anesthetic complications, and (c) improves maternal satisfaction.

11. A postpartum tubal ligation [i.e., within 8 hours of delivery]: (a) does not increase maternal anesthetic complications, (b) improves patient satisfaction, and (c) improves cost/efficiency.

VII. Management of Complications

12. Availability of resources for management of hemorrhagic emergencies reduces maternal, fetal & neonatal anesthetic complications.

13. Availability of equipment for management of airway emergencies reduces maternal, fetal & neonatal anesthetic complications.

14. Peripartum invasive hemodynamic monitoring for preeclamptic patients reduces maternal, fetal & neonatal anesthetic and obstetric complications.

15. Immediate availability of basic and advanced life-support equipment in the operative area of labor and delivery units reduces maternal, fetal & neonatal complications.

.

Scientific evidence was derived from aggregated research literature with meta-analyses utilized when appropriate, and from surveys, open presentations and other consensus-oriented activities. For purposes of literature aggregation, potentially relevant clinical studies were identified via electronic and manual searches of the literature. The electronic search covered a 33-year period from 1966 through 1998. The manual search covered a 59-year period of time from 1940 through 1998. Over 4000 citations were initially identified, yielding a total of 2347 nonoverlapping articles that addressed topics related to the 33 evidence linkage. Following review of the articles, 1819 studies did not provide direct evidence, and were subsequently eliminated. A total of 528 articles (from 57 journals) contained direct linkage-related evidence.

A directional result for each study was initially determined by classifying the outcome as either supporting a linkage, refuting a linkage, or neutral. The results were then summarized to obtain a directional assessment of support for each linkage. The literature relating to 8 evidence linkages contained enough studies with well-defined experimental designs and statistical information to conduct formal meta-analyses. These eight linkages were: linkage 6a [epidural versus parenteral techniques for labor], 6b [epidural versus single-shot spinal techniques for labor], 6c [epidural local anesthetics with opioids versus equal dosages of local anesthetics without opioids], 6d [epidural local anesthetics with opioids versus higher concentrations of local anesthetics without opioids], 6e [epidural infusion of local anesthetic (bupivacaine) concentrations of less than 0.125% versus concentrations equal to 0.125%], 6h [combined spinal-epidural techniques versus epidural local anesthetics for labor], 6k [epidural anesthesia for trial of labor], and 9c [general anesthesia versus epidural or spinal anesthesia for cesarean delivery].

Combined probability tests were applied to continuous data, and an odds-ratio procedure was applied to dichotomous study results. Two combined probability tests were employed as follows: (1) The Fisher Combined Test, producing chi-square values based on logarithmic transformations of the reported p-values from the independent studies, and (2) the Stouffer Combined Test, providing weighted representation of the studies by weighting each of the standard normal deviates by the size of the sample. An odds-ratio procedure based on the Mantel-Haenszel method for combining study results using 2 × 2 tables was used with outcome frequency information. An acceptable significance level was set at $p < 0.01$ (one-tailed) and effect size estimates were calculated. Interobserver agreement was established through assessment of interrater reliability testing. Tests for heterogeneity of the independent samples were conducted to ensure consistency among the study results. To control for potential publishing bias, a "fail-safe N" value was calculated for each combined probability test. No search for unpublished studies was conducted, and no reliability tests for locating research results were done.

Meta-analytic results are reported in Table 4 . To be considered acceptable evidence, both the Fisher and weighted Stouffer combined test results must agree. Significant combined test values were found for: (1) *analgesic efficacy* linkages 6a (epidural versus parenteral techniques for labor) and 6c (epidural local anesthetics with opioids versus equal dosages of local anesthetics without opioids); (2) *duration of analgesia* -linkage 6c (epidural local anesthetics with versus without opioids), and (3) *incision-to-delivery time* -linkage 9c (general anesthesia versus epidural or spinal anesthesia for cesarean delivery). Weighted effect size values for these linkages ranged from $r = 0.13$ to $r = 0.41$, representing small-to-moderate effect size estimates.

To be considered acceptable evidence, combined test results must agree with Mantel-Haenszel odds-ratios when both types of data are assessed. Odds ratios were significant for the following outcomes: (1) *analgesic efficacy* -linkage 6c (epidural local anesthetics with opioids versus equal dosages of local anesthetics without opioids); (2) *mode of delivery* - linkage 6a (epidural versus parenteral techniques for labor); (3) *motor block;* linkage 6c (epidural local anesthetics with opioids versus equal dosages of local anesthetics without opioids), 6d (epidural local anesthetics with opioids versus higher concentration of local anesthetics without opioids), and 6e (epidural infusion of local anesthetic concentrations of less than 0.125% versus concentrations equal to 0.125%); (4) *pruritus* - linkage 6c (epidural local anesthetics with opioids versus equal dosages of local anesthetics without opioids), 6d (epidural local anesthetics with opioids versus higher concentrations of local anesthetics without opioids) and 6h (combined spinal-epidural techniques versus epidural local anesthetics for labor); (5) *nausea* - 6h

* All studies in series were randomized comparative studies.

All studies in series were comparisons using bupivacaine as the local anesthetic and fentanyl or sufentanil as the opioid.

Only studies reporting both motor block and mode of delivery values were compared.

TABLE 5 -- Consultant Survey Summary: Weighted Responses

Evidence Linkages	N *	Improves Maternal Analgesia	Reduces Maternal Complications	Reduces Fetal Complications	Reduces Neonatal Complications	Improves Patient Satisfaction	Improves Cost/Efficiency	Important To Evaluate
1. Directed history and physical exam	111		0.97	0.81	0.67	0.76	0.52	0.91
2a. Routine platelet count	114		-0.66					0.02
2b. Platelet count for PIH	111	0.46						0.66
3. Blood type and screen	111	0.14						0.30
4. Recording of fetal heart rate	114				0.32			0.86
5a. Intake of clear liquids	114		-0.35			0.79		0.74
5b. Intake of solids	114							0.91
6b. Epidural local anesth vs spinal opioids	114	0.43	0.15	-0.59		0.32		
6c/6d. Epidural local with vs without opioids	114	0.79	0.61		0.84	0.80		
6e. <0.125% local + opioid infusion *vs* 0.125%	114	-0.30	-0.12		0.37	0.30		
6g. Spinal vs parenteral opioids	114	0.90	0.21		0.63	0.81		

6h. CSE Techniques vs epidural local anesth	114	-0.05	-0.10		0.50	0.06		
6l. MAC/standby anesth care	111		0.77		0.73			0.80
7. Regional anesthesia for retained placenta	114	0.55	0.54			0.56	0.14	0.71
8. Nitroglycerine for uterine relaxation	114		0.50 §					0.51
9a. Spinal anesthesia for cesarean section	111		0.75	0.35	0.31	0.80	0.42	0.87
9b1. Epidural anesthesia for cesarean section	111		0.84	0.42	0.37	0.71	-0.53	0.86
9b2. Epidural vs spinal anesthesia for cesarean	114		0.64		0.86	-0.57		
9c1. General anesthesia for cesarean section	111		-0.93	-0.78	-0.86	-0.64	-0.77	0.80
9c2. General vs regional for cesarean	114		-0.87		-0.24	-0.92		
9d. CSE for cesarean	114		0.16		0.66	-0.40		
10a. Local anesthesia for PPTL	111	-0.59	-0.30			-0.84	-0.57	0.01
10b. Spinal anesthesia for PPTL	111	0.86	0.48			0.66	0.26	0.80
10c. Epidural anesthesia for PPTL	111	0.82	0.51			0.59	-0.60	0.68
10d. General anesthesia for PPTL	111		-0.87			-0.33	-0.60	0.64
11. Immediate postpartum tubal ligation	114		0.75 ¶			0.59	0.85	0.65
12. Hemorrhagic resources	111		1.00		0.79			0.99
13. Airway resources	111		1.00		0.96			1.00
14. Routine invasive hemodynamic monitoring	114		-0.42		-0.52			0.39

* Two surveys were administered at different times.

Some responses are centered because the question referred to fetal/neonatal complications combined.

38% agreed that clear liquid intake increases aspiration risk.
§Refers to success in removing retained placenta.
¶Refers to the safety of performing a postpartum tubal ligation (PPTL) less than 8 h after delivery.

(combined spinal-epidural techniques versus epidural local anesthetics for labor; (6) *Apgar scores at 1-minute* - linkage 6a (epidural versus parenteral techniques for labor), and linkage 9c (general anesthesia versus epidural or spinal anesthesia for cesarean delivery), and (7) *Apgar scores at 5-minutes* - linkage 9c (general anesthesia versus epidural or spinal anesthesia for cesarean delivery).

For the findings noted above, tests for heterogeneity of statistical tests and effect size were *nonsignificant* for the following outcomes and linkages: (1) *analgesic efficacy - linkage* 6c; (2) mode of delivery - linkage 6a; (3) motor block - linkages 6c, 6d, and 6e; (4) pruritus - linkages 6c and 6d; (5) *nausea* - linkage 6h; (6) *Apgar scores at 1-minute - linkage* 6a; and (7) *Apgar scores at 5-minutes - linkage 9c.*

These findings indicate that the pooled studies provided common estimates of significance and population effect sizes.

For the findings noted above, tests for heterogeneity of statistical tests were significant for the following outcomes and linkages: (1) analgesic efficacy - linkage 6a; (2) Apgar scores at 1-minute - linkage 9c; (3) Apgar scores at 5-minutes - linkage 9c, and (4) incision-to-delivery time - linkage 9c. Tests for heterogeneity of effect size were significant for the following outcomes and linkages:

(1) analgesic efficacy - linkage 6a; (2) duration of analgesia - linkage 6c; (3) pruritus - linkage 6h; (3) Apgar scores at 1-minute - linkage 9c; and (4) incision-to-delivery time - linkage 9c. For analgesic efficacy, the heterogeneous findings for linkage 6a may reflect the differential influence of the various statistical tests combined with a small number of studies used in the analysis. For pruritus, variability in the reported odds ratios may reflect the varying use of opioids in the epidural local anesthetic groups, in contrast with consistent opioid use in the CSE groups, and further analysis may need to control for opioid use in both groups. For incision-to-delivery times and Apgar scores at 1-minute, variability in statistical tests and effect sizes may be the result of nonrandomized comparisons in these meta-analyses. Due to the small number of studies included in these meta-analyses, examination of the analyses for moderator variables could not be conducted.

Agreement among Task Force members and two methodologists was established by interrater reliability testing. Agreement levels using a Kappa statistic for two-rater agreement pairs were as follows: (1) type of study design, k = 0.79 to 0.83; (2) type of analysis, k = 0.57 to 0.73; (3) evidence linkage assignment, k = 0.65 to 0.93; and (4) literature inclusion for database, k = 0.54 to 1.00. Three-rater chance-corrected agreement values were: (1) design, Sav = 0.80, Var (Sav) = 0.004; (2) analysis, Sav = 0.64, Var (Sav) = 0.008; (3) linkage identification, Sav = 0.76, Var (Sav) = 0.040. (4) literature database inclusion, Sav = 0.65, Var (Sav) = 0.040. These values represent moderate to high levels of agreement.

The findings of the literature analyses were supplemented by the opinions of Task Force members as well as by surveys of the opinions of a panel of Consultants as described in the text of the Guidelines. The rate of return was 78% (N = 114/147). The percentage of Consultants supporting each linkage is reported in Table 5 . Consultants were supportive (i.e., they agreed that the specified linkage improved analgesia, reduced the risk of adverse outcomes or improved maternal satisfaction) of the following linkages: linkage 1 (history and physical exam), linkage 4 (recording of fetal heart rate), linkage 6c/d (epidural local anesthetics with versus without

opioids), linkage 61 (monitored/stand-by anesthesia care), linkage 7 (regional anesthesia for retained placenta), linkage 8 (nitroglycerin for retained placenta), linkage 9a (spinal anesthesia for cesarean delivery), linkage 9b (epidural anesthesia for cesarean delivery), linkage 10b (spinal anesthesia for PPTL), linkage 10c (epidural anesthesia for PPTL), linkage 11 (immediate postpartum tubal ligation), linkage 12 (availability of hemorrhagic resources), and linkage 13 (availability of airway resources). Consultants were not supportive of linkage 9c (general anesthesia for cesarean delivery), linkage 10a (local anesthesia for PPTL), 10d (general anesthesia for PPTL), and linkage 14 (invasive hemodynamic monitoring). Consultants believed that all of the linkages were important issues for the Guidelines to address.

Seventy-six percent of the responding Consultants indicated that fasting times for solids should be determined either on a case-by-case basis or by institutional protocol. Fifty-five percent reported a safe fasting time (for solids) for uncomplicated vaginal delivery of no less than 8 hours. Seventy-six percent indicated a safe fasting time (for solids) for elective cesarean delivery of no less than 8 hours.

The Consultants were asked to indicate which, if any, of the evidence linkages would change their clinical practices if the Guidelines were instituted. The rate of return was 59% (N = 86/147). The percent of responding Consultants expecting no change associated with each linkage were as follows: history and physical exam - 98%; routine platelet count - 96%; blood type and screen - 96%; fetal heart rate recording - 98%; oral intake of liquids - 92%; oral intake of solids - 95%; epidural local anesthetics for labor - 100%; epidural infusion for labor - 100%, spinal opioids for labor - 98%, CSE for labor - 98%, cervical dilation - 98%, monitored/stand-by anesthesia care - 100%, retained placenta analgesia - 99%, nitroglycerin for retained placenta - 94%, cesarean anesthetic choices - 100%, tubal ligation - 96%, hemorrhagic emergencies - 99%, airway emergencies - 96%, hemodynamic monitoring - 99%, and CPR - 99%. Ninety-eight percent of the respondents indicated that the Guidelines would have no effect on the amount of time spent on a typical case. Readers with special interest in the statistical analyses used in establishing these Guidelines can receive further information by writing to the American Society of Anesthesiologists: 520 North Northwest Highway, Park Ridge, Illinois 60068-2573.

APPENDIX: Systeme International

SYSTEME INTERNATIONAL

The following information on Systeme International (SI) units and factors for conversion between SI and older conventional units is provided for the convenience of readers and authors. Reprints of these tables are available on request from. The Canadian Anaesthetists' Society Journal, 178 St. George Street, Toronto, Canada, M5R 2M7. [R]

Basic SI Units

Physical Quantity	Name	Symbol
Length	Metre	m
Mass	Kilogram	kg
Time	Second [*]	s
Electric current	Ampere	A
Thermodynamic temperature	Kelvin	K
Luminous intensity	Candela	cd
Amount of substance	Mole	mol

*Minute (min), hour (h) and day (d) will remain in use although they are not official SI units.

Prefixes for SI Units

Factor	Name	Symbol	Factor	Name	Symbol
10^{18}	Exa-	E	10^{-18}	Atto-	a
10^{15}	Peta-	P	10^{-15}	Femto-	f
10^{12}	Tera-	T	10^{-12}	Pico-	p
10^{9}	Giga-	G	10^{-9}	Nano-	n
10^{6}	Mega-	M	10^{-6}	Micro-	mu
10^{3}	Kilo-	k	10^{-3}	Milli-	m
10^{2}	Hecto-	h	10^{-2}	Centi-	c
10^{1}	Deca-	da	10^{-1}	Deci-	d

Derived SI Units

Quantity	SI Unit	Symbol	Expression in Terms of SI Base Units or Derived Units
Frequency	Hertz	Hz	1 Hz = 1 cycle/s (1 s^{-1})
Force	Newton	N	1 N = 1 kg · m/s^2 (1 kg · mps^{-2})
Work, energy, quantity of heat	Joute	J	1 J = 1 N · m
Power	Watt	W	1 W = 1 J/s (1 J · s^{-1})
Quantity of electricity	Coulomb	C	1 C = 1 A · s
Electric potential, potential difference, tension, electromotive force	Volt	V	1 V = 1 W/A (1 W · A^{-1})
Electric capacitance	Farad	F	1 F = 1 A · s/V (1 A · s · V^{-1})
Electric resistance	Ohm	Omega	1 Omega = 1 V/A (1 V · A^{-1})
Flux of magnetic induction, magnetic flux	Weber	Wb	1 Wb = 1 V · s
Magnetic flux density, magnetic induction	Tesla	T	1 T = 1 Wb/m^2 (1 Wb · m^{-2})
Inductance	Henry	H	1 H = 1 V · s/A (1 V · s · A^{-1})
Pressure	Pascal	Pa	1 Pa = 1 N/m^2 (1 N · m^{-2})
			= 1 kg/m · s^2 (1 kg · m-1 · s^{-2})

The litre (10^{-3} m^3 = dm^3), though not official, will remain in use as a unit of volume as also will the dyne (dyn) as a unit of force (1 dyn = 10^{-5} N).

Base excess	mmol/litre	mEq/litre	Numerically equivalent	
Glucose	mmol/litre	mg/100 ml	0.0555	18
Plasma				
Sodium	mmol/litre	mEq/litre	Numerically equivalent	
Potassium	mmol/litre	mEq/litre	Numerically equivalent	
Magnesium	mmol/litre	mEq/litre	0.5	2
Chloride	mmol/litre	mEq/litre	Numerically equivalent	
Phosphate (inorganic)	mmol/litre	mEq/litre	0.323	3.0
Creatinine	mumol/litre	mg/100 ml	88.4	0.01
Urea	mmol/litre	mg/100 ml	0.166	6.0
Serum				
Calcium	mmol/litre	mg/100 ml	0.25	4.0
Iron	mumol/litre	mug/100 mol	0.179	5.6
Bilirubin	mumol/litre	mg/100 mol	17.1	0.06
Cholesterol	mmol/litre	mg/100 ml	0.0259	39
Total proteins	g/litre	g/100 ml	10.0	0.1
Albumin	g/litre	g/100 ml	10.0	0.1
Globulin	g/litre	g/100 ml	10.0	0.1

Biochemical Content of Other Body Fluids

Measurement	SI Unit	Old Unit	Conversion Factors	
			Old to SI (Exact)	SI to Old (Approx.)
Urine				
Calcium	mmol/24 h	mg/24 h	0.025	40
Creatinine	mmol/24 h	mg/24 h	0.00884	113
Potassium	mmol/litre	mEq/litre	Numerically equivalent	
Sodium	mmol/litre	mEq/litre	Numerically equivalent	
Cerebro-spinal fluid				
Protein	g/litre	mg/100 ml	0.01	100
Glucose	mmol/litre	mg/100 ml	0.0555	18

Haematology

Measurement	SI Unit	Old Unit	Conversion Factors	
			Old to SI	SI to Old
Haemoglobin (Hb)	g/dl	g/100 ml	Numerically equivalent	
Packed cell volume	No unit*	Per cent	0.01	100
Mean cell Hb conc.	g/dl	Per cent	Numerically equivalent	

Mean cell Hb	pg	mumug	Numerically equivalent			
Red cell count	Cells/litre	Cells/mm^3	10^6		10^{-6}	
White cell count	Cells/litre	Cells/mm^3	10^6		10^{-6}	
Reticulocytes	Per cent	Per cent	Numerically equivalent			
Platelets	Cells/litre	Cells/mm^3	10^6		10^{-6}	

*Expressed as decimal fraction, e.g., normal adult male value 0.40 to 0.54.

pH and nmol/litre of H* Activity

pH	nmol/litre
6.80	158
6.90	126
7.00	100
7.10	79
7.20	63
7.25	56
7.30	50
7.35	45
7.40	40
7.45	36
7.50	32
7.55	28
7.60	25
7.70	20
