This method of treatment is appealing, particularly for locally advanced malignant lesions, when conventional modalities are unlikely to produce local tumor control. Theoretical advantages over conventional external radiotherapy are the ability to increase tumor dose with less damage to adjacent healthy tissues and more accurate localization of the radiation field. Disadvantages of this technique are that an operation is needed, optimal dose combinations of external-beam and radiation and IORT are complex to calculate, [157] and complications are not infrequent. These complications include pelvic abscess, small bowel obstruction, ureteral obstruction, [159] and peripheral neuropathy. [160] All patients treated with IORT at Mayo Clinic in Rochester, Minnesota, are specifically told about possible nerve-related side effects. [161] In most patients treated with IORT, surgery alone would not achieve local control, and external radiation doses needed for local control would exceed normal tissue tolerance. [162]

The largest clinical experience with IORT has been with gastrointestinal cancers in adults. Of patients treated with IORT at Mayo Clinic, the most frequent diagnosis is locally advanced colorectal cancer. [161] Moderate experience has also been obtained with locally advanced retroperitoneal sarcomas, [156] as well as with recurrent genitourinary and gynecologic cancers. [163]

Most of the advances in the use of radiation have been achieved by an improved dose distribution and better differentiation of dose delivered to tumor and normal tissue. Delivering the radiation during the surgical procedure permits direct observation of tumor size and density and of tissue at risk for microscopic spread of tumor. Shielding of nearby sensitive structures from the intense local radiation field is possible by surgical manipulation. [164] By moving normal and noninvolved tissue out of the path of the electrons, the radiation

Figure 66-11 Intraoperative radiation therapy room. Anesthesia, incision, radiation, and closure occur in this dedicated area.

Figure 66-12 A sterile Lucite cylinder is adjusted to isolate the tumor mass and displace surrounding normal structures.

is confined to the cancer, and the therapeutic ratio can be maximized. [165] Patient selection for IORT should include no contraindications to surgery and the belief that surgical intervention alone will not result in local tumor control. The tumor should be a localized focus of disease, and no distant metastasis should be apparent [156] ; therefore, the treatment is seen as potentially curative. [164] Clotting parameters should be checked preoperatively, particularly in patients with obstructive jaundice. [166]

Ideally, anesthesia, incision, radiation, and closure occur in a single dedicated IORT room (Fig. 66-11) . At the Mayo Clinic, both the operative procedure and delivery of IORT are performed in a dedicated IORT room within the operating suite. [100] [162] [167] A dedicated IORT room has the advantages of allowing surgery and radiation therapy to be accomplished in a single setting without moving the patient through a nonsterile environment. Other advantages of a dedicated IORT room within the surgical suite include the close proximity of other ancillary facilities (e.g., blood bank) and the immediate availability of additional anesthesia and surgical personnel and/or equipment.

Alternatively, induction of anesthesia, surgical incision, and tumor isolation can be accomplished in a modified operating room within the radiation oncology area. [163] This alternative allows the linear accelerator room to be used without interruption for treating other patients while the patient who is to undergo IORT is being prepared. Following preparation, the anesthetized and surgically draped patient is transported a short distance to the accelerator treatment room. Following radiation treatment, the patient is returned to the modified operating room for closure of the incision.

Patients typically receive a conventional general anesthetic regimen with endotracheal intubation. After surgical incision and exploration, the tumor is exposed and isolated. A sterile Lucite cylinder then is inserted to cover the tumor mass, to define the radiation beam, and to displace normal structures outwardly circumferentially around its perimeter [166] (Fig. 66-12) . Radiation therapy may then be focused directly on the isolated tumor.

During IORT, the patient is ventilated automatically. Monitoring includes devices customarily used for any major surgical procedure (e.g., ECG, blood pressure, heart rate, pulse oximetry, gas analysis, temperature, and neuromuscular function). During the actual radiation treatment period, all personnel must leave the treatment room to avoid receiving high radiation exposure, and the patient, anesthesia equipment, and monitors are observed continuously by closed-circuit television (Fig. 66-13) . Following treatment, the patient is transported to the recovery room.

Patients who undergo IORT may present special challenges to anesthesiologists. The patient's physical status may be compromised by the malignant disease process or by chemotherapy and surgery may involve advanced resection of tumor and considerable blood loss. [168] Nutritional support is important in these patients, many of whom will have lost 20 percent or more of their body weight because of the malignant disease and may have been subjected to multiple operations. A feeding-tube jejunostomy frequently is inserted selectively during the IORT procedure to facilitate nutritional support during convalescence. Perioperative deaths due to intraoperative cerebrovascular accidents, postoperative hemorrhage, hepatorenal syndrome, and aspiration have been reported. [169]

External-Beam Radiation of Cancer in Children

Optimal treatment of essentially all children with cancer uses planned combined modality therapy incorporating chemotherapy, surgery, and radiotherapy (Ch. 59) .

Figure 66-13 Patient chest movements and pulse oximeter, electrocardiographic, and arterial blood pressure monitors are remotely observed on closed-circuit television screens.

solid tumors; either resection or radiation is needed for local tumor control. [170] Children with radiosensitive malignant tumors typically require radiation therapy for a number of sessions over several weeks. Although the treatments are painless, young children cannot be depended on to remain absolutely motionless in the strange and frightening surroundings of radiation therapy rooms. Because immobility during treatment is mandatory, sedation or general anesthesia usually is necessary. [171]

Anesthetizing locations within the therapeutic radiology department should have facilities and monitors that satisfy, or exceed, the current standards promulgated by the ASA. [3] Sedative medication doses required to produce predictable immobility may be associated with unwanted side effects (e.g., loss of airway in unattended patients, respiratory and cardiovascular depression, [172] and prolonged recovery). General anesthesia may be preferable when potential airway problems exist or when control of intracranial pressure is critical. [173]

Anesthetic regimens for external-beam radiation in children should provide brief periods of anesthesia at a depth that ensures immobility and minimal time to recovery. [174] Airway management should be appropriate in whatever body position the patient requires for the radiation. Because all personnel must leave the room during the actual delivery of radiation, the anesthetic technique should facilitate remote monitoring of the patient, thus allowing continuous assessment of the patient. [174] During the actual radiation treatment period, the patient, anesthesia equipment, and monitors are observed continuously by closed-circuit television.

General anesthesia may be indicated. The anesthesia team occasionally is asked to provide general anesthesia in a location where there is no means to scavenge waste anesthetic gases. Scavenging of waste gases is desirable and has been recommended by the National Institute of Occupational Safety and Health [175] and the American Society of Anesthesiologists. [3] A modified stethoscope has been developed that allows remote auscultation of heart and breath sounds during the radiation period. [176]

Typically, patients require a series of treatments and hence a series of anesthetic regimens. It is therefore desirable to avoid repeated invasive procedures to the degree feasible [174] and to keep the anesthesia technique as simple as possible. The laryngeal mask airway has proved to be a simple and safe airway device for use in children undergoing general anesthesia for external-beam radiation. [177] [178] Other techniques for administering general anesthesia for external-beam radiation in children without use of an endotracheal tube have been described. [174] Intravenous propofol infusion can also be used satisfactorily in these children. [23] [179] If the patient does not have an intracranial mass lesion, intramuscular administration of ketamine can provide satisfactory conditions. [180] A need to increase the ketamine dose gradually with successive radiation treatments (tachyphylaxis) may be observed. [25] Similar increasing dose requirements have been noted with propofol. [24] The anesthesiologist must watch for excessive salivation and postoperative vomiting. [180] Others have described the use of oral ketamine as a satisfactory induction technique. [19] [20]

When overt or potential intracranial hypertension is a concern, ketamine should not be used (Ch. 52) . Hypercarbia should be avoided, and moderate hypocarbia should be achieved prior to the introduction of a volatile agent. Induction of anesthesia may be satisfactorily achieved with intravenous thiopental or propofol, plus some short-acting narcotic if indicated.

We recommend that skeletal muscle response to tracheal intubation be abolished with a nondepolarizing muscle relaxant. Pharmacologic blunting of the hemodynamic response to intubation also helps to prevent an increase in intracranial pressure. End-tidal CO_2 may be monitored. In

the absence of initial intravenous access, an inhalation induction can be accomplished safely, with conversion to, or supplementation with, intravenous agents that decrease cerebral metabolic rate and cerebral blood flow as soon as the child is anesthetized sufficiently to allow insertion of an intravenous cannula.

ELECTROCONVULSIVE THERAPY

Electroconvulsive therapy (ECT) was introduced in the 1930s as a treatment for schizophrenia. [181] Although use of this therapy declined through the 1970s because of negative publicity, interest in and use of ECT increased through the 1980s and 1990s. Current acceptance of this procedure is in part due to the use of general anesthesia to reduce the physical and psychologic trauma associated with ECT.

ECT consists of programmed electrical stimulation of the central nervous system to initiate seizure activity. The precise mechanism of therapeutic effect of ECT remains unknown, despite increasing research into this area. The electrical stimulus results in generalized tonic activity for approximately 10 seconds, followed by generalized clonic activity for a variable period ranging from a few seconds to more than 1 minute. It has been generally believed that overall seizure duration is a primary determinant of treatment efficacy, but this view is changing. [182] [183] [184] However, seizure durations of less than 25 seconds are believed to be ineffective. Seizure duration depends on many factors, including patient age, energy of stimulus delivered, electrode placement, seizure threshold, and medications administered, including anesthetics. [185] [186] Electrodes may be placed bilaterally or unilaterally. Bilateral placement is more effective, but it results in greater cognitive side effects. [187] The seizure threshold varies among patients, and the initial ECT treatment may require several stimulations as the stimulus energy is titrated upward to a point where the energy delivered is higher than the patient's seizure threshold. Excessive energy delivery increases cognitive side effects of the treatment. ECT is administered as a series of treatments, usually two to three times per week initially, and continued until the patient improves or the treatment is deemed ineffective. Some patients may benefit from "maintenance" ECT delivered every several weeks, especially if their psychiatric disorder is severe or if they have a history of relapse. [188]

Indications and Contraindications

Indications for ECT include severe major depression (especially patients with delusions and psychomotor retardation), acute schizophrenia, acute mania, and catatonia. [189] ECT is the treatment of choice in those patients requiring a rapid response to treatment, such as patients with catatonia or who are clearly suicidal. Pheochromocytoma is a contraindication to ECT. Relative contraindications include increased intracranial pressure, recent cerebrovascular accident, cardiovascular conduction defects, high-risk preg-nancy, and aortic and cerebral aneurysms. [181] [190] In these conditions, the risk of the patient's psychiatric illness and side effects of antidepressant medications must be weighed against the risk from ECT and anesthesia.

Physiologic Effects

Seizure activity causes initial parasympathetic discharge, manifested by bradycardia, occasional asystole, and/or premature atrial and ventricular contractions. Hypotension and salivation may be noted. The parasympathetic discharge is followed by sympathetic discharge, associated with tachycardia, hypertension, premature ventricular contractions, and rarely ventricular tachycardia. The tachycardia peaks at 2 minutes after stimulus and is normally self-limited. [191] [192] ECG changes including ST-segment depression and T-wave inversion may also be seen following ECT, without myocardial enzyme changes consistent with myocardial infarction. These ECG changes are presumed to be secondary to the sympathetic discharge. [193] [194] ECT has been found to be relatively safe even in high-risk cardiac patients, provided careful management is provided. [195] [196]

Neurologic side effects noted frequently include headache, confusion, agitation following ECT, and cognitive impairment, which is generally transient. [183] [197] [198] [199] Cerebrovascular changes include initial increases in cerebrovascular resistance followed immediately by increased cerebral blood flow and cerebral metabolic rate. This situation can be problematic in patients with increased intracranial pressure or intracranial mass lesions, and caution must be exercised in these cases, although successful treatment with ECT has been reported in such patients. [200] [201] [202] The electroencephalogram demonstrates seizure activity, which is generally more prolonged than the peripheral clonic activity. Following the treatment, electroencephalographic depression is noted. [181]

Neuroendocrine responses to ECT include increased levels of stress hormones, including adrenocorticotropic hormone, cortisol, and arginine vasopressin, and of prolactin and growth hormone. [181] [203] Norepinephrine and epinephrine increase immediately after ECT, and epinephrine levels decrease more rapidly thereafter. Glucose homeostasis may be variably affected by ECT. Improvement is generally noted in control of non-insulin-dependent diabetes, whereas hyperglycemia may be seen when diabetes is insulin dependent. A single report noted hyperglycemia in a patient with no prior history of diabetes. [204]

Antidepressant Drug Therapy

Most patients presenting for ECT are receiving tricyclic antidepressants, monoamine oxidase inhibitors (MAOI), and/or lithium carbonate. Tricyclic antidepressants block the reuptake of norepinephrine, serotonin, and dopamine into presynaptic nerve terminals, thus increasing central sympathetic tone. [205] [206] Tricyclic antidepressants have antihistamine, anticholinergic, and sedative properties and also slow cardiac conduction. [207] These side effects are less common with newer types of antidepressant agents such as trazodone, bupropion, and fluoxetine. [207] Combination of centrally acting anticholinergics, such as atropine, with tricyclic antidepressants can increase postprocedural delirium. [208]

Clinical use of MAOI is increasing. These drugs inhibit monoamine oxidase by irreversibly combining with it to form a stable complex, thus blocking the metabolism of norepinephrine, serotonin, and dopamine. Use of indirectly acting

sympathomimetics in patients receiving MAOI can result in hypertensive crises. [205] [206] An exaggerated response to direct-acting sympathomimetics may also be seen. Hypotension in these patients should be treated with reduced doses of direct-acting sympathomimetic agents. MAOI can inhibit hepatic microsomal enzymes. MAOI may interact with opioid analgesics and may cause excessive depression. Used concomitantly with meperidine, MAOI may result in severe, possibly fatal, excitatory phenomena. [209]

Lithium carbonate prolongs the action of neuromuscular blocking agents. [210] Elevated lithium levels, higher than the therapeutic range, can prolong the action of benzodiazepines and barbiturates. Patients receiving lithium may demonstrate more cognitive side effects following ECT.

Anesthetic Technique

Anesthesia and neuromuscular blockade are necessary during ECT to prevent psychologic and physical trauma. Rapid recovery is desirable. Careful preoperative evaluation is necessary, with particular attention paid to coexisting neurologic and cardiac disease, osteoporosis and other causes of bone fragility, and medications the patient may be receiving. The patient may be a poor historian because of the psychiatric condition, and accompanying caregivers may provide necessary history and assurance of fasting status. Standard monitors include ECG, noninvasive blood pressure measurement, and pulse oximetry. Pretreatment with glycopyrrolate,

which does not cross the blood-brain barrier, can reduce the occurrence of bradycardia and the amount of oral secretions associated with ECT, as discussed later. Following preoxygenation, anesthesia is administered via peripheral intravenous catheter, and neuromuscular blockade is induced. When relaxation is adequate and satisfactory mask ventilation with oxygen is ensured, a bite block is placed, and the stimulus is delivered to induce the seizure. If the patient has a hiatal hernia and gastroesophageal reflux, rapid sequence induction and endotracheal intubation with cricoid pressure may be a reasonable approach. Adequate ventilation is ensured during the procedure because, among other detrimental effects, hypoxia and hypercarbia decrease seizure duration. [211] [212] The peripheral seizure is monitored by electromyogram, and the central seizure is monitored by electroencephalogram. It must be remembered that central seizure duration may outlast peripheral clonic manifestations. A blood pressure cuff inflated on the leg to isolate the limb prior to neuromuscular block administration can assist in monitoring of peripheral seizure. If this is the initial ECT treatment, more than one stimulus may be necessary, and additional anesthesia and/or neuromuscular blockade may need to be administered. Following the procedure, ventilation with oxygen via mask is continued until the patient awakens and is breathing adequately. During this time, tachycardia and hypertension, if persistent and/or of hazardous magnitude, may require treatment. The patient is monitored (ECG, pulse oximetry, and blood pressure) in the recovery area following the procedure until routine discharge criteria are met. Some patients demonstrate significant oxygen desaturation following ECT, and we routinely administer oxygen by nasal cannula until the patient is fully awake. [213]

Certain intravenous anesthetic agents have been used to induce anesthesia for ECT, including methohexital, thiopental, propofol, and ketamine. Propofol was found to reduce seizure duration, and this was believed to decrease the efficacy of ECT. However, more recent studies demonstrated no difference in outcome when propofol was compared with methohexital. [214] [215] [216] Methohexital, as well as propofol, administration is associated with pain on injection, which may be poorly tolerated by psychiatrically fragile patients. Use of thiopental avoids pain on injection, but it is associated with more hypertension and tachycardia than propofol. [217] Etomidate may prolong seizures and recovery. [218] Benzodiazepines result in undesirably short seizure duration. [219] Ketamine has been demonstrated not to increase seizure length or to produce excessive postprocedural agitation. [220]

Complete neuromuscular blockade is not necessary for ECT and may not be desirable because monitoring of peripheral seizure duration would be impeded. Partial neuromuscular blockade is necessary, however, to reduce the peripheral manifestations of the seizure and to prevent trauma to the patient. Succinylcholine has been used most frequently for neuromuscular blockade during ECT, because of its short duration of action and low frequency of side effects. An initial dose of 0.5 mg/kg is administered and is adjusted for subsequent treatments based on the patient's response. Mivacurium has been suggested as an alternative to succinylcholine, but it may not be as effective as succinylcholine at preventing tonic-clonic muscle contractions, which could result in traumatic injury to the patient. [221] [222] Mivacurium also necessitates prolonged postprocedural ventilatory support, thus increasing anesthetic requirements. [223] Both succinylcholine and mivacurium are metabolized by plasma cholinesterase, and alternative nondepolarizing muscle relaxants may need to be used for patients with plasma cholinesterase deficiency. Prolonged neuromuscular blockade may need to be accepted in such patients in order to avoid trauma from the seizure.

Prophylactic medications have been advocated to avoid various side effects of ECT. Transient asystole is rare during ECT, but it may be prevented with anticholinergic pretreatment. Glycopyrrolate is preferred to atropine because glycopyrrolate has no central anticholinergic side effects. In addition, glycopyrrolate is an effective antisialagogue. Both esmolol and labetalol have been successfully used to control hypertension and tachycardia following ECT. [224] There is some evidence that esmolol reduces seizure duration. [225] [226] Routine treatment with esmolol or labetalol is not recommended because the hypertension and tachycardia are usually self-limited, as are premature ventricular contractions.

Anesthetics and neuromuscular blocking agents administered to each patient should, as in other anesthetic cases, be accurately recorded. This is especially important with ECT, because the treatment is repeated over several weeks to months, and consistent patient conditions must be provided for predictable ECT stimulus response. In addition, patients' responses, such as development of arrhythmias or agitation, to previous treatment and additional medications, such as beta-antagonists or benzodiazepines, that were required should be noted, so that additional precautions can be taken at subsequent treatments. Proper anesthetic care allows for safe administration of ECT in patients with multiple

coexisting medical complaints, even in very elderly patients. [227]

Chapter 67 - Clinical Care at Altered Environmental Pressure

Richard E. Moon
Enrico M. Camporesi

INTRODUCTION

The modern clinical application of hyperbaric oxygen (HBO) began in the late 1950s, in parallel with an increased understanding of blood gas analysis and gas exchange physiology. Use of O_2 at high pressure for the treatment of decompression sickness had previously been documented, [1] but it remained an isolated medical curiosity. Exposure of patients to hyperbaric pressures for therapeutic purposes had been introduced in several large facilities even decades before, following the principles elucidated by Paul Bert. These early applications, however, based on vague pathophysiologic principles, suffered from an overoptimistic view of the results. Hyperbaric spas flourished in the early 1900s on the North American continent and in Europe. Lack of a firm physiologic basis and poor choice of indications caused scientific stasis in the field for many subsequent years. [2] [3]

In the early 1960s, two institutions preeminently pursued the clinical aspects of high-pressure oxygenation. In the surgical department of the University of Amsterdam, Boerema, followed by Bakker, developed the use of intermittent HBO for the treatment of gas gangrene. The second major focus of interest in this area was the Royal Infirmary in Glasgow, where various anesthetic and surgical applications were developed (treatment of necrotizing infection, anesthesia under hyperbaric conditions). In 1968, Duke University in North Carolina expanded a long-standing program of environmental physiology with the construction of interconnected multiplace hyperbaric chambers. From the outset, this facility was intended for patient care in addition to providing an experimental facility, and various clinical protocols were developed.

Since about 1970, several large hyperbaric systems of similar nature and many more single-chamber facilities have been installed worldwide. Instructional courses are continuously organized, often under the guidance of the Undersea and Hyperbaric Medical Society (headquarters in Kensington, Md). This medical organization publishes an extensive bibliography with a list of indications for hyperbaric oxygenation, updated every 2 to 3 years. [4]

TABLE 67-1 -- Partial List of Conditions for Which Hyperbaric Oxygen Has Been Used

Gas-bubble disease
Air embolism [53] [54] [182]
Decompression sickness [53] [54]
Poisoning
Carbon monoxide [29] [33] [183]
Cyanide [29] [184]
Carbon tetrachloride [185] [186]
Hydrogen sulfide [29] [187] [188]
Infections
Clostridial myonecrosis [58] [59] [189] [190]
Other soft tissue necrotizing infections [60] [61] [190]
Refractory chronic osteomyelitis [191] [192]
Mucormycosis [193] [194]
Acute ischemia
Crush injury [195]
Compromised skin flaps [11] [12] [196] [197]
Chronic ischemia
Radiation necrosis (soft tissue, radiation cystitis, an osteoradionecrosis) [198] [199] [200] [201] [202]
Ischemic ulcers, including diabetic ulcers [203] [204]
Central nervous system edema [205]
Acute hypoxia
Support of oxygenation during therapeutic lung lavage [65] [66]
Exceptional blood-loss anemia (when transfusion delaye unavailable) [67]
Thermal injury (burns) [206] [207] [208] [209]
Brown recluse spider envenomation [210] [211]

The still limited number of facilities providing well-integrated care within medical centers may explain the varied perception among physicians of HBO as a poorly defined therapeutic modality. Nevertheless, clear evidence exists for efficacy of HBO in a variety of acute and chronic illnesses (Table 67-1) , and anesthesiologists are often called on to provide care of patients in this unusual environment.

Interest in the physiologic and medical aspects of altitude originated because of mountaineering and high-altitude balloon exploits in the 19th century. This body of knowledge has been increasingly useful, as ever-increasing numbers of people fly in aircraft, travel from low to high altitude, and live or work at higher elevations (Table 67-2) . Exposure to altitude is accompanied by well-known physiologic changes and often unique clinical syndromes. Significant effort has been devoted to techniques for prophylaxis and treatment of these illness in recent years. In addition, increasingly sensitive methods of monitoring oxygenation during anesthesia have led to the recognition that routine anesthetic care at even moderate altitudes may require some modifications in order to avoid hypoxia in normal individuals. Moreover, millions of individuals are exposed acutely to high altitude during commercial aircraft flight. The effects of the small reduction in inspired O_2 pressure (P_{O_2}) may be clinically significant for individuals with cardiorespiratory or cerebrovascular disease.

PHYSIOLOGIC EFFECTS OF INCREASED GAS PRESSURE

Increased Barometric Pressure

Some effects of altered ambient pressure are summarized in Figure 67-1 . An increase in environmental pressure is accompanied by significant adiabatic heat production, whereas decompression generates cooling. This results in an increase in chamber temperature during compression and significant cooling and precipitation of water droplets during decompression. These phenomena may limit the rate of compression in manned chambers in order to maintain temperature within a comfortable range.

Additionally, the pockets of trapped gas within body cavities either contract or expand on compression or decompression.

TABLE 67-2 -- Range of Terrestrial Altitudes

ALTITUDE[a]		AMBIENT PRESSURE		
(ft)	*(m)*	*(ATA)*	*(mm H g)*	*COMMENTS*

0	0	1.00	760	Sea level

[a] Altitudes and barometric pressures are shown for Mt. Everest and several locations inhabited at least part time. Barometric pressures have been obtained from the International Civil Aviation Organization standard atmosphere table, [216] except for values with an asterisk (*), which were obtained by direct measurement. [213]

Figure 67-1 Ambient pressure as a function of altitude and water depth. Whereas ambient pressure increases linearly with depth, pressure and altitude are not linearly related. As air is inspired and humidified, there is a small and usually insignificant drop from atmospheric P_{O_2} to inspired P_{O_2} . At altitude, however, this decrease comprises a greater proportion of the total ambient pressure. The O_2 partial pressure line in the water is shown for a constant F_{IO_2} of 21 percent. At increasing depth the inspired P_{O_2} eventually exceeds the pulmonary toxic limit (14 m depth) and the central nervous system toxic limit (70 m depth). The threshold for high-pressure nervous syndrome and pressure reversal of anesthesia (observed in nonnarcotic atmospheres) is around 150 to 200 m depth. The shaded red bars represent the depth or altitude ranges over which the risk progresses from low (light shading) to high (dark shading).

These pockets include gas in the middle ear and paranasal sinuses, intestinal gas, pneumothorax, and gas pockets within monitoring and life-support systems. The changes in gas volume occur according to Boyle's law:

such that a doubling of environmental pressure (P) causes the volume (V) of a gas-filled cavity to decrease by half. This effect also underlies one of the major beneficial effects of hyperbaric treatment of pathologic gas, as in arterial gas embolism or decompression sickness (see later). A comparison of pressure units used clinically with those in common use in hyperbaric environments is shown in Table 67-3 .

Increased Partial Pressure of Oxygen

Breathing O_2 at increased ambient pressure leads to elevation of alveolar O_2 tension (P_{AO_2}), which can be calculated according to the alveolar gas equation for O_2 :

where P_{IO_2} and F_{IO_2} are the inspired partial pressure and fractional O_2 concentration, respectively; P_{ACO_2} is alveolar P_{CO_2} , assumed to equal arterial P_{CO_2} (Pa_{CO_2}); and R is the respiratory quotient (usually 0.8). Typical values are shown in Table 67-4 . From these values of Pa_{O_2} , arterial P_{O_2} (Pa_{O_2}) has been estimated,

assuming that the arterial/alveolar P O_2 ratio remains constant. [5] Whereas at 1 atmosphere absolute (ATA) the fraction of O_2 in arterial blood that is carried dissolved in the plasma is minimal, it can be seen that at elevated Pa O_2 in the range of 1,000 to 2,000 mm Hg, significant quantities of O_2 may exist in dissolved form (Fig. 67-2)

Increased Pa O_2 has at least four pharmacologic effects: (1) increased blood O_2 content; (2) vasoconstriction; (3) antibacterial action, particularly against anaerobic bacteria; and (4) inhibition of endothelial neutrophil adhesion in injured tissue. The increased arterial O_2 content underlies the rationale for administering HBO for the treatment of ischemic conditions, for example ischemic, nonhealing wounds. The elevation in Pa O_2 leads to an increase in tissue P O_2, which can be estimated using transcutaneous P O_2 electrodes, even in ischemic tissue. [6] The second effect is an explanation for the effectiveness of HBO in the treatment of traumatic edema (e.g., crush injury). The mechanism of

[a] Assuming constant Pa O_2 /Pa O_2 ratio [5]

Figure 67-2 Blood O_2 content versus P O_2. Virtually complete saturation of hemoglobin (Hb) with O_2 occurs at a P O_2 of 100 mm Hg. Further increases in P O_2 do not alter the quantity of O_2 bound to Hb. However, there is a linear increase in total blood O_2 content with P O_2 due to increasing quantities of O_2 dissolved in plasma.

HBO-induced vasoconstriction appears to be inactivation of nitric oxide because of increased production of superoxide [7] and possibly decreased release of nitric oxide from circulating S-nitrosohemoglobin. [7] [8]

These two effects, increased O_2 content and vasoconstriction, lead to hemodynamic changes that have been described by Whalen et al [9] and are shown in Table 67-5 . The elevation in Pa O_2 that occurs while breathing 100 percent O_2 at 3.06 ATA results in a drop in cardiac output and heart rate and an increase in total peripheral resistance. There is also a slight increase in mean arterial pressure.

The other major pharmacologic effect of increased Pa O_2 is the inhibition of toxin production and growth of certain anaerobic bacteria. Additionally, increased Pa O_2 has been shown to return phagocytic ability and the ability of aminoglycosides to kill aerobic bacteria in ischemic tissue to normal. These bacteriologic effects of HBO have been reviewed by Park et al. [10]

HBO also has some poorly characterized microcirculatory and cellular effects. Zamboni et al [11] [12] [13] have described a reduction in blood flow occurring on reperfusion of ischemic myocutaneous tissue flaps. This decrease in flow appears to be due to leukocyte adherence to the capillary endothelium mediated by leukocyte adhesion glycoprotein CD18, [14] an effect that is prevented and ameliorated by HBO treatment. [11] [12] [13] In an animal model, timely administration of HBO also appears to decrease the lipid peroxidation in the brain that occurs after treatment of carbon monoxide (CO) poisoning. [15]

Elevation of Inert Gas Partial Pressure

Elevation of the partial pressure of the inert gas (usually nitrogen) present in a breathing mixture is associated with a narcotic effect, predictable by the Meyer-Overton hypothesis. Based on its olive-oil solubility, nitrogen has approximately 0.03 to 0.05 times the narcotic potency of nitrous oxide. At 3 ATA (breathing air), most people experience mild euphoria. At 6 ATA, there may be memory loss and poor judgment. At 10 ATA, some individuals lapse into unconsciousness. Nitrogen narcosis has been compared with alcoholic intoxication, an increase in ambient pressure of 1.5 ATA resulting in an effect that is said to be similar to drinking one martini. Argon and to a lesser degree, hydrogen, are narcotic, whereas helium has minimal if any narcotic effect.

Elevation of Absolute Pressure

High-Pressure Nervous Syndrome

High pressure induces a constellation of symptoms consisting of tremor, ataxia, nausea, and vomiting, known as the high-pressure nervous syndrome. [16] It occurs at an ambient pressure greater than 15 to 20 ATA and was first described during the compression phase of deep dives with a helium-O_2 atmosphere. This syndrome is ameliorated by slow compression and addition of a narcotic gas (e.g., nitrogen) to the breathing mix. [17]

Pressure Reversal of Anesthesia

High pressure has the tendency to reverse general anesthesia. Elevations in partial pressure in the absence of a narcotic inert breathing gas tend to decrease the effectiveness of both inhaled and intravenous anesthetics. At 50 ATA, approximately a 20 percent increase in the 50 percent effective dose (ED_{50}) has been observed in mice for a variety of inhaled anesthetics. At this same ambient pressure, the effective dose of thiopental increases approximately 30 percent in rats and mice. Winter et al [18] demonstrated a reversal of phenobarbital anesthesia in rats under high pressure, with a 63 percent increase in ED_{50} at 103 ATA as compared with 1

[a] Obtained from a catheter with tip at the junction of the superior vena cava and right atrium

ATA. At 31 ATA, the effective concentration for half maximal effect (EC_{50}) of propofol for loss of righting reflex in tadpoles is increased by 19 percent and at 61 ATA, 38 percent. [19] Using the same technique, the EC_{50} for dexmedetomidine at 31 ATA is nearly double the value at 1 ATA, and it is increased 2-fold at 61 ATA. [20] This effect of pressure reversal of general anesthesia has been reviewed by Wardley-Smith and Halsey [21] and Wann and Macdonald [22] (Ch. 3) .

Effects of Hyperbaric Exposure on Drug Disposition

A few studies have examined the disposition of drugs and drug effects at increased environmental pressures. Studies in awake dogs at pressures up to 6 ATA and ambient P_{O_2} up to 2.8 ATA have shown that liver plasma flow decreased when either ambient pressure or P_{O_2} was raised. There was an apparent increase in plasma volume at 1.3 ATA and a return toward 1 ATA values at higher pressures. In the same studies, plasma volume was inconsistently affected by ambient pressure, but it was reduced by increases in P_{O_2} . [23]

Major pharmacokinetic or pharmacodynamic differences for most drugs up to pressures used for most clinical purposes (6 ATA) would not be expected. Indeed, up to 6 ATA, the pharmacokinetics of meperidine [24] and of pentobarbital [25] are unchanged under hyperbaric and hyperoxic conditions in the dog. No significant effects of hyperoxia or increased ambient pressure were demonstrated on the total plasma clearance, volume of distribution, or elimination half-life of these two drugs. Canine studies have also demonstrated no alteration in either theophylline [26] or salicylate [27] kinetics at ambient pressures to 6 ATA and inspired P_{O_2} up to 2.8 ATA.

Stoudemire et al [28] described the use of benzodiazepines, chlorpromazine, and lithium carbonate for the treatment of agitation, auditory and visual illusions, agitation, and paranoia in a previously normal subject participating in an experimental dive to 650 m (66 ATA). The symptoms, poorly controlled with diazepam 120 mg and temazepam 60 mg per day, ultimately responded to chlorpromazine 300 mg per day. Lithium carbonate subsequently administered in conventional doses appeared to display normal pharmacokinetics. Although the effect of chlorpromazine appeared clinically to be appropriate, the authors were uncertain whether the failure of benzodiazepines to elicit a desired therapeutic response was due to the diver's condition or to a pressure-reversal phenomenon. In summary, clinical experience and the published literature indicate that for a variety of drugs, conventional parenteral drug dosing schedules may be used safely under hyperbaric conditions.

RATIONALE FOR THE TREATMENT OF SPECIFIC SYNDROMES

Carbon Monoxide Poisoning

Hemoglobin (Hb) binds CO with an affinity much higher (by a factor of about 200) than that for O_2. This binding of CO with Hb to form carboxyhemoglobin (COHb) has two

TABLE 67-6 -- Carbon Monoxide Elimination Half-Times While Breathing Air or 100 Percent Oxygen at 1 and at 2.5 Atmospheres Absolute

BREATHING GAS (ATA)	MEAN HALF-LIFE (MIN)[a]	NO. SUBJECTS
Air: 1	214	10
Oxygen: 1	43	15
Oxygen: 2.5	19	10

[a] Mean values from data of Pace et al [183]

major effects. First, that proportion of Hb that is occupied by CO molecules is unavailable for O_2 transport, resulting in a functional anemia. Second, the avidity with which the remaining Hb binds O_2 is increased (shift to the left of the Hb-O_2 dissociation curve). The result of this is a decreased ability to unload O_2 from blood to tissue at the capillary. Previously, it was believed that these effects were totally responsible for the toxicity of CO. However, evidence has since been presented to show that the binding of CO to intracellular pigments (e.g., cytochrome, myoglobin) may contribute significantly to the toxicity of CO. This intracellular toxicity of CO has been reviewed by Piantadosi. [29] These mechanisms result in toxicity to multiple organ systems, including brain and heart. [30] Late neurologic sequelae remain an important secondary toxic effect, often after a clear window of lucidity. [31]

High P_{O_2} hastens the removal of CO from blood, such that the half-life of COHb is greatly reduced by HBO therapy (Table 67-6) . Additionally, the increased dissolved O_2 in plasma may support tissue oxygenation pending removal of CO from Hb and other proteins important for O_2 transport. Although the treatment of CO poisoning with HBO remains somewhat controversial, there is mounting evidence that for poisoning in which neurologic symptoms occur, HBO treatment may decrease both early and late morbidity from this condition. Two comparable series containing relatively large numbers of patients have been published since 1985, one group (115 patients) having been treated with HBO, [30] the other (79 patients) with 100 percent O_2 at 1 ATA. [32] In those patients who had impaired consciousness, mortality in the group administered HBO was 15 percent, versus 30 percent of those treated with normobaric O_2. In a randomized, prospective trial of HBO versus normobaric O_2, Thom et al [33] demonstrated that HBO treatment results in a significant reduction in neurologic sequelae.

The diagnosis of CO poisoning is made by a history of exposure (internal combustion engine exhaust, fire, improperly adjusted gas or oil heating, charcoal or gas grills, or exposure to paint stripper containing methylene chloride, which is metabolized by the liver to CO). Confirmation of the diagnosis is made by finding an elevated COHb in either arterial or venous blood. COHb concentration in anticoagulated blood samples is stable for several days. Therefore, if COHb determination is not available at a referring facility, the diagnosis can be confirmed using a blood sample obtained at the time of initial evaluation and transported with the patient. Fetal Hb (HbF) produces a falsely elevated reading for COHb on certain four-wavelength laboratory co-oximeters. In the first few weeks of life, blood from normal

infants' measurements may therefore falsely indicate 7 to 8 percent COHb.

Actual COHb levels measured on arrival in the emergency room correlate poorly with clinical status and should not be used as the sole criterion to determine the need for treatment. Because of the lower intracellular P_{O_2}, elimination of CO from intracellular binding sites occurs more slowly. Significant mental obtundation, vomiting, and headache may remain even in the face of a normal COHb level.

Brain CT imaging may reveal a variety of abnormalities, including hypodensities in the globus pallidus and subcortical white matter, cerebral cortical lesions, cerebral edema, hippocampal lesions, and loss of gray-white differentiation. Except to exclude other disorders, brain imaging is not useful for determining who should receive HBO, but it may provide prognostic information. CT scans in a group of 40 patients who had received HBO for CO poisoning were systematically reviewed by Pracyk et al. [34] Twenty of 23 patients (87%) with a normal scan had a favorable clinical outcome, in contrast to only 6 of 17 patients (35%) with an abnormal scan.

Supportable guidelines for the application of HBO therapy in CO poisoning include the following: a history of neurologic impairment (including loss of consciousness); symptoms or evidence of cardiac abnormalities (ischemia, arrhythmias, ventricular failure); and a COHb level that has been higher than 25 percent. Fetuses are particularly susceptible to CO toxicity. Pregnant women who fulfill the foregoing criteria or cases of fetal distress should be treated with HBO. Case reports, [35] [36] [37] published series, [38] [39] and a critical review [40] support the concept that inadequately treated CO poisoning is a serious risk to the mother and fetus, and the benefits of HBO outweigh the theoretical risks to the fetus of HBO treatment. Potential adverse effects of currently implemented HBO treatment protocols are extremely rare in clinical practice.

Gas Embolism and Decompression Illness

Introduction of gas into the arterial circulation (arterial gas embolism [AGE]) has traditionally been associated with scuba divers and has been attributed to pulmonary barotrauma during ascent from a dive while breathing compressed gas. However, it may also occur iatrogenically in several clinical circumstances, such as during cardiopulmonary bypass or as a result of inadvertent injection of air during a diagnostic arteriogram or hemodialysis. Additionally, large amounts of gas may enter the venous system, for example, during neurosurgical procedures with the patient in the sitting position, hemodialysis, Harrington rod insertion, total hip replacement, cesarean section, laparoscopy, intrauterine laser surgery, arthroscopy (from air escaping from a faulty air-powered drill) and hydrogen peroxide irrigation or oral ingestion (from elaboration of gaseous oxygen from tissue and blood catalase). Venous gas embolism (VGE) can also occur when a central venous catheter is opened to air. Severe VGE has also occurred during orogenital sex after blowing air intravaginally. [41] VGE has also been reported in patients with adult respiratory distress syndrome (ARDS) who were ventilated with positive end-expiratory pressure. [42] VGE in sufficient quantity may overwhelm the ability of the pulmonary vasculature to filter the gas, thus allowing bubbles to pass into the arterial circulation. Even small amounts of venous gas (e.g., VGE due to decompression from

diving) have been implicated in neurologic syndromes in scuba divers because of transatrial passage through a patent foramen ovale. [43]

The effects of gas embolism are not solely due to vessel obstruction by bubbles. Bubble-endothelial interaction causes increased capillary permeability and extravasation of fluid. [44] [45] Another effect has been demonstrated in a model of AGE in anesthetized rabbits by Helps et al, [46] [47] who showed that small doses of intracarotid air may pass through the cerebral microcirculation yet produce sustained vasodilatation, delayed reduction of cerebral blood flow, and neurophysiologic impairment. Leukocytes are required for this effect, because inducing neutropenia prior to the experiment abolishes the effect. [48] This phenomenon of delayed reduction of cerebral blood flow may be responsible for the clinical observation of initial neurologic improvement after AGE, followed by delayed deterioration. [49]

A related syndrome that results from pathologic effects of tissue and blood gas bubbles is decompression sickness, seen in aviators and compressed gas divers. The gas bubbles in these situations occur because of a decrease in ambient pressure at rate sufficient to induce local inert gas supersaturation, resulting in formation of bubbles *in situ* from tissue stores.

Symptoms of AGE classically consist of impaired consciousness, hemiparesis, or seizures, but they may be less severe. Decompression sickness most commonly presents with any combination of joint pain, paresthesias, motor weakness, bladder or bowel sphincter dysfunction, vertigo, tinnitus, or hearing loss. Additional details regarding the clinical presentation of decompression illness can be found in Elliott and Moon [50] and in the annual report of the Divers Alert Network. [51]

Treatment principles for both forms of gas bubble disease, AGE and decompression sickness, are the same and consist of fluid resuscitation, administration of a high inspired O_2 concentration, and increasing the ambient pressure. Increasing arterial P_{O_2} by administering supplemental O_2, even at ambient pressure as a first aid measure, results in an increased rate of resolution of gas bubbles because of the resulting higher partial pressure gradient for diffusion of inert gas from the interior of the bubble into the surrounding tissue or blood. Fluid resuscitation replenishes intravascular volume, reduces hemoconcentration, and helps to maintain microcirculatory flow, principles that have been confirmed by both animal [52] and human clinical data. [44]

Hyperbaric therapy causes a diminution in gas volume according to Boyle's law and hastens resolution further. The usefulness of hyperbaric treatment of diving-related or aerospace-related gas embolism associated with rapid decompression is well documented. [53] [54] Less recognized but equally documented is the use of HBO in the treatment of iatrogenic embolism. In the authors' experience in treating iatrogenic AGE, HBO may affect neurologic improvement even after a significant delay between the embolic event and treatment. A retrospective review of the authors' experience in 14 patients revealed no relationship between outcome

and delay of HBO for up to 42 hours, [55] although severe abnormalities are unlikely to resolve unless treated promptly. Treatment of AGE is usually performed at ambient pressures from 2.8 to 6 ATA (see the later discussion of treatment schedules).

The morbidity of recompression treatment for gas bubble disease is extremely low, and the efficacy is high. Therefore, whenever adequate recompression facilities are available, it is usually appropriate for all symptomatic individuals with gas embolism or decompression illness to receive hyperbaric treatment. In addition, most physicians who administer HBO recommend treatment even for asymptomatic patients who have experienced gas embolism to the central nervous system (CNS), in expectation that delayed effects of bubble-endothelium interaction [46] [47] [49] an be prevented.

The decision to administer recompression treatment should be based on clinical evaluation. The only appropriate role for brain or spinal imaging (e.g., computed tomography [CT], magnetic resonance imaging [MRI]) is to exclude other disorders such as hemorrhage, and only if there is a high degree of suspicion that bubbles are not the cause of a patient's symptoms. It has been suggested by Dexter and Hindman [56] that patients with AGE should only be treated with HBO if CT of the brain reveals air. In the authors' experience, brain imaging of patients who respond clinically to HBO shows abnormalities in a minority of cases. Furthermore, HBO-responsive phenomena, besides occlusion of vessels by macrobubbles, such as edema or delayed reduction in cerebral blood flow, may not be detectable using currently available imaging techniques. Unless there is a strong clinical suspicion of disease other than AGE that requires urgent exclusion, performing CT, MRI, or other imaging prior to recompression serves only to delay appropriate treatment. Neither single photon emission tomography (SPECT) nor positron emission tomography (PET) has yet been demonstrated to provide clinically useful information in the management of patients with gas bubble disease. Further details of treatment of AGE and decompression illness have been described by Moon and Gorman [53] and Moon and Sheffield. [54]

Acute Infections

Anaerobic bacteria are especially sensitive to increased tissue P_{O_2}, as mentioned previously, probably because of the lack of antioxidant defenses such as superoxide dismutase in these bacteria. Inhibition of exotoxin production, especially the alpha-toxin by *Clostridium* species, by high O_2 tensions has been demonstrated. [57] Because the systemic manifestations of clostridial infection are largely attributable to the production of toxin, the clear beneficial effects of HBO in this type of infection are attributed to this mechanism. A large clinical series of clostridial myonecrosis was published by Bakker and van der Kleij, [58] [59] and it appears that the early treatment of disease with HBO, in addition to antibiotics and appropriate surgical debridement, can be limb-saving and probably lifesaving. Immediate clinical response to HBO may often be seen in these patients, with reduction in tissue crepitus and decreased heart rate, cardiac output, and other signs of sepsis. Hyperbaric treatment should not be delayed and may be used beneficially prior to surgery to preserve viable infected tissue and to allow better demarcation for surgical debridement. [58] [59]

Typical treatment schedules for clostridial myonecrosis are up to 3.06 ATA for 90 minutes while the patient breathes 100 percent O_2. Commonly, three HBO treatments are administered within the first 24 hours, five times within the first 48 hours, and then twice daily for a total of seven to nine treatments, by which time the clinical course of the infection is usually evident.

The rationale for treatment of nonclostridial soft tissue necrotizing infections is that high tissue P_{O_2} inhibits the growth of anaerobic bacteria. Initially, it may be difficult to differentiate clostridial from nonclostridial infections, and there is evidence that such patients benefit from HBO in a manner similar to that of documented clostridial infection. HBO also appears to offer a significant reduction in morbidity and mortality in nonclostridial necrotizing infections, as documented in a controlled trial. [60] [61] A meta-analysis of 554 published cases indicated a mortality of 44 percent in patients not treated with HBO versus 20 percent in HBO-treated patients. [62] Because many of these infections are indolent, treatment beyond the first 3 or 4 days may be beneficial.

Support of Arterial Oxygenation

For circumstances in which patients may otherwise be severely hypoxemic, such as cyanotic heart disease, HBO may offer a margin of safety during anesthesia. Smith [63] reported 45 cases of surgical correction of cyanotic heart disease in children operated on under HBO. Although most of these patients had Pa_{O_2} around 25 mm Hg or less while breathing 100 percent O_2 at 1 ATA, the Pa_{O_2} values increased to 50 mm Hg or greater in the majority of patients at ambient pressures up to 4 ATA. Halothane anesthesia was used in most cases. No complications were reported, and it was concluded that HBO was useful to maintain Pa_{O_2} in these critically ill infants. There was no evidence that increased concentrations of anesthetic were required to maintain anesthesia at the pressures used.

Li et al [64] reported a series of 48 patients with open heart surgery under HBO at 3 ATA, anesthetized with intravenous fentanyl. In several of the patients, the blood Hb concentration was reduced by phlebotomy to 3 to 4 g/dL during HBO. It is pointed out that a major advantage of this technique is a reduction in transfusion requirements.

HBO has been reported to be a safe and effective method of supporting arterial oxygenation while therapeutic lung lavage is performed under general anesthesia using one-lung ventilation. [65] [66] In the authors' experience of more than 60 procedures, arterial oxygenation has been satisfactorily maintained with no resulting complications (Fig. 67-3) . A reversible simulation of pulmonary gas exchange during the lavage procedure can be provided by temporarily ventilating the lung to be lavaged with 5 percent O_2. This reduces P_{AO_2} in that lung to approximately the level of mixed venous P_{O_2}, thereby confining O_2 exchange to the contralateral lung. If, during a 5-minute period of unilateral hypoxic ventilation, the patient's arterial Hb-O_2 saturation drops below 90 percent, then it is likely that lavage at 1 ATA will be accompanied by arterial hypoxemia.

Figure 67-3 Pa O_2 during unilateral lung lavage under hyperbaric conditions. The open circles represent measured Pa O_2 at various ambient pressures (abscissa). The solid circles represent the predicted Pa O_2 at 1 ATA, calculated on the assumption of a constant Pa O_2 /P AO_2 ratio. [5] It can be seen that six of the eight patients would have had Pa O_2 values lower than 50 mm Hg had the procedure been performed at atmospheric pressure.

Maintenance of Oxygen Transport in Severe Anemia

The ability of HBO to increase arterial O_2 content in plasma to clinically useful levels may allow support of tissue O_2 delivery even in the absence of Hb. This finding has led to the application of HBO for temporary support of severely anemic patients pending availability of definitive therapy in the form of crossmatched blood. Hart et al [67] reported the use of this technique in 26 patients. The mean hematocrit of all patients was 12.9 percent. Mean heart rate decreased from 124 to 98 beats/min after 30 minutes of breathing 100 percent O_2 at 2 ATA. Although the indication for this treatment is extremely uncommon, the temporary use of HBO to support the patient pending appropriate blood crossmatching may be lifesaving.

THERAPEUTIC SYSTEMS

The traditional method of administering hyperbaric therapy is with a multiplace chamber, which accommodates two or more persons (Fig. 67-4) . Size may vary from a small, portable two-person chamber used for transporting patients in the field to one 20 ft or more in diameter, in which up to a dozen patients may be comfortably admitted, in addition to tenders. The largest multiplace chamber ever built was a 20-m-diameter sphere, which could be compressed to 3 ATA. [3] Multiplace chambers are compressed with air, while the patient breathes O_2 with a head tent (Fig. 67-5) , face mask, or endotracheal tube. Because of the immediate access to the patient by accompanying nursing personnel or physicians, monitoring is relatively straightforward. Intravenous lines can be inserted during treatment, and airway control may be exercised. Surgery has even been performed inside multiplace hyperbaric chambers. The operation of these chambers is complex. They have a large space requirement for installation and are costly.

The other type of chamber is the monoplace, which is large enough to accommodate only one patient (Fig. 67-6) ; a tender can only be used with a child. The chamber wall in many types is manufactured of Plexiglas, facilitating close observation of the patient. The chamber is usually compressed with 100 percent O_2 . The advantage of monoplace chambers is their relatively low cost and ease of installation. The chamber may be put into use merely by connecting the O_2 inlet to the hospital supply, although some modification may be required of the main supply piping to accommodate

Figure 67-4 Multiplace hyperbaric chamber, which is large enough for one or more patients and tenders. Chamber atmosphere is compressed air. The patient receives 100 percent O_2 via mask, head tent, or endotracheal tube. Monitors are usually kept outside the chamber because of electrical safety considerations. Monitoring is possible through a porthole. Personnel lock and transfer lock allow physicians, nurses, or other personnel, in addition to medications, food, and blood samples, to be moved into and out of the chamber without repeated compression and decompression of the patient.

Figure 67-5 Head-tent circuit for use in a multiplace chamber. Fresh gas (100% O_2) flows at a constant rate (>30 L/min) through the head tent. Exhaust gas may be either vented outside the chamber or recirculated through a CO_2 scrubber. The sample line attached to the exhaust hose allows monitoring of the patient breathing gas.

large flow rates. Operation of the chamber is relatively simple, but it has the disadvantage of lower flexibility. The patient inside the chamber at pressure cannot be evaluated "hands on," monitoring is somewhat more remote, and emergency care of the airway cannot be provided. Development of a pneumothorax, particularly a tension pneumothorax, although rare, can be fatal because of the impossibility of inserting a chest tube prior to decompression. The other major disadvantage of these chambers is that the ambient

Figure 67-6 Monoplace chamber. This type of chamber has room for one patient or a tender with a small child. Chamber atmosphere is 100 percent O_2 . The chamber is constructed of transparent plastic to allow easy observation. Through-hull penetrators (not shown) near the head of the patient allow monitoring and intravenous fluid administration and control of a ventilator inside the chamber.

pressure limit is 3 ATA, and for practical reasons treatment times are limited. Moreover, intermittent periods of air breathing, in order to decrease the risk of O_2 toxicity (see later), require installation of an additional gas-delivery system. Nevertheless, monoplace technology now permits intravenous fluid administration from the outside of the chamber, invasive intravascular monitoring, mechanical ventila- tion, and utilization of pleural drainage systems incorporating regulated suction. Additional details can be found in a monograph available from the Undersea and Hyperbaric Medical Society. [68] Many chambers are now equipped additionally with mask systems from which the patient may intermittently breathe air (called "BIBS" for built-in breathing system), permitting the administration of U.S. Navy treatment tables for decompression illness (see later).

HYPERBARIC TREATMENT SCHEDULES

Ideally, a patient who has therapeutic indication for hyperbaric O_2 would be exposed for an unlimited time until the condition resolves. Unfortunately, several factors limit the dose and duration of HBO: O_2 toxicity; decompression obligation for nursing staff (or other tenders) accompanying patient; difficulty of monitoring; and patient discomfort.

Treatment schedules have been developed that are compromises between O_2 partial pressure and exposure time on one hand and O_2 toxicity and other practical limiting factors listed on the other. The original schedules (or "tables") were developed by the various navies of the world to treat decompression sickness and gas embolism in divers. Two U.S. Navy tables are shown in Figure 67-7 .

U.S. Navy Table 6 (see Fig. 67-7) prescribes an initial exposure to 2.8 ATA (60 ft of sea water [fsw], equivalent to 18 m of sea water [msw]), followed by slow decompression to 1.9 ATA (30fsw). Periods of O_2 breathing are interspersed with 5- or 15-minute periods of air breathing to decrease O_2 toxicity (see later). This schedule remains the mainstay of treatment for decompression illness in multiplace chambers throughout the world. Patients who remain symptomatic during treatment may have their exposure extended in time at both 2.8 and 1.9 ATA. U.S. Navy Table 6A (see Fig. 67-7) is occasionally used for the treatment of air embolism, in which larger amounts of intravascular gas may be present. In Table 6A, the Table 6 schedule is preceded by a period of 30 minutes at 6 ATA while breathing air (see Fig. 67-7). More recently, 40 or 50 percent O_2 has been advocated during this period in order to hasten the elimination of nitrogen bubbles and to increase O_2 delivery to ischemic tissue. In practice, patients are treated once according to either of these schedules and then are reassessed. Incomplete relief of signs or symptoms may be treated with repeated applications of the protocols of these tables on a daily basis. An alternative method of treating severe gas bubble disease is saturation treatment. The principle is that the patient is subjected to elevated pressure (e.g., 2.8 ATA) and is allowed to remain at that ambient pressure until symptoms have stabilized. Periodic O_2 breathing is given according to a recommended schedule as tolerated. Because saturation treatment results in a much larger degree of nitrogen uptake in both the patient and the tender, decompression must occur

Figure 67-7 U.S. Navy treatment tables. (A) U.S. Navy Table 6A. This schedule is designed for the treatment of arterial gas embolism. A 30-minute period at 6 ATA breathing air was designed to compress gas bubbles to one-sixth of their original volume. Subsequent periods at 2.8 and 1.9 ATA breathing 100 percent O_2 allow for oxygenation of ischemic tissue and faster resolution of intravascular gas than would occur if the patient were breathing air. Short periods of air breathing (air breaks) diminish the rate of occurrence of pulmonary O_2 toxicity (see Fig. 67-9 (Figure Not Available)). (B) U.S. Navy Table 6. This table was designed for the treatment of decompression sickness. Both tables may be extended, with additional periods of O_2 breathing at both 2.8 and 1.9 ATA. Stippled areas, O_2 breathing; clear background, air breathing. When Table 6 or 6A is extended, additional safety for the tender can be provided by administering 100 percent O_2 for the last 30 to 90 minutes at 30 fsw (1.9 ATA) according to the number of extensions at 60 fsw (2.8 ATA): 30 minutes (no extensions), 60 minutes (1 extension), 90 minutes (2 extensions); 100 percent O_2 is breathed by the tender for the entire period of decompression from 30 fsw (1.9 ATA) to "surface" (1 ATA). Further details can be found in the U.S. Navy Diving Manual. [85]

much more slowly, usually over 24 to 36 hours. [69] [70] Although this therapy avoids the theoretical disadvantage of intermittent treatment--failure of resolution of gas bubbles, it is also considerably more labor intensive. Because hyperbaric chambers used for saturation treatments require additional hardware (e.g., CO_2 scrubbing capability) and personnel, the application of this method outside the military and commercial diving has been limited.

A schedule used for treatment of patients with clostridial myonecrosis or other life-threatening anaerobic infections is shown in Figure 67-8 . This schedule consists of 85 minutes at 3.06 ATA, followed by a 33-minute decompression stop for the tenders at 1.3 ATA. This stop may be omitted for the patient if a second team is available to lock in and decompress with the patient. The original tenders can then remain at 1.3ATA for the required decompression time. This treatment schedule was designed to maximize Pa_{O_2} (and hence tissue bactericidal activity due to O_2) without an undue risk of hyperoxic seizures.

Administration of HBO to patients with chronic diseases (e.g., radionecrosis) is usually performed using shorter tables at lower ambient pressure. The most commonly employed schedule is 1.5 to 2 hours at 2 to 2.5 ATA (see Fig. 67-8). Because of the lower ambient pressure, the risk of O_2 toxicity is minimal and an exposure of this duration is not particularly onerous for the patient on a repetitive basis once or twice daily.

SIDE EFFECTS OF HYPERBARIC THERAPY

Oxygen Toxicity

A major toxic effect of HBO therapy is due to the O_2 itself. In fact, O_2 toxicity is the factor that limits the maximum allowable P_{O_2} and duration of a hyperbaric treatment. Current opinion is that O_2 toxicity is caused by excessive production of oxygen free radicals (e.g., superoxide, hydroxyl radicals, and singlet oxygen). Mechanisms within the body to scavenge these free radicals may be overcome by increased rates of free-radical production at high O_2 partial pressures. [71] With the use of supplemental O_2 at 1 ATA, the manifestations of O_2 toxicity are almost exclusively confined to the lung. Because of the close proximity of pulmonary tissue cells to gas-containing spaces, tissue P_{O_2} within the lung may increase nearly 5-fold while the patient is breathing 100 percent O_2. Despite the corresponding elevation in Pa_{O_2}, tissue P_{O_2}

Figure 67-8 Clinical hyperbaric O_2 treatment schedules. (A) The patient breathes 100 percent O_2 for 2 hours at an ambient pressure of 2 ATA. Usually this schedule is used for repetitive treatments for chronic conditions (e.g., osteoradionecrosis). (B) Therapeutic schedule for the treatment of clostridial myonecrosis. The patient spends 85 minutes at an ambient pressure of 3.06 ATA and breathes 100 percent O_2, with the exception of two 5-minute air breaks to minimize pulmonary and central nervous system O_2 toxicity. A decompression stop is made at 1.3 ATA, according to the U.S. Navy standard air decompression table. This decompression stop is designed to prevent decompression sickness in the tenders, who breathe air throughout the period at 3.06 ATA.

Figure 67-9 (Figure Not Available) Decrease in vital capacity (VC) as a function of time breathing 100 percent O_2 at 2 ATA in humans. The diagram illustrates the value of intermittent O_2 (20 min O_2, 5 min air) versus continuous O_2 administration in the prevention of pulmonary O_2 toxicity in humans. The numbers in parentheses represent the number of subjects tested. *(From Clark [217])*

in other organs may not be substantially elevated at 1 ATA.

O_2 toxicity during HBO therapy principally affects mainly three organ systems: the lung, the CNS, and the eye. Pulmonary toxicity in the conscious patient is heralded by symptoms of tracheobronchial irritation, namely, cough and burning chest pain. Prolonged exposure may result in a decrease in vital capacity (VC), ARDS, and, ultimately, in pulmonary fibrosis. The rate of development of pulmonary O_2 toxicity may be slowed by intermittent air-breathing periods ("air breaks"). Data supporting the use of air breaks are shown in Figure 67-9 (Figure Not Available) .

The degree to which O_2 is toxic is related to the P_{O_2} of the inspired gas. At 1 ATA, 100 percent O_2 is as toxic as 16.7 percent O_2 at 6 ATA or 2 percent O_2 at 50 ATA. An attempt to quantify O_2 exposure was made by Clark and Lambertsen. [72] In this system (uni pulmonary toxic dose, or UPTD) the number of UPTD units (U) is calculated by the following formula:

where t is the exposure time in minutes; P is the inspired P_{O_2} in ATA, and m is a slope constant that has an empiric value of 1.2. After 1,425 UPTD units of O_2 exposure, there is an average 10 percent decrease in VC; After 2,190 UPTD units, there is an associated decrease of 20 percent. Complete reversal of VC decrements as large as 40 percent of control has been observed after extended O_2 exposure at 2 ATA. [72]

Although the UPTD system may be useful as a rough guide to safe O_2 exposures, particularly in intubated patients who may be unable to report symptoms, its use as an accurate guide to the development of pulmonary O_2 toxicity is limited. Reanalysis of a larger data set than the one used for the UPTD model, which included those data, resulted in a different prediction equation:

where P and t are the same as for equation 1. [73] Interindividual variability may be substantial, however. In a study 12 healthy men who breathed gas containing a P_{O_2} = 0.3 ATA for 12 hours and then a P_{O_2} of 1.05 ATA for 48 hours experienced decrements in VC ranging from 0 to nearly 30 percent. [74] Furthermore, O_2 toxicity can be modified by humidity, [75] circulating catecholamine and corticosteroid levels, leukocyte accumulation in the lungs (e.g., with pneumonia), and circulating endotoxin. A more useful guide in practice is the patient's symptoms. Asymptomatic persons usually have minimal or no change in VC.

Some of the effects of pulmonary O_2 toxicity can be cumulative. Patients given supplemental O_2 to breathe between hyperbaric treatments often complain of burning chest pain. Therefore, in patients receiving multiple HBO treatments, between hyperbaric exposures it is best to use the minimum inspired O_2 compatible with clinical safety (e.g., in the intensive care unit).

Some antineoplastic agents, such as bleomycin [76] and mitomycin C, [77] [78] appear to predispose to fatal pulmonary O_2 toxicity (ARDS and respiratory failure) from what should otherwise have been well-tolerated doses of supplemental O_2. The risk of pulmonary O_2 toxicity due to HBO therapy in patients with previous exposure to such agents is unknown, although the authors have treated several such individuals with a remote history of bleomycin treatment with repetitive doses of HBO. The protocol has been a longer than usual interval between HBO exposures during the initial phase of treatment (e.g., daily instead of the usual twice daily therapy) and close monitoring of spirometry, CO transfer factor, and arterial blood gases. Patients are instructed to seek immediate medical evaluation if they develop progressive dyspnea or cough after an HBO session. If after 1 week of daily therapy there have been no O_2 toxicity symptoms or pulmonary mechanical or gas exchange deterioration, then

the frequency of therapy is increased to twice daily. Some of these individuals have developed mild pulmonary O_2 toxicity symptoms such as retrosternal chest tightness, but none have developed severe O_2 toxicity using a treatment schedule of 2 ATA for 2 hours.

CNS O_2 toxicity is manifested in its most severe form as nonfocal tonic-clonic seizures. This toxicity may occur without warning, but it is sometimes preceded by premonitory signs or symptoms (e.g., nausea, facial numbness, facial twitching, bradycardia, unpleasant olfactory or gustatory sensations, or acoustic symptoms). The probability of seizures increases with increasing Pa_{O_2} and time of exposure. In a study of 36 divers breathing 100 percent O_2 at 3.7 ATA, all experienced one or more of these symptoms within 100 minutes or less. [79] [80] In clinical practice, convulsions are rare at 2 ATA. In the authors' experience, hyperoxic convulsions occur in less than 0.02 percent of HBO treatments at 2 ATA for 2 hours. The probability of a convulsion is greater at higher P_{O_2}, but it is less than 5 percent even at ambient pressures of 3 ATA. Metabolic factors may reduce the seizure threshold, such as the administration of high-dose penicillin (e.g. for clostridial infection), sepsis, and hypoglycemia.

The treatment of hyperoxic seizures is easily accomplished by immediately decreasing the inspired O_2 concentration. In a multiplace chamber, the head tent or face mask should be removed. An intubated patient should be removed from the ventilator and manually ventilated with compressed air using a bag-valve system until the seizure has stopped. In a monoplace chamber, 100 percent O_2 in the chamber atmosphere may be replaced by air. The chamber should not be decompressed while the patient is actively having a seizure because airway closure and failure to exhale during this period may result in pulmonary barotrauma such as pneumothorax or AGE. Seizure threshold may be elevated with benzodiazepines or with therapeutic serum concentrations of phenytoin or phenobarbital. Some physicians routinely administer an anticonvulsant such as phenobarbital, phenytoin, or a benzodiazepine after a hyperoxic seizure, although others do not believe this is necessary. Other than pulmonary barotrauma (which can occur if chamber decompression is performed during a seizure, as noted earlier), hyperoxic seizures have no sequelae and rarely recur despite continuation of HBO, particularly if anticonvulsant prophylaxis is used. Thus, hyperoxic CNS symptoms should not be a reason to discontinue a series of HBO treatments.

Hyperoxic effects on the eye may be acute (narrowing of the visual fields) or chronic (change in the refractive index of the lens resulting in myopia). Myopia may occur during the course of intermittent HBO therapy over several weeks and usually resolves in a similar period. However, some patients may be left with residual myopia, particularly the elderly. [81] It has been suggested that hyperbaric therapy may promote nuclear cataract formation. [82] However, the population of patients most likely to require hyperbaric treatment (elderly people with peripheral vascular disease and diabetes) also have a high prevalence of cataracts. Moreover, cataractous lenses tend to progress without hyperbaric exposure, and the changes are difficult to quantify, as pointed out by Anderson and Shelton. [81] Therefore, more definitive data are required before the hypothesis that HBO may result in cataracts can be accepted. Additional toxic effects of O_2 on the neonatal retina have been well described and may result in retrolental fibroplasia. Concern has been raised about the risk of this complication in the unborn child of a woman who may require acute HBO therapy during pregnancy. Although many pregnant women have been treated with single exposures to HBO (e.g., for CO poisoning), the authors are not aware of any incidents of retrolental fibroplasia in the child after birth. The authors therefore recommend that pregnant women with acute, symptomatic illness for which HBO is indicated (e.g., CO poisoning) be treated with HBO because the risk to the fetus of the underlying condition is usually much greater. O_2 toxicity of other organs has been suggested or demonstrated in experimental animals, but its clinical importance has not become evident, at least not with currently used HBO schedules.

Inert Gas Uptake

Breathing air at high ambient pressure may result in two "toxic" effects that are due to the nitrogen. The first is a dose-dependent decrement in cerebral performance known as nitrogen narcosis, which is due to the anesthetic properties of nitrogen. This often becomes apparent to an outside tender trying to communicate with a nurse inside the chamber, for whom actions requiring fine motor control (e.g., starting an intravenous line) and rapid decision-making may be more difficult. This is particularly true at 6 ATA; however, most therapeutic recompressions are limited to 3 ATA, at which narcotic effects are usually tolerable. Narcosis may be avoided entirely by using helium-O_2 (heliox) as the chamber atmosphere rather than nitrogen-O_2. However, this is expensive and engenders communication difficulties because the speech of people inside the chamber becomes relatively unintelligible in a helium atmosphere ("Donald Duck voice"). Heliox recompression is usually reserved for saturation treatment of helium-breathing divers. Although there is anecdotal evidence that helium-O_2 may be more efficacious than nitrogen-O_2 mixtures for the treatment of nitrogen-induced decompression sickness, [83] [84] this contention has yet to be supported by a systematic trial.

The second major adverse effect of nitrogen is that it is taken up by body tissues and must therefore be released during and after decompression. Overly rapid decompression may result in the formation of bubbles within the tissues and blood, leading to decompression sickness manifested by joint pains or neurologic symptoms referable to the spinal cord. Neither this nor nitrogen narcosis is a problem for the patient, who breathes O_2 throughout most of the therapeutic hyperbaric exposure. However, the tender in a multiplace chamber breathes compressed air in the atmos-phere. Therefore, decompression schedules must be designed to minimize the risk of decompression sickness in tenders. Most hyperbaric facilities use U.S. Navy compressed air decompression tables (see Fig. 67-7). [85] Additional safety for the tender can be provided by requiring the tender to breathe 100 percent O_2 for a period immediately prior to and during decompression (Table 67-7) . O_2 breathing results in increased nitrogen elimination because of the resulting rapid lowering of tissue partial pressure of nitrogen.

TABLE 67-7 -- Duke Modifications of the U.S. Navy Air Decompression Tables

Standard air decompression time calculation for tenders
Within 2 ft of standard Navy depth divisions, use the next greatest depth
Within 2 min of standard Navy time divisions, use the next greatest time
During decompression of the chamber after a compressed air dive, breathe 100% O_2 from an equivalent depth of 50 fsw (2.5 ATA) to the surface or for 15 min, whichever is shorter
Time for decompression
68-30 fsw (3.06-1.9 ATA): 3 min
30-20 fsw (1.9-1.6 ATA): 1 min
20-10 fsw (1.6-1.3 ATA): 1 min
10 fsw (or last stop)-"surface" (1.3-1.0 ATA): 5 min
For decompression from USN treatment tables, see legend for Figure 67-7 .

Rare episodes of decompression sickness in tenders are usually minor, generally consisting of mild joint pain.

Exposure to Trace Gases

Because the chamber is an enclosed environment, there is a possibility for build-up of other gases that may be toxic. CO_2 is produced by the patient and tender, and significant accumulation in the atmosphere may result in elevated Pa_{CO_2}, which may augment nitrogen narcosis as well as CNS O_2 toxicity. The chamber atmosphere must therefore be carefully monitored, and action must be taken to lower individual gas concentrations if threshold limits are exceeded. Most hyperbaric facilities require that the atmospheric P_{CO_2} not rise above 4 mm Hg. Other potentially toxic gases may be produced from smoldering or burning of electrical components or may be released from batteries. All batteries produce small quantities of hydrogen. Lithium- sulfur dioxide batteries, although hermetically sealed with an interior pressure of 4.5 ATA, may vent sulfur dioxide in the event of a seal failure. (Minimization of these risks is discussed later.) CO is released into the atmosphere in a closed chamber by body metabolism and by other environmental factors, and during saturation dives (prolonged chamber exposures at a constant pressure) it may accumulate unless converted to CO_2 by catalysis. Because monoplace chambers are continuously ventilated with 100 percent O_2 at high flow rates, this issue pertains mostly to multiplace chambers.

Barotrauma

As the ambient pressure is altered, the pressure within gas-containing spaces in the body must equalize with the ambient pressure or must undergo a change in volume. Volume change can easily occur in compliant compartments such as the gastrointestinal tract, but if free flow of gas into and out of containing spaces surrounded by a rigid shell, such as the lung, paranasal sinuses, and middle ear, is impeded, then tissue disruption and hemorrhage can occur (see later). Despite the number of potential adverse effects of HBO therapy, major complications are extremely rare.

PRACTICAL ASPECTS OF HYPERBARIC THERAPY

Middle Ear Pressure Equilibration

Probably the most common patient side effect of hyperbaric chamber use is the difficulty that some patients experience in equilibrating the pressure in the middle ear. This is manifested by acute pain, tympanic membrane stretching or tearing, and hemorrhage into the middle ear (referred to as ear "squeeze"). Difficulty in equilibrating middle ear pressure may also result in labyrinthine window (round or oval window) rupture. [86] Equilibration may be accomplished using several techniques, such as performing intermittent Valsalva maneuvers, swallowing while the nose is pinched, thrusting the jaw forward, or simply swallowing intermittently during compression. Children can often be induced to equalize their ear pressure adequately by having them drink small amounts of liquid during compression. Most patients can learn the technique; however, others may be unable to clear their ears, sometimes because of acute respiratory tract infection. In these patients, equilibration can sometimes be aided by application of a topical nasal vasoconstrictor (e.g., oxymetazoline 0.05% [Afrin]), which may shrink the nasopharyngeal mucosa and increase the patency of the eustachian tube. Myringotomy is usually reserved for patients who cannot equalize the pressure despite these measures or for obtunded or intubated patients. For patients who cannot equalize the pressure and who require hyperbaric therapy beyond 2 or 3 days, placement of tympanostomy tubes will ensure a patent opening into the middle ear. Squeeze may occasionally also affect the sinuses, resulting in acute pain. Despite the common occurrence of middle ear or sinus squeeze on compression, symptoms on decompression, because of inability of gas to exit via the eustachian tubes or sinus ostia (reverse squeeze), are extremely rare.

Pulmonary Pressure Equilibration

Areas of poor ventilation within the lung must also reach equilibration during compression and, more important, during decompression in order to prevent pulmonary barotrauma, which may result in pneumothorax, pneumomediastinum, or AGE. Patients with bullae on a chest radiograph could therefore be disqualified from hyperbaric therapy. Patients with obstructive pulmonary disease should have bronchodilator therapy optimized prior to commencement of HBO. However, despite the relatively frequent occurrence of pulmonary barotrauma in scuba divers (
100 cases/ yr from the continental United States reported to the Divers Alert Network [51]), pulmonary barotrauma during HBO therapy is increasingly rare. The authors are aware of only one case of AGE resulting from decompression of a patient inside a hyperbaric chamber. This finding is perhaps surprising, given that many such patients have been heavy smokers and therefore frequently have some degree of obstructive lung disease. Possibly, the reason is that immersion in water elevates pulmonary closing volume (CV), which may result in areas of lung that are pneumatically isolated from the tracheobronchial

tree. Incomplete emptying of these areas during decompression from the dive may result in alveolar rupture. Prefaut et al [87] measured the relationship of closing volume to expiratory reserve volume in air and during immersion in water. In six healthy volunteers in air, expiratory reserve volume was larger than closing volume; in four of six of these persons, however, immersion in water caused closing volume to exceed expiratory reserve volume. This finding implies that, in these persons, immersion in water resulted in closure of lung units at lung volumes higher than functional residual capacity. In addition, rates of ascent in hyperbaric chambers can be much more accurately controlled and are generally slower (5 to 6 fsw/min, as compared with up to 60 fsw/min in divers).

Although a pneumothorax would be expected to diminish in size and to resorb more quickly after compression, continuing leakage of air from the lung may result in tension pneumothorax during decompression. Pneumothorax detected prior to treatment is usually treated by insertion of a chest tube and water seal or Heimlich-type valve. Caution must be exercised when using certain commercially available pleural suction regulators, which can exert high negative pleural pressures during chamber compression. [88] Such excessive suction can be relieved by an attendant inside a multiplace chamber by using the manual pressure-relief valve.

Patient Monitoring

Despite the changes in the acoustic properties of compressed air, blood pressure measurement may be performed without difficulty with a standard sphygmomanometer and stethoscope. It is recommended that aneroid pressure gauges be used rather than mercury columns because of the risk of atmospheric contamination due to spillage of mercury in the chamber. More detailed monitoring of the electrocardiogram and of intravascular pressures requires some planning and engineering. It is advisable to minimize the number of electronic devices inside the chamber. Electrocardiographic and pressure transducer cables can be plumbed through the chamber wall to the preamplifiers kept outside. Provision of appropriate cable connectors inside the chamber will minimize the delay necessary in connecting a patient to the monitors after being placed in the chamber. Two simultaneous displays should be available, one for viewing by an outside observer and one facing through a porthole for use by the inside attendant. Standard intensive care monitors can be used to provide simultaneous measurement of arterial and pulmonary artery pressures and intermittent measurement of cardiac output by thermodilution. Occasionally, the increase in ambient temperature induced by chamber compression may alter the zero offset of pressure transducers, with the older nondisposable type exhibiting greater drift than the newer, disposable ones, which have smaller diaphragms. The authors therefore recommend that transducers be zeroed again immediately after compression. Additionally, if pressure bags are used to drive continuous-flow systems for vascular monitoring, it is necessary to repressurize the bags during compression. Similarly, intermittent venting of pressure bags will be necessary as the chamber is decompressed. This minor inconvenience can be solved by using a spring-loaded system to compress the flush bag.

Pulmonary artery catheter balloon ports should be vented to chamber pressure (i.e., remove the balloon inflation syringe from the port and ensure that the gate valve is open) prior to compression and decompression, to avoid forceful implosion and breakage during compression and hyperexpansion and rupture during decompression. Although general recommendations suggest the filling of tracheal tube cuffs with water (see later) to avoid loss of seal with compression, pulmonary artery catheter balloons should never be inflated with liquid, which may cause balloon rupture.

Because of increased fire hazard in a hyperbaric chamber and the possibility of electrical sparking during defibrillation, this procedure must be accomplished in an extremely careful manner and only in a multiplace chamber. Flammable materials, including tape that may have been used to secure the head tent to the patient's torso, must be removed from the immediate area of the defibrillator paddles. An adequate conductive bridge must be obtained between the electrode paddle and the skin by using gel designed for the purpose. A low-resistance gel is recommended, because it has been suggested that high-resistance gels may pose a fire risk because of the increased amount of heat generated at the paddle-skin interface during defibrillation. [89] An alternative, possibly safer, approach from the point of view of sparking employs preapplied conductive disposable ("R-2") pads. [90] Control of the defibrillator by an outside person minimizes the risk that the device will be unintentionally fired.

Intravenous Fluid Administration

In multiplace chambers, there is no intrinsic difficulty in giving fluid intravenously, because the intravenous fluid container and the patient are at the same ambient pressure. The only practical difficulty is that the meniscus within the drip chamber moves upward as the air volume is compressed during the compression phase of

the HBO treatment and downward due to expansion during decompression. Careful adjustment of the fluid level in the drip chamber during decompression prevents air infusion into the patient. Abbott Lifecare "Plum" Infusion Systems (Abbott Critical Care Products, Morgan Hill, Calif.) do not require an air-filled interface to regulate flow, and they work well in multiplace chambers. Particular care must also be taken if glass bottles are used for the fluid because large pressure gradients across the glass wall of a bottle containing fluid and air may cause fracture, unless the bottle is vented with a tube passing from the gas pocket within the bottle directly to the outside. Use of glass bottles in hyperbaric chambers is best avoided entirely.

In monoplace chambers, administration of fluids is technically more difficult because most intravenous infusion devices must be used outside the chamber. Therefore, fluids must be pumped in against the pressure within the chamber (up to 3 ATA or 1,500 mm Hg pressure gradient across the chamber wall). This may be accomplished by a variety of standard intravenous fluid pumps. It is recommended that

intravenous tubing with check valves be used, in order to prevent inadvertent backflow of blood from the patient in the event of disconnection of the pump while the intravenous line is unclamped. Because it is impossible to manipulate intravenous tubing within the monoplace chamber during treatment, the tubing should be arranged to minimize the possibility of a kink. The use of rigid arterial-pressure transducer tubing can prevent this problem.

Blood Gas Assessment and Ventilator Management

The therapeutic administration of O_2 in most hospital settings is guided by measurement of arterial blood gases. Because elevation of tissue P_{O_2} is usually the major therapeutic aim with the use of HBO, it would be preferable if blood gases could be used in exactly the same way in this setting. However, there are several practical reasons that make it difficult to attain this goal. First, blood gas values in a sample taken from a patient in the hyperbaric chamber may not remain stable. In any sample of arterial blood, there is a tendency of gas to diffuse from the blood into the small bubbles that inevitably exist within the syringe unless extremely careful technique is employed to remove them. Under normal clinical conditions, the diffusion of O_2 and CO_2 from blood into a small bubble in a syringe results in only minor changes in blood gas tensions. The reason is that partial pressure changes are buffered by the relatively large contents of O_2 (because of Hb binding) and CO_2 (because of the relatively high solubility of CO_2 in plasma). It is obvious that relatively large changes in P_{O_2} may result from delay in measurement of an arterial blood sample, changes that are compounded if the measurement is to be made outside the chamber. In that situation, small bubbles present in the syringe prior to decompression would be correspondingly increased in size after decompression to 1 ATA. Furthermore, at an ambient pressure of 760 mm Hg, the O_2 in the blood sample will be supersaturated and will tend to move rapidly out of solution into small bubbles, as the CO_2 in carbonated beverages tends to do when the cap is removed from the bottle. Finally, it is impossible to calibrate blood gas machines accurately for gas tensions higher than ambient barometric pressure. Therefore, ideally blood gas tension measurement should be performed inside the hyperbaric chamber, which requires a dedicated analyzer and a skilled technician.

If these facilities are not available, there are two approaches to estimate Pa_{O_2}. The first is simply to draw the arterial blood sample, extrude bubbles as carefully as possible, decompress the sample to 1 ATA, and measure the sample as quickly as possible. Modern blood gas analyzers can produce a Pa_{O_2} estimate by extrapolating the calibration curve obtained from lower O_2 tensions. Weaver and Howe [91] demonstrated that O_2 tension in blood samples obtained at 3 ATA in a hyperbaric chamber can be measured accurately at 1 ATA if analysis is performed immediately after decompression of the blood sample.

Another approach is to estimate the Pa_{O_2} based on measurements obtained at 1 ATA. Gilbert and Keighley [5] demonstrated that at 1 ATA the ratio of arterial/alveolar P_{O_2} (Pa_{O_2}/P_{AO_2}, or $a/_A$ ratio) is relatively constant over a wide range of inspired O_2 concentrations. The authors have examined this ratio over a range of inspired O_2 concentrations, from 0.21 to 1.0, and ambient pressures from 1 to 3 ATA. Arterial blood gases were obtained at 1 ATA, from which the $a/_A$ ratio was calculated. Predicted values for Pa_{O_2} were then calculated for breathing air or 100 percent O_2 at elevated ambient pressure and were correlated with actual measurements of Pa_{O_2} inside the chamber. There was reasonable agreement between predicted and actual values (Fig. 67-10) (Figure Not Available) up to Pa_{O_2} values of 1,700 mm Hg. The following equations may be used to predict Pa_{O_2} at pressure.

The alveolar gas equation (Equation 2) is required to calculate P_{AO_2}:

where Pb and P_{H_2O} are, respectively, ambient and saturated water vapor pressures. If $F_{IO_2} = 0.2$, R = 0.8, and body temperature = 37°C, Equation 5 can be simplified to the following:

Having calculated P_{AO_2} and measured Pa_{O_2}, the $a/_A$ ratio can then be obtained at 1 ATA. The predicted Pa_{O_2} at increased ambient pressure while breathing 100 percent O_2 may then be obtained from Equation 6:

where ATA is the chamber pressure in atmospheres absolute. Although as yet there are no dose-response curves

Figure 67-10 (Figure Not Available) Measured versus predicted Pa_{O_2} at increased ambient pressure. Predicted Pa_{O_2} is calculated from room air arterial blood gases, assuming arterial/alveolar PO_2 ratio (Pa_{O_2}/P_{AO_2}, or $a/_A$ ratio) is a constant. Data are shown both for persons with normal lungs ($a/_A$ ratio 0.75) and for patients with gas exchange abnormalities ($a/_A$ ratio <0.75). It is evident that Pa_{O_2} predicted in this way is close to the actual measured Pa_{O_2}. *(From Moon et al [216])*

TABLE 67-8 -- Hemodynamic and Oxygen Data in a 77-Year-Old Woman With Necrotizing Fasciitis

	AMBIENT PRESSURE (ATA)	F_{IO_2}	Pao_2 (mm Hg)	Pv^-o_2 (mm Hg)	Sv^-o_2 (%)	CARDIAC OUTPUT[a] ($L \cdot min^{-1}$)	HEART RATE (min^{-1})
A	1	2 $L \cdot min^{-1}$	130	33	61	3.7	102
B	2.5	1.0	>1,000	45	79	2.6	95
C	2.5	1.0	>1,000	56	88	3.6	101

[a] Note the decrease in cardiac output and heart rate with hyperbaric oxygenation (A, B). There was a significant increase in $Pv^-_{O_2}$, which increased further when cardiac output was increased because of a reduction in afterload with sodium nitroprusside infusion (C). At pressure, $Pv^-_{O_2}$ and $Sv^-_{O_2}$ are significantly higher than usually observed at 1 ATA.

for HBO, the authors arbitrarily aim to raise Pa_{O_2} to more than 1,000 mm Hg for routine long-term therapy and to as high a level as possible consistent with patient

safety for treatment of acute necrotizing infections.

A better monitor of tissue oxygenation may be mixed venous P_{O_2} ($P_{\bar{v}O_2}$), which, in the absence of shunts, may be a reasonably accurate estimate of mean tissue P_{O_2}. [92] In critically ill patients with pulmonary artery catheters, routine measurement of $P_{\bar{v}O_2}$ is a convenient method of estimating the degree to which HBO therapy is delivering additional O_2 to tissue. A low value usually indicates insufficiently high oxygen delivery. An example is shown in Table 67-8 .

Normal values for pH and P_{CO_2} under hyperbaric conditions are the same as they are at 1 ATA. This has been shown up to an ambient pressure of 66 ATA. [93] P_{CO_2} (and hence pH) should not be expected to change significantly in blood samples that are decompressed, as noted earlier. Therefore, values of P_{CO_2} and pH measured in a blood gas laboratory at 1 ATA on samples of blood decompressed from a chamber can be relied on for clinical purposes.

Mechanical ventilation in a hyperbaric environment presents a variety of challenges. The ideal requirements for ventilation include small size, no electrical requirement, no use of flammable lubricants, ability to operate on a volume-cycled basis over a wide range of tidal volumes and respiratory rates, minimal modification requirement for installation, and ability to provide positive end-expiratory pressure, as well as to ventilate in intermittent mandatory ventilation and assist/control modes. [94] Additionally, the ideal gas source to actuate the ventilator should minimize the risk of combustion caused by build-up of static electricity.

As ambient pressure increases, gas density is proportionately raised, whereas there is relatively little change in gas viscosity. Therefore, in regions of turbulent flow (i.e., in the large airways), airway resistance would be expected to increase. Indeed, Anthonisen et al [95] found that lung conductance (the reciprocal of resistance) during tidal breathing changed with gas density according to the following formula:

where G is lung conductance at gas density rho; G_0 is the conductance at gas density 1.1 g/L (1 ATA); and kappa is a constant that was found to have a mean value of -0.39. At 6 ATA, this equation would predict that lung conductance would decrease by 50 percent, which is equivalent to a doubling of pulmonary resistance. A similar decrement in maximum voluntary ventilation has been observed at gas densities up to 25 times greater than at atmospheric pressure. [93] [96] The effect of increased gas density in raising flow resistance also applies to ventilator circuits.

These findings are of importance when mechanically ventilating healthy persons, because a higher peak inspiratory pressure is expected. They are of considerably greater importance when ventilating a person with high airway resistance. A patient requiring mechanical ventilation at a minute volume close to that individual's maximum voluntary ventilation at 1 ATA may not be adequately ventilated in a hyperbaric chamber, with resulting hypercapnia because of pulmonary mechanical limitation. This problem may be compounded by an increase in physiologic dead space, which has been observed in saturation divers while breathing gas with density 8 to 17 times greater than sea level air. [93] The cause of this is unknown; however, its result is an increased ventilatory requirement. Clinical experience suggests that it is not a major factor at 3 ATA; however, there is insufficient clinical experience at higher ambient pressures used clinically (e.g., up to 6 ATA) to estimate its effect. The probability of hypercapnia during mechanical ventilation of patients undergoing hyperbaric therapy can be minimized by routine measurement of Pa_{CO_2} and appropriate ventilatory adjustment.

Several types of ventilators have been used and tested in hyperbaric chambers. Pressure-cycled devices such as the Bird ventilator have been used with some success, because their compactness admirably fulfills the requirement for small size. However, continual adjustment of rate and cycling pressure is necessary with changes in ambient pressure. Systematic evaluation of two Bird (Bird Products Corp., Palm Springs, Calif. http://www.birdprod.com) ventilator models and a Mark 2 model modified for hyperbaric use by adding inspiratory and expiratory flow cartridges was performed by Gallagher et al. [97] Two of the Bird ventilators failed at 3 ATA, and one failed at 4 ATA. All the devices tested varied their tidal volumes and ventilatory rates with changes in ambient pressure. Several volume-cycled ventilators have been tested and found to be superior. The pneumatic Emerson ventilator (JH Emerson Co., Cambridge, Mass. http://www.jhemerson.com) functioned satisfactorily up to 6 ATA. [97] The disadvantages are that this ventilator was designed only to be used in control mode, and its leather bellows are lubricated with mineral oil, which violates most hyperbaric safety standards. The Penlon Oxford ventilator

(Penlon Ltd., Abingdon, Oxon, UK) has been tested to 6 ATA in a compressed-air environment and to 31 ATA in heliox. [98] It delivered 800-mL tidal volume at stable rates and expired volume over its entire pressure range. The Monaghan 225 ventilator (Monaghan Medical Corp., Plattsburgh, New York) works well in the hyperbaric environment, delivering up to 18 L/min at 6 ATA over a range of tidal volumes from 0.2 to 2 L. [94] Its main disadvantages are its tendency to decrease cycling rate with increasing pressure, requiring some adjustment of rate during compression, and the requirement of its standard mode of operation to be supplied with compressed O_2 rather than with air. However, a simple modification allows it to be powered with compressed air (Fig. 67-11). (Figure Not Available) The authors have used this ventilator for hundreds of hours without malfunction. Another ventilator that has been used in a hyperbaric environment is the Siemens 900C [99] (Siemens Medical Systems Inc., Danvers, Mass http//www.siemens.vents.com). This ventilator is widely used in critical care units and would be an excellent clinical tool in the hyperbaric setting because of its flexibility and compactness. However, tidal volume measured by the ventilator is inaccurate at increased ambient pressure because of the use of screen-type pneumotachographs, which have density-dependent characteristics. Other ventilators used in the hyperbaric environment include the Bennett PR-2, [100] Drager Hyperlog [101] (Dragerwerk, Lubeck, Germany http://www.draeger.com), LAMA-RCH (Laboratoires de Mechanique Appliquee, Egly, France), [102] Logic-03, [103] Penlon Nuffield 200 (Penlon Ltd., Abingdon, Oxon, UK), [104] Pneumatic Emerson (JH Emerson Co., Cambridge, Mass., http://www.jhemerson.com) [97] PneuPAC variant HB (Pneupac Ltd., Luton, Bedfordshire, UK), [105] and Sechrist 500A (Sechrist Industries Inc., Anaheim, Calif. http://www.sechristind.com). [100]

Two safety considerations are worthy of mention. First, in any ventilator delivering enriched O_2, there is a potential for O_2 build-up within the housing. A fire hazard may exist if electrical components surrounded by high O_2 concentration overheat or spark. Moreover, leakage of O_2 from the housing into the chamber may cause rapid O_2 build-up in the chamber atmosphere. The O_2 leakage rate of the Monaghan 225 specified by the manufacturer is on the order of 18 to 20 L/min at 1 ATA. At 2.8 ATA, this was estimated to be close to 60 L/min, [94] a rate that may be inconveniently high in a small chamber. The effect of this leakage on chamber O_2 concentration may be minimized in practice by inserting scavenging tubing into the ventilator cowling, thus removing a large proportion of the leakage O_2 through the chamber overboard dump system. Modification of this ventilator to compressed air actuation [94] eliminates O_2 leakage other than from the patient's expired gas. The other safety consideration is the reliability and safety of electrical components. Large sealed components such as power transistors, Nixie tube displays and cathode ray tubes are inherently fragile at high ambient pressure. Integrated circuit chips, light-emitting diode displays, and discrete components such as resistors

Figure 67-11 (Figure Not Available) Monaghan 225 ventilator modified for use in hyperbaric chamber. A gas-mixing system with two ball rotameters has been added to provide the inspired gas, which enters the ventilator via a conduit attached to the air intake. The F_{IO_2} setting has been permanently set at 21 percent in order to force the ventilator to use the externally mixed gas as the breathing gas. The F_{IO_2} adjustment knob has been removed. A 5-L reservoir bag is attached to the patient gas circuit. A reservoir relief valve prevents overpressurization of the reservoir bag. A subambient pressure-relief valve allows entrainment of room air if insufficient gas is provided to the reservoir bag. *(From Moon et al [94])*

and capacitors are relatively resistant to changes in ambient pressure. Nevertheless, whenever there is a risk of overheating of a component, purging the device with an inert gas will likely prevent ignition (see later).

Air-filled endotracheal tube cuffs tend to lose volume during compression and reexpand during decompression. Therefore, either continuous adjustment of the air pressure within the cuff manually or the easier measure of filling the cuff with water obviates these difficulties.

Atmosphere Control

Careful control of the chamber atmosphere is essential to provide a safe environment for the patient and tender. The major components of atmosphere quality control

are O_2 , CO_2 , and trace gases.

In a multiplace chamber, it is essential that the patient breathe as high a concentration of O_2 as possible (usually 98%) and that the O_2 concentration within the chamber be maintained at close to 21 percent in order to minimize fire hazard. In some hyperbaric units, head-tent O_2 concentration is routinely monitored. In others, the concentration is assumed to be high because of a high rate of O_2 flow through the head tent. Leakage of O_2 from head tents, masks, and ventilators tends to raise the atmospheric O_2 concentration. Typically, an upper limit of around 23 percent is used as a criterion for ventilating the chamber with air or 100 percent nitrogen until the O_2 concentration decreases. Monoplace chambers are continuously ventilated at 85 to 240 L/min, a rate that usually keeps the O_2 content close to 100 percent.

CO_2 control, particularly within a head tent, is important because significant elevations of inspired CO_2 concentration potentiate O_2 toxicity, as noted earlier. Some physicians believe that a small amount of CO_2 in the inspired gas may be beneficial in order to vasodilate ischemic tissue and increase O_2 delivery. No data are available to recommend one approach over the other. A typical standard for the upper limit for head-tent CO_2 is 1 percent "surface equivalent" CO_2 , equal to a partial pressure of 7.6 mm Hg. Chamber CO_2 is usually limited to around 0.5 percent surface equivalent (ambient P_{CO_2} 4 mm Hg), although in nonsaturation dives, it is very unlikely that CO_2 would approach this value except in a very small chamber. Using a nonscrubbing (open-circuit) system, head-tent O_2 flow rates of 40 to 60 L/min (measured at chamber pressure) are usually adequate to keep CO_2 levels appropriately low.

Trace gases that may enter the environment include CO and hydrocarbons from improperly functioning compressors or from automobile exhaust that may be near the compressor air intake. Volatile gases such as alcohol vapor from skin disinfectant solutions and mercury vapor from spillage of sphygmomanometer columns may also pollute the atmosphere. Trace gases become extremely important in hyperbaric chambers because of the increase in partial pressure that occurs with increasing ambient pressure. For example, although a CO concentration of 50 ppm is acceptable for a short time at 1 ATA, the same concentration at 6 ATA is equivalent to 300 ppm, a level that is clearly unacceptable. Compressed air from the chamber banks should be submitted periodically for analysis of trace gases. Nonvolatile skin preparation solutions such as benzalkonium or iodine compounds minimize pollution of the chamber atmosphere. It is recommended that mercury in any form should be excluded from hyperbaric chambers. There is at least one chamber in the United States that had to be decommissioned because of pervasive mercury vapor contamination due to spillage. Acute mercury poisoning has also occurred in occupants of a hyperbaric chamber when mercury from a broken thermometer fell on the floor and remained undetected.

Considerations of battery use may have implications for chamber atmosphere control as well as fire hazards. All batteries release small quantities of hydrogen, although not usually in amounts that would be hazardous. As mentioned previously, lithium-sulfur dioxide batteries carry a theoretical risk of sulfur dioxide discharge. Similarly, there is an objection to the use of mercury cells. Release of inert gas taken up by the battery during the dive may theoretically result in leakage of mercury into the atmosphere. The risk of this must be weighed against the potential benefits (e.g., of using mercury cell-powered temporary pacemakers). Alkaline cells are considered safe, although temporary failure has been observed at extremely high ambient pressures (40-60 ATA). The only battery that has been specifically tested at increased ambient pressure is the lead-acid, gelled electrolyte battery, which has been specifically tested up to 8 ATA. [106] After pressure compensation with mineral oil, these batteries in fact may operate satisfactorily to an ambient pressure of 680 ATA.

Fire Hazards

Although fires in hyperbaric chambers are rare, they are usually lethal. The effects of fire at elevated ambient pressure can be devastating so fast that the fire extinguisher system may not be activated until all occupants of the chamber have died. The very real risk of fire in hyperbaric chambers has been illustrated by accidents in which chamber fires were started by a hand warmer, a sparking toy, and other sources of ignition carried into the chamber in the patient's clothing. Minimization of these risks involves the following: control of chamber O_2 concentrations (irrelevant in a monoplace chamber); minimizing the use of combustible materials within the chamber; controlling sources of heat and spark; and chamber fire extinguisher system.

The geometric increase in burning rate with increases in O_2 concentrations mandates careful monitoring of chamber O_2 , as already noted. At increased ambient pressure, burning occurs more rapidly, even when the O_2 concentration is 21 percent. It is important to ensure that patients do not carry cigarette lighters, matches, battery-operated devices, or other sources of combustion into the chamber. Cotton garments, which tend not to result in build-up of static charges, are generally considered safest. Flame-retardant materials may be of benefit, but in a monoplace chamber, they will probably burn nearly as quickly as untreated material. Hair grease should be removed. Humidification of the O_2 within the head tent helps to minimize the risk of static electricity build-up in hair. Hydrocarbon lubricants (e.g., for stretcher wheels) should be scrupulously avoided because they may spontaneously ignite on contact with aluminum in the presence of high O_2 tensions. Nonflammable fluorocarbon lubricants are recommended.

Sources of sparks from electrically powered equipment should be minimized. Plugging and unplugging electrical cables during hyperbaric treatments are sources of sparking that can be eliminated by taping all electrical plugs onto female receptacles prior to compression. In multiplace chambers, the flammability of electrically powered devices (e.g., intravenous controllers) can be reduced by purging with 100 percent nitrogen or helium via ports drilled in the covering, at a rate sufficient to keep O_2 concentration at a level that does not support combustion, typically at a flow rate of two to three times the internal volume per minute. Electrical systems used in monoplace chambers must comply with specific codes, which specify the types of switches, grounding, and insulation that can be used. [68]

Fluorinated anesthetics can be combustible at 1 ATA in high concentrations. Brown and Morris [107] observed that, in 100 percent O_2 , halothane up to saturation (33%) in an open tube was nonflammable. In a closed-tube concentrations of 20 to 22.5 percent would allow propagation of ignition. Lower halothane concentrations propagated ignition when nitrous oxide was used as the diluent gas. Electrical sparking did not result in ignition of enflurane at concentrations up to 5 percent in 100 percent O_2 or nitrous oxide in a closed tube at 3 ATA. [108] Isoflurane and sevoflurane Drager vaporizers have been tested up to 3 ATA using 100 percent O_2 , with no evidence of spontaneous combustion at room temperature. Given the experience with halothane under hyperbaric conditions, without any reported fires, and the resistance to combustion in 100 percent O_2 at 1 ATA, in the absence of a source of ignition, it is not likely that any of the modern fluorinated anesthetics pose a fire safety hazard in the hyperbaric environment.

Evaluation of a Patient for Safety of Hyperbaric Oxygen Treatment

In addition to ensuring that HBO is indicated for the disease process in question, it is important to assess the patient in terms of general effectiveness and safety of HBO. The following issues should be addressed: whether a sufficient elevation in Pa_{O_2} can be obtained; whether the patient can equilibrate middle ear pressure; adequacy of control of seizure disorders; optimization of reversible obstructive lung disease and the presence of pulmonary bullae or blebs; whether hyperoxic myopia may critically affect vision; and whether claustrophobia may occur during treatment.

Predicted Pa_{O_2} in the hyperbaric chamber may be calculated by Equation 7. It can easily be predicted, for example, that a patient who has sufficient lung disease or injury such that Pa_{O_2} during treatment would not exceed 1,000 mm Hg would probably obtain marginal benefit from HBO unless the reason for HBO is gas bubble disease.

The ability to vent the middle ears may be estimated by observing directly the tympanic membrane while the patient holds his or her nose or performs a Valsalva maneuver. Movement of the eardrums indicates a patent eustachian tube and the ability to equilibrate middle ear pressure. If otic barotrauma is unlikely to be avoided (e.g., with mental obtundation or the presence of an endotracheal tube) or because of a condition that may render the patient susceptible to inner ear injury (e.g., stapedectomy), myringotomy or tube placement is often performed.

The presence of pulmonary bullae or blebs should be considered relative contraindications to HBO treatment. The low risk of pulmonary barotrauma must be weighed against the urgency or efficacy of HBO for treatment of the patient's disease process.

Because hyperoxia may result in generalized seizures, it is prudent to ensure that anticonvulsant medication has been optimized. It should be noted that HBO will

accelerate existing pulmonary O_2 toxicity. Therefore, significant pre-HBO exposure of the patient to high levels of inspired O_2 may also be a relative contraindication to HBO therapy, depending on the urgency of treatment.

For patients requiring more than 20 to 30 HBO treatments, periodic checks of visual acuity may be helpful to determine the onset of hyperbaric myopia. Consultation with an ophthalmologist may be required to advise the patient with impaired vision and in whom myopia due to HBO may further reduce vision. Because most hyperbaric chamber systems are small and cramped, patients who cannot tolerate enclosed spaces may require anxiolytic therapy to facilitate toleration of the HBO therapy.

Delivery of Anesthesia at Increased Pressure

A review of the problems of anesthesia under HBO was published as a report to a committee of the American Society of Anesthesiologists. [109] The report explored various issues, including the potential for nitrous oxide to be used as a sole anesthetic.

Anesthesia may be required as a procedure incidental to the hyperbaric exposure. Ross et al [110] considered the problems of anesthesia up to 35 ATA, in order to provide care for injured divers while in a saturation diving system (e.g., in North Sea oil fields). They suggested using intravenous agents for general anesthesia rather than gaseous anesthetics because of the problems of pollution of the chamber environment with the latter. Regional anesthesia was recommended whenever possible. The authors noted that muscle relaxants should be titrated to effect because some degree of pressure reversal at around 10 ATA has been reported.

Since the 1960s, anesthesia has been performed at increased ambient pressure using a variety of agents to facilitate surgery for carotid stenosis, [111] to perform cesarean section for fetal distress in a hypoxic patient, [112] to allow therapeutic lung lavage for patients with alveolar proteinosis, [65] [66] to perform emergency surgery in a saturation dive, [113] to increase oxygenation in open heart surgery, [63] and to enhance the effectiveness of irradiation of carcinoma. [114]

Inhaled Anesthesia

Nitrous Oxide

The increased ambient pressure in a hyperbaric chamber allows nitrous oxide to be used at partial pressures exceeding its minimum alveolar concentration (MAC). [115] Russell et al [116] observed that it was a less than ideal anesthetic during studies in normal volunteers administered 75 percent nitrous oxide in O_2 for 2 to 4 hours in a hyperbaric chamber at

an ambient pressure of 2 ATA. Hornbein et al performed a similar study at 1.87 ATA (82% nitrous oxide). Although in both studies induction of anesthesia by nitrous oxide was rapid (<60 s), it was accompanied by tachypnea, tachycardia, hypertension, diaphoresis, muscle rigidity, catatonic jerking of the extremities, eye opening, and opisthotonos. After 2 to 4 hours of anesthesia, subjects emerged rapidly from the anesthetic; however, the majority subsequently experienced nausea and vomiting, which was often severe. In a study of two volunteers briefly anesthetized with nitrous oxide at pressures up to 2 ATA, Smith et al [115] observed unexpectedly prolonged recovery in one subject.

A potential problem associated with nitrous oxide anesthesia at high ambient pressures is the possibility that tissues could become supersaturated during decompression, thus allowing bubbles to form (decompression illness). This was not observed by Russell et al, [116] who used an empirical staged decompression schedule with a decompression stop for 30 minutes at 1.3 ATA while the patients breathed 100 percent O_2. Bubble formation can occur without decompression if the patient breathes one gas while surrounded by an atmosphere of another gas that is more soluble. For example, breathing air while in a helium-O_2 environment at 5 to 7 ATA can lead to urticaria and vestibular dysfunction [117] because of rapid diffusion of helium into tissues, causing local inert gas pressure to exceed ambient pressure (isobaric gas counterdiffusion). This phenomenon can even occur at normal atmospheric pressure if a person breathes nitrous oxide-O_2 while surrounded by helium. [118] Therefore, it is imperative that nitrous oxide never be administered in a helium atmosphere.

If a rapid decompression procedure is implemented while the patient continues to breathe a nitrous oxide-O_2 mixture, large amounts of dissolved nitrous oxide will move from the tissues and blood into the lungs, possibly causing a significant degree of diffusion hypoxia. Therefore, an O_2-enriched breathing mix should be administered for several minutes prior to decompression.

Inhaled anesthesia of any type will pollute the enclosed chamber atmosphere with anesthetic gases. Russell et al [116] reported nitrous oxide concentrations in chamber air of 2,500 ppm; ventilation of the chamber with air at a high rate (3,500 L/min of air) was required to reduce the concentration to 25 to 75 ppm. Contamination of the chamber atmosphere may exert pharmacologic effects on medical personnel inside the chamber, particularly at high ambient pressures.

In patients who have recently engaged in scuba diving or have suffered decompression illness, nitrous oxide should be avoided even at 1 ATA, because its administration may result in tissue or blood bubble growth and recrudescence of pain or neurologic symptoms. Such a case, in a patient who developed neurologic symptoms after a nitrous oxide anesthetic regimen following apparent spontaneous resolution of decompression illness, has been reported by Acott and Gorman. [119]

Volatile Anesthetics

Halothane, the most commonly administered volatile agent, has been found both safe and effective in the hyperbaric environment. Although the effect of increased ambient pressure in reversing anesthesia is minimal at 6 ATA, there are effects of increased ambient pressure on the behavior of vaporizer systems.

The effect of a volatile anesthetic on a patient is proportional to the partial pressure of that anesthetic, not to the alveolar concentration. For example, the effect of 1 percent halothane at 1 ATA (with a partial pressure of 7.6 mm Hg) is equivalent to a 0.5 percent concentration at 2 ATA (with the same partial pressure).

Consider the behavior of a traditional copper kettle vaporizer system, in which oxygen saturated with anesthetic vapor is blended with fresh gas. The percentage concentration of an anesthetic in the gas leaving the system is given by the following formula:

where P_v and P_b are the anesthetic vapor pressure and barometric pressures, respectively, and V_k and V_b are the kettle and bypass gas flows. Multiplication of the right side of this equation by P_b gives the partial pressure of the anesthetic:

Calculation of partial pressures of halothane leaving the vaporizer system at 1, 2, and 3 ATA, using bypass gas flow of 5 L/min, kettle flow of 0.1 L/min, and vapor pressure of halothane 243 mm Hg, produces values of 6.94, 5.65, and 5.92 mm Hg, respectively. Despite the 300 percent increase in ambient pressure from 1 to 3 ATA, there is only a 23 percent change in delivered halothane partial pressure at constant flow settings. Therefore, one can estimate delivered anesthetic potency using the same rules of thumb regarding flow rates at any clinically useful ambient pressure. One caveat is that rotameter flowmeters calibrated at 1 ATA indicate falsely high values in the chamber because of the increased gas density. McDowell [120] reported the following relationship for rotameter flow:

where $Flow_{actua}$ and $Flow_{read}$ are the actual and scale reading flows, and rho_1 and rho_P are the gas densities at 1 ATA and P ATA, respectively. This inaccuracy in rotameter performance up to 4 ATA has been confirmed by others [109] (Fig. 67-12) (Figure Not Available) . Although both V_b and V_k are indicated inaccurately by a rotameter, the ratio of flow rates, (V_b /V_k), should be indicated within tolerable clinical accuracy. Therefore Equation 10 remains valid within clinically acceptable limits.

As discussed previously, copper kettle systems should deliver anesthetic partial pressures that are relatively unchanged at varying ambient pressures. The behavior of an anesthetic-specific calibrated vaporizer also should theoretically deliver a constant partial pressure of anesthetic if the ratio of gas flow through the vaporizer to bypass the flow remains the same (Fig. 67-13) (Figure Not Available) . Because of the effect of increased gas density on this flow ratio, in practice the delivered

Figure 67-12 (Figure Not Available) Performance of anesthetic vaporizer system at increased ambient pressure. (A) Flow characteristics of a rotameter system as shown. At 4 ATA the actual delivered flow is less than 60 percent of the flow indicated by the rotameter. (B) Fluotec vaporizer output in partial pressure of halothane as a function of ambient pressure. A small increase in delivered partial pressure is evident at 3 ATA, particularly at 2 and 3 percent settings. *(From Committee on Hyperbaric Oxygenation, [219] copyright 1966, by the National Academy of Science. Courtesy of the National Academy Press, Washington, D.C.)*

partial pressure is somewhat dependent on ambient pressure. A slightly increased partial pressure of halothane delivered by a Fluotec vaporizer at 3 ATA has been observed [109] (see Fig. 67-12 (Figure Not Available)). Drager isoflurane and sevoflurane vaporizers deliver constant vapor partial pressures with acceptable accuracy at ambient pressures up to 3 ATA.

Intravenous Anesthesia

Intravenous agents behave similarly and are unlikely to be affected within the usual clinical range of ambient pressure. There is no evident alteration in the pharmacokinetics of either meperidine [24] or pentobarbital [25] at ambient pressures up to 6 ATA. For therapeutic lung lavage, the authors have provided anesthesia at ambient pressures up to 3 ATA using conventional doses of ketamine and benzodiazepines or propofol and narcotics with nondepolarizing muscle relaxants.

Regional Anesthesia

Regional anesthesia is likely to be both safe and effective in a hyperbaric environment by avoiding the requirement for mechanical ventilation. A bowel resection has been performed at an ambient pressure 6.75 ATA in a helium-O_2 environment using local injection of lidocaine supplemented with parenteral meperidine. [113] When administering intravenous solutions or spinal or epidural anesthesia at increased ambient pressure, care should be taken to avoid injecting air bubbles, which would then expand during decompression and could cause symptoms. Extreme care should be taken to ensure sterile technique because of the

Figure 67-13 (Figure Not Available) Behavior of an ideal Fluotec vaporizer at 1 and 3 ATA. If the ratio of the O_2 flows (anesthetic vaporizer flow/bypass flow) is unchanged at different ambient pressures, it can be seen that the partial pressure of halothane delivered at the exit of the vaporizer is constant. *(From Smith [65])*

propensity for enhanced bacterial growth in the warm, humidified environment of a hyperbaric chamber, particularly during saturation chamber exposures.

EFFECTS OF ALTITUDE

There are approximately 40 million people worldwide living permanently at altitudes higher than 2,439 m and possibly an equal number who visit high altitudes each year, [121] many of whom will require medical care. There is therefore clearly a need for anesthesia and critical care practitioners to understand the physiology of this environment.

Unlike the relationship between ambient pressure and water depth, the relationship between pressure and altitude is nonlinear (see Fig. 67-2 .) The physiologic effects of altitude exposure are mainly attributable to reduction in the following three variables: inspired P_{O_2}, ambient pressure, and gas density. Extreme or prolonged altitude exposure may be accompanied by additional factors, which may modulate physiologic responses, such as hypothermia, exertion, dehydration, and polycythemia.

Hypoxia

Physiologic Changes

O_2 partial pressures from inspired to venous, at various altitudes, are shown in Figure 67-14 (Figure Not Available) . The major mechanism resulting in hypoxia at altitude is the reduction in inspired P_{O_2}. However, an additional reason for arterial hypoxemia is the failure of erythrocytes in the pulmonary circulation to equilibrate fully with alveolar gas (diffusion nonequilibrium). [122] This is especially likely to be important during exercise, when increased pulmonary blood flow reduces capillary transit time. In addition, there is increased ventilation/perfusion ($\dot{V}_A/\dot{Q}$) mismatch, believed to be related to pulmonary hypertension. [123]

The effects of hypoxia on normal physiology have been reviewed by Kafer and Sugioka [124] and by West. [125] The responses to acute hypoxia include increased heart rate and cardiac output. There is a corresponding increase in organ blood flow, including cerebral blood flow. Hypoxia also induces hyperpnea (because of increased breathing rate), to a degree that varies considerably among individuals. End-tidal P_{CO_2} measured in one subject breathing air at the summit of Mt. Everest (barometric pressure 263 mm Hg) was 7.5 mm Hg, whereas P_{AO_2} was 37.6 mm Hg. [126] This hypocapnia has several effects. It results in an increased affinity of Hb for O_2 (leftward shift of the Hb-O_2 dissociation curve), which enhances oxygenation of blood at the lung while simultaneously interfering with transport of O_2 from tissue capillary to mitochondrion. The overall effect on O_2 transport is beneficial. [127]

Hypoxemia may be particularly accentuated during sleep. Figure 67-15 (Figure Not Available) depicts continuous ear oximetry during sleep at an altitude of 4,400 m, demonstrating the severe degree of arterial Hb-O_2 desaturation that can occur. [128]

Acute exposure to altitudes in the range of 4,000 to 5,000 m results in arterial hypoxemia (Pa_{O_2} 40 mm Hg) and an arterial Hb-O_2 saturation of approximately 75 percent. Although

Figure 67-14 (Figure Not Available) Oxygen tension at rest and during exercise, from inspired air to mixed venous blood. Circles indicate sea level (P_{IO_2} 149 mm Hg); upward triangles signify P_{IO_2} 80 mm Hg; squares indicate P_{IO_2} 63 mm Hg; downward triangles represent P_{IO_2} 49 mm Hg; diamonds represent P_{IO_2} 43 mm Hg (equivalent to the inspired O_2 tension at the summit of Mount Everest). Data were obtained from Operation Everest II, in which normal male volunteers underwent decompression over 40 days to simulate a climb to the peak of Mount Everest. *(From Sutton et al [220])*

colors may be perceived as somewhat less bright than normal, other than limitation of exercise capacity, at these altitudes there are no other major temporary or permanent impairments of performance. Acute exposure to mild hypoxia appears not to result in any permanent ill effect. Crow and Kelman [129] found no detriment on test of free recall and visual scanning when healthy subjects were exposed to a simulated altitude of 3,658 m (inspired P_{O_2} 92 mm Hg). One measure of performance during hypoxia that is used in aviation physiology is the effective performance time, defined as the amount of time the individual is able to perform useful flying duties. [130] In an unacclimatized person at 5,500 m altitude, the effective performance time is 20 to 30 minutes, which is reduced to 2.5 to 3 minutes at 8,500 m and 1 to 2 minutes at 9,100 m.

Gradual exposure to altitude or long-term exposure results in a series of adaptive changes, allowing individuals to function extremely well and to do substantial physical work at altitudes at which newcomers can barely function. For instance, Mt. Everest has been climbed without the benefit of supplemental O_2, whereas acute exposure to such an altitude would result in rapid loss of consciousness. Subjects exposed to a progressively lower barometric pressure, reaching to simulated altitude of 8,848 m in a hypobaric chamber

Figure 67-15 (Figure Not Available) Ear oximetry in a subject at an altitude of 4,400 m on Mt. McKinley. The subject had no symptoms on the evening of the study, but the next day developed severe acute mountain sickness when he attempted to ascend to a higher altitude. He exhibited no increase in ventilation when exposed to hypoxia (absent hypoxic ventilatory response). *(From Hackett and Roach [126])*

over the course of 40 days, were able to work on an exercise ergometer at 120 watts while their mean Pa_{O_2} was only 30 mm Hg (arterial Hb-O_2 saturation 58%). [131] In the same study, blood Hb concentration increased from 13.5 to 17.0 g/dL (hematocrit, 40.4-51.9%). The development of polycythemia is perhaps one mechanism by which tolerance to hypoxia occurs. However, the mechanisms of adaptation are still incompletely understood.

One of the adaptive mechanisms is a gradual reduction in plasma bicarbonate, [131] preceded by a decrease in cerebrospinal fluid bicarbonate, [132] tending to offset the initial respiratory alkalosis. After a 40-day simulated climb of Mt. Everest in a hypobaric chamber, resting serum bicarbonate had decreased from 22.2 to 9.9 mmol/L, whereas pH had increased from 7.43 to 7.56. [131] Other adaptive changes include increases in hematocrit and capillary density, as well as undoubtedly other mechanisms as yet undiscovered.

Despite the adaptive mechanisms, careful neuropsychologic testing of subjects before and after mountaineering expeditions to altitudes of 7,000 m or greater have shown evidence of mild persistent performance impairment. [133] [134] Although it is not certain that these abnormalities on for-mal testing are of any functional significance, investigators have reported that impairments may last for up to several months after exposure. Individuals who have the most vigorous hypoxic ventilatory response, and who therefore hyperventilate the most, usually tolerate altitude exposure the best. However, Hornbein et al [133] have shown that neuropsychologic impairment after prolonged extreme altitude exposure is correlated with a brisk hypoxic ventilatory response. These authors hypothesized that despite a higher Pa_{O_2} in individuals with a vigorous hypoxic ventilatory response, brain O_2 delivery may be lower because of hypocapnic cerebral vasoconstriction.

Support for this hypothesis is provided by a study in which hypocapnia was shown to result in a reduction in brain blood volume and cytochrome redox. [135]

Effect of Maternal Hypoxia on the Fetus

Data on the fetal effects of maternal hypoxia are sparse. However, using changes in fetal heart rate as an end point, the fetus appears to be relatively resistant to moderate degrees of maternal hypoxia. Administration of 15 percent O_2 (inspired P_{O_2} = 108 mm Hg, equivalent to 2,500 m altitude) for 4 minutes to 5 primigravid women at 36 to 38 weeks' gestation resulted in an increase in fetal heart rate of only 2 to 3 beats/min. [136] The same investigator observed no change in fetal heart rate after administration of mixtures as low as 10 percent O_2 (inspired P_{O_2} = 71 mm Hg, equivalent to 5,300 m altitude) for 20 minutes in 8 of 28 pregnant women. Polvi et al [137] administered 10 percent O_2 for 10 minutes to pregnant women at 35 to 41 weeks' gestation. Fetal heart rate, heart rate variability, and Doppler velocimetry in the umbilical and middle cerebral arteries of the fetus were unchanged from baseline. Acute hypoxia of this magnitude appears to exert no detectable effects on the healthy fetus, because of augmentation of uterine blood flow. It is therefore unlikely that acute exposure to altitudes up to 2,500 to 3,000 m would adversely affect the fetus.

Additional adaptations to long-term altitude exposure specific to pregnant women include an increase in placental capillary volume and a reduction in villous membrane thickness. [138] Babies born at altitude, even as high as 4,329 m, have scalp vein O_2 tensions similar to values obtained from babies born at sea level. [139] Consequently, a significant reduction in maternal O_2 delivery can be tolerated without any impact on fetal O_2 consumption.

Mountain Sickness

Acute exposure to altitude often results in a constellation of signs and symptoms known as acute mountain sickness (AMS). The most common symptoms are headache, decreased appetite, nausea and vomiting, insomnia, and peripheral edema. [140] AMS can occur after several hours of exposure to elevations higher than 2,500 to 3,000 m, although there is interindividual variation in susceptibility. Approximately 25 percent of visitors to ski resorts in the American Rockies (altitude 1,920-2,960 m) develop AMS. [141] Parenthetically, it is tempting to speculate that the headache that frequently occurs in patients receiving narcotic analgesia after surgery may be due to a form of "AMS" caused by mild hypoxemia. Effective prophylactic measures against AMS in mountaineers include slow ascent (300 m/d) or "staging" in which several days are spent at an intermediate altitude of around 2,000 m. [140] Pharmacologic prophylactic measures include the administration of acetazolamide, [142] which is believed to work by augmenting the ventilatory response to hypoxia because of the metabolic acidosis that occurs following its administration. A dose of 250 mg orally twice daily begun the day before ascent is effective. Dexamethasone has also been shown to be effective in a dose of 4 mg every 6 hours, although symptoms may occur as soon as it is discontinued. [143] [144] Despite its value in preventing HAPE (see later), nifedipine does not prevent AMS symptoms. [145]

Less frequent complications of hypoxia are high-altitude pulmonary edema (HAPE) and high-altitude cerebral

edema (HACE). [146] [147] [148] A hemodynamic pathophysiology for HAPE is suggested by its tendency to occur when pulmonary vascular flows or pressures are particularly high, such as in individuals with an exaggerated pulmonary hypertensive response to hypoxia and in the lung contralateral to a unilateral absence of the pulmonary artery. [149] In addition, in HAPE-susceptible individuals, the probability of a recurrence can be reduced by administration of slow-release nifedipine, 20 mg every 8 hours. [150] On the other hand, bronchopulmonary lavage in subjects with HAPE has revealed that the protein content of the edema fluid is high, implicating an increase in permeability. [151] [152] Paradoxically, measurement of transcapillary escape rate of albumin has revealed no altitude-related increase. [153] A hypothesis that connects mechanical forces in the pulmonary circulation with increased pulmonary capillary permeability suggests that HAPE may be caused by stress failure of pulmonary capillaries resulting from the acute elevation of pulmonary artery pressure. [154]

Most individuals recover from AMS after several days at altitude. However, patients with severe cases, in which there is HAPE or HACE, require treatment, the most efficacious of which is descent or administration of supplemental O_2 . Descent can be simulated by placing the patient inside a commercially available lightweight collapsible bag (Gamow bag), which can be pressurized to about 120 mm Hg higher than ambient pressure with either a foot-powered or an electric pump. Kasic et al [155] have reported that the Gamow bag is as effective as supplemental O_2 for the treatment of AMS at an altitude of 2,850 m. Acetazolamide has also been reported to be effective; when 250 mg was given orally and repeated 8 hours later, symptoms of AMS at 4,200 m were eliminated in five of six climbers within 24 hours. [156] Dexamethasone 4 mg every 6 hours is also effective [157] ; in a randomized, controlled trial at an altitude of 4,559 m, dexamethasone, 8 mg orally followed by 4 mg every 6 hours, provided more sustained improvement, although less rapid relief of symptoms, than 1 hour of compression in a Gamow bag to a gauge pressure of approximately 0.2 atm. [158] The headache may respond to aspirin, acetaminophen, and nonsteroidal anti-inflammatory drugs or small doses of a narcotic such as codeine. Sumatriptan, 100 mg orally, also appears to provide temporary relief of the headache associated with AMS. [159] Pulmonary artery pressure can be lowered in patients with HAPE with nifedipine, hydralazine, or phentolamine. [160] Scherrer et al [161] administered 40 ppm nitric oxide (inspired O_2 concentration 20%) by inhalation to individuals with HAPE at 4,559 m altitude (barometric pressure 440 mm Hg) and observed a reduction in pulmonary artery pressure and improvement in arterial Hb-O_2 saturation (67% preinhalation to 73%) after breathing nitric oxide for 15 minutes. When treating a patient with HAPE, if descent or treatment with O_2 are not immediately possible, then pharmacologic reduction in PA pressure should be initiated. Nifedipine, 10 mg sublingually followed by 20 mg of a slow-release preparation administered orally every 6 hours, was successful in treating six patients with HAPE. [162]

A few high-altitude residents develop symptoms consisting of headaches, bone pain, confusion, sleeplessness, and a sensation of congestion in the head, often accompanied by extreme polycythemia, a constellation of findings known as Monge's syndrome. [163] Clinical improvement and increased work capacity often result from phlebotomy, and descent to lower altitudes relieves the symptoms completely.

Reduction in Ambient Pressure

Acute ascent to altitude can cause bubbles to form within tissues as a result of local supersaturation of inert gas. Symptoms of decompression illness rarely occur unless a rapid ascent occurs from sea level to an altitude of 5,000 to 6,000 m, [164] although symptoms have rarely occurred after ascent to only 2,437 m. [165] After scuba diving, exposure to even lower altitudes (2,400 m) within 12 to 24 hours can precipitate decompression illness. [166] In order to reduce the risk of decompression illness, it is the practice of individuals planning a rapid decompression to low ambient pressure (e.g., military pilots, astronauts) to denitrogenate their tissues by prebreathing 100 percent O_2 for periods ranging from a few minutes to several hours, depending on the altitude of the planned exposure.

Reduction in Gas Density

Reduction in gas density results in lower breathing resistance. Varene et al [167] examined the effect of ambient pressure from 0.5 to 5 ATA on airway resistance in healthy persons. Their data can be summarized by either of the following equations:

or:

where P_{ATA} is ambient pressure in ATA, R_P is airway resistance at ambient pressure; and R_0 is airway resistance at 1 ATA. For example, at an ambient pressure of 0.5 ATA (5,486 m), airway resistance is reduced by approximately 20 percent. Under resting conditions, differences in breathing pattern during altitude exposure,

compared with a similar degree of hypoxia at sea level, are minor. [168]

Other Environmental Stresses at Altitude

Individuals at altitude are subjected to low temperature, wind, and ultraviolet radiation. The effects of hypoxia may therefore be compounded by hypothermia, dehydration, frostbite, and sunburn.

Anesthesia at Altitude

General Principles

Because of the reduced ambient P_{O_2} at high altitudes, the risk of perioperative hypoxia is likely to magnified. Newcomers

to altitude are likely to be particularly susceptible. Opiates depress both the tachycardia and hyperpnea that normally occur in response to acute hypoxemia. Slow recovery of consciousness and postanesthetic headache have been reported after anesthesia using thiopental with air or nitrous oxide. [169] When ventilation was assisted or controlled during the anesthetic regimen and when postoperative supplemental O_2 was administered, these complications did not occur, a finding that suggests that intraoperative or postoperative hypoxemia may be a pathophysiologic factor. On the other hand, long-term residents at altitude may be more tolerant of hypoxemia; in such individuals, other considerations may be important, including the higher baseline hematocrit, pulmonary hypertension, and lower Pa_{CO_2} and bicarbonate concentrations. [131] [170] In order to prevent renal retention of bicarbonate, which reduces ventilatory drive, patients requiring controlled ventilation should have the Pa_{CO_2} maintained at its baseline value rather than in the traditionally normal range. Similarly, maintenance of Pa_{O_2} within the sea level normal range results in loss of adaptation and difficulty in readapting the patient to room air breathing.

Increased oozing of blood from surgical wounds at altitude has been reported. [146] This has been attributed to higher venous pressure, blood volume, vasodilatation, and increased capillary density. Camporesi [171] reviewed the topic of anesthesia at both high and low ambient pressures.

Anesthesia Equipment

James and White [172] tested Fluotec Mark II and Drager Vapor halothane vaporizers at sea level and at 5,000 ft (1,524 m), and 10,000 ft (3,048 m) of altitude. At any given setting, the delivered percentage of halothane increased with altitude; however, its partial pressure remained constant. Therefore, when these devices are used at a given vaporizer setting, anesthetic is delivered at a constant potency regardless of altitude.

The same authors [172] also examined the effect of altitude on floating-bobbin or floating-ball gas flowmeters. At 10,000 ft (3,048 m) of simulated altitude, both nitrous oxide and O_2 flowmeters underread the actual flow rate. The percentage error progressively increased up to 4 L/min, at which point both flowmeters were approximately 20 percent in error. A hazard may therefore arise when a low flow of O_2 is mixed with a higher flow of nitrous oxide. Unless an O_2 analyzer is available, the delivered percentage of O_2 may be significantly lower than that calculated on the basis of the flowmeter readings. Venturi-type gas mixing devices tend to deliver higher concentrations of O_2 at altitude than they do at sea level [172] ; at 10,000 ft (3,048 m) of altitude, a mask designed to deliver 35 percent O_2 at sea level actually delivered 41 percent O_2 .

General Anesthesia

The potency of anesthetic gases is proportional to their partial pressure. Therefore, as barometric pressure is reduced, fixed concentrations of inhaled anesthetics have lower potency. Cleaton-Jones et al [173] reported insignificant differences in the effect of nitrous oxide at sea level and at 1,700 m altitude. On the other hand, at an altitude of 3,300 m, James et al [174] showed a significant reduction in efficacy of 50 percent nitrous oxide in reducing pain threshold in normal volunteers (Table 67-9) . Because of this reduced effectiveness and the errors in administered gas concentration, which can occur because of altered gas flowmeter performance (see later), in the absence of accurate inspired gas monitoring, the risks associated with use of nitrous oxide at altitudes higher than about 2,000 m may exceed the benefit.

Because supplemental O_2 may not be available in some mountain locations, it may be imperative to choose an anesthetic technique that is least likely to suppress ventilation. Pederson and Benumof [175] reported using ketamine anesthesia with spontaneous ventilation in 23 patients requiring general anesthesia at an altitude of 1,830 m. Two patients developed significant, though brief, desaturation, which resolved quickly. The authors concluded that this form of anesthesia is a practical method in a rural hospital setting at altitude without access to supplemental O_2 . Nunn [176] reported successful induction of general anesthesia using halothane in a hypobaric chamber at a barometric pressure of 375 mm Hg (equivalent altitude = 5,490 m). A standard halothane vaporizer (Fluotec Mark II) was used, with an inspired O_2 concentration of 60 percent. Recovery was rapid and uneventful.

Regional Anesthesia

Spinal anesthesia has been reported to result in unacceptably high incidence of dural puncture headache. [169] Possible causes include chronically increased cerebrospinal fluid pressure, dehydration, and altered sensitivity of the altitude resident's CNS to intracranial pressure changes. [169] Headaches

TABLE 67-9 -- Effect of 50 Percent Nitrous Oxide on Pain Threshold in Normal Volunteers at High Altitude [a]

ALTITUDE (m)	BAROMETRIC PRESSURE (mm Hg)	INCREASE IN PAIN THRESHOLD (%)	SIDE EFFECTS
0	760	71.5	3 subjects, nausea; 2 subjects, semicomatose
1,460	636	40.0	None
3,300	517	19.0	None

Data from James et al [174]

[a] Pain threshold was measured in 20 subjects at each altitude by applying pressure to the anterior aspects of the tibia using a spring balance. Simulated altitude exposures were in a hyperbaric chamber. At increasing altitudes, a fixed concentration of nitrous oxide is progressively less effective.

were not reported in 20 young native mountain dwellers in whom Severinghaus obtained cerebrospinal fluid samples with 25-gauge needles. [169]

Perioperative Supplemental Oxygen

At high altitude, alveolar P_{O_2} is normally increased by hyperventilation induced by the hypoxic ventilatory drive. Administration of anesthetics or narcotic analgesics, both of which types of drugs blunt the hypoxic ventilatory drive, may therefore precipitate hypoxia. The resulting hypoxic symptoms of irritability, confusion, and restlessness may be misinterpreted as due to pain, and misguided administration of additional narcotics would only compound the problem. Nunn [176] refers to analgesic-induced respiratory depression as a likely cause of death in a Sherpa who had debridement of frostbitten fingers at 4,300 m altitude. Therefore, if analgesia

is necessary, supplemental O_2 may be required to prevent fatal hypoxia.

Effects of Commercial Air Travel

Cotrell [177] and Aldrete and Aldrete [178] recorded actual cabin altitude during commercial pressurized aircraft flights at 2,700 m, at which Pa o_2 in healthy individuals is likely to be around 50 to 55 mm Hg. This degree of mild hypoxemia (Sa o_2
90%) is well tolerated by healthy individuals. However, in a group of patients with chronic obstructive pulmonary disease (mean sea level Pa o_2 , 68 mm Hg), Pa o_2 at an altitude of 2,250 m was reduced to a mean of 44.7 mm Hg (lowest 25 mm Hg). [179] Arterial desaturation of this magnitude may be expected to cause symptoms. Indeed, Dillard et al [180] reported 44 patients with chronic obstructive pulmonary disease who had traveled by commercial aircraft. Of the 44 patients, 8 had experienced one or more of the following symptoms during flight: dyspnea, edema, wheezing, cyanosis, and chest pain.

It has been recommended that patients with baseline hypoxemia be considered for in-flight O_2 administration. Gong et al [181] described a high-altitude simulation test in which subjects were given hypoxic concentrations of O_2 in order to simulate the inspired P o_2 at altitude. The authors derived the following prediction equation for Pa o_2 at altitude:

SUMMARY

Increasingly widespread use of HBO to treat critically ill patients has created a demand for individuals skilled in using this technology. Planning and design of monitoring capabilities will enable optimal control of hemodynamics and oxygenation. Careful attention to detail will maximize patient safety in this environment. Optimized treatment schedules will evolve from further studies of mechanism of action. Advances in prevention and treatment of O_2 toxicity may allow more prolonged therapy than can currently be safely administered and hence a more aggressive approach to ischemic and infectious syndromes.

The reduction in ambient pressure and ensuing hypoxia associated with acute altitude exposure result in well-described physiologic changes, often associated with clinical symptoms. Methods for prophylaxis and treatment have been described. Safe anesthesia at altitude requires some modification of sea level techniques, not only because of the hypoxia and reduced ambient pressure, but also because suboptimal equipment may be available in mountain conditions.

Chapter 68 - The Postanesthesia Care Unit

Thomas W. Feeley
Alex Macario

INTRODUCTION

Recovery from anesthesia is, for most patients, a smooth, uneventful emergence from an uncomplicated anesthetic regimen and operation. However, for a significant number of patients, recovery from anesthesia can be a life-threatening process best managed by prompt intervention delivered by skilled medical and nursing personnel. For anesthesiologists, involvement in optimizing recovery from anesthesia is one component of perioperative medicine. The postanesthesia care unit (PACU) often faces the task of simultaneously caring for patients waking up from routine surgery, patients recovering from regional anesthesia, critically ill postoperative patients, and children emerging from the frightening world of anesthesia and surgery. The facilities and staff must be experienced and flexible to deal with these diverse situations as well as meet the requirements of various users including surgeons and patients. Each user values the PACU differently. Patients may value adequate analgesia, a friendly staff, and prompt relief of nausea and vomiting, whereas surgeons and anesthesiologists value skilled nursing care.

HISTORY

Although methods of general anesthesia have been available for more than 150 years, PACU have only become common in the past 40 years. The first description is from 1801 at the Newcastle Infirmary in England and predates modern anesthesia. There were two five-bed rooms adjacent to the operating room that were reserved for patients who were seriously ill or who had just undergone a major operation. [1] Another early description came in 1863, when Florence Nightingale [2] wrote: "It is not uncommon, in small country hospitals, to have a recess or small room leading from the operating theater in which the patients remain until they have recovered, or at least recovered from the immediate effects of the operation."

The first description of a recovery room in the United States was from 1873 at the Massachusetts General Hospital. Charles Tomes, a British dental surgeon, was invited to deliver the graduation address to dental students at Harvard. There he observed ether being administered in an induction room separate from the operating room as well as the use of a recovery room: "Also, patients were apt to be noisy after recovery, so they are, at this hospital, temporarily placed in a small ward, whence, after complete recovery, they are transferred to their own wards." [3]

In the 1920s and 1930s, the complexity of surgical procedures increased, and several PACUs were opened in the United States and abroad. In 1923, a three-bed neurosurgical unit was opened at Johns Hopkins Hospital by Dandy and Firor. [4] [5] It was not until World War II, however, that a large increase in the number of PACUs occurred. The major reason for the increase was the shortage of nurses that existed in the United States. PACUs were created so that an adequate level of nursing care could be provided for the immediate postsurgical patient. [6] PACUs were opened at the Mayo Clinic in 1942, at New York Hospital in 1944, and at the Ochsner Clinic in 1945. [7]

In addition to conserving nursing facilities, postoperative care saved lives. In 1947, the Anesthesia Study Commission of the Philadelphia County Medical Society issued a report

---

that further stimulated growth of PACUs. [8] The Commission found that, in an 11-year period, nearly one-half of the deaths that occurred during the first 24 hours of surgery were preventable. They also found that at least one-third of those deaths could have been prevented by improved postoperative nursing care. [5] [7] Following this report, many U.S. hospitals opened postanesthesia care units. [9] [10] [11] In 1949, the Operating Room Committee for New York Hospital [12] stated: "Today it can be stated categorically that an adequate recovery room service is a necessity to any hospital undertaking modern surgical therapy."

During the 1950s, the uses of these units expanded even further. This increase allowed for a better understanding of the nature and course of the more common postanesthetic complications. The 1950s and 1960s also witnessed the rapid growth of surgical intensive care and postoperative respiratory support. This resulted in an ever-increasing number of complex surgical procedures and increased numbers of patients who required postoperative mechanical ventilation. In many hospitals, the original intensive care unit (ICU) proved too small to handle the large number of cases requiring intensive postoperative care. Many PACUs were therefore forced to serve as short-term ICU for surgical patients. The increased use of invasive monitoring techniques in the 1970s, as well as a continued trend toward providing prophylactic postoperative ventilatory support, required many PACUs to manage both routine recovery from anesthesia and critically ill postoperative patients receiving respiratory and circulatory support. The late 1980s and 1990s have seen the emergence of outpatient surgery. The PACU staff must now manage patients who will be going home following anesthetic recovery and not to a hospital ward.

ECONOMICS

With the increased prevalence of prepaid care, hospitals and operating room suites are reducing costs as a primary strategy for managing profitability. This approach has transformed the operating room suite, including the PACU, from revenue centers to cost centers. This means that minimizing costs replaces maximizing revenue as the financial objective.

In a study of 715 inpatients undergoing diskectomy, prostatectomy, appendectomy, or laparoscopic cholecystectomy, 3.85 percent of the total costs for a patient's hospitalization was allocated to the PACU. [13] However, PACU charges (as they appeared on the patient's hospital bill) were 3.2 percent of the overall hospital charge. The mean cost-to-charge ratio for the PACU is 0.54 (Table 68-1) (Table Not Available) . The differing cost-to-charge ratios result when hospitals mark up the charges for services in one area (i.e., PACU) to invest in other unreimbursed hospital departments (i.e., medical records) or to pay for development of new clinical programs.

The PACU has a high fixed (does not change in proportion to number of patients treated) cost component. Variable costs, or labor and supplies directly involved in producing a specific patient service, account for 33 percent of overall PACU cost. [13] Because the remaining two-thirds of PACU costs are fixed, even if a patient spends an extra 20 minutes in the recovery room, institutional costs may not be affected significantly. This is not an argument for avoiding drugs with better recovery profiles or avoiding more costly antiemetics because patient satisfaction with care may be higher with the use of these agents. Mathematic modeling of PACU time and cost data suggest that what is most likely to produce cost savings in the PACU is optimizing the timing of the arrival of patients into the PACU to reduce peak requirements of nursing personnel. [14]

A survey at a university hospital revealed that recovery room nurses consider 60 minutes to be a minimum period of time to check the patient in, process the paperwork, and prepare the patient for transfer to the floor. [15] Because of this requirement and the high fixed cost structure of the PACU, reasonably achievable decreases in the times to PACU discharge by improvements in anesthesia practice are unlikely to reduce PACU costs substantially. More rapid awakening after anesthesia may be associated with decreased PACU costs if the patient bypasses the recovery room entirely, or if fewer staff members are required. Identifying anesthetics that can allow the patient to bypass the PACU is under investigation at both academic centers and community hospitals. Appropriate patients receiving monitored anesthesia care or regional anesthesia may not need to recover in the PACU. For example, deciding whether to leave a patient in the PACU until a motor block wears off from a conduction anesthetic deserves further study. Independent predictors of PACU length of stay include complexity and length of the surgical procedure, anesthetic type, and American Society of Anesthesiologists (ASA) status. [16] Some patients may need to remain in the PACU for monitoring and treatment of surgical problems, not anesthesia-related issues. Instead of requiring a minimum PACU stay for all patients, PACU stay can be adjusted according to patient and surgical factors--sicker patients having extensive surgery require extended recovery.

TABLE 68-1 -- Cost Ratios for Selected Hospital Departments

(Not Available)

Modified from Macario et al [13]

DESIGN AND STAFFING

Location and Size

The PACU should be located close to the operating suite to permit anesthesiologists and surgeons to be nearby and to permit rapid return of the patient to the operating room if necessary. The PACU should have good access to immediate roentgenographic, blood bank, blood gas, and other clinical laboratory services. Having the PACU located near the ICU is also useful, especially because nursing staff is shared between the units.

The size of the unit is determined by the surgical caseload of the institution. Approximately 1.5 PACU beds per operating room utilized are usually adequate. This is roughly equivalent to two beds for every four procedures performed in a 24-hour period. [17] [18] An open ward is optimal for patient observation; however, at least one isolation room is a helpful addition to every PACU for the management of those patients with either contaminated wounds or severe immunosuppression. A separate pediatric PACU is also useful when the volume of pediatric cases is high (Ch. 59) .

Facilities

The ward itself should have large doors, adequate lighting, efficient environmental control, and sufficient electrical and plumbing facilities. In addition to the bed spaces, there should be a central nursing station and physician station, as well as storage and utility rooms (Fig. 68-1) (Figure Not Available) . Each bed space should have piped-in oxygen, air, and vacuum for suction (both intermittent pressure for gastric suction and high pressure for airway and chest suction).

Equipment

There should be an automated blood pressure device or sphygmomanometer and intravenous supports by each bed. Pulse oximetry is an essential monitoring technique in the PACU. An area for charting and storage of bedside supplies is also necessary, with sterile suction catheters, needles, syringes, gloves, and face-mask oxygen available at every bedside. Electrocardiographic monitoring is routinely available for all patients. The capability for direct interarterial monitoring of blood pressure and of intracranial pressure is also required in hospitals where critically ill postoperative patients use the PACU.

A supply of immediately available emergency equipment should also be located in the PACU. This should include an airway cart consisting of the following: oral and nasal airways; orotracheal, nasotracheal, and tracheostomy tubes; laryngoscopes; bronchoscopes; and hand-ventilating devices. Self-inflating bags with positive end-expiratory pressure (PEEP) valves are also useful. A defibrillator capable of synchronized defibrillation should be available, as well as an electrocardiogram (ECG), pacemaker, and pacing wires. Equipment for pulmonary artery catheterization should be available. This includes an introducer set, [19] pulmonary artery catheters, transducers and flushing system, and a cardiac output computer. A "crash cart" containing cardiopulmonary resuscitation equipment and emergency drugs should be available and fully stocked at all times. Chest-tube trays, cutdown trays, and tracheostomy trays are necessary. A wide variety of intravenous solutions should also be available.

A new technology becoming increasingly prevalent is an automated patient-tracking system that uses computers to provide real-time information on the location and status of

Figure 68-1 (Figure Not Available) The postanesthesia care unit should be well lighted, spacious, and equipped to deal with any possible postanesthetic emergency. A central nursing and physician station is useful. Each bedside should be fully equipped with air, oxygen, and suction. *(Courtesy of Dr. Fred Mihm)*

surgical patients in the operating room suite. These systems provide video displays in which real-time surgical case information is available. The information is maintained by the use of bar-code scanners, magnetic readers, or common keyboard-based input terminals. Patient flow is tracked using bar-coded charts and bar-coded identification bracelets. Automated patient tracking systems can provide the PACU with information regarding room utilization, delays and cancellation, transit times, and expected arrival to the recovery room. This information may facilitate staffing. Whether this technology improves staff efficiency and operating room utilization deserves study.

Personnel

The personnel required will vary somewhat from unit to unit, but a nursing ratio of one nurse to every three patients is usually sufficient. If critically ill patients are admitted, the ratio is increased to one nurse to two patients (and occasionally, as high as two nurses to one patient). [17] [18] A charge nurse should oversee nursing care. Most PACUs are under the medical direction of the anesthesia department; however, few provide continual physician coverage with a full-time physician in the PACU. In most hospitals, the anesthesiologist responsible for the surgical anesthetic regimen remains responsible for the patient in the PACU and intervenes when necessary. The anesthesiologist is usually responsible for patient discharge to the postsurgical ward, ICU, or home.

Efficient staff scheduling is important in minimizing the costs of running a PACU. The two factors that affect the actual number of patients in the PACU at a given time of day are the hourly admission rates and the times to discharge. Because personnel costs are a major component of PACU costs, hospitals are creating a lower-cost team of personnel who can provide the same quality of service. To maintain an efficient recovery room, employees must possess multiple skills to cover various assignments because the type and amount of work fluctuate. Cross-training of nurses to care for patients in the preoperative area in the morning and in the postoperative area at midday and in the afternoon may increase efficiency. In addition, substitution of higher-cost labor with technicians, along with flexible work schedules, may better match supply and demand. A ward clerk and an orderly are helpful members of a busy PACU staff. In addition, structural changes in facilities, such as having nearby office facilities for surgeons to see patients between cases or a separate base adjacent to the PACU where family members can aid in caring of the patient, may improve cost efficiency. Because the major determinant of PACU cost is the distribution of admissions, PACU costs are unlikely to change without a decline in peak census. [14]

/das/book/view/29494766/875/751.html

ROUTINE RECOVERY

Factors Influencing Awakening

The recovery of a patient following an uncomplicated anesthetic regimen and operation is often routine. The recovery process actually begins in the operating room when the operation and anesthetic are completed and the trachea is extubated. [20] The time to recovery from inhaled anesthetics is a function both of the solubility coefficient of the agent and of the level of alveolar ventilation of the patient [21] (Ch. 4) . Some forms of premedication can delay recovery, such as high doses of rectally administered midazolam (2 mg/kg). [22] Alveolar hypoventilation is a common reason for delay in awakening from inhaled anesthetics. Administration of high concentrations of inhaled anesthetics for a long procedure is another common cause of delayed awakening. Recovery from morphine-based anesthetics is often a function of the dose administered and of postoperative renal function [23] (Ch. 10) . Propofol-based anesthesia is associated with a quicker return to normal activities than thiopental-isoflurane anesthesia in patients undergoing outpatient procedures. [24]

The introduction of sevoflurane has resulted in several studies that have examined its recovery characteristics. Although one study demonstrated a significantly faster time to eye opening as compared with time with isoflurane, [25] another did not, but the patients in the latter study felt less clumsy than those who received isoflurane. [26] Despite more rapid time to eye opening, patients receiving sevoflurane were not ready for discharge home any faster than patients receiving isoflurane. [25] When compared with those patients who received propofol-based anesthesia, patients who received sevoflurane had more rapid eye opening and were extubated sooner in one study, [27] but not in another. [28] However, the sevoflurane-treated patients had a higher incidence of vomiting. [26] When compared with desflurane, sevoflurane had a slower time to emergence and extubation. There were no differences in time to recovery of cognitive functions or time to discharge. [29]

Recovery from neuromuscular blockade is a function of the agent given, the dose, and the presence or absence of renal or hepatic disease (Ch. 12) . In addition, the dose of reversing agent, the patient's temperature, acid-base status, and the presence of drugs that increase neuromuscular blockade are also important. [30] The introduction of mivacurium, with its short duration of action, into clinical practice has led some anesthesiologists to omit reversal of the drug. If this is done, some adults exhibit residual neuromuscular blockade in the PACU and may require reversal there. [31] In addition, there have been two case reports of prolonged neuromuscular blockade following mivacurium in patients with low plasma cholinesterase levels. [32] [33]

Transportation

After tracheal extubation, the patient is transferred from the operating room table to a stretcher with side rails that can be moved into both Trendelenburg and head-up positions, if necessary. The patient should be transported from the operating room in the lateral position to minimize the risk of airway obstruction or aspiration of gastric contents from vomiting.

Report

When the patient arrives in the PACU, the anesthesiologist should give the nurse a full report of the events during

surgery. This report should include the patient's name, age, surgical procedure, medical problems, preoperative medications, allergies, anesthetic drugs and methods, fluid and blood replacement, blood loss, urinary output, gastric output, and surgical or anesthetic complications encountered.

Care

Following major surgical procedures, all patients should receive oxygen therapy via a face mask or nasal prongs. Healthy patients, following a brief minor surgical procedure, may not require oxygen therapy and can be guided by pulse oximetry. The routine administration of oxygen in the PACU is mildly controversial in the modern PACU equipped with a pulse oximeter. [34] [35] The nurse should be informed of any special medications, tests, or procedures that will be necessary in the PACU. Vital signs should be recorded at least every 15 minutes during the first postoperative hour. The nurse should also encourage the patient to wake up, cough, breathe deeply, and move about, if possible.

Discharge Considerations

Some patients may meet discharge criteria on arrival to the recovery room. Neither an arbitrary time limit nor a discharge score can be used to define a medically appropriate length of stay in the recovery room accurately.

The patient should be seen again by the anesthesiologist before being discharged from the PACU, and the patient's condition should be recorded in the chart. Before discharge, the patient who has undergone general anesthesia should be arousable and oriented, have stable vital signs for at least the prior hour, and be comfortable. Patients who have had recent large doses of narcotic analgesics should be observed for at least 30 minutes. The patient should be able to obtain nursing help while in the surgical ward if necessary. Patients discharged without supplemental oxygen need to have their arterial oxygen saturation measured by pulse oximetry while they are breathing room air.

Discharge of the patient from the recovery room following regional anesthesia depends on the type of block used and sedation administered. Nerve blocks of the upper extremities do not need to have resolved completely prior to discharge. However, patients should be able to ambulate if necessary in a ward (Chs. 42 to 44) . A full description of the patient's course should then be given by the recovery room nurse to the ward nurse before the patient is transferred.

Various system-based, nonmedical factors (i.e., no available bed, waiting for test results, transport delay, lack of physician release) account for many delayed discharges from the PACU. In the ambulatory setting, even after discharge criteria are satisfied, most patients have delayed discharge because of the unavailability of escorts or the lack of their discharge medications. Delays longer than 30 minutes for nonmedical reasons occur in 54 percent of outpatients, most commonly because the patient's companions are not immediately available. [36]

/das/book/view/29494766/875/752.html

STANDARDS

The ASA has the following standards for postanesthesia care, updated in October, 1994, by the ASA House of Delegates [37]:

```
These Standards apply to postanesthesia care in all locations. These
Standards may be exceeded based on the judgment of the responsible
anesthesiologist. They are intended to encourage quality patient care, but
cannot guarantee any specific patient outcome. They are subject to revision
from time to time as warranted by the evolution of technology and practice.
Under extenuating circumstances, the responsible anesthesiologist may waive the
requirements marked with an asterisk (*); it is recommended that when this is
done, it should be so stated (including the reasons) in a note in the
patient's medical record.
```

Standard I

All patients who have received general anesthesia, regional anesthesia or monitored anesthesia care shall receive appropriate postanesthesia management.

1. A Postanesthesia Care Unit (PACU) or an area which provides equivalent postanesthesia care shall be available to receive patients after anesthesia care. All patients who receive anesthesia care shall be admitted to the PACU or its equivalent **except** by specific order of the anesthesiologist responsible for the patient's care.
2. The medical aspects of care in the PACU shall be governed by policies and procedures which have been reviewed and approved by the Department of Anesthesiology.
3. The design, equipment and staffing of the PACU shall meet requirements of the facility's accrediting and licensing bodies.

Standard II

A patient transported to the PACU shall be accompanied by a member of the Anesthesia Care Team who is knowledgeable about the patient's condition. The patient shall be continually evaluated and treated during transport with monitoring and support appropriate to the patient's condition.

Standard III

Upon arrival in the PACU, the patient shall be re-evaluated and a verbal report provided to the responsible PACU nurse by the member of the Anesthesia Care Team who accompanies the patient.

1. The patient's status on arrival in the PACU shall be documented.
2. Information concerning the preoperative condition and the surgical/anesthetic course shall be transmitted to the PACU nurse.
3. The member of the Anesthesia Care Team shall remain in the PACU until the PACU nurse accepts responsibility for the nursing care of the patient.

Standard IV

The patient's condition shall be evaluated continually in the PACU.

1. The patient shall be observed and monitored by methods appropriate to the patient's medical condition. Particular attention should be given to monitoring oxygenation, ventilation, circulation and temperature. During

recovery from all anesthetics, a quantitative method of assessing oxygenation such as pulse oximetry shall be employed in the initial phase of recovery.* This is not intended for application during the recovery of the obstetrical patient in whom regional anesthesia was used for labor and vaginal delivery.
2. An accurate written report of the PACU period shall be maintained. Use of an appropriate PACU scoring system is encouraged for each patient on admission, at appropriate intervals prior to discharge and at the time of discharge.
3. General medical supervision and coordination of patient care in the PACU should be the responsibility of an anesthesiologist.
4. There shall be a policy to assure the availability in the facility of a physician capable of managing complications and providing cardiopulmonary resuscitation for patients in the PACU.

Standard V

A physician is responsible for the discharge of the patient from the PACU.

1. When discharge criteria are used, they must be approved by the Department of Anesthesiology and the medical staff. They may vary depending upon whether the patient is discharged to a hospital room, to the Intensive Care Unit, to a short stay unit or home.
2. In the absence of the physician responsible for the discharge, the PACU nurse shall determine that the patient meets the discharge criteria. The name of the physician accepting responsibility for discharge shall be noted on the record.

/das/book/view/29494766/875/753.html

QUALITY IMPROVEMENT AND CLINICAL PATHWAYS

The Joint Commission on Accreditation of Health Care Organizations requires continuous quality improvement of hospitals. Quality improvement is the effort to measure the level of current performance, to find ways to improve that performance, and to implement new and better methods. [38]

Teams of physicians, nurses, and other staff members may have little knowledge of the practice of others. Clinical pathways, also called care pathways or critical pathways, put providers caring for a patient "on the same page." Clinical pathways are an application of continuous quality improvement to health care. Hospitals are using clinical pathways to cut costs and to reduce unnecessary variation in care. These scientifically grounded, continuously reviewed treatment strategies facilitate multidisciplinary communication, data collection, data analysis, and feedback with a goal of quality outcomes at low cost. In nonmedical sectors, simplification and standardization of production processes to eliminate waste and duplication of effort have reduced costs.

The effect of clinical pathways on the PACU is largely unknown. Hospitals have tried to reduce anesthesia drug costs through written guidelines. Limiting neuromuscular blocking drug use, for instance, increased the average time from end of surgery to PACU arrival by an average of 3 minutes. [39] Although this finding was statistically significant, the economic effect of this change may be limited.

Institutional differences in clinical practice and cost may make it difficult for some cost-saving interventions to succeed. For example, if institutional policy requires a minimal period of PACU observation following all surgical procedures, the economic benefits to the PACU of completing a higher fraction of surgical procedures using monitored anesthesia care instead of general anesthesia may not be obtained.

Many studies of recovery room care compare intermediate end points such as early awakening or return to baseline on psychometric test. Although fewer patients are required to establish significant differences in these end points in clinical studies, comprehensive PACU outcome measures need to include other outcomes including patient satisfaction, incidence of unplanned hospital admissions, and ability to begin postoperative rehabilitation.

COMPLICATIONS

Survey Results

Until recently, studies of complications in the PACU were rare in the anesthesia literature. During the past 4 years, four separate groups have performed large surveys of complications occurring in the PACU. The first was a survey from Yale. Hines and colleagues [40] studied 18,473 PACU admissions in a university hospital. These investigators found that the incidence of PACU complications was high, with significant events occurring in nearly 24 percent of all patients. The most common complications were nausea and vomiting (9.8%), need for airway support (6.9%), hypotension (2.7%), dysrhythmia (1.4%), hypertension (1.1%), altered mental status (0.6%), rule out myocardial infarction (0.3%), and major cardiac events (0.3%) (Fig. 68-2) (Figure Not Available) . A survey of 120 anesthesia-related incidents from Australia found that nearly two-thirds of the reported incidents were respiratory. [41]

Figure 68-2 (Figure Not Available) Complications in the postanesthesia care unit (PACU). Two studies examined the frequency of PACU complications. Among inpatients, 24 percent of patients had a complication, whereas among outpatients, only 8 percent of patients had a complication. Nausea and vomiting were the most common in both studies. Life-threatening cardiovascular and respiratory complications were rare among outpatients. Nausea and vomiting accounted for 90 percent of the complications in outpatients. Dotted bars, outpatients *(data from Duncan et al [43])*; lined bars, inpatients *(data from Hines et al [40])*; CNS, central nervous system; CV, cardiovascular; N & V, nausea and vomiting. *(Redrawn from Hines et al [40] and Duncan et al [43])*

Figure 68-3 (Figure Not Available) Soft tissue roentgenograms of the head and neck of an awake patient show that with the head in the neutral position in a supine patient, the air clearance at the base of the tongue is about 3 mm. When the patient is unconscious, this small opening is often lost, and airway obstruction results. *(From Ruben et al [46])*

The factors that appeared to have the greatest influence on the complication rate in the Yale study were ASA class II, a duration of anesthesia between 2 and 4 hours, emergency procedures, and the type of surgical procedure, with abdominal and orthopedic procedures having the highest incidence of complications. Hypothermia also prolonged the recovery room stay. [40] A history of smoking also results in longer stays in the PACU. [42]

The complications in an ambulatory surgical PACU are similar, but they follow a different distribution. Duncan et al [43] found that because cardiac and respiratory events were infrequent, nausea and vomiting emerged as the major complication in outpatients (Fig. 68-2) (Figure Not Available) .

Respiratory Complications

The major respiratory complications encountered in the PACU are airway obstruction, hypoxemia, hypercapnia, and aspiration. Prompt recognition and treatment of these life-threatening problems are crucial in good postanesthesia care. Rose et al [44] defined these events as a critical respiratory event (CRE). In an evaluation of 24,157 consecutive PACU admissions over a 33-month period, these investigators found that for patients receiving a general anesthetic, the risk of a CRE was 1.3 percent (hypoxemia 0.9%, hypoventilation 0.2%, and airway obstruction 0.2%). A wide variety of factors increased the risk of a CRE such as increased age, obesity, long or emergency operations, use of opioids, and use of thiopental in contrast to propofol. Patients who did have a CRE had longer PACU stays and more cardiac problems, and they were more likely to require ICU admission. [44]

Airway Obstruction

The most common cause of postoperative airway obstruction is pharyngeal obstruction from a sagging tongue in the unconscious patient [45] (Fig. 68-3) (Figure Not Available) (Ch. 39) . Laryngeal obstruction can also occur secondary to laryngeal spasm or direct airway injury. [46] [47] [48] The most effective method of dealing with airway obstruction due to pharyngeal obstruction is a combination of backward tilt of the head with anterior displacement of the mandible (Figs. 68-4 (Figure Not Available) and 68-5) (Figure Not Available) . The proper position for each patient depends on trial and error until one has a completely patent airway. If the obstruction is not immediately reversible, a nasal or oral airway can be inserted. The nasal airway is preferred because it is better tolerated by patients. The oral airway may stimulate gagging and vomiting as well as laryngeal spasm. If the airway obstruction

Figure 68-4 (Figure Not Available) A combination of backward head tilt and anterior mandibular displacement is most effective in relieving airway obstruction resulting from pharyngeal blockade by the tongue. This maneuver is also helpful in relieving obstruction due to laryngeal spasm. *(From Ruben et al [46])*

Figure 68-5 (Figure Not Available) Radiographs of the head and neck of an anesthetized patient show that combining backward head tilt with anterior mandibular displacement results in an increased clearance at the tongue base to 22 mm (see Fig. 68-3) (Figure Not Available) . *(From Ruben et al [46])*

is due to laryngeal spasm, this sometimes can be relieved with similar airway maneuvers. If the obstruction cannot be relieved by simple maneuvers, 10-mg dexamethasone intravenously may reopen the airway. Small doses of succinylcholine, 10 to 20 mg intravenously, have been used, but this practice is risky owing to the nonspecific relaxation of all muscles, including the diaphragm. All patients with airway obstruction should receive oxygen via face mask. (F_{IO_2}, 1.0). When the airway cannot be opened by physical means, positive-pressure ventilation with a bag, mask, and 100 percent oxygen is indicated. If succinylcholine has been given, assisted ventilation should be continued for at least 5 to 10 minutes, even if the obstruction has been relieved. [49] For all cases of airway obstruction, if an adequate airway cannot be established by simple physical or pharmacologic means, one must be established via orotracheal intubation using direct laryngoscopy. The laryngeal mask airway may be useful in certain patients and has even been used to provide pressure support ventilation in the PACU. [50] In the very rare case in which the trachea cannot be intubated, an emergency cricothyroidotomy will relieve the obstruction. This procedure is probably safer than emergency tracheostomy, because excessive bleeding is common with the latter procedure done under emergency conditions. Prompt action is crucial in airway obstruction because the partial arterial carbon dioxide pressure (Pa_{CO_2}) increases 6 mm Hg during the first minute of total obstruction and then at a rate of 3 to 4 mm Hg per minute thereafter. In such cases, there is also a progressive fall in Pa_{O_2}, owing to the continuously falling alveolar P_{O_2}.

Patients with obstructive sleep apnea are at high risk of airway obstruction when they are sedated. Nasal continuous positive airway pressure can be very useful in these patients from the time of tracheal extubation onward. [51]

Hypoxemia

Hypoxemia is a common and potentially serious postoperative complication. [52] [53] [54] The pulse oximeter has allowed for more careful evaluations of the incidence of

postoperative hypoxemia than ever before in the history of the PACU. In a survey performed in Denmark, 55 percent of patients had one or more episodes of hypoxemia (Sa_{O_2} < 90%) often despite the presence of routine supplemental oxygen. Ninety-five percent of those episodes went unrecognized by the PACU staff. Factors predisposing to these incidents were duration of anesthesia, use of general anesthesia, and a history of smoking. [55] The same group performed a randomized, blinded study of the effects of oximetry and found that episodes of extreme hypoxemia (Sa_{O_2} < 80%) were not seen in patients in whom the PACU staff had access to the pulse oximetry data but were encountered when they did not. Interestingly, the overall complication rates in the two groups were not different. [56]

Hypoxemia following anesthesia and surgery can be caused by many factors. Evaluation of the hypoxemic postoperative patient should include consideration of each of the classic causes of hypoxemia: (1) low inspired concentration of oxygen; (2) hypoventilation; (3) areas of low ventilation-to-perfusion relations; and (4) an increased intrapulmonary right-to-left shunt. Situations such as increased age, postanesthetic shivering, and a lowered cardiac output may worsen the degree of hypoxemia in postsurgical patients when an intrapulmonary shunt is present. [57] [58] [59]

Low inspired concentrations of oxygen (F_{IO_2} < 0.21) is fortunately a rare cause of significant postoperative hypoxemia; however, the delivery of hypoxic gas mixtures to postoperative patients is possible. Crossing of nitrous oxide and oxygen pipelines during hospital construction resulted in the loss of more than 30 lives in a Canadian hospital. Pipelines have crossed in hospital modernization projects. Switching of all adapters can also lead to delivery of the wrong gas, as can purging the system with nitrogen for pipeline repairs [60] (Ch. 7) .

The most common cause of postoperative hypoxemia is an increase in the right-to-left intrapulmonary shunt. Increases in the intrapulmonary shunt can be caused by many processes. Atelectasis is the most common cause of an increased right-to-left shunt. Atelectasis occurs as the result of collapse of an entire lung, lobe, or lung segment, or it can occur in a diffuse pattern. Bronchial obstruction from secretion or blood is a frequent cause of atelectasis. Lobar and segmental collapses often result from bronchial obstruction with secretions and are best managed by providing adequate humidification of the inspired gases, coughing, deep breathing, and postural drainage. Endobronchial intubation with collapse of the opposite lung is a serious complication and should be avoided.

Pneumothorax is a cause of hypoxemia that can have serious sequelae. Pneumothorax causes hypoxemia due to atelectasis and an intrapulmonary shunt. Pneumothorax occurs as a result of direct lung or airway injury from trauma, rib fractures, or attempts at percutaneous vascular cannulation. Pneumothoraces resulting from mechanical ventilation per se are rare unless airway pressures are high. [61] [62] Treatment depends on the size of the pneumothorax and the patient's condition. A 10 to 20 percent pneumothorax in a spontaneously breathing patient can be observed with frequent upright chest roentgenograms. A pneumothorax of more than 20 percent in a spontaneously breathing patient or any pneumothorax in a mechanically ventilated patient should be treated by insertion of a chest tube for drainage. This is usually done in the second intercostal space in the midclavicular line. A tension pneumothorax occurs when the pleural cavity fills with air and compresses the mediastinum, resulting in circulatory compromise. Tension pneumothorax is treated in the same manner; however, one should not await roentgenographic confirmation of the diagnosis if tension pneumothorax with circulatory depression is diagnosed. A 14-gauge needle inserted in the second intercostal space can relieve the tension prior to chest-tube insertion.

Arterial hypoxemia may be present in postoperative patients who have no discernible change in the chest roentgenogram. These patients may have an increased right-to-left intrapulmonary shunt due to diffuse airway collapse. The relationship between the functional residual capacity (FRC) of the lung and closing capacity is a prime determinant of this effect. [63] [64] When the closing capacity exceeds FRC, airways collapse during tidal breathing and an intrapulmonary shunt develops. Any situation that results in either increased closing capacity (e.g., increasing age) or reduced FRC (pulmonary edema, infection, aspiration,

Figure 68-6 (Figure Not Available) In a study of 40 cases of postoperative pulmonary edema, the cumulative incidence of pulmonary edema (percentage) is plotted with respect to the end of the operation (minutes). Most cases occurred within the first 30 minutes, and most were preceded by hypertension. *(From Cooperman and Price [66])*

obesity) places the patient at increased risk for hypoxemia. Difficulties in interpreting the closing capacity led some investigators to question the FRC/closing capacity relationship as being the sole determinant of impaired gas exchange during the perioperative period. [65]

Pulmonary edema can result in hypoxemia in the postoperative period. Although pulmonary edema has been well studied in patients with left ventricular failure, [66] [67] studies of this process in the immediate postoperative period are rare. Cooperman and Price [68] examined 40 cases of perioperative pulmonary edema and found one-half of the patients to have preoperative evidence of cardiovascular disease. [68] The most common time of appearance of pulmonary edema was observed within 60 minutes of completion of surgery (Fig. 68-6) (Figure Not Available) . More than one-half of these cases were preceded by hypertension, a finding suggesting that this problem may be related to the high pulmonary vascular pressures seen in acute, postoperative hypertension. Detection was made frequently by the presence of wheezing. Elevation of the central venous pressure and neck vein distention were not common findings. Patients develop pulmonary edema postoperatively because of high hydrostatic pressure in the pulmonary capillaries, increased capillary permeability, or sustained reductions in the interstitial hydrostatic pressure. The last-named type of pulmonary edema is seen following prolonged airway obstruction. [69] [70] Patients with a permeability injury can have their pulmonary edema exacerbated by increases in hydrostatic pressure. High-pressure pulmonary edema is usually caused by ischemic or valvular heart disease. Pulmonary edema characterized by a permeability injury is seen following a wide variety of serious clinical situations such as disseminated intravascular coagulation, shock, trauma, massive transfusion, sepsis, and anaphylaxis. This type of pulmonary edema is frequently called the adult respiratory distress syndrome and is characterized by hypoxemia, diffuse pulmonary infiltrates on roentgenogram, and reduced lung compliance. A common early pathologic finding is neutrophil accumulation in the lung vasculature and tissue. There is increasing evidence that activation of arachidonic acid metabolites, the prostaglandins and the leukotrienes, may be responsible for the permeability injury seen in humans. [71] Experimentally, leukotriene D_4 increases pulmonary permeability. [72] Because more is being learned about these substances, future breakthroughs in the adult respiratory distress syndrome probably will center around the use of naturally occurring inhibitor substances of key reactions.

Current treatment of both forms of pulmonary edema centers around lowering the hydrostatic pressure in the lungs to the lowest possible level consistent with adequate perfusion of all organ systems. This is done with diuretics, fluid restriction, vasodilators, or dialysis if there is associated renal failure. Positive-pressure ventilation is useful if there is severe hypoxemia or respiratory acidosis. Ventilation with end-expiratory pressure improves oxygenation by increasing lung volume, not by decreasing lung water. [73] Monitoring with a pulmonary artery catheter is often helpful. Monitors of extravascular lung water employing double-indication dilution techniques are available and accurate, but they are probably too technically demanding for routine clinical use. [74] [75] Respiratory support with oxygen and mechanical ventilation are frequently necessary while the patient receives definitive treatment. Vomiting and aspiration of gastric contents during and after anesthesia can produce a severe permeability injury resulting in pulmonary edema and hypoxemia.

Pulmonary embolism occurring in the immediate postoperative period is a serious event that can lead to profound hypoxemia. The exact physiologic explanation of the hypoxemia is unclear. Patients at bed rest for prolonged periods prior to surgery are very susceptible to emboli. The diagnosis is suspected in a patient with sudden pleuritic chest pain, shortness of breath, pleural effusion, or tachypnea. Evidence of right heart strain can sometimes be seen on the ECG. Massive emboli result in hypotension, pulmonary hypertension, and an elevated central venous pressure. Because the treatment of choice is anticoagulation, the establishment of an accurate diagnosis is imperative so that patients in the immediate postsurgical period are not needlessly exposed to the risks of anticoagulation. The only certain way to make the diagnosis is pulmonary angiography. This is often the procedure of choice for this type of patient. Once the diagnosis is made, heparin is given via continuous intravenous infusion to keep the patient's partial thromboplastin time 2 to 2.5 times control. If emboli recur or if bleeding develops with adequate heparinization, vena caval obstruction by percutaneously placed umbrella may be indicated.

Posthyperventilation hypoxemia and diffusion hypoxemia can occur but are rarely seen in clinical practice because oxygen administration prevents the clinical manifestations of the events. Following anesthetic techniques that use hyperventilation, the body's supplies of carbon dioxide are restored from endogenous carbon dioxide production and ventilation. P_{AO_2} is reduced accordingly. The top solid line in Figure 68-7 (Figure Not Available) illustrates the theoretic drop in P_{AO_2} that would occur. Diffusion hypoxia occurs when nitrous oxide is replaced with air at the end of the anesthetic. Because nitrous oxide is 31 times more soluble than nitrogen, there is dilution of the inspired

Figure 68-7 (Figure Not Available) Posthyperventilation hypoxia and diffusion hypoxia. The upper (dashed) line represents normal P_{AO_2} during breathing of air. Posthyperventilation hypoxia is indicated by the upper solid line, assuming that the patient hyperventilated for an hour was then allowed to accumulate CO_2 for 10 minutes before zero time. Diffusion hypoxia (following equilibration

with 79% nitrous oxide [N_2 O]) was added to posthyperventilation hypoxia as described earlier, except the inspired gas was changed to air at zero time. *(From Marshall and Wyche [57])*

air with nitrous oxide and the P_{AO_2} falls. The combination of hyperventilation and nitrous oxide can result in the drop in P_{AO_2} seen in the bottom line of Figure 68-7 (Figure Not Available) . [59]

The type of anesthetic and the site of operation influence the reduction in Pa_{O_2} seen following anesthesia and surgery. Abdominal operations are associated with the most prolonged reductions in Pa_{O_2} . Although the Pa_{O_2} may be normal during the immediate postoperative period, abdominal operations under regional anesthesia are associated with the greatest reduction in Pa_{O_2} after 24 hours. [57] This is likely because of the reduced vital capacity seen following upper abdominal surgery. A shift from diaphragmatic to rib cage breathing probably accounts for this well-recognized decrease in postoperative vital capacity. [76]

Reductions in cardiac output can contribute to large decreases in Pa_{O_2} in patients with existing intrapulmonary shunts. This is due to the effect of the lowered mixed venous P_{O_2} , which is added directly to the arterial circulation through the right-to-left shunt [59] (Fig. 68-8) (Figure Not Available) . Postoperative shivering can result in increases in oxygen consumption of as much as 500 percent; however, this only rarely contributes to arterial hypoxemia. [58] Shivering also reduces the Pa_{O_2} in patients with an intrapulmonary shunt by lowering of the mixed venous oxygen tension. Significant increases in postoperative oxygen consumption also occur following anesthesia for burn treatment leading to inadequate oxygen delivery. [77]

Recognition of hypoxemia can be difficult during the recovery from anesthesia if pulse oximetry is not used. Lowered hemoglobin concentrations may prevent the detection of peripheral cyanosis. The ventilatory and circulatory responses to hypoxemia may also be attenuated in elderly patients. Currently, the best method of assessing hypoxemia during anesthetic recovery is with a pulse oximeter. [78] Comparisons of the measured with the oximeter correlate closely with measurements made from samples of arterial blood. The system provides information about early reductions in oxygen saturation that serves as an early warning, so that therapeutic intervention can be made before life-threatening hypoxemia develops. The device is useful for monitoring patients at high risk of developing postoperative hypoxemia during recovery from anesthesia. [79] The response time for this device is faster than that using transcutaneous techniques. [80]

The ability to evaluate Pa_{O_2} continuously during and following anesthesia has led to some interesting results. Monitoring during transport to the PACU without supplemental oxygen has demonstrated that about one-third of adult and pediatric patients develop hypoxemia (Sa_{O_2} < 90%) during transport to the recovery room. [81] [82] During a patient's stay in the recovery room, arterial desaturation is not an uncommon event. In children, hypoxemia does not correlate with wakefulness. [83] In adults, the risk factors for postoperative hypoxemia are age, obesity, length of surgery, and ASA physical status. In one study, the most common time hypoxemia

Figure 68-8 (Figure Not Available) Relationship between cardiac index and arterial oxygenation with shunt fractions (Q_{VA}/Q_T) ranging from 5 to 30 percent. With large intrapulmonary shunts, a small drop in cardiac index results in a large fall in arterial oxygenation. *(From Philbin et al [59])*

Figure 68-9 (Figure Not Available) Relationship between shunt fraction and arterial oxygen tension (Pa_{O_2}) for varying inspired concentrations of oxygen (P_{AO_2} 100-680 mm Hg). Patients with small shunt fractions have large increases in Pa_{O_2} with increasing inspired oxygen, whereas patients with high shunt fractions have a small response to increasing oxygen concentration. *(From Pontoppidan et al [85] ; graph courtesy of Dr. M.A. Duvelleroy)*

was observed was just prior to transfer to the postsurgical ward. [84] The findings of these studies suggest that all patients should have oxygen saturation assessed during their stay in the PACU and that a measurement of the arterial oxygen saturation should be made in every patient prior to discharge.

Treatment of hypoxemia by face-mask oxygen is effective in restoring the Pa_{O_2} in many cases. The Pa_{O_2} response to oxygen breathing depends on the degree of intrapulmonary shunt. Increasing the F_{IO_2} from room air to 100 percent results in a large increase in Pa_{O_2} when the shunt fraction is small; however, oxygen has little effect on the Pa_{O_2} in patients with a large shunt fraction [85] (Fig. 68-9) (Figure Not Available) . If hypoxemia persists (Pa_{O_2} <60 mm Hg) despite maximal oxygen therapy (F_{IO_2} , 1.0), tracheal intubation and mechanical ventilation should be initiated. In such patients, ventilation with PEEP increases the functional residual capacity and improves arterial oxygenation. Ventilation with PEEP eventually permits a reduction in F_{IO_2} without a fall in Pa_{O_2} .

Continuous positive airway pressure (CPAP) by an external mask (mask or nasal CPAP) is increasingly used for treatment of patients with severe hypoxemia who have adequate carbon dioxide elimination [86] (Ch. 72) . Certainly, patients have avoided tracheal intubation because of the use of mask or nasal CPAP. However, many patients who have a trial of mask or nasal CPAP fail that trial and need to receive tracheal intubation and mechanical ventilation. Good candidates for mask or nasal CPAP are patients with severe hypoxemia requiring more than 80 percent oxygen to have a Pa_{O_2} higher than 60 mm Hg. They must have a normal or low Pa_{CO_2} and not have severe respiratory distress. They must be awake and alert. Mask or nasal CPAP is most useful when the cause of hypoxemia can be quickly corrected, such as cardiogenic pulmonary edema, because the mask becomes very uncomfortable for the patient even after several hours of use. Newer mask designs have improved on this problem, but they have not eliminated it.

Hypoventilation

Hypoventilation is defined as reduced alveolar ventilation resulting in an increase in Pa_{CO_2} . During the postoperative period, hypoventilation occurs as a result of poor respiratory drive, poor respiratory muscle function, a high production rate of carbon dioxide, or acute or chronic lung disease.

Central respiratory depression is seen with any anesthetic. Narcotic anesthetics produce respiratory depression that is detectable by a shift of the carbon dioxide curve downward and to the right (Ch. 10) . Neuroleptic anesthetic techniques can produce a biphasic respiratory depression with respiratory depression intraoperatively, which dissipates on arrival in the recovery room, only to be followed by a second period of respiratory depression [87] (Fig. 68-10) (Figure Not Available) .

Figure 68-10 (Figure Not Available) Slopes of CO_2 response curves are expressed as percentage of control slopes at the time of the last dose of fentanyl or Innovar (time = 0) at the end of operation, at the time they are steepest, flattest, and at the end of the operation. Patients receiving neuroleptic agents as supplements to nitrous oxide (N_2O) anesthesia exhibit biphasic respiratory depression. *(From Becker et al [87])*

Narcotic-induced respiratory depression can be reversed by use of narcotic antagonists. [88] When small doses are used, these agents can reverse the narcotic-induced respiratory depression without altering pain relief; however, the duration of action of currently available antagonists is shorter than most narcotics and the dose has to be repeated at least once. Larger doses of these agents reverse the analgesic effects of the narcotics and result in a patient in severe pain who often develops profound increases in heart rate and blood pressure. These increases in rate pressure product (heart rate × systolic blood pressure) signify large increases in myocardial oxygen consumption and can result in ischemia in patients with coronary artery disease. An inadequate central respiratory drive can also be seen after certain neurosurgical procedures, such as cervical cordotomy.

Poor respiratory muscle function occurs following surgery and often contributes to hypoventilation. The site of the incision affects the ability to take a large breath, as measured by the vital capacity. Nearly all patients have reductions in vital capacity that are the greatest on the day of surgery. Patients undergoing upper abdominal surgery have the greatest reduction in vital capacity, showing as much as a 60 percent reduction on the day of surgery [89] (Fig. 68-11) (Figure Not Available) . This problem, secondary to diaphragmatic impairment, results in problems with both carbon dioxide elimination and oxygenation. [76]

Failure of reversal of neuromuscular blocking agents may result in inadequate respiratory muscle function postoperatively. This can be due to inadequate excretion of the drug, as in renal failure, or to the presence of other drugs that accentuate neuromuscular blockade, such as gentamicin, neomycin, clindamycin, or furosemide [90] [91] (Ch. 12) . Hypermagnesemia potentiates neuromuscular blockade, as does hypothermia. [30]

Obesity, gastric dilation, tight dressings, and body casts also inhibit respiratory muscle function and can predispose

Figure 68-11 (Figure Not Available) Change in vital capacity seen following surgical procedures in various sites. All patients manifest the lowest vital capacity on the day of surgery. Upper abdominal surgery is associated with the greatest reduction in vital capacity, and spinal surgery is associated with the least. *(From Ali et al [85])*

to carbon dioxide retention. A high level of carbon dioxide production from sepsis or shivering can result in carbon dioxide retention, especially if the patient cannot increase minute ventilation. [49]

The direct measurement of Pa CO_2 is the best method of detecting hypoventilation in the postoperative period. Although hypertension and tachycardia commonly occur during carbon dioxide retention, they may not be seen in postsurgical patients and the elderly, who have an attenuated response to increased levels of carbon dioxide (Ch. 61) . Transcutaneous electrodes can continuously monitor the CO_2 tension and are useful in high-risk patients. Measurements of the vital capacity and maximum inspiratory force are good guides to the ability of the postsurgical patient to breathe spontaneously in the postoperative period. [49] The vital capacity should be at least 10 mL/kg body weight, and the inspiratory force should be numerically greater than -20 cm H_2O. [92] If these minimum values cannot be maintained, the patient should receive controlled mechanical ventilation until he or she is awake enough to generate adequate respiratory muscle function. End-tidal carbon dioxide measurements can be used in the patient whose trachea is intubated whether breathing spontaneously or with mechanical ventilation. [93]

Treatment of serious respiratory failure necessitates emergency tracheal intubation. The need to perform reintubation is rare, occurring in 0.2 percent of about 13,000 patients studied in one series. [94] In that series, 77 percent of the reintubations occurred within the first hour in the PACU and were more common in children and the elderly. Many of the cases were believed to be preventable and related to excessive anesthetic and sedative drugs, excessive fluid administration, persistent effects of muscle relaxants, and upper airway obstruction.

Circulatory Complications

Critical cardiovascular events in the PACU are the second major group of life-threatening complications for patients in this setting. The risk factors for and the ultimate outcome were evaluated by Rose et al [95] in a study of 18,380 patients following general anesthesia in Toronto. These investigators found that patients who developed hypertension or tachycardia in the PACU had more unplanned critical care admissions and had a higher mortality rate than those who did not. In contrast to respiratory events, anesthetic factors only contributed in a minor way to the development of cardiovascular problems in the PACU, whereas patient and surgical factors were more important risk factors. [95]

Hypotension

Hypotension in the recovery phase of anesthesia usually signifies decreased ventricular preload, reduced myocardial contractility, or a profound reduction in systemic vascular resistance. Decreased ventricular preload is caused by intravascular volume depletion due to blood loss, excessive third-space fluid loss, unreplaced urinary losses, or septicemia with vasodilatation and capillary leakage of fluid (Chs. 45 46 and 62) . Acute, massive pulmonary embolism

produces hypotension by blocking the flow of blood to the left heart. Reductions in myocardial contractility occur because of continued effects of anesthetic drugs, preexisting ventricular dysfunction, or the development of a perioperative myocardial infarction. Profound reductions in systemic vascular resistance usually occur with septicemia, but they are also seen in chronic liver failure.

Prompt diagnosis and treatment are important, because prolonged hypotension can result in hypoperfusion of vital organs and subsequent ischemic damage. Quickly assess whether the hypotension is real or an artifact of the measurement system. If the hypotension is real, ventricular preload can be increased by elevation of the patient's legs and administration of intravenous fluids. Physiologic saline and lactated Ringer solution are effective and inexpensive choices. The surgical wound area is examined for evidence of rapid blood loss, and a hematocrit determination is ordered. If hypotension persists despite attempts to restore intravascular volume, ventricular preload must be further assessed. In patients with normal left ventricular function, the central venous pressure estimates ventricular preload. In the presence of left ventricular dysfunction, the central venous pressure is not an accurate guide to ventricular filling pressure, and a flow-directed pulmonary artery catheter should be inserted (Ch. 30) . During this time, administration of a vasopressor prevents a prolonged period of hypotension while hemodynamic monitoring is established. Following insertion of the pulmonary artery catheter, ventricular preload can be assessed by examining the pulmonary artery occlusion pressure. The pulmonary artery catheter also allows for bedside measurement of the cardiac output by the thermodilution technique. With skilled personnel, this type of catheterization can be carried out in the PACU in less than 30 minutes. With the pulmonary artery catheter, various forms of shock can be assessed.

Despite the widespread acceptance of the pulmonary artery catheter to enable the clinician to diagnose the etiology of shock states and the state of the intravascular volume accurately, carefully controlled trials evaluating its use have been absent from the literature. One study suggests that patients who are treated in critical situations with a pulmonary artery catheter have a higher mortality rate, use more costly resources, and have a longer length of hospital stay than patients treated without a pulmonary artery catheter. [96] This study was done in ICU patients and not in patients undergoing anesthesia or in the PACU; however, the implications of the study suggest that anesthesiologists should reexamine their use of this device in the perioperative period. It has been suggested that specific uses of the pulmonary artery catheter be subject to randomized, controlled clinical trials, or that the U.S. Food and Drug Administration (FDA) ban their use entirely. [97]

Hypovolemic shock is characterized by a low pulmonary artery occlusion pressure (PAOP <5-10 mm Hg) with a normal low cardiac index (normal, 2.5-4.0 L/min/m^2) and a normal or elevated systemic vascular resistance:

Normal = 900 to 1,400 dynes/s/cm^{-5} , where SVR is systemic vascular resistance, MAP is mean arterial pressure, CVP is central venous pressure, and CO is cardiac output (Chs. 16 and 30) .

Cardiogenic shock is characterized by increased PAOP (>15 mm Hg) with a low cardiac index and elevated systemic vascular resistance. Patients in whom left ventricular failure is suspected should have an ECG and chemical analysis of the cardiac enzymes, especially a fractionated creatinine phosphokinase (CPK) to rule out a myocardial infarction. Elevation of the myocardial fraction of the CPK (CPK-MB) in the first 24 hours is a specific test for myocardial muscle death and provides prompt, accurate evidence of infarction in the postsurgical patient. Examination of the total CPK alone is of no use in the surgical patient because it is elevated frequently secondary to skeletal muscle damage. Newer methods of measuring the CPK-MB have made this test rapid, and results can be available in less than 1 hour.

In *septic shock* PAOP is usually low with a very high cardiac output and low systemic vascular resistance. The patient often has fever, an elevated white blood cell count, and some other sign of systemic infection.

Treatment of such prolonged hypotension is now guided by following the variable of ventricular preload, cardiac output, and urinary output. Hypovolemic shock is treated by intravenous administration of blood and crystalloid. The role of albumin replacement in this setting is controversial but widely used (Chs. 45 and 46) . Albumin is no more effective than crystalloid in restoring intravascular volume and can cause deterioration of renal function when used for hypovolemic resuscitation. [98] Albumin is also far more expensive than crystalloid. Comparison of the use of albumin versus crystalloid for hypovolemia shows that the only difference in the two groups of patients was a more costly resuscitation in the albumin-resuscitated group. [99] Starch solutions are a less expensive and an effective alternative to albumin and saline. [100] When lung injury exists, resuscitation with crystalloid, albumin, or starch solutions will not further damage the lung if resuscitation is not performed with increased pulmonary hydrostatic pressure. [101]

Cardiogenic shock is managed by first optimizing the ventricular preload. Although the heart normally functions with a low preload (PAOP 3-8 mm Hg), when the left

ventricle fails, it often functions best when the preload is elevated. Therefore, one should attempt to give fluid or blood intravenously to increase the preload and follow the cardiac output (CO) and stroke volume (SV):

where HR is heart rate.

Most patients have an optimal cardiac output when the PAOP is increased to 15 to 20 mm Hg (Chs. 16 and 30) . Occasional patients with severe, long-standing ventricular failure require PAOP of 20 to 25 mm Hg to maintain cardiac output. In addition to an optimal preload, these patients also require inotropic support with dopamine in the range of 3 to 10 mug/kg/min. Dopamine in that dosage acts as a beta-adrenergic-receptor agonist as well as acting on dopaminergic receptors in the kidney, thus increasing renal blood flow. This effect is most prominent in the lower dosage range (1-3 mug/kg/min), but it also is present to some degree up to 10 mug/kg/min. At a higher dose, an alpha-adrenergic effect

Figure 68-12 (Figure Not Available) The normal Starling relation of the heart is depicted on the upper line, where increasing left ventricular filling pressure (LVFP) increases stroke volume (SV). In the presence of ventricular dysfunction, this curve is shifted downward and to the right. The depressed curve can be shifted toward normal by inotropic drugs (I) or vasodilator drugs (V). Infusion of both (V + I) produces a synergistic effect. Diuretics (D) reduce filling pressure without increasing output. The dashed line suggests that SV may rise later. *(From Cohn and Franciosa, [102] copyright 1977 Massachusetts Medical Society. All rights reserved.)*

dominates. Some patients with left ventricular failure still have a low cardiac output and high systemic vascular resistance despite optimal preload and inotropic support. In that situation, careful addition of a peripheral vasodilator such as sodium nitroprusside or hydralazine lowers the outflow impedance to ventricular ejection (lowered vascular resistance and increased stroke volume). Combined inotropic and vasopressor support often restores cardiac output to near-normal values [102] (Fig. 68-12) (Figure Not Available) . In this setting, vasodilator therapy should not be abruptly terminated because a rebound rise in vascular resistance often results in worse ventricular function than was present before the drug was begun [103] (see Ch. 14 for a detailed discussion of these autonomic drugs). Vasodilator therapy should not be used without first increasing preload and increasing the inotropic state of the heart. Vasodilators can only be used in this setting if the hypotension has been first reversed with fluid and inotropic therapy.

Septic shock is managed by replacing the fluid lost from capillary endothelial leak with crystalloid. Use of albumin in this situation is possibly harmful, because the albumin can leak out into the interstitium and may draw intravascular fluid with it. [104] An inotropic agent such as dopamine is often necessary to increase cardiac output further and to raise the arterial blood pressure. On occasion, patients with severe sepsis remain hypotensive with a high cardiac output and lowered vascular resistance despite infusion of fluids and an inotropic drug. In this situation, prolonged lowered diastolic pressure results in insufficient coronary blood flow and myocardial ischemia. This usually manifests itself as a sudden and irreversible ventricular dysrhythmia. To prevent this problem, an alpha-adrenergic agonist, such as norepinephrine or phenylephrine, could be introduced. Use of these agents is successful only if the septic process can be brought under control. Use of vasoconstrictors for more than 24 hours may result in renal and gastrointestinal ischemia.

Hypertension

When hypertension develops in the PACU, it is often due to pain, hypercapnia, hypoxemia, or excessive intravascular fluid volume. Any patient who manifests hypertension in the PACU should have those causes investigated and treated. Severe hypertension can lead to left ventricular failure, myocardial infarction, or a dysrhythmia from a sharp increase in myocardial oxygen consumption. Acute hypertension may also precipitate acute pulmonary edema or a cerebral hemorrhage.

Preexisting hypertension is present in more than one-half of the patients who develop hypertension in the recovery room. [105] Such hypertension can be made worse if antihypertensive medications have to be abruptly withdrawn preoperatively. [106] When hypertension does develop during recovery from anesthesia, it usually begins within 30 minutes of the end of the operation [105] (Fig. 68-13) (Figure Not Available) .

Treatment of acute hypertension involves first treating pain, hypercapnia, hypoxemia, or fluid overload. If hypertension is still present, an antihypertensive drug is necessary. Because most postoperative hypertension is resolved within 4 hours of surgery, long-acting antihypertensive drugs are unnecessary. Most patients without preexisting hypertension do not need prolonged treatment. [105] A rapid-acting drug such as sodium nitroprusside is effective in treating postoperative hypertension because its onset is prompt and its effects can be quickly reversed by discontinuing the drug. Nitroprusside is a vasodilator that acts directly on the vessel walls, both of the arterioles and venules. Nitroprusside is administered as a continuous infusion beginning at 0.5 to 1.0 mug/kg/min and titrating the blood pressure to acceptable

Figure 68-13 (Figure Not Available) Time of onset of hypertension in 60 patients in whom hypertension developed after surgery. More than one-half had a history of hypertension. Pain, emergence excitement, hypercapnia, hypoxemia, and volume overload were common causes. *(From Gal and Cooperman [105])*

levels. Nitroprusside should be used in conjunction with close monitoring of the arterial blood pressure, preferably using direct intra-arterial monitoring. An automatic blood pressure device is an adequate alternative that can provide frequent, accurate information about the mean arterial pressure. [107] The dose should not exceed 5 mug/kg/min or a total of 3 mg/kg in 24 hours, because nitroprusside is metabolized to cyanide, which may result in general blockade of oxidative phosphorylation resulting in diffuse cellular injury. This complication is best prevented by close observation of the dose administered. The best sign of cyanide toxicity is the finding of progressive metabolic acidosis [108] (Chs. 14 and 41) , which, if present, dictates discontinuation of the nitroprusside and substitution of another antihypertensive drug.

An alternative to nitroprusside is trimethaphan, which produces a decreased arterial blood pressure resulting from ganglionic blockade. Trimethaphan is also given as a continuous infusion. Advantages to trimethaphan are that it prevents the reflex tachycardia seen with nitroprusside by virtue of its ganglionic blockade and it prevents reflex increase in pulse pressure sometimes seen when nitroprusside is given to patients with a hyperdynamic circulation such as patients with aortic dissection or atherosclerotic cardiovascular disease. The major disadvantage is that it produces ileus and urinary retention secondary to ganglionic blockade. Tachyphylaxis to the drug is common after 12 to 24 hours of use. Hydralazine is another vasodilator that can be given intravenously for acute hypertension as a 5- to 10-mg injection. The onset is delayed 15 to 30 minutes and does not permit prompt control. In addition, tachycardia is a common complication of its use as an antihypertensive.

Beta-blocking drugs such as propranolol, labetalol, and esmolol are all effective in treating hypertension during recovery. Labetolol, a combined alpha and beta blocking agent, is commonly used in the PACU. When used for treatment of postoperative hypertension, its beta effects predominate, and the reduction in blood pressure results from its negative inotropic effects. [109] When used in the PACU, its effects are prompt and no further treatment is needed in most cases. Labetalol can be given in intravenous 5-mg increments, with the effect on blood pressure apparent in several minutes. [110] Labetalol is also effective in neurosurgical patients already receiving high doses of nitroprusside. [111] Esmolol is an ultrashort-acting beta blocker that is effective in treating postoperative hypertension and tachycardia. Its short half-life means it must be given as a continuous infusion at rates of 25 to 300 mug/kg/min [112] (Ch. 14) .

Dysrhythmias

The factors predisposing to development of postoperative dysrhythmias are electrolyte imbalance (especially hypokalemia), hypoxia, hypercapnia, metabolic alkalosis and acidosis, and preexisting heart disease (Chs. 23 32 and 49) . When a dysrhythmia occurs in the PACU, it is often a sign of some metabolic or perfusion problem. Dysrhythmias appearing in the PACU rarely need long-term treatment. The most common dysrhythmias are sinus tachycardia, sinus bradycardia, ventricular premature beats, ventricular tachycardia, and supraventricular tachyarrythmias. These are discussed in Chapter 32 .

Failure to Regain Consciousness

The evaluation of the patient who does not regain consciousness following general anesthesia requires a careful evaluation of the patient. Preoperative factors such as drug or alcohol intoxication should be sought. The most common reason for persistent somnolence is residual effects of anesthetics, sedatives, and preoperative medications. [113] In most such cases, some level of responsiveness should be achieved within 90 minutes following the completion of the anesthetic regimen. Initial management should include pharmacologic reversal agents aimed at the most likely sedative drug. Naloxone in small doses (0.2 mg IV) will increase ventilatory rate if narcotic sedation is the problem. Physostigmine (1.25 mg IV) can reverse the effects of some sedatives and inhalation anesthetics. [114] The sedative and amnestic effects of the benzodiazepines can be reversed by the use of flumazenil (up to 1.0 mg IV). [115] [116] Because profound neuromuscular blockade can make a patient appear unconscious, this should also be considered. This cause is unlikely, however, in the absence of significant respiratory compromise as well as unconsciousness. Once pharmacologic causes are ruled out, metabolic and structural origins must be sought. Profound hypothermia (temperature <33°C) can produce unconsciousness, as can profound abnormalities of serum glucose such as hyperglycemia or hypoglycemia. Blood glucose, electrolytes, and blood gases should be evaluated in all such cases. If there is reason to suspect hypoglycemia, 50 percent dextrose should be administered immediately, and a blood glucose determination should not be awaited. If the diagnosis remains unclear, a structural neurologic abnormality should be sought. Raised intracranial pressure may occur following head trauma or neurosurgery. Thromboembolic cerebrovascular accidents can occur in the postoperative period, but they are uncommon. [117] [118] Intraoperative cerebral hypoxia from hypoxemia or poor cerebral perfusion can produce diffuse encephalopathy. Emergency computed tomography scanning can be used to evaluate the presence of raised intracranial pressure or an acute intracranial hemorrhage as the cause of the delayed emergence. Rarely, overdose with lidocaine can present as unconsciousness. [119] Old age per se does not account for delayed emergence from general anesthesia. [120]

Postoperative Agitation and Pain

Postoperative pain and agitation are common problems. Pain can usually be simply controlled using small doses of intravenous narcotics; however, certain patients need large doses of narcotics to control severe pain. In addition, patients occasionally awaken from anesthesia in a violent, agitated state, often requiring manual restraint to prevent them doing harm to themselves or PACU personnel. Although this type of exaggerated response may be due to pain, several other important factors could be involved. Hypoxemia, hypercapnia, gastric distention, and urinary retention with bladder distention can all result in marked agitation. These problems can be easily managed, usually with resolution of the agitated state. The use of scopolamine, phenothiazines, and barbiturates as premedicants without narcotics increases the incidence of postoperative excitement. [121] The

administration of 3 to 4 mg of physostigmine reverses the agitation associated with scopolamine. [122] [123] Agitation also occurs in young patients who are apprehensive about the findings at operation, as well as in persons who fear pain.

Management of the agitated patient involves ascertaining the adequacy of blood gas exchange, evaluating possible urinary or gastric distention, and administering a small dose of intravenous narcotic. Restraints are sometimes needed. Often a change in the patient's position in bed is helpful.

Pain is one of the most common problems requiring recovery room management. Many factors influence the onset, incidence, and severity of postoperative pain. The age of the patient is important. The very young and very old seem to experience less pain than do people in the middle years of life. Preoperative neurotic personality traits tend to increase postoperative pain, as does the fear of pain itself. The way in which a patient is prepared for the experience of pain preoperatively can markedly alter the perception of postoperative pain [124] (Fig. 68-14) (Figure Not Available) . Preoperative medication is important in that agents such as scopolamine and barbiturates given alone appear to worsen postoperative pain. The use of a narcotic as a premedicant delays the first postoperative request for pain, but it does not affect the total dose required (see Ch. 23 for different premedication suggestions). The site of the operation certainly influences the severity of pain. Thoracotomy appears to be, in general, the most painful operation, with upper abdominal surgery a close second. Lower abdominal surgery is less painful. Patients who receive

Figure 68-14 (Figure Not Available) Ninety-seven patients having abdominal surgery were divided into two groups. The control group had a preoperative visit in which the anesthetist discussed the patient's medical condition but did not explain postoperative events. The special-care group had a careful preoperative explanation about postoperative pain, including its character, intensity, and management, stressing that it was a normal occurrence. The special-care group required significantly less morphine for pain relief than the control group, stressing the importance of the preoperative visit in postoperative care. *(From Egbert et al [124])*

no narcotic preoperatively or during the operation need a narcotic sooner during the postoperative period than those patients who do receive a narcotic. The type of anesthetic, however, does not seem to influence the total amount of narcotic analgesic required. [125] Most cases of postoperative pain can be managed by giving small intravenous doses of narcotics. Narcotics for pain relief result in a decreased respiratory rate, decreased tidal volume, and a regularization of the pattern of respiration. The presence of pain does not prevent narcotic-induced respiratory depression. [126] Patients need encouragement to cough and to breathe deeply. This maneuver is better tolerated by a patient who has received a narcotic; however, narcotics do not completely eliminate the pain associated with coughing and deep breathing. The use of small intravenous doses of narcotic in the PACU permits titration of the dose needed for adequate pain relief while carefully observing for the respiratory- and circulatory-depressant effects. Maximal narcosis does not occur for 30 minutes. Patients in pain can be given 1 to 3 mg of morphine (or the equivalent amount of meperidine) every 15 to 30 minutes with careful observation of the degree of pain relief and the amount of respiratory depression. Careful titration often results in more prompt pain relief than with intramuscular administration, as well as a smaller total dose. [126] [127] The continuous infusion of narcotic analgesics may result in a smoother course when these agents are used for postoperative pain relief. Such an infusion requires careful monitoring and titration. Patients receiving narcotics by continuous infusion maintain constant blood levels of analgesic and receive less total drug. [128] Patient-controlled analgesia allows the patient to determine the timing of analgesic doses and allows for improved titration of analgesia. It also minimizes patient anxiety. Patients receiving this form of pain therapy should have it begun in the PACU. [129] Although morphine has been the standard for this form of therapy, patients who use hydromorphone are in a better mood; however, they have decreased cognitive function when compared with patients receiving patient-controlled analgesia with morphine. [130] Some institutions have eliminated patient-controlled analgesia with meperidine because of reports of central nervous system toxicity and seizures in patients receiving high doses.

The use of narcotics in the epidural space to control postoperative pain is a very effective approach (Ch. 69) . Morphine, 2 to 4 mg diluted to 10 mL, provides prompt analgesia with a duration of action of about 12 hours. Complications include respiratory depression, which is dose related and can occur as long as 6 hours after injection of the morphine. Significant respiratory depression occurs in less than 1 percent of patients receiving epidural narcotics and can be reversed with naloxone. Synthetic narcotics have also been used successfully for epidural analgesia. [131] [132] About 15 to 20 percent of patients complain of pruritus. Nausea and urinary retention have also been reported. One case of paresis occurring during epidural morphine treatment was thought to be secondary to anterior spinal artery thrombosis. The technique is most useful when used for patients undergoing major thoracic or abdominal surgery who are at high risk for complications of parenteral analgesic therapy. [133] [134] [135] [136] [137]

Other methods of narcotic administration have been used, such as transdermal administration and intra-articular administration following knee surgery. Studies do not

demonstrate any apparent benefits of giving narcotics by these routes. [138] [139] Addition of bupivacaine to morphine in intra-articular administration may provide better pain relief than either agent used separately. [140] Bupivacaine plus morphine has a longer duration of action than bupivacaine plus fentanyl. [141]

Regional anesthesia has been used for the relief of postoperative pain to avoid narcotic-induced respiratory depression (Ch. 42 to 44 and 69) . Intercostal nerve blocks, when used for relief of pain of cholecystectomy, result in less fluctuation in arterial blood gases, in earlier ambulation, and in earlier hospital discharge than in narcotic-treated patients. [142] The availability of longer-acting local anesthetics makes this method possible for managing postoperative pain; however, the placement and the repetition of the block do take time, and there is always the risk of pneumothorax. Nevertheless, intercostal nerve blocks can be effective in patients with severe lung disease in whom narcotic analgesics may provide too little analgesia and too much respiratory depression and who have a contraindication to placement of an epidural catheter for narcotic administration. Bilateral intrapleural use of bupivacaine also reduces the need for narcotic analgesics when it is used in patients undergoing major thoracic and upper abdominal surgery. [143] Finally, instillation of local anesthetic into a wound can be very efficacious and is simple to perform. [144]

Continuous epidural block can provide good postoperative analgesia and, when administered in the thoracic space, can permit early postoperative ambulation [145] (Ch. 69) . Use of epidural analgesia probably results in somewhat better arterial oxygenation; however, the incidence of postoperative respiratory complications appears no better than with narcotics. [146] Patients having epidural pain relief can ambulate earlier, and this permits earlier hospital discharge. [147] Hypotension

requiring treatment is still a problem. The use of regional anesthesia for postoperative pain relief appears to be best suited for the patient with preexisting lung disease in whom narcotics would be hazardous and in whom a regional technique could relieve pain without adversely affecting respiration. [148] Although this technique has been used extensively, we find the use of epidural narcotics safer and far less complicated than the use of postoperative regional anesthesia in most patients.

Nonnarcotic analgesics are being used increasingly for postoperative pain. The most common agents used are the nonsteroidal anti-inflammatory agents. Ketorolac was among the first to be available for parenteral administration and is free of respiratory-depressant effects. Although ketorolac is not as potent as the narcotics, it can be an effective alternative to narcotic analgesics without major complictions. [149] [150] Anecdotal concerns about ketorolac center around the possibility of increased bleeding in patients receiving this agent; however, well-controlled evaluations of this potential problem are lacking at this time. Finally, ibuprofen has been suggested as a reasonable alternative to narcotic analgesics in patients undergoing laparoscopic surgery. [151]

Nausea and Vomiting

Postoperative nausea and vomiting are common complications that result in patient discomfort, prolonged stay in the PACU, and, rarely, one of the pulmonary aspiration syndromes. Postoperative nausea and vomiting are often multifactorial in origin. [152] There is little strong evidence that any one anesthetic technique has a lower incidence of nausea and vomiting than others, with the exception that propofol appears to have an inherent antiemetic effect. [153] [154] Propofol-based anesthetic regimens consistently have lower incidence of postoperative nausea and vomiting than other techniques, even when potent antiemetics such as ondansetron are combined with inhalation agents. [155] [156] The use of nitrous oxide does appear to increase the incidence of nausea and vomiting. [157] Even though occasional studies have been unable to implicate nitrous oxide in postoperative nausea and vomiting, [158] [159] one survey of the literature reviewed 27 publications and found that all but 3 contained evidence implicating nitrous oxide in postoperative nausea and vomiting. [157] This finding is not meant to imply that nitrous oxide should be abandoned but that its use must be evaluated carefully when attempting to design an anesthetic regimen with a lower incidence of nausea and vomiting. [160]

The type of surgical procedure has an important influence on the occurrence of nausea and vomiting. Patients having laparoscopic surgery and strabismus surgery are at increased risk for nausea and vomiting. After laparoscopy for tubal ligation, patients who are menstruating have a higher risk of nausea and vomiting, which is not prevented by droperidol. [161]

Antiemetics can be given postoperatively. Droperidol (75 mug/kg IV) can be very effective for patients who develop nausea and vomiting. Droperidol combined with propofol, however, increases the incidence of nausea and vomiting. [162] Metoclopramide has also been shown to be an effective and safe antiemetic for both the prevention and the treatment of postoperative nausea and vomiting. [163] [164] Transdermal scopolamine patches can be very effective in reducing the incidence of nausea associated with epidural narcotics if the patches are applied several hours preoperatively [165] ; however, in many places, they are no longer available. Although these patches are effective in reducing nausea, side effects can include blurring of vision and mental confusion in elderly patients.

The approval by the FDA of the serotonin antagonist ondansetron for treatment of postoperative nausea and vomiting has caused great interest among anesthesiologists because of the high incidence of the problem and its effects on patients undergoing anesthesia and surgery. The serotonin antagonists have been known for many years; however, they have only recently been used for treatment of nausea and vomiting due to chemotherapy for cancer. [166] [167] [168]

Ondansetron is more effective than placebo in preventing postoperative nausea and vomiting in gynecologic surgery. [169] It was also found to be more effective in preventing nausea and vomiting than both droperidol and metoclopramide. [170] When used to treat nausea and vomiting after it develops, ondansetron was also more effective than placebo in two separate studies. [171] [172] Although droperidol and ondan- setron are equally efficacious, droperidol prolongs the PACU stay. [173] [174] The usual dose is 4 mg intravenously. Ondansetron can be given orally to children as an effective premedication (0.1 mg/kg). [175]

Granisetron, a newer serotonin antagonist, is currently being evaluated. It appears that a dose of 40 mug/kg is an effective

prophylactic agent as well as a treatment. [176] [177] The combination of granisetron with dexamethasone in one study produced a striking reduction in the frequency of nausea and vomiting even when compared with the serotonin antagonist alone. [178] Further studies of combined serotonin antagonist-steroid therapy seem warranted.

Hypothermia and Shivering

Inadvertent hypothermia is a common occurrence following major surgical procedures (Ch. 37) . The major adverse effects are patient discomfort, vasoconstriction, and shivering. Full recovery sometimes takes many hours. [179] Shivering increases metabolic rate and hence the need to increase cardiac output and minute ventilation. Not all patients who shiver postoperatively are hypothermic, a finding suggesting that the mechanism of this event may be related to inadequate descending control of spinal reflexes following inhalation of anesthesia. [180] Longer anesthetic regimens are associated with a higher frequency of shivering. [181] Prevention is important, and the use of a heated humidifier results in higher patient temperature when the patient arrives in the PACU. [182] Patients who have had propofol have a lower incidence of shivering than those receiving thiopental. [183] Once in the PACU, hypothermic patients should have supplemental oxygen, warm intravenous fluids and blood, and external warming. External warming can be accomplished with thermal blankets or thermal ceilings, which lower oxygen consumption. [184] Patients who develop shivering should receive supplemental oxygen. Although many drugs have been used to treat postanesthetic shivering, meperidine (25-30 mg IV) is very effective in both stopping the shivering and decreasing oxygen consumption. In some patients, a second dose is necessary. [185] Fentanyl is also effective, but for a shorter interval. [186]

OUTPATIENT SURGERY

Increasing numbers of surgical procedures are being done without admitting the patient to the hospital (Ch. 65) . Surveys indicate that more than 50 percent of all surgical procedures are performed on an outpatient basis. This approach is safe and effective for properly chosen patients. These patients need to be able to leave the hospital shortly after discharge from the PACU. Once awake, the outpatient attempts to ambulate with assistance. After 1 to 3 hours of observation, stable vital signs, and satisfactory ambulation, the patient may leave, with provision for follow-up as necessary. Patients should always be accompanied by another person. Because virtually all anesthetic techniques impair psychomotor skills, driving or operating machinery should not be attempted for 8 to 24 hours. [187] [188] [189]

Chapter 69 - Acute Perioperative Pain *

L. Brian Ready

FUNDAMENTAL CONSIDERATIONS

Past Deficiencies and Current Directions in the Treatment of Perioperative Pain

Many millions of patients worldwide undergo surgery each year and benefit from knowledge, skills, and sophisticated technology that characterize most aspects of modern surgical treatment. Although effective pain control is essential for optimal care of surgical patients, [1] [2] [3] and despite advances in knowledge of pathophysiology, pharmacology of analgesics, and the development of more effective techniques for perioperative analgesia, many patients continue to experience distressing pain. [1] [2] [3] [4] [5] [6] [7] [8] [9] [10] [11] [12] [13] [14] [15] [16] [17] [18]

The concept of perioperative pain management by anesthesiologists is now established in North America and in many other parts of the world. [19] [20] [21] [22] [23] [24] [25] [26] [27] [28] [29] [30] [31] [32] [33] [34] [35] Basic changes in long-established practices such as pain management have received attention not only from clinicians, but also from economists and politicians. One manifestation of this attention in the United States is a clinical practice guideline entitled *Acute Pain Management: Operative or Medical Procedures and Trauma.*[3] This document was commissioned, published, and distributed by the Office of the Forum for Quality and Effectiveness in Health Care, of the Agency for Health Care Policy and Research, U.S. Department of Health and Human Services. The text of the guideline is extensive. Important elements include recognition of historic inadequacies in perioperative pain management, clear acknowledgment of the importance of good pain control, and a statement of the need for the involvement of specialists in appropriate cases. The guideline also emphasizes a need for a process of accountability for adequate provision of perioperative analgesia by health care institutions. It recommends placing responsibility for that activity in the hands of those with the greatest knowledge and interest in perioperative pain.

In the United States the American Society of Anesthesiologists (ASA) has developed clinical practice guidelines for acute pain management in the perioperative period. [36] That document is based on an extensive literature search and meta-analysis as well as on the collective opinions of many experts (see Appendix for full text of this guideline). It offers recommendations that, if followed, will result in a variety of improved outcomes for surgical patients. It also provides a number of templates that may be useful to practitioners who wish to begin providing improved pain relief to their surgical patients.

There is currently a great deal of interest in redefining the role of the specialty of anesthesiology. The popular term "perioperative physician" reflects the physician anesthetist as a consultant and therapist throughout an institution as well as a highly skilled expert in the operating room. The provision of effective analgesia for surgical (and other) patients is an important component of this vision for the future.

Pain Pathways

The International Association for the Study of Pain has defined pain as "an unpleasant sensory and emotional experience

---

* *See Appendix I, Practice Guideliness for Acute Pain Management in the Perioperative Setting*

associated with actual or potential tissue damage, or described in terms of such damage." [37] Surgery produces local tissue damage with consequent release of algesic substances (prostaglandins, histamine, serotonin, bradykinin, 5-hydroxytryptamine, substance P) and generation of noxious stimuli that are transduced by nociceptors and transmitted by A delta and C nerve fibers to the neuraxis. Further transmission is determined by complex modulating influences in the spinal cord. Some impulses pass to the anterior and anterolateral horns to provoke segmental reflex responses. Others are transmitted to higher centers via the spinothalamic and spinoreticular tracts, where they produce suprasegmental and cortical responses.

Segmental reflex responses associated with surgery include increased skeletal muscle tone and spasm with associated increases in oxygen consumption and lactic acid production. Stimulation of sympathetic neurons causes tachycardia, increased stroke volume, cardiac work, and myocardial oxygen consumption. Tone is decreased in the gastrointestinal and urinary tracts. Suprasegmental reflex responses result in further increased sympathetic tone and hypothalamic stimulation. Metabolism and oxygen consumption are further increased.

Cortical responses in awake, unanesthetized patients after surgery are provoked by nociceptive impulses reaching the highest brain centers where complex systems concerned with integration and perception of pain are activated. Apprehension and anxiety may accompany pain resulting in additional hypothalamic stimulation. [38] [39] [40] [41] [42] [43] [44]

Adverse Effects of Perioperative Pain

Physiologic Responses

Physiologic responses to injury and stress include the following: pulmonary, cardiovascular, gastrointestinal, and urinary dysfunction; impairment of muscle metabolism and function; and neuroendocrine and metabolic changes as components of the stress response. Many of these responses can be eliminated or reduced with currently available analgesic techniques.

Respiratory Effects

Surgery involving the upper abdomen or thorax produces a number of pulmonary changes including reduced vital capacity, tidal volume, residual volume, functional residual capacity, and forced 1 second expiratory volume (FEV_1). These changes and their significance are discussed in Chapter 15 . Painful surgical incisions involving the upper abdomen result in a reflex-mediated increase in tone in the abdominal muscles during expiration [45] and a decrease in diaphragmatic function. [46] The result is reduced pulmonary compliance, muscle splinting, inability to breathe deeply or to cough forcefully, and in some cases, hypoxemia, hypercarbia, retention of secretions, atelectasis, and pneumonia. Increased muscle tone is a contributing cause of increased oxygen consumption and lactic acid production. Distended bowel associated with postoperative ileus or tight binders or dressings may further impair ventilation, and fear of producing or aggravating pain can cause patients to avoid breathing deeply or coughing. Opioids administered by a variety of routes to relieve pain and improve pulmonary function can themselves induce or contribute to respiratory failure. [47] [48] [49] [50] [51] [52] [53] [54] Nonopioid analgesics can also cause respiratory system morbidity. [55]

Cardiovascular Effects

Pain causes stimulation of sympathetic neurons and subsequent tachycardia, increased stroke volume, cardiac work, and myocardial oxygen consumption. The risk of

myocardial ischemia or infarction may be increased, as is the risk of deep vein thrombosis when fear of aggravating pain results in reduced physical activity, venous stasis, and platelet aggregation. [56] Some of these sequelae may be reduced by using effective perioperative analgesic therapy. [57] [58] [59]

Gastrointestinal and Urinary Effects

Ileus, nausea, and vomiting following surgery can occur for a number of reasons that include nociceptive impulses from viscera and somatic structures. Pain can also cause hypomotility of the urethra and bladder and consequent difficulty with urination. [2] [60] These effects can be very unpleasant for patients and, especially in the case of ileus, may prolong hospital stay. Postoperative epidural analgesia has been shown to speed the return of bowel function following a variety of abdominal surgical procedures. [61] [62] [63] [64] [65] [66]

Stress Response: Neuroendocrine and Metabolic Effects

The stress response has been termed "the integrated, adaptive living web of neuroendocrine, immunologic, and intercellular biochemical signals evoked by tissue injury." [67] The dominant neuroendocrine responses to pain involve hypothalamic-pituitary-adrenocortical and sympathoadrenal interactions. Suprasegmental reflex responses to pain result in increased sympathetic tone, hypothalamic stimulation, increased catecholamine and catabolic hormone secretion (cortisol, adrenocorticotropic hormone, antidiuretic hormone, growth hormone, cyclic adenosine monophosphate, glucagon, aldosterone, renin, angiotensin II), and decreased secretion of anabolic hormones (insulin, testosterone). [68] The effects of these changes include sodium and water retention and increased blood glucose, free fatty acids, ketone bodies, and lactate. Metabolism and oxygen consumption are increased, and metabolic substrates are mobilized from storage depots. A catabolic state and negative nitrogen balance result if the process continues. There is considerable current interest in the endocrine-metabolic stress response in the surgical patient, its possible consequences, and inhibition by various anesthetic and analgesic methods. The interested reader can review this subject further. [67] [69] [70]

Psychologic Responses

Not surprisingly, perioperative pain can be a major source of fear and anxiety in hospitalized patients. When prolonged,

---

it can lead to anger, resentment, and adversarial relationships with doctors and nurses who are perceived to be withholding pain relief. Insomnia may accompany the process, with further detriment to recovery. In some cases, increased pain reporting may represent patients' attempts to obtain pharmacologic relief for these problems.

Factors that Modify Perioperative Pain

A number of factors may influence the intensity, quality, and duration of perioperative pain. [2] The most important of these are as follows: (1) the site, nature, and duration of surgery; (2) the type and extent of the incision and other surgical trauma; (3) the physiologic and psychologic makeup of the patient; (4) the preoperative psychologic, physiologic, and pharmacologic preparation of the patient; (5) the presence of complications related to the surgery; (6) the anesthetic management before, during, and after surgery; (7) the quality of perioperative care; and, as discussed in the next section (8) preoperative treatment to eliminate painful stimuli prior to surgery. By considering how each of these factors applies to individual patients, optimal care becomes more likely.

Preemptive Treatment of Perioperative Pain

The traditional approach to postoperative analgesia is to begin therapy when surgery is completed and pain is experienced. Preemptive analgesia has been defined as "antinociceptive treatment that prevents the establishment of altered central processing, which amplifies postoperative pain." [71] Intense noxious stimulation can sensitize portions of the central nervous system (CNS) to subsequent input. [72] Such stimulation, in the form of a surgical incision, may lead to functional changes in the dorsal horn of the spinal cord (sometimes called "windup") and other consequences that later cause postoperative pain to be perceived as more "painful" than it would otherwise have been. [73] Although the rationale for clinically useful preemption of surgical pain seems sound, the reported results are mixed. Some investigators have found benefit, [74] [75] [76] [77] [78] [79] [80] [81] [82] [83] [84] [85] [86] [87] [88] [89] [90] whereas others have not. [91] [92] [93] [94] [95] [96] [97] [98] In-depth reviews of the subject have been written, [99] [100] [101] and thoughtful commentary has been offered bearing both on the complexity of the subject and on factors to consider in reconciling differences in the findings of various studies. [71]

It is possible that preemptive analgesia, in addition to reducing acute perioperative pain arising from surgical wounds, may also offer prophylaxis against certain pathologic chronic pain states. Amputees have been found less likely to experience phantom limb pain if they were rendered pain-free with epidural blockade for a period of time prior to surgery. [75] [84] [102] In these populations of amputees, the incidence of phantom limb pain may have been reduced by decreasing the amount of CNS sensitization present at the time of amputation. The amount of acute pain experienced immediately after thoracotomy appears to predict the probability of subsequent chronic post-thoracotomy pain. [90]

Multimodal Approaches

For purposes of this discussion, multimodal therapy is defined as two or more analgesic agents or techniques used in combination. The ASA "Practice Guidelines for Acute Pain Management in the Perioperative Setting" [36] (Appendix) contains the following statement:

> During the administration of anesthetics for surgery, the needs of many patients may best be met by taking advantage of the combined effects of a number of agents. Similarly, there is growing conviction that a multimodality approach to providing perioperative analgesia has advantages over the use of a single modality. The literature supports the efficacy of two or more analgesic techniques (including non-pharmacologic methods) used in combination for the control of perioperative pain, especially when different sites and/or mechanisms of action are involved and/or when synergy of effect is achieved. In addition, the literature indicates that multimodality approaches are associated with side effects no greater than those resulting from single analgesic techniques for perioperative pain management.

Examples of how multimodal therapy may be applied include using an opioid and a nonsteroidal anti-inflammatory drug (NSAID) together, combining two or more agents in an epidural infusion, and providing therapy for perioperative anxiety as well as for pain. The terms "multimodal" and "balanced analgesia" are sometimes used interchangeably. [100]

Postoperative Rehabilitation

Effective treatment of perioperative pain is, in itself, an important goal. However, comfort after surgery should be used to facilitate other desirable outcomes. A comprehensive and integrated approach to the accelerated recovery of the postoperative patient has been termed *postoperative rehabilitation.* Key elements in this approach include early mobilization and return to enteric nutrition, prevention of postoperative fatigue and impairment of pulmonary function, and early discharge from hospital. [103] Such an approach appears to hold much promise for the future.

/das/book/view/29494766/875/759.html

TREATMENT METHODS

Systemic Opioids

Opioids produce analgesia primarily as a result of their agonist effects on opioid receptors in the CNS. Effective doses of appropriate drugs can be administered by the oral, rectal, transdermal, or sublingual route or by subcutaneous, intramuscular, or intravenous injection or infusion (Ch. 10) . Of these options, intramuscular opioids have been the most common treatment choice for patients after surgery. This practice has been based on the apparent simplicity and universal applicability of the technique. A dose of an opioid is ordered to be given as often as the physician or nurse considers it necessary and safe. Unfortunately, the orders frequently provide for a "standard dose" that is optimal for only a small proportion of patients, and the "as needed" part of the order is often interpreted to mean "as little as possible."

There is typically little flexibility in doses or injection intervals for individual patients. The resulting conservative prescriptions result in inadequate analgesia for many patients.

Highly variable pharmacodynamic and pharmacokinetic dose-response curves for individual patients have been demonstrated. A standard dose of intramuscular opioid can result in 5-fold differences in peak blood levels among different patients, the time to reach peak levels may vary as much as 7-fold, and serum opioid levels required to produce analgesia in different patients vary as much as 4-fold. [104] [105] There does not appear to be a significant correlation between gender and analgesic requirement, and there is no scientific justification for the calculation of analgesic doses on the basis of body weight or surface area. [106] Although intramuscular injections are generally considered safe and require no special precautions, apnea and abnormal respiratory patterns may occur, and oxygen desaturation may be more severe than with some newer methods of opioid administration. [51] [107] Because the intramuscular route is such an unpredictable delivery system, using it effectively and safely requires careful ongoing assessment of patients, with adjustments in doses and frequency of administration until individual care is optimized.

Intravenous opioid infusions can abolish wide swings in drug concentration and may permit prompt titration of drug to the needs of individual patients. Accumulation may occur using drugs having an intermediate or long half-life, so that ongoing assessment and adjustment of dose to meet changing needs are a necessity. Respiratory depression of life-threatening severity has been reported, [108] and concern for this risk has limited the widespread use of continuous opioid infusions for perioperative pain. Intravenous administration during general anesthesia of a single dose of 20 mg of methadone, an opioid with a long half-life and low clearance, can produce postoperative analgesia that lasts many hours. [109] At the other end of the spectrum, the analgesic effects of remifentanil, a very short-acting synthetic opioid, last only a few minutes after discontinuing an intravenous infusion. [110] [111] Termination of the analgesic effect must be anticipated to avoid periods of severe pain after surgery.

Transdermal delivery of fentanyl after surgery has been demonstrated to be effective. [112] This method of opioid administration avoids the discomfort of injections and offers a useful alternative for patients unable or unwilling to swallow oral medications. Therapeutic blood levels are achieved, and the usual side effects associated with opioid administration (including respiratory depression) are seen. As with other routes of administration, dosing must be individualized under medical supervision.

Oral opioids in appropriate doses are remarkably effective. They can frequently be used in place of parenteral drugs 12 to 24 hours after superficial surgery and, after some intra-abdominal procedures, as soon as oral intake is possible. Placing oral opioids (and other analgesics) at the bedside can improve analgesia by permitting patients to choose the dose and frequency of administration best suited to their individual needs. The concept of patient-controlled analgesia (PCA), as discussed in the following section, is not limited to parenteral administration. A detailed discussion of the pharmacology and use of oral opioids is beyond the scope of this chapter.

Tramadol (Ultram) has been in use in a number of European countries for many years and has been approved by the Food and Drug Administration (FDA) in the United States. The drug's analgesic effects are thought to result from a combination of weak opioid receptor binding and norepinephrine and serotonin reuptake inhibition. Early studies [113] [114] found a lack of association with development of dependence, tolerance, and respiratory depression. However, subsequent domestic reports to the FDA resulted in March 1996 in labeling changes warning physicians of a risk of drug abuse, seizures, and anaphylactoid reactions. This development raises questions about the risk-to-benefit ratio of tramadol as a routine analgesic for surgical patients.

Traditionally, opioids are administered for the purpose of producing analgesia through their actions within the CNS. There is evidence of analgesic effects that result from activation of opioid receptors outside the nervous system following topical application, intravenous regional injection, or perineural injection in the vicinity of nerve trunks. Clinical studies have investigated peripheral analgesic effects of opioids on postoperative pain with demonstration of significant analgesia [115] and with contrasting findings of no significant analgesia. [116] [117]

Patient-Controlled Analgesia

PCA, the self-administration of small doses of opioids by patients when they experience pain, was originally conceived and developed to minimize the effects of pharmacokinetic and pharmacodynamic variability among individual patients. [118] [119] [120] It is based on the premise that a negative feedback loop exists: when pain is experienced, analgesic medication is demanded; when the pain is reduced, there are no further demands. The loop fails and risks are increased if nurses, relatives, or parents assume responsibility for drug administration. As discussed later in this chapter, the loop also fails if patients choose to self-administer drugs for reasons other than pain relief.

Most intravenous PCA devices consist of a microprocessor-controlled pump triggered by depressing a button. When the pump is triggered, a preset amount (incremental dose) of opioid is delivered into the patient's intravenous line. A timer in the pump prevents administration of an additional bolus until a specified period (lockout interval) has elapsed. Thus, individual patients titrate opioids to their own needs within safe clinical parameters. Many commercially available devices for this purpose are now available.

The safety of PCA, especially in relation to respiratory depression, has been addressed by a number of investigators. In two studies, serial blood gas analyses showed normal values in patients using PCA. [121] [122] No differences in respiratory mechanics (FEV_1 , functional residual capacity, peak flow rates) were found between patients using PCA and those using intramuscular opioids. [123] [124] However, cases of respiratory depression during PCA use have been reported. [122] [125] [126] Advanced age, hypovolemia, large incremental doses, and use of a background continuous-infusion mode were thought to be contributing factors by some investigators. Some investigators reported the incidence of respiratory depression among PCA patients managed by an anesthesiology-based acute pain service (Table 69-1) . [127] [128] [129] [130] Included in the table is the unpublished experience of the

TABLE 69-1 -- Respiratory Depression With Patient-Controlled Analgesia

AUTHOR	PATIENTS RECEIVING PATIENT-CONTROLLED ANALGESIA	INCIDENCE OF RESPIRATORY DEPRESSION (%)

Ready et al, 1996	15,000	0.31

University of Washington Medical Center obtained from the pain-service database.

Quality of analgesia with PCA has been consistently reported as superior or equal to that with intramuscular opioids. Less PCA opioid use compared with intramuscular control groups is sometimes observed, [131] and satisfaction of patients and nurses is high. The principal advantages of PCA to patients are high-quality analgesia, autonomy, elimination of delay in decisions to medicate for pain, and freedom from painful intramuscular injections. It may take nurses less time to provide for the analgesic needs of postoperative patients using PCA.

Optimal efficacy and safety using PCA, as with other forms of treatment for perioperative pain, require careful planning, establishment of appropriate policies and procedures, education of physicians and nurses, and frequent medical assessment of individual patients (Table 69-2) (Table Not Available) . Preoperative patient teaching further facilitates optimal results. A number of opioid analgesics can be self-administered by patients. Those best suited are potent opioids with rapid onset and intermediate duration of action. Morphine, meperidine, and hydromorphone are widely used in North America. Table 69-3 lists suggested starting incremental doses and lockout intervals for these and other opioids. Initial PCA therapy should be preceded by a titrated opioid loading dose if severe pain is present. The PCA pump should be available as soon after surgery as the patient is capable of using it--often in the postanesthesia care unit. If adequate analgesia is not achieved with initial pump settings, the incremental dose should be increased and/or the lockout interval decreased.

Most PCA pumps offer the option to add a continuous background infusion to the basic patient-controlled mode. Theoretic advantages include the following: (1) a more constant opioid serum level; (2) improved analgesia, especially during sleep; and (3) modulation of the final opioid dose by patients, to achieve optimal analgesia. Theoretic disadvantages include the following: (1) difficulty predicting the optimal infusion rate for individual patients and thus the possibility of a prescribed overdose; (2) loss of an important safety element because sleeping patients continue to be medicated; and (3) more human errors in PCA pump programming because more steps are involved. Findings from controlled studies show that, compared with the PCA mode used alone, with addition of the continuous-infusion mode, patients receive more opioid, pain relief is unchanged, and dangerous pump-programming errors may occur. [126] [132] [133] [134] [135] [136] [137] [138] [139] [140] Recommendations for use of the background continuous-infusion mode are as follows: (1) avoid routine use of continuous-infusion mode; (2) add the continuous-infusion mode

Nalbuphine (1 mg/mL)	1-5	5-15
Buprenorphine (0.03 mg/mL)	0.03-0.1	8-20

[a] Precede with titrated intravenous loading dose if necessary to establish initial analgesia. Individual patient requirements vary widely. Small doses should be used initially for elderly or compromised patients.

for specific indications (e.g., pain during sleeping hours); (3) base the rate of infusion on established need (e.g., 30-50% of what a patient self-administered with the demand mode); (4) decide whether the continuous-infusion mode is needed only at night or around the clock; (5) provide regular in-service education to ward nurses on PCA pump-programming procedures.

There are times (difficult intravenous access, no option for enteric analgesics) when the use of PCA delivery systems via the subcutaneous route can be of value. [141] [142] [143] [144] [145] Additional experience has been reported in treating cancer pain. [146] [147] [148] [149] [150] A standard PCA pump attached to an administration set is all the equipment necessary. The administration set can be a small-gauge "butterfly" needle or a special device designed for the purpose (Baxter Sub-Q-Set) (Hooksett, NH). Choice of opioids is the same as for the intravenous PCA route (see Table 69-3) . The concentration of the opioid solutions should be increased 5-fold to reduce their volume. The same incremental doses and lockout intervals as for the intravenous route are programmed into the pump, and a continuous background infusion can be used, if needed. No basic intravenous solution is infused into the subcutaneous tissue.

Side effects (nausea, vomiting, itching) resulting from PCA can be treated by changing the opioid in the pump or by using drugs that provide symptomatic relief. Monitoring of vital signs should be according to protocols established to suit the needs of the patients and practices in each institution. A preprinted set of standard orders used throughout an institution can facilitate a uniform standard of care (Fig. 69-1) .

The PCA paradigm has been used to provide intranasal analgesia with meperidine [151] and fentanyl. [152] Intravenous patient-controlled midazolam has been provided to treat postoperative anxiety. [153] [154]

Regional Anesthetic Techniques

Regional anesthetic techniques used for surgery produce the following: positive respiratory, cardiovascular, and neuroendocrine effects; reduced thromboembolic complications and blood loss; and reduced convalescence (Chs. 42 to 44) . A variety of neural blockade techniques continued into the postoperative period can result in effective and safe analgesia. These include local infiltration of incisions with long-acting local anesthetics, peripheral nerve or plexus blocks, and continuous block techniques at various sites in the periphery or neuraxis.

A single injection of 0.25 percent bupivacaine into incisions after inguinal hernia repair produces effective analgesia for outpatients, [155] whereas repeated subcutaneous injections of a 0.5 percent solution through an epidural catheter provide sustained benefit. [156] Long-acting local anesthetics used for nerve or plexus anesthesia during surgery also eliminate early postoperative pain. Interscalene brachial plexus blocks for surgery on the shoulder can provide total comfort for 12 to 24 hours. [157] Sciatic and femoral nerve blocks can produce similar results after surgery on the ankle and foot, whereas intercostal blocks produce effective and safe analgesia for 6 to 12 hours after thoracic and upper abdominal surgery. [158]

Following thoracic or upper abdominal surgery, administration of long-acting local anesthetics through a catheter placed in the interpleural space can produce unilateral analgesia with little or no evidence of sensory block. The effect is presumably a result of multiple intercostal nerve blocks caused by spread of the local anesthetic through the parietal pleura. [159] [160] [161] Although the technique appears to provide effective analgesia in some situations, its use is controversial. The reported doses of local anesthetic required to produce analgesia vary among investigators and in some cases result in serum levels traditionally thought to be associated with signs and symptoms of toxicity. Clamping of chest tubes with each local anesthetic administration following thoracotomy may be necessary to avoid loss of the drug, and analgesia may be positional, with loss of effect in sitting or ambulating patients. Tension pneumothorax has been reported, [162] as have bronchospasm [163] and intrapulmonary catheter placement. [164]

Postoperative local anesthetic infusions into the axillary sheath, [165] femoral sheath, [166] and the vicinity of the sciatic nerve [167] have been used to maintain analgesia and sympathetic blockade after a variety of surgical procedures. These techniques may be particularly useful to facilitate perfusion

Figure 69-1 Pain service intravenous patient-controlled analgesia (PCA) physician orders.

after extensive revascularization or reimplantation surgery, to maintain a normal range of motion following joint surgery, and to administer to anticoagulated patients in whom spinal or epidural block may be considered with caution.

Spinal anesthesia can provide pain relief for several hours after the completion of surgery if long-acting agents containing vasoconstrictors are used. Continuous epidural anesthesia through a catheter offers several options for perioperative

analgesia. Local anesthetic boluses or infusions can provide profound analgesia, with advantages over parenteral opioids that include earlier ambulation, improved bowel function, higher arterial oxygen tension, and fewer pulmonary complications. [168] [169] For optimal results with the least amount of local anesthetic, the epidural catheter tip should be near the segments innervating the incision. Placement of thoracic or cervical epidural catheters should only be considered by those experienced in the use of lumbar catheters.

Intraspinal Analgesia

Opioids

Following the initial reports in 1979 of clinical efficacy of intrathecal [170] and epidural opioids, [171] these drugs have been used to control pain following a wide variety of surgical procedures. [172] Intrathecal opioids have the appeal of ease of administration, either at the time of spinal local anesthetic injection for surgical anesthesia or as a separate technique when general anesthesia is administered. Many patients remain comfortable for 24 hours or more after a single injection of intrathecal morphine. It is possible that in the future, sustained-release preparations of morphine may further extend that duration of analgesia. [173]

The epidural route has been used much more extensively for perioperative pain control. Reasons include popularity of the technique alone or in combination with light general anesthesia during surgery, willingness to leave an epidural catheter in place for extended periods to maintain analgesia, familiarity with perioperative analgesia using epidural local anesthetics, and freedom from the risk of post-lumbar-puncture headache. Several reports regarding the use of epidural opioids for postoperative pain control are of special note. Stenseth et al [174] published a prospective study reporting the efficacy and side effects of epidural morphine in 1,085 patients after thoracic, abdominal, urologic, or orthopedic surgery. This large experience from a single institution provides a wealth of observations that are instructive to the clinician contemplating the use of epidural opioids.

In a randomized double-blinded study by Rawal et al [62] of obese patients undergoing gastroplasty for weight reduction, the effects of intramuscular and epidural morphine were compared with respect to analgesia, ambulation, gastrointestinal motility, early and late pulmonary function, duration of hospitalization, and occurrence of deep vein thrombosis in the postoperative period. With a protocol designed to provide adequate analgesia by either route, the average dose of intramuscular morphine was up to seven times higher than that required by the epidural route. Patients receiving epidural morphine reported superior analgesia, ambulated sooner, had fewer pulmonary complications, had earlier return of bowel function, and were discharged from hospital earlier than patients receiving intramuscular morphine.

Yeager et al [175] randomized high-risk surgical patients to two groups: the first received general anesthesia and conventional postoperative analgesia (i.e., intramuscular or intravenous opioids), whereas the second group received combined epidural/general anesthesia and epidural opioids for postoperative pain. [175] Mortality rate, overall complication rate, infection rate, time to extubation, and hospital costs were significantly lower in the group receiving epidural therapy.

Although not as effective as regional analgesia with local anesthetics for controlling pain associated with vaginal delivery, intraspinal opioids for control of pain following cesarean section are widely used. These drugs may be offered when spinal or epidural anesthesia is chosen for surgery. Although most reports focus on the latter application, good results have also been reported using the intrathecal route. [176] Pain after vaginal delivery originating from a large episiotomy or a perineal tear may also be managed with intraspinal opioids.

Table 69-4 lists a number of opioids used for intraspinal analgesia, suggested dose ranges, expected latency, and duration of analgesia. Doses necessary to produce analgesia and their duration of effect vary considerably from one patient to another, depending on age, medical condition, site of injection, type of pain, and other factors. Incorporating some of these factors, Table 69-5 suggests starting doses of epidural morphine, the most widely used opioid for incisional pain. The recommended doses are only guidelines. A dynamic ongoing assessment of adequacy of pain relief for individual patients with changes in dose or frequency of injection as necessary is the logical approach. Preservative-free morphine preparations have been used in a wide range of concentrations with no apparent difference in efficacy. The commercially available 0.1 percent solution is satisfactory without dilution. The addition of epinephrine to morphine is not recommended. Although most experience with morphine has involved intermittent injection, the drug has been used with success as a continuous infusion. Effective doses may range from less than 0.1 to 1.0 mg/h.

Elderly patients may require remarkably small doses of epidural morphine. In evaluating women after abdominal hysterectomy, a significant inverse relationship has been found between age and effective total dose of epidural morphine needed each 24 hours to achieve analgesia. The relationship can be expressed by the following equation:

[177]

A lipophilic drug such as fentanyl is useful when rapid onset of epidural analgesia is important. Intermittent epidural boluses of 50 to 75 mug can be used to achieve analgesia promptly in the immediate postoperative period if an initial epidural morphine dose is not adequate. Used as the sole opioid, a 25- to 100-mug epidural bolus can be followed by a continuous infusion of 25 to 100 mug/h. Epidural meperidine is widely used in some parts of the world and is gaining popularity in North America. [178] As with other opioids, respiratory depression can occur. [53]

Although not widely used in North America, epidural opioids with mixed agonist-antagonist actions (e.g., buprenorphine) are popular in some places. [179] [180] [181] It is not likely that this family of drugs offers significant benefits over pure opioid agonists for most postoperative patients.

Until it is possible to identify and eliminate the factors that occasionally lead to severe respiratory depression in patients receiving intraspinal opioid analgesia, it must be assumed

TABLE 69-4 -- Intraspinal Opioids for the Treatment of Perioperative Pain

DRUG	SINGLE DOSE[a] (mg)	INFUSION RATE[b] (mg/h)	ONSET (min)	DURATION OF SINGLE DOSE[c] (h)
Epidural				
Morphine	1-6	0.1-1.0	30	6-24
Meperidine	20-60	10-60	5	4-8

Diamorphine	1-2	--	?	20
Fentanyl	0.005-0.025	--	5	3-6

[a] Low doses may be effective when administered to the elderly or when injected in the cervical or thoracic region.
[b] If combining with a local anesthetic, consider using 0.0625-0.125 percent bupivacaine.
[c] Duration of analgesia varies widely; higher doses produce longer duration.

that all patients offered these techniques are at risk. To prevent serious injury or death, there is no substitute for a high level of vigilance. This may be provided by a nurse trained to check the rate and depth of respiration as well as general status and level of consciousness at frequent intervals. Respiratory monitors that sound an alarm if ventilation is not detected may augment this process, but they should not be viewed as substitutes for alert, well-trained human observers.

Intensive care facilities are well suited to this level of monitoring and should be used for patients at special risk (advanced age, serious underlying conditions, extensive surgery). However, the expense and limited availability of these facilities render them impractical for routine use. A "step-down unit," intermediate between intensive care and a regular ward, is an appealing alternative. It has been demonstrated that with extensive nursing education, careful patient selection, frequent monitoring of ventilation, protocols for immediate treatment of complications, and immediate availability of medical personnel, this care can safely be offered in conventional hospital wards. [182] A preprinted set of standard orders used throughout an institution can facilitate a uniform high standard of care (Fig. 69-2) . Delegation of all responsibility for pain control to one group of physicians within an institution can minimize errors of conflicting or duplicated orders or inadvertent administration of parenteral opioids to patients receiving intraspinal opioids.

Early respiratory depression occurring in the first 2 hours following epidural opioid injection is the result of vascular uptake and redistribution (i.e., the same mechanism that follows intramuscular injection). Delayed respiratory depression occurring between 6 and 12 hours following spinal or epidural injection is likely the consequence of rostral spread of opioid in cerebrospinal fluid (CSF). The target site is thought to be the respiratory center located superficially in the floor of the fourth ventricle. The actual incidence of this event is not known and is dependent on a number of factors including the population studied, how they are monitored, and the definition of respiratory depression that is chosen. In a large, multi-institutional Swedish questionnaire

TABLE 69-5 -- Initial Dose of Epidural Morphine for Perioperative Pain [a]

PATIENT AGE (y)	NONTHORACIC SURGERY	THORACIC SURGERY	
	(LUMBAR OR CAUDAL CATHETER) (mg)	*THORACIC CATHETER (mg)*	*LUMBAR CATHETER (mg)*
15-44	4	4	5
45-65	3	3	4
66-75	2	2	3
76+	1	1	2

[a] These doses should only be considered as guidelines. They are based on the use of undiluted 0.1 percent preservative-free morphine. Safe and effective doses for individual patients may vary considerably.

Figure 69-2 Pain service epidural analgesia physician orders.

survey, the incidence of "depression requiring naloxone" was 0.25 to 0.40 percent. [50] In a questionnaire survey of 74 U.S. institutions, the incidence of "respiratory insufficiency" was 1.9 to 2.3 percent, [183] and in a prospective study of 1,085 patients in a single institution, the incidence of "respiratory depression" was 0.9 percent. [174] At the University of Washington Medical Center in Seattle, the incidence was found to be 0.2 percent. [182]

It is not known whether the risk of severe respiratory depression is greater after intraspinal opioids than following opioid administration by more conventional routes. It has been reported that 860 hospitalized patients receiving morphine orally or parenterally (intravenously, intramuscularly, subcutaneously) demonstrated a 0.9 percent incidence of "life-threatening" respiratory depression. [47]

The risk of delayed respiratory depression after intraspinal opioid administration appears to be greatest early in the course of therapy. There are no reported cases of this complication occurring later than 24 hours after administration of the initial dose of drug. Consistently impressive among predisposing risk factors in reported cases are advanced age, concomitant use of systemic opioids or other CNS depressants, and extensive surgery. Therefore, large parenteral doses of perioperative opioids or long-acting sedatives should be avoided, as should perioperative parenteral opioids in patients receiving epidural opioid analgesia.

Respiratory rate alone is not an adequate indicator of ventilatory status in postoperative patients receiving epidural opioids. [19] [184] A more global assessment is necessary, particularly during the first 24 hours of treatment. This should include assessment of level of consciousness because increasing sedation (presumably due to central drug effect and CO_2 narcosis) has been noted with advanced respiratory depression. Healthy volunteers breathing CO_2 mixtures have been observed to lose consciousness at CO_2 pressure (P_{CO_2}) levels of about 80 mm Hg. [185] Every patient receiving intraspinal opioids whose level of consciousness deteriorates unexpectedly should be assumed to have respiratory depression until disproved by arterial blood gas analysis.

The immediate treatment of severe respiratory depression is support of ventilation. Equipment to deliver oxygen with positive pressure must be readily available, and personnel in the area must be familiar with its use. Naloxone titrated in small doses (0.1 mg) intravenously usually restores adequate spontaneous ventilation promptly, but repeated doses are sometimes necessary. This drug should be readily available for immediate use.

Pruritus is common in patients receiving intraspinal opioids. The incidence is particularly high in obstetric patients. Itching may be generalized or localized, with the face being a common site. This side effect is seen both with opioids containing preservatives and with preservative-free preparations. Although the pruritus is probably not due to histamine release, antihistamines often provide symptomatic relief. Nalbuphine may also be of value. [186] [187] [188] Naloxone is consistently effective, but repeated doses or infusions may sometimes be necessary.

The incidence of urinary retention is higher in volunteers than in patients, and it is higher in males. Naloxone may help to prevent or reverse urinary retention, but doses approaching those that antagonize analgesia may be needed. Some patients require bladder catheterization. On the other hand, most patients with indwelling urinary catheters in place following surgery are able to void spontaneously when the catheters are removed, even when epidural opioid therapy is continued.

Nausea and vomiting are believed to be the result of rostral spread of opioid in CSF to the vomiting center and the chemoreceptor trigger zone located superficially in the floor of the fourth ventricle. Relief is frequently possible with antiemetics, but these may also produce unwanted sedation or may even contribute to the risk of respiratory depression. [189] Transdermal scopolamine patches applied to the mastoid area have been found to be effective. [190] [191] At the University of Washington Medical Center, they are commonly used in combination with intravenous metoclopramide. Intravenous droperidol in small doses is used as second-line therapy, whereas ondansetron is also sometimes considered (Fig. 69-2) .

Sedation produced by intraspinal opioids, rarely a significant problem with moderate drug doses, may be the result of spread of the drug in CSF to receptors in the thalamus, limbic system, or cortex. Hypercarbia and associated CO_2 narcosis can augment the clinical picture of sedation. [185] Epidural buprenorphine 0.15 mg has been shown to produce prolonged depression of the CO_2 response that lasted 8 to 12 hours. A similar observation was made after 2 to 4 mg doses of epidural butorphanol. [192]

Opioid-Local Anesthetic Mixtures

The rationale for combining epidural opioids and local anesthetics is to use lower doses of each agent, to preserve effective analgesia, and to reduce the side effects and problems associated with the use of the individual drugs. Some degree of blunting of the stress response may also be possible. Whereas the opioid in the mixture acts by inhibiting the release of substance P in the dorsal horn of the spinal cord, the local anesthetic blocks transmission of impulses at the level of the nerve axonal membrane. These two distinctive actions may contribute to the synergy of analgesic effect that has been demonstrated.

Bupivacaine is the most widely used local anesthetic for perioperative analgesia because of its tendency to block sensory fibers preferentially, with relative sparing of motor fibers. Dilute bupivacaine solutions can therefore provide analgesia while preserving the ability of some patients to ambulate. Even dilute solutions can lead to some degree of sympathetic, sensory, and motor block. Associated unwanted effects are listed in Table 69-6 . In Table 69-7 , two commonly used concentrations of bupivacaine (0.0625% and 0.125%) are compared with regard to these effects. Figure 69-3 shows the frequency of bupivacaine-related motor block limiting ambulation using either lumbar or thoracic epidural catheters at the University of Washington Medical Center. It is possible that dilute ropivacaine infusions will provide analgesia equivalent to that provided by bupivacaine with less impact on motor function.

TABLE 69-6 -- Unwanted Effects With Epidural Local Anesthetic Techniques

FUNCTION BLOCKED	POSSIBLE PROBLEM
Sympathetic	Hypotension (thoracic > lumbar)
Proprioception	Difficulty ambulating
Sensory	Pressure injury
	Mask a complication
Motor	Loss of function (cough, ambulation)

TABLE 69-7 -- Comparison of Two Common Bupivacaine Concentrations

BUPIVACAINE CONCENTRATION	0.0625%	0.125%
Hypotension	Absent	Rare
Loss of proprioception	Subtle effect (lumbar > thoracic)	Marked effect (lumbar > thoracic)
Sensory block	Variable	Common
Motor block	Variable	Common
Clinical application	High-volume infusion	Low-volume infusion (segmental block)

Various opioids are commonly combined with bupivacaine. The most common in the United States are fentanyl and morphine, with concentrations of both varying widely among different users. Monitoring of patients receiving epidural mixtures of opioids and local anesthetics should include strategies to detect side effects or problems associated with both components (see Fig. 69-2) .

Epidural opioids used alone in effective doses for relief of perioperative pain do not appear to mask certain postoperative complications, in particular compartment syndrome in the lower extremity. [193] It is not known whether this is also true using epidural infusions that contain local anesthetics. Because there is a possibility of producing dense sensory block that could mask the pain associated with this complication, epidural local anesthetic solutions may best be avoided or used with special monitoring precautions in patients at high risk of developing a compartment syndrome.

Ketamine

Ketamine is a phencyclidine derivative with analgesic properties probably mediated by several mechanisms including interactions with cholinergic, adrenergic, and serotonergic systems. Some clinical studies show satisfactory analgesic efficacy of epidural ketamine [194] [195] [196] [197] whereas others do not. [198] [199] [200] [201] Intrathecal administration is also reported. [202]

Side effects such as sedation, blurred vision, tachycardia, hypertension, and hallucinations have been reported following epidural administration of ketamine. [198] [203] [204] [205] It should be noted that there has been a lack of consensus regarding the neurotoxic potential of the drug. In one study, intrathecal administration in baboons showed no neurotoxic

Figure 69-3 Motor block impairing ambulation using epidural bupivacaine infusions.

changes [206] whereas in another, the same authors observed focal degeneration with loss of myelin and axoplasm in monkeys. [207] Histologic changes in rats have also been seen. [208] The routine use of epidural or intrathecal ketamine in humans cannot be recommended at this time.

Clonidine

The alpha$_2$ -adrenergic agonist clonidine has been extensively studied and is currently in clinical use as an intraspinal agent in some parts of the world. Clonidine administered by the oral route can augment spinally mediated opioid analgesia [209] whereas epidural or intrathecal clonidine can provide effective analgesia alone. [210] [211] [212] [213] [214] [215] [216] [217] [218] [219] [220] [221] [222] [223] [224] [225] [226] Intrathecal clonidine does not provide surgical anesthesia. [227]

Neostigmine

Neostigmine represents a novel approach to providing analgesia. Unlike with local anesthetics, unwanted axonal blockade does not occur, and unlike alpha $_2$ -adrenergic agonists, neostigmine is not a direct agonist stimulating all receptors of a certain type. Intrathecal neostigmine provides analgesia by inhibiting breakdown of acetylcholine, an endogenous spinal neurotransmitter. Early studies involving its administration to humans are promising, [228] [229] [230] [231] [232] but determining the possible role of this agent in clinical practice will require further study. Analgesia and side effects associated with intrathecal neostigmine were found to be dose-dependent. [228] A single dose through a no. 19.5 needle of 50 mug showed no measurable effect. A dose of 150 mug caused mild nausea, and 500 to 750 mug produced subjective leg weakness, decreased deep tendon reflexes, and sedation. The 750-mug dose was associated with anxiety, increased blood pressure and heart rate, and decreased end-tidal CO_2 .

Intraspinal Analgesia in Patients Receiving Anticoagulants

Thromboembolic complications following major surgery can be catastrophic. Many surgeons seek to minimize this risk through the prophylactic use of a variety of anticoagulants. These include unfractionated heparin, low-molecular-weight heparin (LMWH), and oral anticoagulants such as

coumarins. Higher heparin doses are required during surgery when major cardiac or vascular surgery is performed. Platelet aggregation-inhibiting drugs (aspirin and NSAIDs) are also commonly administered in the perioperative period. Thrombolytic agents (e.g., streptokinase, urokinase) are also used in some patients facing surgery. The development of spinal hematomas is a rare event. Such hematomas have been reported spontaneously in "normal" patients exposed neither to anticoagulants nor to neuraxial blocks. They have also been reported during the use of either low-dose anticoagulants or neuraxial blocks alone, and they have been reported when these forms of therapy have been combined. (There are no studies evaluating epidural catheter insertion in fully anticoagulated patients.) What can one learn from published reports on this subject?

Evidence of Safety

Tryba [233] reviewed 13 case series totaling more than 850,000 patients having epidural block. Three spinal hematomas occurred. Using statistical analysis with a 95 percent confidence interval, the estimated incidence was 1:150,000. Seven other case series involved 650,000 intrathecal blocks without a bleeding complication (estimated incidence, 1:220,000). Another review by Vandermeulen et al [234] documented 18 case series from 1952 to 1989 that found no spinal hematomas after epidural or intrathecal anesthesia. The large aggregates in these and other major reviews [235] [236] [237] [238] offer considerable reassurance about the overall safety of intraspinal analgesic techniques. Further, at least 25 prospective reports involving a total of more than 30,000 patients document the safe utilization of epidural and intrathecal anesthesia in the presence of anticoagulants. Notable among these are the reports of Rao and El-Etr [239] and Odoom and Sih. [240]

There is wide variation in response to subcutaneous low-dose heparin. Yet Lowson and Goodchild [241] and Allemann et al [242] reported no cases of spinal hematoma in a combined total of 204 epidural and 119 spinal anesthetic regimens in patients who received 5,000 U of unfractionated subcutaneous heparin 2 hours prior to needle placement. Schwander and Bachmann [243] noted no spinal hematomas in 5,528 patients who received varying doses of subcutaneous heparin in combination with spinal or epidural anesthesia. Spinal hematomas in patients undergoing major conduction block while receiving low-dose heparin are very rare; there are only 3 cases reported. [244] [245] [246]

Various preparations of LMWH have been widely used for a number of years in Europe. In a literature review, Bergqvist et al [247] identified 44 articles on LMWH for thromboprophylaxis. At least 9,013 of the patients received spinal or epidural anesthesia during LMWH treatment. There were no reported cases of spinal hematoma with neurologic dysfunction in these patients. Schwander and Bachmann [243] reported no spinal hematomas after epidural or intrathecal blocks in 13,917 patients receiving LMWH. Although the actual number of patients who have received LMWH in combination with central neural blockade is not known, pharmaceutical companies estimate it to be at least one million.

Few data exist regarding the risk of spinal hematoma in patients with indwelling spinal or epidural catheters who are subsequently anticoagulated with coumarins. Odoom and Sih [240] performed 1,000 continuous lumbar epidural anesthetics in 950 patients undergoing vascular procedures and who received oral anticoagulants preoperatively. There were no neurologic complications. In another study, there were no reported spinal hematomas in 192 patients receiving postoperative epidural analgesia in conjunction with low-dose warfarin after total knee arthroplasty. [248]

Although epidural or spinal needle and catheter placement with subsequent heparinization appears relatively safe, the risk of spinal hematoma in patients who receive thrombolytic therapy is less well defined. Two cases of spinal hematoma have been reported in patients with indwelling epidural catheters who received thrombolytic agents. [249] [250]

A number of studies of patients receiving aspirin or NSAID showed no spinal hematomas following epidural or intrathecal anesthesia. [251] [252] [253] Of additional note is the Collaborative Low-Dose Aspirin Study in Pregnancy (CLASP), in which 1,422 high-risk obstetric patients who received 60 mg of aspirin daily underwent epidural anesthesia without any neurologic sequelae [254] (Ch. 57).

Evidence of Risk

Groen and Ponssen [255] reviewed 199 patients who suffered "spontaneous" spinal epidural hematomas. A coagulopathy (drug-induced, acquired, or congenital) was present in 25 percent of these patients. Vandermeulen et al [234] published details of reported cases of spinal hematoma after epidural or intrathecal block. In their retrospective search spanning the years from 1906 to 1994, 61 cases were found. Thirty-two patients had received epidural blocks; 29 had received intrathecal blocks. It is notable that 42 of the 61 spinal hematomas (68%) occurred in patients with impaired coagulation (either on the basis of anticoagulant therapy or disease). Technical difficulties (bleeding, multiple attempts, difficult needle placement) were also commonly noted. In 15 of 32 patients (47%) receiving an epidural catheter, spinal bleeding occurred shortly after catheter removal.

Conclusions

Whether the use of anticoagulants in patients receiving epidural and intrathecal anesthesia increases the risk of spinal hematoma is not known (Ch. 42) . In their review article, Vandermeulen et al [234] concluded: "The presence of anticoagulants (mainly therapeutic levels of heparin, and to a lesser degree, low-dose thromboprophylaxis with UH [unfractionated heparin] or LMWH) . . . must be considered critical in the formation of a spinal bleeding complication."

Whenever possible, it is desirable to correct defects in coagulation status before proceeding with epidural or intrathecal anesthetic/analgesic techniques (and before removing intraspinal catheters). However, it is likely that the risk of fatal pulmonary embolus because of an omitted

thromboprophylactic treatment is higher than the risk of spinal hemorrhage when unfractionated heparin or LMWH is combined with epidural or intrathecal block. In a fully anticoagulated patient, it is recommended that the necessity of the anticoagulation be determined, as well as whether it may be reversed during the period of epidural catheter placement and use. Central neural block should probably be avoided in patients who must remain fully anticoagulated or who may receive thrombolytic therapy.

When intrathecal anesthesia/analgesia is used in a patient with abnormal coagulation, frequent neurologic examination is essential. Opioid-based epidural analgesia or the use of dilute local anesthetics can facilitate frequent neurologic examination. If spinal hematoma develops, the treatment of choice is immediate decompressive laminectomy.

Decisions to combine epidural or intrathecal anesthesia with anticoagulant therapy should be made on a caseby-case basis after careful evaluation of the possible risks and benefits (including risks and benefits of alternative options).

Patient-Controlled Epidural Analgesia

There is currently considerable interest in attempting to combine the potent analgesic effects of drugs delivered into the epidural space with the advantages of patient participation associated with the PCA concept. [178] [179] [256] [257] [258] [259] [300] [301] The technique involves epidural catheter placement in standard fashion, establishment of comfort with a loading dose (opioid, local anesthetic, or both), setting of the PCA pump to define the size of patient-activated bolus doses and lockout interval between doses, and usually a continuous background epidural infusion rate.

Patient-controlled epidural analgesia (PCEA) based on morphine has been described by several investigators. Chrubasik et al [257] compared the effectiveness of several epidural opioids administered on demand. They found that the self-administered dose of morphine required to provide analgesia was significantly less than amounts required by continuous epidural infusion or by intravenous PCA. Sjostrom et al [259] also reported the use of morphine via PCEA (bolus, 1 mg; lockout 30 min). Average utilization was 0.5 mg/h. Walmsley [278] reported effective and safe PCEA morphine in more than 4,000 postoperative patients using a 2- to 3-mg loading dose, bolus dose of 0.2 mg, lockout of 10 to 15 minutes, and continuous infusion of 0.4 mg/h. The maximum dose was limited to 1.2 mg/h.

PCEA fentanyl has been used successfully. However, some investigators have shown that drug requirements, pain levels, and plasma fentanyl levels were no different when compared with intravenous PCA fentanyl administration. [279]

Hydromorphone as a PCEA opioid is reported by some therapists. [272] [276] Drug requirements following cesarean section were 4- to 5-fold less than in patients receiving intravenous PCA hydromorphone. [272] Additional observations included more rapid return of bowel function and a shorter hospital stay.

Although PCEA appears to have great future potential, there has been little systematic comparison of different drugs and dosing regimens. There appear to be almost as many formulas as there are publications on the subject, and many of the clinical reports to date relate to use of the technique in obstetric patients. Considerable further research will be needed to establish criteria for patient selection, optimal drugs or drug mixtures, and PCA pump settings. Table 69-8 includes a few examples of the many recommended protocols. Dose schedules are generally those recommended for use through lumbar epidural catheters. Doses should be reduced when a thoracic epidural catheter is used.

Combined Spinal-Epidural Technique

Combined spinal-epidural analgesia/anesthesia has become popular in obstetrics (Ch. 57) and has also been used in the operating room setting. With this technique, an epidural needle is first placed in the epidural space. A small-bore spinal needle is then advanced through the epidural needle until the subarachnoid space is entered. An intrathecal dose of opioid and/or local anesthetic is injected, and the spinal needle is removed. Finally, a catheter is threaded into the epidural space prior to removal of the epidural needle. It has been claimed that an advantage of the spinal-epidural technique in the operating room is rapid onset of surgical anesthesia obtained with an initial subarachnoid local anesthetic injection followed by the

TABLE 69-8 -- Examples of Patient-Controlled Epidural Analgesia Regimens [a]

DRUG	CONCENTRATION	LOADING DOSE	INCREMENTAL DOSE	LOCKOUT (min)	CONTINUOUS INFUSION/h
Morphine	50 mug/mL	2-4 mg	100-200 mug	10-15	300-600 mug
Hydromorphone [b]	10 mug/mL	0.5-1.5 mg	20-30 mug	6-8	80-120 mug
Fentanyl	5 mug/mL	75-100 mug	10-15 mug	6	30-75 mug
Sufentanil	2 mug/mL	30-50 mug	4-6 mug	6	5-10 mug
Meperidine	5 mg/mL	30 mg	30 mg	30	None
Bupivacaine plus fentanyl	0.625% + 2 mug/mL	0.5% bupivacaine	3 mL	6	6 mL

[a] Doses for use with lumbar epidural catheters; consider reductions if thoracic catheters are used.
[b] Bupivacaine 0.031% was added in most cases.

availability of an epidural catheter for ongoing postoperative analgesia.

There are at least three significant issues relevant to postoperative analgesia in choosing this technique. First, when an initial spinal anesthetic is initiated, it becomes impossible to test the function of the subsequently placed epidural catheter adequately. A conventional epidural test dose of local anesthetic that contains epinephrine may help to exclude an intravascular catheter placement, but that test provides no assurance that the catheter will provide effective postoperative analgesia when it is needed. An untested epidural catheter in a surgical patient in severe pain can represent a real diagnostic and therapeutic problem.

Second, it is possible that the hole in the meninges produced by a spinal needle will increase spread of subsequently injected or infused epidural solutions. [302] If so, the risk of respiratory depression (from epidural opioids) or extensive block (from epidural local anesthetics) may increase.

Third, following an intrathecal dose of a hydrophilic opioid such as morphine, analgesia is likely to be present for many hours. When analgesia recedes, however, often in the middle of the night, alternative measures are needed, and the smooth transition from intrathecal morphine to another analgesic technique can be challenging. There is also potential additional risk because one may be faced with administering systemic opioids while substantial residual intrathecal effects are still present. This combination of opioid administration routes has been noted as a common feature in many of the reported cases of respiratory depression during intraspinal opioid therapy. With these issues in mind, it is the preference of the writer to avoid combined spinal-epidural techniques under most circumstances when superior postoperative analgesia is expected to be necessary for more than a few hours.

Role of the Anesthesiologist in Providing Intraspinal Analgesia

Whatever intraspinal agents are used, anesthesiologists offering intraspinal analgesia in the perioperative period should provide regular bedside assessment and should be prepared to meet the changing needs of individual patients. A list of suggested functions and responsibilities involved in meeting this obligation is presented in Table 69-9 (Table Not Available) .

Intra-Articular Analgesia

Small doses of intra-articular morphine have been administered in an attempt to provide analgesia following arthroscopic and other joint surgery. [303] [304] [305] [306] [307] [308] [309] From these conflicting

TABLE 69-9 -- Elements of Intraspinal Analgesia Daily Care by Anesthesiologists

(Not Available)

Modified from Ready et al [36]

reports, the presence of peripheral opioid-mediated analgesia remains controversial. Following arthroscopic surgery in outpatients, a combination of systemic ketorolac and intra-articular bupivacaine decreased analgesic requirements and pain. Ketorolac alone or in combination with bupivacaine did not alter the recovery time. [310]

Nonopioid Analgesics

Nonsteroidal Anti-Inflammatory Drugs

Although parenteral opioids have historically been the primary form of therapy for patients experiencing severe postoperative pain, in a number of studies this approach has been found to lack efficacy. Attempts to improve analgesia have included the addition of a second agent such as a phenothiazine derivative or hydroxyzine. The result has frequently been unwanted sedation and other side effects associated with the additive with little improvement in comfort. The concept of combining an opioid with a nonsedating, nonopioid analgesic is a simple form of multimodal therapy and has been used to advantage for many years in drug combinations available for administration by the oral route (e.g., codeine or oxycodone plus acetaminophen). Although a detailed discussion of the pharmacology of NSAIDs is beyond the scope of this chapter, brief reference is made to ketorolac tromethamine, an NSAID used primarily as an analgesic and the first injectable NSAID available in the United States.

NSAIDs act principally through inhibition of prostaglandin synthesis. Advantages over opioids include a reduction in opioid-related side effects, especially respiratory depression, absence of tolerance or addiction potential, and less sedation. Most evaluations of NSAIDs for postoperative pain relief have involved comparison with opioids in "either/or" protocols. With an improved understanding of perioperative pain and its consequences, there is growing emphasis on the advantages of combined pharmacologic approaches to therapy (i.e., multimodal therapy). [311] [312] Systemic opioids with centrally mediated actions and concurrent NSAIDs with peripheral sites of action appear to have advantages over either class of drug used alone.

It is unlikely that NSAIDs can completely replace opioids in most patients suffering moderate and severe postoperative pain immediately after surgery. [313] Under such conditions, NSAIDs are best considered as adjuncts to opioid therapy with benefits that include a reduction in opioid requirements. There is evidence that later in the postoperative period, as pain begins to subside, NSAIDs alone can provide adequate analgesia. In a single-dose comparison between intramuscular ketorolac and morphine postoperatively, it was found that both 10 and 30 mg of ketorolac were equal in analgesic effect to 12 mg of morphine on postoperative day 1 or 2. [314] In a comparison of intramuscular ketorolac 30 mg and morphine 10 mg for pain relief after cholecystectomy, it was concluded that, compared with morphine, ketorolac alone provided poor pain relief in the immediate postoperative period. The next day, the analgesic effects of the two drugs were similar. [315]

The concurrent use of PCA opioids and supplemental parenteral ketorolac after surgery has been reported. In a study of women using PCA opioids after abdominal hysterectomy, no difference in the incidence of common side effects was seen in a group who received ketorolac intraoperatively and postoperatively compared with controls. However, opioid requirements, time to return of bowel function, and time to hospital discharge were reduced. [316] Another study evaluated women using PCA morphine after intra-abdominal gynecologic surgery. Pain scores were comparable in each treatment group, but there was a ketorolac dose-related reduction in morphine use. [317]

As with all drugs, ketorolac may cause side effects. These include bronchospasm, [55] [318] gastrointestinal bleeding, [319] [320] alteration in platelet function and possibly associated perioperative bleeding, [321] [322] [323] [324] [325] [326] and impairment of renal function. [319] In balance, ketorolac and other NSAIDs can be used safely to provide perioperative analgesia by therapists who thoroughly understand the pharmacology of these drugs.

Nitrous Oxide

Under some circumstances, N_2O can be a useful (Ch. 4) analgesic, especially for acutely painful experiences of short duration. [327] [328] Examples include repeated postoperative dressing changes or superficial wound debridement. The low solubility of N_2O provides rapid onset of analgesia and rapid elimination on cessation of inhalation. N_2O in concentrations of 30 to 50 percent delivered through an anesthetic apparatus or a calibrated mixer is said to be as potent as 10 mg of intramuscular morphine.

Care must be exercised using N_2O in combination with other CNS depressants because "anesthesia" and its associated risks may occur. In particular, the risk of aspiration of gastric contents should be considered. With chronic administration of N_2O, bone marrow depression leading to leukopenia may occur secondary to impairment of methionine synthetase. This is reversible when detected early. Trace gas exposure of medical personnel can be minimized with scavenging devices attached to the N_2O delivery apparatus. N_2O use is widespread in the United Kingdom, where it is available as a commercial 50 percent mixture with oxygen (Entonox).

Ketamine

Ketamine was originally introduced as a dissociative anesthetic and has been widely used, especially in burn surgery (Ch. 9) . It has also been found to be useful in "subdissociative" doses as an analgesic. [81] [329] [330] [331] [332] [333] [334] [335] Suggested typical infusion rates are 3 to 4 mg/kg/h following an initial bolus of 1 mg/kg. Ketamine has been used in combination with morphine [336] [337] and self-administration of ketamine by patients has been reported. [336] [338] Epidural ketamine is discussed in an earlier section of this chapter.

Although systemically administered ketamine may have a place as a short-term analgesic, some concerns have limited its widespread acceptance. Little analgesia is possible without sedation and unpleasant emergence delirium, and hallucinations are common following both anesthetic and analgesic doses. Their incidence and intensity may be reduced

---

with opioid and scopolamine premedication, concomitant administration of physostigmine, or small doses of barbiturates, benzodiazepines, or droperidol. Ketamine may have a role in providing analgesia in patients with extreme degrees of opioid tolerance. [339]

Cryoanalgesia

Cooling peripheral nerves to temperatures between -5 and -20°C causes disintegration of axons and breakdown of myelin sheaths while the perineurium and epineurium remain intact. Interruption of conduction is prolonged, lasting an average of several weeks. [340] Recovery of function is dependent on the rate of nerve regeneration and the distance of the lesion from the end organ. A typical cryoanalgesia instrument includes a regulating system to deliver compressed gas (N_2O or CO_2) to a probe where expansion through a small orifice results in cooling. The probe contains a thermocouple and a nerve stimulator to facilitate nerve localization. Cryoprobes small enough to be used percutaneously are available.

Cryoanalgesia applied directly to intercostal nerves through the parietal pleura at the time of thoracotomy has been shown to be beneficial. [341] [342] The treatment resulted in less reported pain and fewer analgesic requirements. The pain that persisted was frequently not incisional, but rather was related to chest tubes. Lesions applied to the ilioinguinal nerves in patients having hernia repairs also reduced postoperative analgesic requirements. [343] Residual neuropathic pain has been seen following cryoanalgesia.

Transcutaneous Electrical Nerve Stimulation

Transcutaneous electrical nerve stimulation (TENS) (Ch. 70) , widely used to manage chronic pain, can also be used to provide perioperative analgesia. Advantages include absence of opioid-induced side effects such as respiratory depression, sedation, nausea and vomiting, and urinary retention. The technique is simple, noninvasive, and free of toxicity. An element of patient participation and control is provided.

Patients receive information and instruction in the use of the stimulator preoperatively. Using a stimulator that generates an asymmetric, biphasic wave form, initial settings for current output (range, 12-20 mA), stimulus frequency (range, 10-100 Hz), and pulse width (range, 60-150 mus) are selected to produce a vibrating, tingling, soothing sensation that itself is not painful. Immediately after wound closure, sterile adhesive electrodes are applied to the skin on either side of the incision. The wound is dressed, and the electrodes are connected to the stimulator. Stimulation is started using the predetermined settings, with subsequent adjustments on a trial-and-error basis to produce maximum benefit.

The mechanism by which analgesia is produced with TENS is not known. It may be the result of modulation of nociceptive impulses in the spinal cord as predicted by the gate-control theory postulated by Melzack and Wall, [344] activation of inhibitory reflex areas in the brain stem, [345] stimulation of the release of endorphins, or a combination of these and other mechanisms. A placebo effect may also play a role.

Although TENS remains promising, controversy exists regarding its efficacy in relieving perioperative pain, its effect on opioid requirements, and its ability to attenuate expected decrements in pulmonary function. [346] [347] It may facilitate rehabilitation after knee surgery, [348] and it has been reported to benefit patients with protracted ileus after abdominal surgery or trauma. [349] Complications are uncommon. Skin irritation from gel or adhesives at the electrode sites may occur, but it is rarely serious. The presence of cardiac pacemakers and pregnancy in the first trimester are considered contraindications by some clinicians. [346] TENS has been widely used for managing the pain of labor.

Perioperative TENS has been used for purposes other than treatment of incisional pain. TENS applied to the arms of women following total abdominal hysterectomy resulted in approximately 50 percent less vomiting compared with a group having an inactive TENS unit. The two groups were not significantly different after TENS discontinued. [350] Patients with high-intensity TENS reported a 50 percent reduction in mean pain levels compared with controls during distention shoulder arthrography. [351]

Psychologic and Other Methods

Following surgery, patients may suffer "discomfort" from causes unrelated to their incisions. Some of these causes may be physical such as headaches or sensations arising from nasogastric tubes, surgical drains, and intravenous catheters. Others may be the result of nonorganic causes such as anxiety, fear, or insomnia. Therapy for these latter problems can enhance patients' overall sense of well-being and, in some cases, may result in reporting of less "pain." One novel approach involved allowing postoperative patients to self-administer midazolam from a PCA pump. [153] [154]

Some studies have shown that psychologic support in the form of preoperative discussion, reassurance, and provision of information results in less anxiety, less opioid use after surgery, and a shorter hospital stay compared with control groups. [38] [39] [40] Relaxation tapes used by patients prior to surgery also result in reduced analgesic use and a smoother recovery. [352] Hospitals are usually designed for the convenience of the staff and sometimes leave patients feeling "depersonalized" and helpless. Measures that restore freedom, control, and participation in care, even involving simple self-care tasks, are likely to be beneficial. [353] The use of psychologic and other nonpharmacologic methods in combination with conventional analgesics is one approach to multimodal therapy.

PERIOPERATIVE ANALGESIA IN SPECIAL POPULATIONS

Pediatric Patients

As is the case for adults, the treatment of perioperative pain in infants and children may often be inadequate [354] [355] [356] (Ch. 59) . Misconceptions about pain in children are common. They include the belief that children do not feel pain, and that if it is felt it is not remembered. There is no

scientific basis for these attitudes. Pain causes suffering and physiologic abnormalities in children similar to those that occur in adults. This is also true for neonates [357] and for the preterm infant undergoing surgery. [358]

Compared with adults, pediatric surgical patients present some unique problems. In the neonate, safe methods for providing analgesia have been lacking. Opioid clearance is prolonged compared with older children, and infants are apparently more prone to opioid-induced respiratory depression. Because of developmental, cognitive, and emotional differences, the assessment of pain in pediatric patients can be more difficult. Special scales are available to assist young children in self-reporting of pain. In preverbal children, or in those who cannot or will not self-report, the interpretation of behavior must be used to estimate pain intensity. Frequently, these observations are unstructured and are open to misinterpretation. When clear evidence of pain is not seen, the tendency has been to assume that it is not present and to defer treatment.

Fear of needles makes intramuscular injection of opioids less acceptable to children than to adults. Children may choose to suffer in silence knowing that an expression of pain will result in a dreaded injection. In an effort to overcome these problems and to improve the quality of analgesia for pediatric patients, alternatives are being sought to the intramuscular opioid approach. Sublingual, rectal, and transdermal routes are under investigation. With availability of well-trained nurses and structured, medically supervised programs, many of the techniques now available for adults may have a place in pediatric populations.

Carefully titrated intravenous opioid boluses or infusions avoid unpleasant intramuscular injections and produce rapid pain relief, [359] whereas self-administration of small intravenous opioid boluses (PCA) has proved effective in children and adolescents. [360] [361] [362]

Epidural opioid analgesia using a caudal approach can be used to provide effective perioperative analgesia in children. [363] The risks and side effects of this technique are similar to those seen in adults.

Regional anesthetic techniques in some circumstances can offer effective and safe analgesia for pediatric patients after surgery. Dorsal nerve block of the penis or application of lidocaine jelly or aerosol spray provide comfort after circumcision. [364] Emla cream, in addition to providing postoperative analgesia, has been used to provide anesthesia for circumcision. Iliohypogastric and ilioinguinal nerve blocks performed with bupivacaine by the surgeon through the open wound reduce pain after herniorrhaphy or orchiopexy. [365] Infusion of bupivacaine through pleural catheters in children can be effective in controlling post-thoracotomy pain. [366] Other nerve blocks that have been effective after surgery in adults may also have applications in pediatric practice.

Parenteral [367] and oral [368] NSAIDs for postoperative analgesia in pediatric patients have been evaluated. As in adults, these agents are best considered as adjuncts rather than as primary agents for the treatment of moderate or severe postoperative pain.

Elderly Patients

Geriatric patients represent the most rapidly growing segment of the U.S. population (Ch. 61) . The chance of developing surgically treatable disease also increases with age. Thus, it can be expected that the average age of surgical patients will increase in the future and that a higher proportion of patients seen in an operating room will fall into the geriatric category.

Older patients facing surgery can generally be expected to have more complex cases than their younger counterparts. They have more systemic diseases (e.g., cardiac, pulmonary, endocrine), and usually those diseases have advanced to more serious stages. These patients may suffer disability, both physical and mental, and they frequently bring different attitudes and expectations about their treatment to the hospital with them. For example, some older patients are likely to be reluctant to play an active role in their own therapy, thus making some contemporary forms of analgesia (e.g., PCA, PCEA) ineffective. Communication in some elderly patients may present challenges. In the confused or speech-deprived patient, or in the patient displaying a high degree of stoicism, assessment of pain relief therapy becomes more difficult.

Physicians and nurses treating geriatric patients tend to have an unfounded level of fear of complications associated with treating perioperative pain. Although it is known that inadequate analgesia may delay recovery, the treatment of perioperative pain in the geriatric patient remains inadequate, even relative to younger patients. [369] [370] It is known that pain is reported less in the elderly. However, do older patients have a different pain threshold than young patients? Limited information derived under experimental and clinical conditions is available to address this question. [371] [372] [373] [374] [375]

It is well established that there is increased responsiveness to the effects of opioids in the elderly. This may mean that the risk of respiratory depression is increased. [51] The risk of nausea may not increase. [376] Increased sensitivity of older patients to systemic opioids probably involves both pharmacokinetic factors (changes in drug distribution) and pharmacodynamic factors (increased response at opioid receptor sites). Although the mechanisms causing differences in the elderly may be complex, the clinical implications are not. They include slow titration of opioids to allow for long circulation times, lower total doses because of increased sensitivity, and expectation of a longer duration of action because of reduced clearance.

NSAIDs may have benefits for some elderly patients after surgery just as they do for younger patients. These benefits include a peripheral site of action that may be more effective than opioids for some types of pain, opioid sparing when they are used in conjunction with an opioid, and an additional anti-inflammatory effect. However, elderly patients may also be at additional risk for side effects based on decreased renal clearance. It is therefore prudent to decrease the doses of NSAIDs in elderly patients as recommended by the manufacturers and also to limit the duration of use.

As discussed earlier in this chapter, dose requirements for epidural morphine [177] (and probably other opioids) are reduced. Possible reasons for these reduced requirements in older patients include increased responsiveness of spinal cord opioid receptors, higher CSF morphine levels, [377] decreased effectiveness of neural barriers, and overall decline in function of the CNS with age.

Regional anesthesia offers a number of advantages to many patients, particularly the elderly, during and after surgery. These advantages include minimizing physiologic trespass, pharmacologic simplicity, reduced blood loss, fewer thromboembolic complications, reduced endocrine-metabolic stress response, less confusion, and less postoperative pain. The response to local anesthetics in geriatric patients differs from that in the young. Most of these differences can be explained by progressive changes in the nervous system with age. Several clinical studies confirm that dose requirements for local anesthetics decline as age increases. [378] [379] [380]

In the elderly patient, postoperative delirium (POD) is a common complication associated with negative outcomes. [381] It is also a reliable marker for acute onset of underlying medical problems and possibly for underlying dementia. POD has been defined as a transient organic mental syndrome characterized by a global disorder of attention and cognition, a reduced level of consciousness, abnormally increased or decreased psychomotor activity, and a disturbed sleep-wake cycle. The main aspects of cognition, perception, and memory are all distorted, hence the term *global disorder.*

The reported incidence of postoperative delirium in the elderly varies between 7 and 61 percent. It appears to be more common after orthopaedic surgery than after general or cardiovascular surgery. It most commonly appears on postoperative day 3 or 4. Hallucinations are present in about 40 percent of patients and are commonly visual and frightening. Negative outcomes associated with POD include increased length of hospital stay, increased demands on treatment resources, poorer postdischarge functional outcome, and increased risks associated with patients' noncompliance with postoperative care. It is obvious that approaches to postoperative analgesia in the elderly that minimize the risk of POD have the potential to improve outcome. Many causes of POD have been identified, including a collection of metabolic, toxic, environmental, or infectious insults.

Patients With Chronic Pain and/or Chronic Opioid Use

Over the past decade, there has been an increase in the interest of anesthesiologists in the management of perioperative pain (Ch. 70) . However, as has been true in the past, many fewer in the specialty wish to participate in the treatment of chronic pain. Those who already manage perioperative pain realize that it is not always possible, even if it were desirable, to separate these areas of practice completely. Patients with underlying cancer pain commonly face surgery. The patient with chronic low back pain may require relief of surgical pain following a laminectomy. Such examples represent some of the potentially most complex and challenging patients the therapist treating postoperative pain will encounter. It is of practical importance to distinguish basic differences between acute and chronic pain (Table 69-10) . In particular, it should be noted that perioperative pain is usually of short duration and in general is appropriately and effectively treated with opioid analgesics.

TABLE 69-10 -- Comparison of Acute and Chronic Pain

ACUTE PAIN	CHRONIC PAIN
Signal of organic disease process	No useful function served
Cause usually obvious	Cause often unclear
Disappearing with treatment of the cause	Often unresponsive to many forms of therapy
Opioids typically indicated and effective	Opioids rarely indicated or effective
Usually no secondary gains	Secondary gains common

When perioperative pain is encountered in patients with underlying chronic pain, standard approaches to assessment and therapy may be inadequate. Although each patient is a unique human being, a number of general principles involving pain assessment and treatment can be applied: (1) expect high self-reported pain scores; these are common in patients with chronic pain; (2) base treatment decisions primarily on objective pain assessment (ability to deep breath, cough, ambulate); (3) recognize and treat nonnociceptive sources of suffering (e.g., provide an anxiolytic for anxiety); (4) and when opioids are used, continue them for as long as is appropriate for acute pain; avoid extended therapy if it is not appropriate for a concomitant chronic condition.

Any patient with chronic pain can be difficult to manage when acute pain is experienced. The difficulty can be expected to increase when, in addition, patients have been chronic users of opioids, whether for legitimate reasons (e.g., control of cancer pain) or for illegitimate reasons. Greatest difficulty can be expected in the street drug user who requires surgery. In dealing with chronic opioid use, several pharmacologic terms are commonly misused. This practice can lead to misunderstanding and inappropriate treatment decisions. The following definitions should be familiar to all therapists managing pain.

Tolerance is a pharmacologic property of many opioids (and other drugs). It can be defined as less susceptibility to the effects of the drug as a consequence of its prior administration. Clinically, in relation to the treatment of pain with opioids, tolerance is manifested as a pattern of increasing dose requirement to maintain a given level of analgesia. Special caution is needed in dealing with "incomplete cross-tolerance" seen in patients with cancer pain when one opioid is replaced with another. [382] After calculating the equivalent dose of the replacing opioid, therapy should begin with about 50 percent of that amount. The same caution is likely warranted in patients using substantial doses of opioids chronically for noncancer pain.

Physical dependence is another pharmacologic property of opioids characterized by the occurrence of an abstinence syndrome after abrupt discontinuation of the drug or administration of an antagonist. Although it is often associated with signs of tolerance, the emergence of a withdrawal syndrome alone is sufficient reason to use this term. The labels of pharmacologic tolerance and physical dependence do not imply the aberrant psychologic state or behaviors of the addicted patient. *Addiction* is a chronic disorder characterized by the compulsive use of a substance resulting in physical,

psychologic, or social harm to the user and continued use despite that harm.

Patients with a background of chronic opioid use may or may not be clinically obvious. [383] [384] The clinician should consider the possibility of these conditions when the following clinical triad is seen: (1) high self-reported pain scores compared with other patients having similar procedures; (2) high opioid use compared with other patients having similar procedures; (3) a relative absence of opioid-induced side effects. [385]

A number of principles can be applied to the treatment of perioperative pain in patients with chronic opioid use:

1. Recognize the need to identify and treat two major problems: maintenance of a basal opioid requirement and control of incisional pain.
2. Discuss the treatment plan with the patient early (before surgery, if possible); repeat it often.
3. Make it clear that the patient will receive basal opioid replacement unconditionally and irrespective of pain reports.
4. Add appropriate short-term therapy for acute pain.
5. Choose a non-opioid-based approach (e.g., local anesthetic, NSAID) to treat the acute pain whenever possible.
6. Expect high subjective pain scores. Do not rely on them to guide therapy.
7. Recognize that detoxification is usually not an appropriate goal in the perioperative period.

Is there a role for PCA in patients with chronic opioid use? Probably not for the purpose of providing basal opioid replacement. This is usually better accomplished by fixed oral doses or intravenous infusions controlled by the therapist. There probably is a role for short-term PCA in selected patients to provide extra opioids needed for postoperative pain. It is worth recalling that the central premise for successful PCA therapy is based on a simple assumption: that a feedback loop exists such that when pain is present, the patient will self-administer opioids; when pain is relieved, self-administration will cease. It is worth considering, on a patient-by-patient basis, whether this loop is likely to be intact. The advantages of placing "control" in the hands of opioid-naive patients with postoperative pain become liabilities if the basic loop does not exist. Under such circumstances, it is probably best to retain "control" of all analgesic administration in the hands of the therapist.

ROLE OF THE ANESTHESIOLOGIST IN PERIOPERATIVE PAIN MANAGEMENT

Anesthesiologists are a logical choice to provide perioperative pain relief. They are familiar with the pharmacology of analgesics and local anesthetics, are aware of the short- and long-term effects of drugs given intraoperatively, are knowledgeable about pain pathways and their interruption, and are skilled in techniques available to provide superior pain control. Management of postoperative pain by anesthesiologists can be professionally rewarding. Expressions of gratitude from patients free from pain can contribute to feelings of self-esteem and job satisfaction. Additional contact with patients, nurses, other physicians, and administrators helps to define anesthesiologists as valued consultants outside the operating room. Provision of perioperative analgesia is highly compatible with the emerging identity of anesthesiologists as "perioperative physicians."

PERIOPERATIVE PAIN MANAGEMENT SERVICES

Although dedicated individuals can improve perioperative pain control for a few patients, more comprehensive programs developed specifically to treat this problem can provide for the needs of all patients within an institution. Such programs, developed and administered by anesthesiologists, are now widely reported. [19] [20] [21] [22] [23] [24] [26] [27] [28] [29] [30] [31] [32] [34] [35] [386] [387] [388] [389] [390]

The organizational aspects of such comprehensive services are considerable but necessary for effective, safe care (Table 69-11) (Table Not Available) . In-service training for nursing staff is essential before the introduction of new pain-relieving techniques or equipment (e.g., PCA pumps, epidural analgesic infusions). Written nursing protocols and procedures, appropriate preprinted standard orders, and didactic and practical teaching sessions require time, but they are necessary for effective, safe care. Most hospital systems support nursing educators who can assist in this work. By involving nurses early and by inviting their participation in the development of a perioperative pain program, enthusiasm and support are likely to be strong.

Surgeons may be reluctant to allow other physicians to assume responsibility for pain management. Departmental

TABLE 69-11 -- Organizational Aspects of an Anesthesiology-Based Perioperative Pain Program

(Not Available)

Modified from Ready et al [36]

conferences and individual discussion are useful to inform them of the potential benefits to their patients of a perioperative pain service. To avoid potentially dangerous duplication, it is necessary to establish that all pain-related orders, including orders for sedatives, hypnotics, and other CNS depressants, become the responsibility of the pain service.

It is essential that human resources within an anesthesiology department are available at all times to provide coverage for perioperative pain management. The condition of patients after major surgery can change rapidly, requiring reevaluation of many aspects of care including pain relief. It is difficult to meet such needs if the individuals providing care are concurrently assigned to operating rooms.

When professional time is committed to a new clinical activity, financial compensation for that time must be considered. There is a strong medical tradition to support the concept that professional fees for services should be provided to specialists whose knowledge and skills are necessary to treat complex medical problems optimally. Just as critical care anesthesiologists collect professional fees for managing patients on mechanical ventilators after surgery, it is also reasonable to collect professional fees for perioperative pain management. It is the responsibility of those who treat perioperative pain to develop fair and reasonable charges for the care they provide and perhaps in the future to find creative ways to include perioperative pain management in comprehensive health care packages.

Various interactions characterize the daily operation of an in-hospital perioperative pain service. In addition to those already discussed, they include meetings with pharmacists, hospital administrators, suppliers of special equipment and drugs, health care providers, and government agencies. Additional details are contained in the ASA practice guidelines for acute pain management in the perioperative setting. [36] It is gratifying to note that in a survey of 500 institutions of 100 or more beds in the United States, 73 percent of respondents indicated that they had an anesthesiology-based acute pain service. [35] An international view of anesthesiology-based acute pain services is available to interested readers. [390]

Chapter 70 - Chronic Pain *

John C. Rowlingson
Terence M. Murphy

INTRODUCTION

Pain is a sensory and emotional experience associated with actual tissue damage or described in terms of such damage. [1] The blend of the physical and nonphysical components varies depending on whether the pain is acute or chronic in nature *and* with the patient in whom the pain is occurring. The patient's understanding of and attitude about the meaning of the pain influence compliance with treatment and its success. Acute pain is a signal of ongoing or impending tissue damage that provokes the patient to escape from the injurious event or seek treatment. [2] [3] This condition is now referred to as inflammatory pain. When pain persists in spite of therapy (and becomes chronic or neuropathic, in modern-day terminology), it loses its distinct signal function and is entangled by aspects of physical, emotional, and psychosocial disarray as well as neural imprinting that markedly influence its perceived severity. [4] [5] [6] [7] Chronic pain can linger even when the original source is gone because physical deconditioning, behavioral consequences, and/or neurophysiologic disruption may persist. A primary research focus now is the induced changes in neurophysiologic response based on alterations in neural threshold, chemistry, and modulation that are due to the adverse effects of the repetitive bombardment of the central nervous system (CNS) with nociceptive input. [8]

The protocol for patient evaluation must be systematic and thorough, it must encompass the physical and behavioral components, *and* it must respect the neurophysiologic mechanisms that are operative. Pain assessment with tools more scientific than the Visual Analogue Scale (VAS) remains a supreme challenge, as does outcome-based and evidence-based therapy. The wisdom that management of chronic pain demands the coordination of multidisciplinary input with attention to the psychologic, vocational, and rehabilitation aspects, as advocated by such pioneers as Bonica, Beecher, and Fordyce, has been repeatedly borne out over time. [5] [6] [9] This chapter aims to provide insight into the significant issues in the management of chronic (neuropathic) pain and to impart the modalities for treatment based on an appreciation for the rationale of their use.

Given the leadership of anesthesiology in raising awareness about the issues of (chronic) pain management and the enormous effort put forth over the past 5 decades to create pain clinics and pain-management centers as convenient instruments by which to incorporate and proliferate the practice of pain medicine, our specialty has created a certificate of special qualification in pain management. [10] Now, other specialties are recognizing the importance of pain medicine and are considering doing the same. In contemporary practice, not only has the academic domain of the anesthesiologist had to increase, but so has the respect for knowledge about business and practice management principles.

Even single practitioners who are contemplating "adding some pain management" to their practice face many significant challenges: how to gain access to patients with pain problems, how to blend their evaluation and management into the established practice of operating room-based anesthesia, how to prevent being overwhelmed by referrals and subsequent patient demands, and how to be available when questions and aftercare needs arise. These tasks become more daunting as the practice grows in size, the number of physicians and nonphysician health-care professionals and

---

This chapter was originally written by Dr. Murphy. As a tribute to his contributions to the field of pain medicine following his untimely death in 1996, his chapter has been updated rather than rewritten.

support personnel increases, the geographic area covered expands, and the complexity of the patients seen evolves. A pain-management center embodies the fundamental concept that patients with complex acute or chronic pain problems will be best served by a synchronized, integrated team of specialists who have different backgrounds. [4] [5] [6] [7] This structure is more likely to guarantee the comprehensive evaluation of such patients as well as to provide access to reputable, contemporary pain-management philosophy and techniques. It is from pain-management centers that new understanding about the nature of pain and pain-related behavior is being derived. It is important to consider information that is not only physical but also psychosocial, biochemical, ethnocultural, cognitive, affective, and environmental, as it relates to the patient. The data gathered need to be shared freely with all practitioners involved in the care of the patient because the multidimensional workup sequence *must* lead to an accurate diagnosis, one that encompasses the physical as well as the psychosocial contributors to the "pain." Only after achieving this objective can a realistic treatment prescription follow. Dworkin [11] has initiated a movement that identifies risk factors for patients to develop chronic pain.

In the United States, Bonica [5] calculated that as much as one-third of the population has chronic pain conditions, and the estimated annual cost of chronic pain in the United States was at least 80 billion dollars because of the millions of days of lost work, the costs of necessary health care, and the consequences of pain in terms of compensation and litigation. Headaches remain the number 1 chronic pain problem. [12] Back pain is ubiquitous in society and ranks as the second most chronic pain problem. [5] [13] It causes otherwise healthy, productive individuals to lose time from work, recreation, and family pursuits and contributes mightily to health care costs. Statistics reveal that approximately 10 percent of patients with acute low back pain complaints do not improve after 4 to 6 weeks, and a majority will redevelop symptoms within a few years. [13] [14] [15] [16]

MECHANISMS OF PAIN

Comprehension of "pain" is enhanced by appreciating the mechanisms for pain. Physicians have long understood acute pain because the tissue damage is usually obvious, such as a laceration or a broken bone, and the intensity of the pain is perceived to be correlated with the severity of the injury. [1] [3] Physicians readily acknowledge how various mediators are released at the damage site to initiate the blood clotting cascade, to activate the immune system, and to provoke the nervous system response. In the usual conception of pain, tissue-damaging or tissue-threatening stimuli send neurophysiologic messages directly from the peripheral receptors to the sensory cortex via specific pathways in the peripheral and central nervous systems. In this scheme, the greater the stimulation of the peripheral receptor, the more severe the pain. Experience and research indicate that this concept of such direct transmission of pain is naive, especially regarding chronic pain, and that the mechanisms are in fact much more complex. [1] [8] [17] Although specific pathways for transmission of nociceptive nerve impulses do exist (classically, A delta and C fibers) in peripheral nerves, it is now proven that when this information synapses in the dorsal horn of the spinal cord, it is modified, dampened, or augmented, depending on many factors existing within and outside the organism. [18]

Algesic mediators, such as serotonin, histamine, potassium, prostaglandins, and components of the arachidonic acid cascade, such as leukotrienes and thromboxanes, are released from tissues at *and near* the site of injury. Injury can be thermal (heat or cold), the result of direct noxious mechanical stimulation such as intense pressure, or chemical. Various kinins, such as bradykinin and neurokinin, are activated in plasma and substances in the nerves, such as substance P, are elaborated to influence the transmission of impulses from the site of injury to the CNS. The spinal cord is a site at which an extremely complex system of neurochemicals, interneurons (relay neurons), and neuromodulators interplays to determine what subsequent neural response will occur. Traditionally, C fibers (called C polymodal nociceptors because they respond to noxious thermal, mechanical, or chemical stimuli) represent a large number of fibers in peripheral nerves, are unmyelinated, transmit sensations that are perceived as dull, aching, burning, and poorly localized, have large receptive fields, and have input that does not fatigue or extinguish with repeated stimulation. A delta fibers (called high-threshold mechanoreceptors because they increase their firing rate with increased stimulus intensity) are myelinated. Thus, they transmit neural signals faster than C fibers, are associated with pain that is sharp, specific, and well-localized, have more specific representation on the skin (smaller receptive fields), and demonstrate lessening activity with repeated stimulation, although they can become sensitized and increase the frequency of their discharge.

When chemical mediators sensitize and/or stimulate the peripheral nociceptors, sensitization is said to occur. This implies that less stimulation will be necessary to trigger an adverse response in the nervous system. *Allodynia* is the term used to describe the phenomenon that a nonpainful stimulus provokes a painful response. [1] *Hyperesthesia* refers to the condition in which a lower threshold for nonpainful stimuli causes a response, and *hyperalgesia* means that a lower threshold to noxious stimulation provokes an enhanced pain response. [1] These conditions arise in the peripheral and central nervous systems when injury occurs, mediators are elaborated, and the consequences of the neural response become manifest at the dorsal root ganglion (DRG) and within the spinal cord. [18] These mechanisms are best studied in superficial peripheral tissues, but how they relate to pain from deeper tissues such as bone, joints, muscles, and visceral structures is not entirely clear. Free nerve endings, the stimulation of which triggers activity in A delta and C fibers, are present in all these tissues. Exactly how the sympathetic nervous system interplays with the somatic nerves is not perfectly defined. Further confusion comes from the reality that A delta and C fibers innervate visceral organs and travel with sympathetic afferent fibers, leading some to say that blockade of sympathetic afferent fibers blocks visceral pain. [19]

The DRG represents a passageway for much of the sensory input into the spinal cord. The DRG is subject to the enormous influences of chemical mediators, so sensitization and amplified responses are common even at this level. [20]

There can be a number of axon projections from one DRG into various levels of the spinal cord. Particular attention has focused on the layering of axon termination in the lamina of the dorsal horn of the spinal cord, the pharmacology of which is increasingly being determined. [18] Much of the A-delta and C-fiber input terminates in layers I, II (the substantia gelatinosa), and V. Peptides such as substance P, somatostatin, cholecystokinin, enkephalins, glutamate, aspartate, and vasoactive intestinal polypeptide (VIP) act as neurotransmitters; their release continues the propagation of the neural response *and* provides the opportunity for interruption thereof with selective blocking agents or antagonists. Wide dynamic range neurons (located primarily in layers I and V) are an important group of neurons in that they receive input from nociceptive specific *and* nonspecific afferent fibers.

When repetitive stimulation of dorsal horn neurons involved in the pain response occurs, the frequency of discharge can be shown with neurophysiologic techniques to increase. [2] [3] [21] This phenomenon is called sensitization or "wind-up." The clinical correlate is that less peripheral stimulation is required to activate a "pain response" in the nervous system. Thus, stimuli that are not normally painful, such as lightly stroking the skin, cause patients agony because the nervous system response is augmented by maladaptive changes in the processing of sensory input; the touch hurts *and* the pain lingers even after the direct stimulation is stopped because of the hyperirritability of the nervous system and the failure of the usual modulatory systems to dampen the reactivity.

What happens in the more central projections of the nervous system from the spinal cord is still not well understood. Input travels in the spinothalamic tract (STT) from laminae I, V, VII, and VIII and crosses the midline to ascend in the anterolateral quadrant of the spinal cord to nuclei in the thalamus and brain stem. [1] [8] Near the thalamus, the STT divides into a lateral portion, often called the neospinothalamic tract (which is associated with sensory/discriminative aspects of pain perception), and a medial portion, called the paleospinothalamic tract (which is associated with the affective/motivational aspects of pain perception). The paleospinothalamic tract has numerous synapses with the reticular formation of the brain stem, the medial thalamus, the periaquaductal gray matter, and the hypothalamus. Sensory input is processed in the thalamus and passes to the cerebral cortex.

Some contemporary therapy has evolved from the understanding of neural systems that descend from intracranial sites and that can exert a modifying effect on incoming noxious input. [1] [8] [22] That such sites existed was predicted by the gate-control theory of pain proposed by Melzack and Wall in 1965. [23] Many such sites, such as the periaquaductal gray matter, have high concentrations of endogenous opioid neurotransmitters. [1] [8] [22] These areas project to the rostroventral medulla and, via the reticulospinal tracts and the dorsal lateral funiculus, to laminae I, II, and V. Other neurochemicals such as norepinephrine and serotonin are implicated in these inhibitory/modulatory circuits. [8] This knowledge provides abundant opportunity for therapeutic interventions that provoke or intensify the descending modulating systems.

In the past, it was common to classify pain as acute or chronic. Contemporary nomenclature is more mechanism-oriented, and the terms now used are *inflammatory* or *neuropathic pain,* respectively. The implication is that chronic pain is more entrenched because it induces marked changes in the CNS. Previously, alternate terms included *central pain* and *deafferentation pain.* The newer term emphasizes the fact that contributory sources to the ongoing pain actually involve the neuroadaptive process, and it connotes the pervasive changes that occur within the nervous system to complicate the clinical situation: the induction of A alpha and A beta fibers to transmit nociceptive input, the utilization of neurotransmitters that are distinct from those involved in the acute pain response, an increase in receptive fields, remodeling in the CNS and the sensitization of the CNS by the constant bombardment with noxious input.

In its more refractory forms, chronic pain can be influenced by the intensity of the stimulus, the interaction between the stimulus and afferent modulating systems

within the CNS, and, most important, by a variety of behavioral and learned strategies that enhance/intensify or suppress the resulting neurophysiologic event. Thus, it is possible to have at one end of the spectrum a patient who has severe tissue injury yet who shows no sign of pain (i.e., the athlete, a soldier in combat) and at the other end a patient who has no apparent tissue damage or source of injury, yet is debilitated by chronic pain.

The modern-day concept that pain is a mixture of sensory and emotional phenomena precludes anyone from concluding that a patient's pain is "all in his or her head." [1] [4] [6] [6] [7] [9] [11] [24] In the past, this was termed *psychogenic pain.* This was said to be present when patients mislabeled psychologic distress, such as anxiety and depression, and described it using both the language and behavior of tissue damage. Although a peripheral nociceptive source may have existed, the core problem was deemed actually to be a psychologic event. It is creative now to hypothesize that many patients diagnosed as having psychogenic pain had genuine symptoms that only appeared to be exaggerated, when actually, the sensitized status of the neurophysiologic response was the explanation.

Psychogenic pain is *not* synonymous with the common behavioral aspects of acute and chronic pain. Pain is commonly communicated via behavior, because it is only by word, grimace, posture, and other such signals that we know that another person is in pain. [9] [11] For some patients, a precipitating nociceptive event results in appropriate pain behavior at first, but that behavior receives such reinforcement from the psychosocial environment that it persists beyond the healing of tissue damage and contributes to the generation of a chronic pain state. [9] In other instances, pain behavior may persist even when it is not directly reinforced because "well behavior" is aversive; that is, for some patients, normal social and occupational activities are perceived as not being possible, nor do the expectations of family, friends, and coworkers overcome the advantages of having chronic pain. These patients may be using a pain-based lifestyle as a rationale for the inability to cope mentally with the demands of work, recreation, or family activities. The management of pain due to mostly psychologic factors is profoundly distinct from that associated with obvious physical causes, so gaining as complete an understanding as possible about the origin of the "pain" is crucial. It is clinically useful to accept the reality that all pain, be it acute (inflammatory)

or chronic (neuropathic), involves physical and psychological factors, emphasizing again that the causes of chronic pain are complex. Thus, patients with chronic degenerative joint disease may become quite depressed at their inability to hold a job or to function domestically. Such depression could exacerbate nociceptive pain from joints injured by arthritis or trauma. In addition, an overly attentive and sympathetic spouse may reinforce "pain behavior" (i.e., by encouraging staying away from work, resting, assuming the invalid role). In this way, patients may add behavioral aspects to their chronic pain problems. These patients make more progress with therapy that not only is based in a conventional orientation, but also that avails them of additional psychological support, strategies to embolden coping with pain, and behavioral modification, all in order to help them regain more normal functioning.

EVALUATION OF THE PATIENT

From the outset, pain should be acknowledged to be a real problem for the patient. Challenging the authenticity of the patient's pain only provokes more dramatic pain behaviors that cannot help but to impede the diagnostic evaluation and the subsequent therapeutic milieu. The thrust of contemporary pain medicine is *not* to determine whether the patient has organic (real) or psychogenic (unreal) pain because the operative definition of pain now obviates the importance of this distinction. Equally true is that an exact source for every complaint of pain may not be discovered. Still, the patient should feel that the physician does believe that he or she has pain and is suffering. Suffering is not the same as "the pain"; rather, it is a composite of the patient's ability to accept the disease/diagnosis/condition and to cope with it or not. Because all practitioners who interact with patients who have chronic pain now endorse the vast influence that countless psychosocial factors can have on complaints of physical pain, [4] [5] [6] [7] [11] [25] patient evaluation by psychologists and psychiatrists is no longer a terminal event, obtained only after all medical technologies have been tried. This pattern of referral only fostered the opinion that the patient had "imaginary pain." This impression contaminated the productivity of the subsequent evaluation and provoked patients to continue to search for "the" correct diagnosis, maintaining the anguish of friends and family members and greatly increasing the cost of the chronic pain. Homage must be shown by recognizing that patients with chronic pain need (and deserve) a thorough and systematic workup.

Protocols for patient evaluation *must* include attention to factors that influence the patient's presentation of complaints and symptoms as well as compliance with therapy. The clinician must discriminate between those patients who need aggressive intervention and those who need time and observation. The disease of chronic pain involves far more than the physical factors of the original problem. Innumerable psychosocial factors come into play to complicate the evaluation and management of the patient. [4] [5] [6] [7] [25] For the patient, diminishing satisfaction and self-esteem become manifest because endless workups do not reveal "what's wrong," expensive tests fail to explain (or document) the intractable pain, doctors project suspicion about the frequency and intensity of the professed symptoms and alleged disability, and participation in vocational, recreational, and social activities declines.

The history of the pain must include information about the pain onset, location, radiation, quality, characteristics, constancy, and response to previous therapy, whether simple, such as ice or rest, or complicated, such as surgery or spinal cord stimulation. In patients with acute pain, this brief history, in addition to assessment of the general medical condition including such items as medications and allergies, plus findings from the physical examination, and the emotional reaction to this injury (worry, anxiety, frustration at plans being interrupted), may allow the establishment of a differential diagnosis and the choice of a likely diagnosis. When patients have chronic symptoms, the occupational, social, psychologic, emotional, past surgical, cultural, and economic realms of their life *must* also be investigated. [26] Given the enormity of this task, this portion of the history taking is best addressed with the use of questionnaires, whether manual or computerized. It may be advantageous to have the patient fill out this form before the actual office evaluation. Many patients appreciate the thoroughness reflected in the listing of questions and perceive that "here is someone who really understands and cares." A wealth of crucial information becomes available from the questionnaire in a familiar, systematic, usable format. Pain diaries and various scales of pain, distress, and suffering can be included. [27] Records about all the patient's previous episodes of pain and general medical condition should be reviewed. In so doing, one can gauge the magnitude of change in the patient's current signs and symptoms. Furthermore, these records facilitate the clinician's creation of a chronologic outline of the patient's complaints. This imposes an organizational pattern to the history taking and, most important, allows time for the patient to answer the doctor's questions genuinely. Patients are more satisfied when they believe that they were given a chance to "tell their story" to an unhurried, understanding physician. [28] The benefits of this crucial step in establishing an effective and resilient doctor-patient relationship are often incalculable. Therefore, the physician *must* develop an efficient information-gathering routine from which the essence of the patient's problems can be distilled.

Past records assist the clinician in a comparative way when they contain physical examination findings. The data from physical examination are largely subjective, meaning that they can be influenced by the patient's cooperation and motivation (emphasizing again the importance of comparison with previous examination results). In a patient with complaints of low back pain, for example, the patient should be observed for gait and the use of appliances while ambulating from the waiting room to the examination area. Limping, grabbing at walls, grimacing, and the use of canes or walkers are all observable behaviors that help the clinician to formulate an opinion about the intensity and the severity of the patient's complaints. The purpose of the examination is to define the correlation between the patient's complaints and the anatomic possibilities. It is important to remember that the back is a complex machine and rarely is one structure or tissue responsible for all the pain complaints. Tailored neurologic and musculoskeletal examinations confirm or refute the working hypothesis that the practitioner has formulated. Sensory and/or motor abnormalities in dermatomal

areas or in particular nerve distributions suggest a specific anatomic location of the problem. Avoid tests early in the examination sequence that are likely to cause the patient discomfort because the subsequent pain, muscle spasm, and guarding will influence the further cooperation of the patient. For purposes of thorough patient evaluation and for documentation for billing, the more complete the examination process, the better.

How much use to make of laboratory tests in a particular patient is a perpetual and contemporary challenge. Again, using patients with low back pain as an example, both the Quebec Task Force on Spinal Disorders and the more recent U.S. Agency for Health Care Policy and Research (AHCPR) Guidelines for acute back pain encourage little or no diagnostic testing for most patients for the first 4 to 6 weeks of symptoms. [13] [29] Rewards for financial conservatism in managed medical care clearly will elevate the significance of history taking and physical examination skills in the present day. Not accounted for in the AHCPR treatise on acute low back pain (which provides a general outline for the use of laboratory tests, and includes a "red flag" section) is the necessary sensitivity that must be shown to the patient in explaining the findings. As pain becomes more chronic, patients put more hope into a test providing "the answer" for the endless pain. Negative laboratory test results must *not* be presented with the implication that there is no real or significant pain. Laboratory findings have significance for the practitioner who is contemplating invasive therapies, because the results may indicate the presence of blood-borne infection, altered coagulation, metabolic disarray, metastatic disease, or anatomic perturbations. Deyo [30] predicted the difficulty in the evaluation of patients with low back pain by noting "... up to 85 percent of patients with low back pain cannot be given a definitive diagnosis because of the poor association among symptoms, pathologic findings and imaging results."

The clinician should be aware that even positive laboratory studies may not always explain the patient's pain. The patient with chronic pain experiences an expanding frustration with a triad of persistent symptoms (that are often perceived as disabling), changing physical condition, and nonrevealing tests. Thus, attention must be paid to the impact of myriad psychosocial factors that influence the patient's complaints. [4] [5] [6] [7] [9] [11] [25] This domain can be so influential that it is routine in pain medicine for patients to have a psychologic assessment and occasionally a psychiatric evaluation. The appropriateness of selected therapeutic interventions in a given patient, such as nerve blocks, surgery, or long-term opioid therapy, can be more accurately assessed when one entirely understands the patient's attitude about the pain, who he or she believes is to blame for it, the behaviors associated with the pain, the nature of lifestyle accommodations to the pain made by the patient, and the patient's very understanding of and beliefs about the pain. Accurate decisions about the need for neuropsychologic testing can also be made. Most patients with chronic pain do not manifest psychiatric illness. Rather, they experience frustration, despair, anger, anxiety, and depression as they try to deal with the impotence of the health-care system in diagnosing and treating their problem. [31] These feelings can be exacerbated by the compensation/disability system that scrutinizes patients severely and attempts to steal their independence and direct their every move. When previously supportive relationships become contaminated by the patient's chronic pain, self-esteem and self-confidence are replaced by innuendo and doubt. This patient benefits from concurrent therapy that restores his or her feelings of self-worth and the effectiveness of interpersonal skills while the important physical rehabilitation ensues.

/das/book/view/29494766/875/768.html

PRACTICE STYLES FOR PAIN MANAGEMENT

Once it was obvious that no single practitioner could or should be responsible for the comprehensive evaluation of patients with complex chronic pain syndromes such as complex regional pain syndrome (CRPS), headaches, back pain, and postherpetic neuralgia, the concept of coordinated practices emerged. The solo practitioner with only a referral network in his or her community may struggle to establish multidisciplinary alliances. Larger practices likely incorporate the necessary specialists in the same building, thereby facilitating access to each other and enhancing the cohesiveness of the practice. The facility may be freestanding or hospital based, and there are advantages and disadvantages to each style. [32] Pain centers associated with teaching hospitals have extensive programs with physicians and painmanagement specialists from every possible interest available, as are research opportunities and inpatient services. Inpatient services are expensive in terms of time and resources and may serve only a limited number of patients, yet they are necessary when advanced techniques for pain management, such as spinal cord stimulation and implanted intrathecal pumps, are becoming more prevalent. Additionally, inpatient care is excellent for patients needing concurrent drug therapy manipulation, extensive psychologic and/or behavioral therapy, guided physical therapy, and nonambulatory care while the pain treatment program benefits evolve. Those for whom outpatient therapy has failed and those who have such global life disruption and are entrenched in a detrimental home situation that they need to refocus their lives away from the pain also profit from inpatient care.

Outpatient patient therapy costs far less and theoretically puts the burden for improvement squarely on the patient's shoulders because he or she must cooperate with and apply the recommended treatment amid distractions in the home and work environment. On the other hand, activities of daily living such as driving and working can be incorporated into the therapy program and utilized while the patient continues to rehabilitate. Outpatient management demands that local and/or referring physicians be thoroughly educated about the patient's program and become actively involved in the implementation of the treatment plan so that a consistent ideologic approach is provided to the patient even when he or she is away from the pain center. The challenge of outpatient pain management to the physician is establishing a highly efficient, service-oriented office practice. [33]

Patients with chronic pain can stymie and frustrate their referring physician to the point of ineffectiveness. A comprehensive, second-opinion approach to referred patients becomes essential because patients who have been disappointed by uncertain diagnoses and unsuccessful treatment

---

also suffer with anxiety, depression, and desperation. The pain-center staff has an experienced attitude about such complex patients. Staff members apply established protocols for patient evaluation and generate a program of options for pain management that is continually upgraded and adjusted to meet the unique needs of the individual patient. The abundant and broad expertise available at a multidisciplinary center encourages the necessary consideration of emotional, psychosocial, family, and occupational consequences of the patient's pain, critical factors that can be overlooked in the chain of single, subspecialty evaluations. The comprehensive body of data obtained paves the way for the development of a treatment plan that addresses all aspects of the patient's "pain."

The primary care provider must discriminate between patients who need more time to heal and those who need a more thorough workup or referral to a pain center. Some would argue that the pain-center personnel should be the group that differentiates patience from the pursuit of more information. A practical problem is that patients may be viewed adversely early in their course as they act out the personal importance of their pain, or they may receive treatments that may be inappropriate. These adverse or negative experiences taint their consideration of similar therapy in the future, such as another surgical procedure or another nerve block, at a time when more inclusive modalities are also made available and greater appreciation of the extent of the pain problem is demonstrated.

As the practice plan is formulated, consideration must be given to both the medical mission and the business organization. The medical issues are perhaps the easiest to resolve. Physicians are familiar with record and laboratory review, history taking, and performing a physical examination. These data must be condensed into a cohesive differential diagnosis and a treatment plan. What most physicians find far more intimidating is winding their way through the essential business of medicine demands--marketing and advertising, defining the business mission statement and goals, creating a referral system receptive to the needs of the patients and their referring physicians, functioning as a provider of service, communicating with the patient's primary physician and other health care suppliers, maintaining a competitive identity, and being reimbursed fairly for the time spent and the services provided. [32] [33]

STANDARDIZATION OF FACILITIES

Attempts at establishing standardization of facilities and services represent a natural facet of the evolution of pain centers. The leader in this field has been the Commission for Accreditation of Rehabilitation Facilities. [5] As one could anticipate, there is an expectation for any pain center so accredited to match the standards of a rehabilitation facility, which not all pain centers necessarily strive to emulate. Therefore, other organizations, such as the International Association for the Study of Pain, have generated standards for interdisciplinary pain treatment units run by those of many specialties, such as psychology, psychiatry, neurosurgery, physiatry, and anesthesiology. The American Society of Regional Anesthesia has also created standards for facilities that are run primarily by anesthesiologists. By and large, all the standards address the following: the number of specialists involved in patient care; their experience, education, and degree of participation in the subspecialty of pain medicine, such as continuing medical education programs; the breadth of pain problems evaluated in the unit; the variety of therapeutic modalities offered; and the hours the facility functions.

TREATMENT OF CHRONIC PAIN

The aim of the treatment of acute (inflammatory) pain is to eliminate it and to return the patient to a premorbid functional level. [3] The practical goals of chronic pain management are effecting a maximal reduction in pain, helping the patient to cope with the residual pain, and increasing the patient's functional capacity. It is essential to respect the patient's expectations when presenting the treatment plan and to foster an appreciation of how "chronic" pain is entirely different from "acute" pain. When any of the available treatment modalities for pain management is applied in singular fashion, it may decrease the patient's chronic pain by a seemingly insignificant amount. If these same treatments are used *together* in a coordinated program, a significant reduction in chronic pain may be manifested. When clinicians avoid treating all pain in the same way and address the needs of the patient, successful management becomes more likely, as it will if the patient understands the rationale for the chosen therapy and is active in the treatment process. [4] Practitioners must acknowledge, however, that just taking the physical pain away does not instantly eliminate the environmental, cognitive, behavioral, emotional, biochemical, neurophysiologic, and social consequences of the chronic pain. [5] [6] [7] Because of the neuroadaptive changes, the treatment of chronic pain must continue well past the presumed healing period of the patient's injury. [8]

Just as the thrust in the evaluation scheme is multidisciplinary, so must the treatment planning for chronic pain be creative and expansive in consideration yet individualized in application. A limited-scope approach may deny the patient the combination of modalities necessary to achieve pain reduction. Advertisements make many common modalities sound miraculous, and a growing public interest in the alternative/complementary therapies encourages an open-minded attitude about any such therapy. Nevertheless, one physician's survey revealed that when treating low back pain, many physicians expressed "... ignorance or rejection of existing scientific evidence, excessive commitment to a particular mode of therapy or a tendency to discount the efficacy of competing treatments." [34] Guidelines such as those published by the AHCPR will help the practitioner in managing patients. [13] The Quebec Task Force on Spinal Disorders expressed the opinion that, after 3 months of conservative therapy or accumulated time missed from work, the patient with back pain should be sent to a multidisciplinary pain center. [29] The benefits of such a referral are documented by a number of authors. [4] [5] [7] [26] [29] [35] Flor et al [36] and Cutler et al [37] used meta-analysis to document that treatment at pain centers does restore the majority of patients with chronic low back pain to a greater functional status.

It is imperative that the health care professional discuss the conclusions from the assessment *and* the proposed plan

---

of action with the patient. A patient who understands why he or she is having pain and who helps to design the treatment program is more likely to adhere to the therapy. [38] [39] Von Korff et al [40] showed that patients with back pain who were *involved by education* in their care achieved equivalent therapeutic results but with *less* medication, *less* bed rest, and *lower* costs than a comparative group receiving more traditional conservative therapy. Treatment options can be divided into surgical and conservative categories. In the latter group are medications, stimulation techniques, complementary therapies, regional analgesic interventions, physical therapy, and psychologic strategies. Because chronic pain alters the neurochemistry of *both* pain transmission and nervous system processing of noxious information, valid complaints of pain can persist even when the original cause of the pain is gone. In pain treatment, this implies that the adaptive changes in the nervous system do not "heal" as fast as the primary generator.

Medications

Because medication prescription is so easy for the health care provider and so commonly expected by the patient, and because medications are so widely available, so simple to use, and so various in form and effect, medications are the most frequently chosen modality for pain management. Many preparations are available to patients in an over-the-counter form. Although mundane, it is fundamental to understand that medications are but one component of the more comprehensive pain-management plan. Their use can provoke annoying side effects or life-threatening reactions, so cautious choice must be guided by the identified mechanisms for the pain and appreciation for the patient's concurrent physical condition and medical history. [41] Primary analgesics do *not* effectively treat pain that has a strong psychosocial basis. Because chronic pain is a dynamic disease, and because responses to therapy as well as the patient's needs change, follow-up evaluation of the patient with chronic pain who is taking prescribed medications is essential.

Nonnarcotic Analgesics

For most chronic pain of nonmalignant origin, nonsteroidal anti-inflammatory drugs (NSAIDs) and acetaminophen are the most useful analgesics. [42] [43] Perhaps more important than the specific agent is the manner in which the medicines are administered. [41] For chronic pain problems unlikely to resolve within a short time, analgesics should be taken *before* the pain becomes a problem, rather than after. The original purpose of giving analgesics on an "as-needed" basis was to reduce the amount of medication taken. In fact, administration of medicine based on time rather than on symptoms usually results in less medication use and better pain relief. Therefore, analgesics such as the NSAIDs or acetaminophen should be taken at specific time intervals and on a regular basis without regard to the current intensity of the pain. For some patients, a once-a-day or a sustained-released preparation that minimizes drug-taking is preferred. On the other hand, some patients lack faith in such formulations, so alternating therapeutic doses of an NSAID with acetaminophen throughout the day is perceived as being more efficacious.

NSAIDs have potent anti-inflammatory properties and are very useful for bone pain associated with metastatic cancer. These drugs are readily available, mostly inexpensive, and do not generally create physiologic depression. They do have a ceiling effect. Common side effects such as gastric irritation and fluid retention can be troublesome, but complications such as gastrointestinal hemorrhage or renal failure are very worrisome. When NSAIDs are poorly tolerated or contraindicated, acetaminophen is an acceptable alternative drug that lacks the peripheral anti-inflammatory effects of the NSAIDs. It does block spinal hyperalgesia induced by *N*-methyl- D-aspartate (NMDA) and substance P. [44]

Opioid Analgesics

The narcotic analgesics have traditionally been sanctioned for use in acute pain because of its limited duration or for the pain associated with terminal malignant disease, for which such drug administration is also perceived to be relatively finite. [42] [43] Concern has been expressed that patients taking narcotic analgesics, especially patients with chronic, noncancer pain, will develop tolerance to the drug, the first sign of which is decreased analgesic effect from the same dosage. Increased dose requirements and, potentially, physical dependence result. The anticipated clinical situation is complete when drug-seeking behavior becomes a major problem of ongoing patient management. Unfortunately, in the early years of pain management, many patients with chronic pain had already become dependent on narcotics and/or sedative-hypnotic drugs before referral to pain centers, given the overemphasis on the use of these drugs by physicians who believed that they had little more to offer than ongoing prescriptions; thus, initial management also needed to include detoxification. [7] However, as the attitudes about the use of opioids as a *part of an otherwise comprehensive pain-management program* have liberalized, it has become obvious that a majority of *selected* patients can achieve a stable dosing regimen and do not routinely escalate their narcotic usage without a major change in the pathophysiology of the primary disease. [45] [46] [47]

In acute pain circumstances and when patients with otherwise stable chronic pain have a flare-up, NSAID therapy may not be adequate. Consideration is then given

to using opioids for pain relief. Practitioners fear triggering an investigation by regulatory authorities and/or being tricked by the patient who is abusing or selling the prescription drugs while seeming to continue such therapy. These pressures all too frequently result in the prescription of inadequate doses of opioids, if any at all. When the patient asks for more, drug-seeking behavior is suspected, and the opioid trial is summarily stopped. Fortunately, as pain medicine has developed and research has been reported, data show that selected patients can use opioids responsibly on a long-term basis and that physicians' attitudes about such use are changing. [45] [46] [47] Patients receiving opioid therapy should be carefully screened, and documentation of a change in their functional status while continuing these drugs *must be* reported at each follow-up visit. The use of a signed narcotic

agreement details the duties and responsibilities of both the prescribing physician and the patient. This arrangement does not eliminate all attempts at misusing this privilege, but it does clearly establish the guidelines for conduct and places ultimate accountability on the patient. The long-term administration of potent opioids in the absence of other therapy is usually unsuccessful in the management of chronic pain of nonmalignant origin. However, most pain centers have a number of carefully selected and functional patients whose pain seems best controlled by the long-term administration of narcotic analgesics in the absence of other options. [7] Guidelines for the long-term use of opioids are being created (see appendix to this chapter).

Although all narcotics are equally potent at equivalent doses (Table 70-1) , individual variation exists among patients, in that one narcotic may provide more effective relief than another. [42] [43] Undertreatment of cancer pain is *still* common because of inadequate knowledge about the drugs that are already available and their proper use, negative attitudes about patients who take or need "large" doses, state and federal drug regulations that intimidate the wellmeaning physician, and the costs of some medications. [48] [49] The World Health Organization (WHO) and other authorities offer that 70 to 90 percent of cancer patients should be able to achieve comfort through the judicious use of medications. [42] [48] The analgesic ladder method advocates titrating medications to effect: prescribing nonopioid analgesics combined with adjuvant analgesics for mild to moderate pain, then adding oral opioids for moderate pain, and finally administering narcotics "by the clock" for severe pain with permission also to use rescue dosing. [42] [50] This concept bases treatment more on pain intensity than using the most contemporary approach of treating pain based on its cause.

Narcotics have a specific and well-accepted role in the management of pain caused by advanced terminal cancer. [42] [43] [48] [49] [50] Morphine is the gold standard, and longacting oral morphine preparations are very useful for establishing a daily narcotic foundation on which fine-tuning with additional opioids or other therapy can occur. The oral route of administration is preferred because it is the most convenient and cost-effective. Collin et al [51] pointed out that apparent tolerance is more frequently due to progression of

TABLE 70-1 -- Analgesic Equivalents to Methadone

DRUG (TRADEMARK OR SYNONYM)	DOSE	
	ORAL (mg)	*INTRAMUSCULAR (mg)*
Methadone (Dolophine)	10.0	8.8
Alphaprodine (Nisentil)	--	45.0
Buprenorphine (Stadol)	--	2.0
Codeine	200.0	130.0
Diacetylmorphine (heroin)	--	3.0
Fentanyl	--	0.1
Hydromorphone (Dilaudid)	7.5	1.5
Meperidine (Demerol)	200.0	50.0
Morphine	60.0	10.0
Oxycodone (Percodan)	30.0	15.0
Oxymorphone (Numorphan)	--	1.5
Pentazocine (Talwin)	180.0	60.0
Propoxyphene HCl (Darvon)	260.0	--
Propoxyphene napsylate (Darvon-N)	400.0	--

the primary disease than pharmacologic acceptance in patients with cancer pain. The synthetic narcotic methadone has advantages associated with continuous oral administration including being inexpensive and well absorbed orally (in comparison with morphine), having a prolonged effect of 6 to 8 hours, and exhibiting a low side-effect profile even with ongoing use. When methadone is administered orally, four times a day, an excellent plateau of analgesia can be achieved. [52] [53] In some patients with cancer pain, opioids effectively treat the pain, but excessive sedation interferes with their desired participation in activities with family and friends. The combination of dextroamphetamine with narcotics has been claimed to provide better analgesia and to leave the patient more alert. [54] This combination or methylphenidate has been used with success as a means of combating the depressing effects of opioids in patients with terminal cancer. [55] Patient-controlled analgesia (PCA) technology may be used by patients accurately to identify the ideal 24-hour narcotic need, but such patients may require a number of days to become used to the concept of selfdosing, to overcome sleep deprivation secondary to intense pain, and to eliminate other drugs from their body. [42]

Transdermal Systems

There has been some clinical success in administering drugs through the skin. [56] This route has distinct advantages for patients whose gastrointestinal tract is nonfunctional, as in patients with cancer pain or those with sporadic dysfunction, such as patients with nausea and vomiting secondary to chronic pancreatitis. Transdermal fentanyl has achieved significant use, although most experience has been acquired with such nonanalgesics as scopolamine for motion sickness, nitroglycerin for angina prophylaxis, capsaicin for neuropathic pain, and clonidine for hypertension. [57]

Sedative-Hypnotic Drugs

In the past, sedative-hypnotic drugs (primarily the barbiturates and benzodiazepines) were administered frequently by physicians and were misused by patients with chronic pain. [7] The hypnotic effect of many of the drugs used is of relatively short duration, and the risk of physical dependency is well recognized. Prescribing practices have become more appropriate because of an increasing awareness of the hazards of these drugs and more so because of the abundance of knowledge about pain-management strategies that are much more effective. The antihistamines diphenhydramine (Benadryl) and hydroxyzine (Vistaril) in doses of 25 to 100 mg, respectively, may be more useful as sedative medications than long-term administration of barbiturates or benzodiazepines. [7] These antihistamines do not lead to dependency or withdrawal on discontinuation of the drug. Of the benzodiazepines, clonazepam (Klonopin) has a reputation for being the most useful in patients with chronic pain because of its chloride channel blockade. Indirect muscle relaxant drugs, which have sedative effects, may be prescribed to interrupt pain-initiated reflex muscle spasm. These same sedative qualities may limit the daytime use of these drugs, but they can be of benefit with evening dosing

to manage pain-related insomnia in a gentler way than stronger medications. Occasionally, the gamma-aminobutyric acid (GABA) agonist baclofen is prescribed in daily oral doses of 30 to 90 mg to achieve greater muscle spasm control, although it, too, can be sedating. [58]

Anticonvulsants

Neuropathic pain is caused by an area of damage within the nervous system that creates an additional pain generator to other, more external sources. [1] [7] [8] [18] The

consequence is that neural output resembles abnormal epileptiform activity on the sensory input side of the nervous system that requires specific drug therapy. Examples of neuropathic pain states are tic douloureux (trigeminal neuralgia), postherpetic neuralgia, phantom limb pain, and denervation dysesthesias. In these conditions, if a patient has pain in parts of the body lacking an intact nervous supply, such as occurs in paraplegia, amputation, and peripheral nerve injury, conventional analgesics and sedatives will provide little relief.

The most appropriate medications for neuropathic pain states seem to be the anticonvulsants. [8] [57] [59] In the past, phenytoin (Dilantin) and carbamazepine (Tegretol) were popular. A trial of phenytoin, 100 mg three times a day, was not uncommon. However, more refractory pain may require carbamazepine at initial doses of 200 mg per day. Because carbamazepine is a potent drug with significant side effects such as ataxia, disorientation, and nausea, the therapeutic dose is gradually obtained by increasing the dose by one 200-mg tablet per day to a daily maximum of 1500 mg. If distressing side effects occur, the dose is decreased to the previously well-tolerated level, is kept at this level for several days, and then gradually is increased again. This method precisely establishes the therapeutic dose, which, if administered initially, would have produced intolerable side effects. The drug also has a reputation for depressing hematopoiesis, and the patient should be advised to report sore throat or signs of developing anemia. Long periods of carbamazepine (Tegretol) therapy warrant periodic checks of hemoglobin, white blood cell counts, and liver function tests.

Contemporary pain management now centers around the use of new-generation anticonvulsants such as gabapentin (Neurontin) [60] [61] and lamotrigine (Lamictal). [62] These drugs have a milder side-effect profile and are well tolerated by most patients, even those taking significant doses of other medications. Sedation with gabapentin is minimized by gradual upward titration of the drug. Doses start at 100 mg three times daily. Lamotrigine (Lamictal) has a 10 percent incidence of skin rash, so the starting dose of 25 mg at bedtime is continued for a week of observation before the daily dose is increased. Intravenous lidocaine infusion also decreases central pain and provides good temporary relief. [57] Some patients subsequently respond well to mexiletine, an oral form of lidocaine, and other sodium channel blockers have been found to produce significant reduction in pain as compared with placebo. [59]

Calcitonin appears to have significant analgesic activity, [63] [64] although the mechanisms are not fully understood. Calcitonin's actions may involve the modulation of descending pain perception control pathways. It is used in the treatment of osteoporosis and has been demonstrated to have significant pain-relieving effects in those individuals with osteoporotic vertebral compression fractures, [63] as well as phantom limb pain and even reflex sympathetic dystrophy (RSD). [64]

Antidepressant Drugs

One of the earliest assumptions about patients with chronic pain was that they were depressed because depression seemed to accompany chronic pain. [4] [5] [6] [7] [11] [65] [66] Successful treatment of depression was found to be followed by pain relief. Tricyclic antidepressant drugs that blocked serotonin reuptake, such as amitriptyline and doxepin, gained a reputation for helping a significant percentage of patients who had chronic pain. [57] These drugs appear to be tolerated by most patients, and, in oral doses of 25 to 100 mg at bedtime (doses that do not necessarily treat depression), they often effectively modulate the pain complaints, improve mood, and provide a boost in nocturnal sedation in patients with pain-related insomnia. [67] The newer selective serotonin reuptake inhibitors (SSRI) most directly utilize increasing CNS serotonin as a specific therapeutic intervention. [57] However, not all SSRIs have been demonstrated to be effective adjunct analgesics. [68] Our contemporary understanding is that an effect on particular subclasses of serotonin receptors is the significant mechanism involved in the augmentation of analgesia by antidepressants. There is now a wellrecognized discontinuation syndrome associated with this whole class of drugs. [69]

Nerve Blocks

Nerve blocks are often highly successful in controlling acute pain, such as that related to trauma and surgery. [3] Enthusiasm for the use of nerve block therapy in relation to chronic pain has waxed and waned as the role of interventional techniques has come under repeated scrutiny in the search for scientific documentation of undeniable benefits. Caution about the interpretation of nerve blocks traditionally viewed as clearly of value has been raised most recently by Hogan and Abram. [70] Their contention is that few studies exist to verify or to substantiate the diagnostic or prognostic value of most nerve blocks because of the vagaries of anatomy, the varying strengths of the solutions injected, and the bias the practitioner has toward achieving a positive benefit.

Chronic pain states have multiple causes, [1] [4] [5] [6] [7] [25] [71] and it is intuitive that nerve blocks have their greatest therapeutic value in pain problems in which nociceptive stimulation dominates. When chronic pain results from behavioral or psychiatric problems, a nerve block is unlikely to relieve symptoms because there will be multiple, more significant, nonsomatic contributions to the "pain," and one should be concerned about the high possibility of inducing complications that are at least perceived to be related to nerve block therapy. Establishing the source of a pain generator is crucial to appropriate, effective pain treatment. Nerve blocks may be used diagnostically to determine whether an afferent nociceptive stimulus exists and perhaps can aid in establishing which neuropathways are involved. [72] [73] When such information is at hand, prognostic nerve blocks may predict

whether surgical or neurolytic or thermal (radiofrequency [RF] or cryotherapy) interruption of the specific nerve path would be warranted or whether a series of therapeutic nerve blocks should be undertaken. These interventions are exceedingly common and run the gamut from simple infiltration of myofascial trigger points to injection of alcohol or phenol into a major nerve plexus for relief of pain, as in terminal cancer. [72] [73] [74] As the subspecialty of pain medicine grows, the proper place for nerve blocks in patient management will be elucidated, as will the risks of acquired infection for practitioners. [75] As more nonanesthesiologists enter the field, greater emphasis will be placed on the use of treatment modalities other than nerve blocks, a change that will enhance the likelihood that the necessary comparative studies will be done.

General Principles and Patient Assessment

A workup of the patient must precede the use of any nerve blocks, because it is necessary to determine that there are no major medical contraindications to the application of such therapies (including blood-borne infection, infection at the proposed needle insertion site, major anticoagulation, or the patient's or surrogate's refusal). [72] Even when these objections are not found, the crucial question to answer in preparation for nerve block therapy is whether a nerve block is appropriate for *this* patient at *this* time. Just because one can provide the therapy does not mean that it is indicated. The patient must provide written, informed consent following a concise presentation of the risks and benefits and the rationale for the planned procedure. [72] The ability to manage the side effects and complications of any blocks performed is requisite for the safe practice of regional analgesia in contemporary pain medicine.

Because it is of little use to perform diagnostic nerve blocks on patients who have no pain on the day of the procedure, the patient should affirm the intensity of the pain on a verbal 0 to 10 scale, in which 0 equals no pain and 10 is pain so severe that the patient is desperate. [7] [26] Alternately, the patient could make a mark on a VAS. The conventional medical examination preceding any nerve block must include a neurologic examination with particular attention to documenting the preexisting sensory and motor deficits. [26] [72] Often, very nonspecific information is obtained from patients undergoing diagnostic nerve blocks. [7] For example, the response to minor inconveniences (positioning, fitting of the blood pressure cuff, placing an intravenous catheter) gives an important perspective on the patient's demeanor. Some patients describe their pain in dramatic tones and as being of incredible severity, yet they manifest florid pain complaints on assertion of a 25-gauge needle. They may also claim that this pain is more severe than the chronic pain they hope to have relieved. Conversely, patients who tolerate quite uncomfortable needling procedures with great stoicism also provide insight into the reserved nature of their complaints. Relevant studies, such as radiographs, may need to be reviewed, as will the records of any preceding interventional therapy. Large doses of analgesic or sedative drugs may interfere with the patient's feedback about the immediate benefit of the nerve block or a painful complication, so careful consideration should be given to medicating such patients.

Assessment of the response to nerve blocks is both subjective and objective. The rating of the pain on a VAS should be repeated after the block is done. One must relate any reported pain relief to the onset of analgesia and recovery of function in the blocked nerves to the drugs used. The practitioner should check both the dermatomal and myotomal extent of the nerve block and should assess the impact on autonomic function. [72] [73] The extended response of the patient to the nerve block (in addition to his or her verbal report) should be further accentuated by appraisal of changes in the functional activity level, sleep patterns, gait, and medication requirements. The duration of side effects of the nerve blocks should be noted, and the positive effects should be correlated with the subjective and objective results. Repeated nerve blocks, using agents of different duration, will help to confirm the validity of initial impressions about their benefit and to dispel concerns regarding a placebo effect. [76] One must be careful in interpreting the duration of clinical improvement following even short-acting local anesthetics because decreasing the degree of CNS sensitization may result in pain relief that exceeds the expected duration of the drug used. [1] [2] [3] [8] [21] In addition, blocks performed with plain local anesthetics may have profound effects even though the actual period of pain impulse transmission blockade is relatively short because the patient sees, finally, that something really can be done about the pain. With the patient's attitude so affected, benefit from and compliance with other therapy increase. Nerve block therapy is

rarely provided in isolation, so the patient's cooperation with other components of the treatment program must also be assessed.

Nerve blocks can confirm the presence or absence of nociceptive stimulation as the cause of pain and thus may give a clue as to whether pain originates from a peripheral site, the CNS, or psychologic/behavioral sources. [72] [73] Furthermore, nerve blocks can isolate the specific nociceptive pathway by showing that a specific nerve block, such as a median dorsal branch block for facet pain, [77] repeatedly abolishes pain. In this way, nerve blocks can be used in a prognostic fashion to suggest the effects of longer-term procedures such as RF denervation, cryotherapy, neurolytic blocks, or even surgery. Unfortunately, the satisfactory shorter-term effects of nerve blocks performed with local anesthetics are not always manifested when a more permanent nerve block procedure is done. Therefore, destructive nerve blocks are often reserved for carefully selected patients and those with terminal cancer. [74] [78]

The differential (or graduated) spinal anesthetic is of historical interest as a diagnostic tool in pain evaluations. This technique makes use of the fact that different concentrations of local anesthetics can almost selectively block sympathetic, somatic, and motor fibers. [7] [70] [73] [79] Investigators have used differential spinal techniques to diagnose common and obscure pain problems. On the other hand, differential spinal techniques are one of the best examples of the cautions raised by Hogan and Abram [70] concerning the absolute certainty of conclusions drawn from diagnostic and prognostic blocks.

Myofascial Pain and Fibromyalgia

Myofascial pain may be a primary cause of pain after injury to muscles, bones, or joints, or it may be a secondary consequence of pain from a distant site that causes subsequent postural alterations and stress/strain of muscles and supporting tissues over time. [80] [81] [82] Thus, myofascial pain may persist long after the original injury has healed and may be associated with referred pain. This condition must be distinguished from fibromyalgia; characteristic symptoms include complaints of widespread, chronic, nondermatomal musculoskeletal pain (described as being steady, deep, aching, and often associated with reflex muscle spasm), morning stiffness, decreased range of motion of joints, sleep disturbance, activity compromise, fatigue, and multiple areas that are tender. [80] [81] [82] This is a diagnosis made over time and generally without the aid of specific laboratory tests. The disease is characterized by exacerbations and remissions, and no single psychologic profile is associated with it. Criteria for diagnosis are published. [83]

Treatment is based on establishing a *program* of options and educating the patient about the mechanical factors that aggravate the symptoms, such as repetitive motions in unsteady positions. [81] Medications that decrease inflammation (NSAIDs), decrease muscle spasm (cyclobenzaprine, 10 mg tid; baclofen, 10-20 mg PO tid) and enhance stage IV, non-rapid eye movement (REM) sleep (amitriptyline, 25-100 mg PO qhs; sertraline 50-100 mg qd) are beneficial. Exercises that stretch muscles and then restore normal posture have the most lasting effect on the patient's life.

Myofascial Trigger Points

Trigger points are tender areas in the muscles or their supporting tissues that are believed to be caused by trauma from a specific accident or chronic occupational positioning, such as from typing or poor posture. [81] A trigger point can be found by applying pressure that reproduces the patient's pain, which may have a nondermatomal but consistent referral pattern. Several pain areas and trigger points may exist in the same patient, and there is great debate over how many trigger point injections should be provided at one visit and over time. On examination, [81] the painful areas have been described as feeling "rope-like." A positive "jump sign" is said to be present when the trigger point is palpated and the patient "jumps" away from the pain.

Anesthesiologists are frequently asked to perform trigger point injections at the site of maximal tenderness. [7] [81] Dry needling techniques without injecting any drug are said to be successful in relieving pain, a finding suggesting that mechanical stimulation of the trigger point may be more important than the actual injectate. [84] As with most chronic pain states, the earlier such intervention takes place, the better the prognosis. Topical application of vapocoolant spray can precede the actual injection of local anesthetics such as 0.5 to 1 percent lidocaine or 0.125 to 0.25 percent bupivacaine, or saline, all with or without steroids. [81] Follow-up evaluation of the localized analgesic effect is necessary. Trigger point therapy is relatively benign and well tolerated. The ultimate goal is to assist the patient in achieving analgesia such that they can participate in active and passive physical therapy.

Sympathetic Nerve Blocks

Sympathetic nerve blocks have been a traditional modality for diagnosing and treating patients with RSD and causalgia, [70] [72] [73] [79] now referred to as CRPS type I and type II, respectively. [1] The global term sympathetically maintained pain (SMP) has been coined to classify these problems for which chronic pain appears to be associated with sympathetic nervous system dysfunction. [1] This title then refers to syndromes that characterize the effects on the body (usually on an extremity) that are thought to be mediated by sympathetic nervous system dysfunction after trauma such as fractures, lacerations, ligamentous strains/sprains, infections, and surgical incisions or resulting from visceral or CNS diseases. No single theory has exactly explained sympathetic nervous system dysfunction after such varied injuries, and the pathophysiology of SMP is poorly understood. Roberts [85] proposed that input from myelinated lowthreshold mechanoreceptors (LTM) sensitized WDR neurons in the spinal cord, and this triggered atypical CNS processing of noxious *and* non-noxious sensations (allodynia). Eventually, sympathetic nervous system efferent activity can stimulate the peripheral sensory receptors in the absence of cutaneous stimulation. Raja et al [86] postulated that norepinephrine at the site of injury activates alpha$_1$ -adrenoreceptors on the nociceptive afferent fibers and/or causes the release of algesic amines (prostaglandin E, serotonin, and bradykinin) from reactive cells. There is evidence that nerve injury induces the acquisition of an abnormal excitatory response to the presence of norepinephrine in the periphery and at the level of the dorsal horn. This explains the lack of correlation between sympathetic tone and temperature, [87] why sympathetic blocks do not relieve all symptoms, and why sufficient blockade is so difficult to verify. [70] Harden et al [88] measured norepinephrine and epinephrine levels from the extremities of patients with SMP. Rather than reaffirming the traditional concept of sympathetic nervous system hyperactivity in the affected limb, they showed upregulation of peripheral nociceptors that manifested a pathologic response to *circulating* catecholamines. Other proposed mechanisms for SMP include activation of an inflammatory process in the sympathetic ganglion, the release of sympathotropic factors (such as nerve growth factor), increased vascular permeability, and a failure of the "usual" opioid modulation of regional sympathetic ganglia. [89] [90]

Clinically, the degree of inciting trauma bears *no* correlation with the severity of the SMP syndrome. RSD and causalgia are the two most common types of SMP. In RSD (CRPS-type 1), the history of a specific *nerve* injury is *not* always elicited (but *tissue* injury is common), and the original injury does not result in demonstrable neurologic deficits. The incidence of RSD following traumatic brain injury and stroke is in the 12 to 25 percent range, and the treating clinician should maintain a high index of suspicion when caring for such patients. [89] In causalgia (CRPS-type II), there is always at least partial nerve damage as the apparent inciting event. Common to the CRPS syndromes are burning pain, allodynia,

TABLE 70-2 -- History, Signs, and Symptoms of Complex Regional Pain Syndrome

CRPS type 1 (RSD)
Initial noxious event
Distal aspect of extremity involvement
Pain, allodynia, or hyperalgesia
Pain disproportionate to injury
Pain not limited to a single nerve
Associated edema, changes in skin blood flow, abnormal sudomotor activity
What is not CRPS type 1 (RSD)
Pain in an area of decreased sensation

	No cutaneous hyperalgesia or allodynia
	Pain only in a specific nerve distribution
	Proximal symptoms only
CRPS type 2 (causalgia)	
	Burning pain
	Allodynia
	Hyperpathia
	Hand and foot involvement
	Sequela of injury to nerve or major branch
	More discrete localization than type 1 CRPS
	Most common nerves: median, sciatic, tibial, and ulnar

CRPS, complex regional pain syndrome; RSD, reflex sympathetic dystrophy

and hyperesthesia/hyperpathia (which can be thought of as exquisite sensitivity to stimulation). Table 70-2 summarizes the pertinent historical findings, but much variation in patient description and physical presentation is common. The onset of pain after the injury is variable pain and can spread from an initial area of involvement in an extremity to the trunk and even to the contralateral limb. [7] Laboratory studies are frequently not necessary, and tests that detect alterations of blood flow may not be of essential use in the patient's workup or in the documentation of improvement with treatment. Sherman et al [87] showed that videothermography is not an appropriate tool to use alone for either singlesession diagnosis or multisession tracking of RSD. Because of the possible alpha-adrenergic chemosensitivity, 1-10 mg phentolamine given intravenously over 5 to 10 minutes may be useful in distinguishing SMP from neuropathic pain [86] and in predicting the usefulness of Bier block therapy. [91] A decrease in the VAS for *both* the ongoing rest pain and the evoked pain is necessary to view the test as predictive.

The most common treatment for the sympathetically maintained component of the CRPS syndromes has been to provide interruption of the apparent pathologic somatic-sympathetic interaction by means of sympathetic blocks, although the absolute rationale for this approach is challenged at least by consideration of the contemporary mechanisms for SMP. [70] [72] [73] [74] [79] A positive response to a block may relieve only some of the pain and indicates that the patient responded at that time. Treating the cause of the CRPS does *not* constitute its management. The therapeutic or diagnostic effect of the specific techniques of sympathetic blockade should not be confounded by additional sensory or motor block.

Stellate Ganglion Blocks

Because humans do not possess a stellate ganglion per se, the more accurate anatomic term is "cervicothoracic sympathetic block." [72] Up to 15 mL of local anesthetic is injected into the lower cervical sympathetic chain region at the C6 level. [7] [71] [72] [79] The caudad spread in the appropriate prevertebral fascial plane anesthetizes the lower cervical and upper thoracic sympathetic ganglia and effectively blocks transmission of impulses from the ganglia to the ipsilateral upper extremity. Ready et al [92] and Galindo [93] used a side-port needle for cervicothoracic block to ensure the stability of the needle and injection of drug into the proper tissue plane because in so doing one can keep the point of the needle in contact with the Chassaignac turbercle. Satisfactory sympathetic blockade results without the need to withdraw the needle from its bony end point.

Cervicothoracic blocks are usually performed using an anterior paratracheal approach with the patient in the supine position, but other techniques are described in Chapter 43 . The regional anatomy predicts the potential side effects and complications from both the needle and the drugs with these techniques. Spread of the solution into the groove between the esophagus and the trachea blocks the ipsilateral recurrent laryngeal nerve, leaving the patient with a hoarse voice for the duration of the local anesthetic effect. If the solution is administered deep to the prevertebral fascia, the local anesthetic will spread posteriorly and laterally and will involve the somatic components of the brachial plexus. Some or all of the roots of the brachial plexus may then be anesthetized. If local anesthetics are used, this is not a serious problem; however, if neurolytic agents are injected, this complication can be catastrophic.

A serious complication occurs when the local anesthetic solution is injected unexpectedly into the vertebral artery. The vertebral artery is posterior to the anterior tubercle of C6 and runs in the foramina transversaria in the transverse processes of the upper six cervical vertebrae. If the exploring needle passes between these processes and rests on the posterior rather than the anterior tubercle, withdrawal of the needle could leave the tip of the needle in the lumen of the vertebral artery. Small-volume injections (<1 mL) of local anesthetic solution into this vessel can produce convulsions. Therefore, careful aspiration is mandatory, and not more than 1 mL of local anesthetic solution should be administered as a test dose. [94] Treatment of a convulsion consists of oxygen by mask and/or positive-pressure ventilation plus the intravenous administration of a short-acting sedative-hypnotic, i.e., thiopental (Pentothal), midazolam, or propofol. Spread of the local anesthetic solution to the epidural and/or subarachnoid spaces producing profound anesthesia for a variable period of time is conceivable, although uncommon, as is motor blockade of the cervical plexus, leading to phrenic nerve paralysis.

Lumbar Sympathetic Blocks

As the sympathetic chain leaves the thoracic area, it lies alongside the lumbar vertebrae, anterior to the psoas major muscle and its fascia and posterior to the aorta on the left and the inferior vena cava on the right. Because of this positioning, the sympathetic chain can be successfully blocked from a posterior approach (Ch. 43) .

Figure 70-1 shows the approach for a lumbar sympathetic block. [7] In the traditional method, three needles inserted

Figure 70-1 Lumbar sympathetic block. This figure shows the relation of the lumbar sympathetic chain on the anterolateral aspect of the lumbar vertebral bodies to the large vessels and somatic nerves. Inset diagram shows how the needle must traverse and, in its final position, be anterior to the psoas major muscle and its sheath to block the sympathetic chain satisfactorily. If injections are made within the psoas major muscle, its sheath will prevent diffusion of the drug to the sympathetic chain, and somatic nerve block of the lumbar plexus will result. The 10-cm needle is introduced at an angle of 45 degrees, approximately 8 cm lateral to the cephalad end of the L3 vertebral spine, as shown in Figure 70-4 . The block can also be performed with a single needle at the L2 or L4 vertebral level.

at L2, L3, and L4 are advanced through the paravertebral space to the sympathetic chain. It is more common now to insert just one needle at the L2 or L3 level to produce an effective block. [7] [72] [73] [79] [95] This more lateral approach is often more comfortable for the patient (Fig. 70-2) . In the lateral approach, the needle is inserted 8 to 10 cm lateral to the L2 spine. [95] Through a local anesthetic skin wheal, the 10-cm, 22-gauge needle is advanced at a 45-degree angle toward the vertebral body. Injection of a 1-mL bolus of local anesthetic relieves the discomfort felt by the

Figure 70-2 Needle positions for lumbar sympathetic block and celiac plexus block. Although the specific site of entry for the needle may vary, the intent is for the point of the needle to reach the target area of the anterolateral aspect of the L2, L3, or L4 vertebra for the lumbar sympathetic block. The celiac plexus block is usually a bilateral maneuver in which needles approach the celiac plexus, which lies anterior to the T12-L1 junction, from either side. The lateral approach to a celiac plexus block is shown on the left. The needle enters below the 12th rib. An approach angling cephalad ensures correct placement. For lumbar sympathetic block, the needle is inserted as shown on the right at a similar distance from the midline, that is, four finger-breadths. Here, however, the approach of the needle is more horizontal.

patient as the needle passes through the lumbar fascia. As the needle advances through the psoas major muscle, paresthesia may occur in the distribution of the

lumbar plexus and usually over the anterior aspect of the thigh (the genitofemoral nerve distribution). If this occurs, the needle should be redirected until only the vertebral body is contacted. The needle is then withdrawn slightly, and the angle progressively increased until the needle is advanced and slips just anterolateral to the vertebral body. At this point and after an aspiration test is negative, a test dose of local anesthetic with radiographic dye is administered. When accurate location of the needle is confirmed, a 10- to 15-mL bolus of local anesthetic (0.25% bupivacaine or 1% lidocaine) is injected. The patient maintains the prone position to prevent the local anesthetic from tracking back between the origins of the psoas muscle and into the paravertebral space where the lumbar somatic nerves could be anesthetized, thus confounding the effect of the trial block. Extensive infiltration of local anesthetic during needle insertion can anesthetize components of the lumbar plexus (usually the L2 and L3 dermatomes and/or myotomes in the anterior thigh). The use of higher concentrations of local anesthetic can produce motor block and impairment of the ability to walk, necessitating supervision of the patient until this dissipates.

As in the cervicothoracic ganglion block, complications of the lumbar sympathetic block consist of spread of the solution to the neuraxis and somatic nerves (lumbar plexus) and unexpected injection of the solution into a blood vessel. [7] [72] [73] [79] [95] If the transverse process is mistakenly identified as the vertebral body, and a large volume of drug is injected then into the intervertebral foramen, an ipsilateral lumbar plexus block and/or epidural spread of the solution may occur. Therefore, concentrations of drugs that do not produce motor blockade should be used. If the needle is advanced so far that it is sitting in either the aorta or the inferior vena cava, injections of local anesthetic could easily produce systemic toxicity (Ch. 43) .

Neurolytic lumbar sympathetic blockade [74] [78] [95] has been recommended for persistent ischemia of the lower extremity and some forms of persistent pain, because the afferent pathways involved in such problems are believed to pass through the lumbar sympathetic ganglia. For neurolysis with 6 to 10 percent aqueous phenol or 50 to 100 percent alcohol, the needle position *must be* confirmed radiographically prior to injection. Small quantities (2-4 mL) of drug should be injected through two needles placed at L3 and L4, as opposed to the single bolus injection technique used in diagnostic and other therapeutic blocks with local anesthetics, to decrease the dose of neurolytic drug placed at any one site. Minor groin anesthesia occurs in about 8 to 10 percent of these patients for up to 3 to 5 weeks (genitofemoral neuralgia).

With sympathetic block therapy, a staircase pattern of improvement is sought with serial blocks with local anesthetics, meaning that pain is reduced more and for a longer period of time for each block. Wang et al [96] [97] have shown that not all patients treated conservatively or with blocks improve. If benefits are not progressive but have definitive, albeit temporary effects, consideration may be given to RF ablation or thoracoscopic or surgical sympathectomy. [74] Brachial plexus blocks or continuous epidural blocks with solutions of local anesthetics with or without opioids may enhance pain relief and may allow for concurrent physical therapy. The therapeutic benefit of the blocks will be enhanced if physical therapy is provided to restore range of motion and to improve functional recovery of the affected extremity.

Intravenous Regional Sympathetic Blocks

In 1974, Hannington-Kiff [98] produced prolonged sympathetic blockade by the intravenous regional administration of guanethidine. He wanted to provide sympathetic blockade for weeks at a time and to avoid repeated cervicothoracic or lumbar sympathetic blocks using conventional needle techniques. Regional intravenous administration of guanethidine was found to produce a 3-day sympathetic block of dystrophic pain of the upper extremity, whereas a cervicothoracic block with bupivacaine lasted approximately only 10 hours. Bonelli et al [99] reported similar lengths of sympathetic blockade with guanethidine. In another study, [100] reported pain and blood flow were significantly lower, and skin temperature was significantly higher, when this block was compared with placebo injections of saline. Because injectable guanethidine is not available in North America, nor is its replacement, reserpine, other drugs have been sought. Ford et al [101] and Hord et al [102] reported on the use of bretylium in an intravenous regional (IVR) technique. Poplawski et al [103] reported using an IVR technique with local anesthetic and 80 mg methylprednisolone (Solu-Medrol), and Vanos et al [104] reported the successful addition of 60 mg ketorolac to the injectate.

Because anesthesiologists practice pain medicine while providing sympathetic blocks, they should be aware of additional modalities that will enhance the patient's response to treatment: ongoing physical therapy, transcutaneous electrical nerve stimulation (TENS) over vascular channels, NSAIDs, oral steroids, alpha- and beta-adrenergic or calcium channel blocking medications, and self-regulation techniques. [105] Epidural clonidine infusion (10-50 mug/h) in patients who responded to a bolus injection was proposed by Rauck et al. [106] Neurostimulation techniques are showing success in some chronic cases, and implanted narcotic pumps are also finding utility in some selected cases. Topical treatment with Emla, clonidine, or capsaicin is being investigated further. The admixture between SMP syndromes and neuralgic pain suggests that some patients with chronic cases will need management as for neuralgic pain.

Celiac Plexus, Hypogastric Plexus, and Ganglion Impar Blocks

Celiac plexus block is another of the sympathetic block techniques that has been especially useful for patients with intractable pain due to cancer of the pancreas or other upper abdominal viscera. [72] [73] [74] [75] [78] [107] [108] [109] Successful block of the celiac plexus denervates the abdominal organs from the gastroesophageal junction to the splenic flexure of the large colon. Although permanent neurolytic blocks work well for cancer of the pancreas, they are much less successful for nonmalignant pain, such as that due to chronic pancreatitis, because the pain relief lasts only a few months. The technique,

more fully described in Chapter 43 , is strikingly similar to that for lumbar sympathetic block, except an additional 45-degree angle is used to place the needle at the level of L1 rather than at L2 or L3. Figure 70-2 shows the needle position for this block.

The most frequently encountered complication of celiac plexus block is postural hypotension. Because blockade of the vasoconstrictor fibers to the viscera hinders rapid compensation for changes in posture, blood pools in the viscera when the patient assumes the upright position. This problem is usually transient, lasting only a few days after neurolytic blockade. During this period, the patient must learn to assume the vertical position in a slow and deliberate fashion, because rapid movement can cause fainting. The spread of local anesthetic or neurolytic agent to somatic nerves is particularly pertinent because of the large volumes normally required for celiac plexus block. Spread of the agent to the upper lumbar nerves can impair motor power or hip flexion and the ability to walk. This complication is especially problematic if neurolytic agents are used with the technique in patients with nonmalignant disease. Therefore, neurolytic celiac plexus blocks require radiographic confirmation of correct needle placement before the injection of large quantities of neurolytic agents. Because of the proximity of the needle tip to the aorta and the inferior vena cava, aspiration tests and the administration of test doses are necessary to minimize the distinct risk of intravascular injection.

It is possible to perform celiac plexus blocks with alternative approaches to the classic prone position, such as with the patient in a decubitus position. [110] Montero-Matamala et al [111] claimed that the anterior approach is better tolerated by all patients, but in particular by terminally ill, heavily sedated patients and by all those who would have difficulty tolerating the lateral or prone positions. Ultrasound was used to locate the celiac arterial trunk. Claims are made that this technique is faster and more convenient than the lateral or posterior approaches and that a single-needle technique is sufficient. Jain and Ketchedjian [112] more recently wrote about the anterior approach. Boas [113] described a "retrocrural" technique for blocking the splanchnic nerves in an effort to improve the success with this block. Although these different approaches have been described, [114] there is no apparent difference with regard to pain relief. Most techniques appear to be safe when practiced appropriately, which usually means neurolytic procedures are done under radiologic control and with the use of a test dose with local anesthetic prior to the use of neurolytic agents through the same needle.

Sharfman and Walsh [115] challenged the efficacy of neurolytic blocks in patients with pancreatic cancer. The celiac plexus block is a percutaneous technique that interrupts afferent and efferent traffic in the celiac plexus. Brown et al [107] documented the definitive and sustained benefit of this technique when used in selected patients. They also showed that the incidence of side effects and complications was low, but not zero. Eisenberg et al [108] provided meta-analysis of the literature concerning neurolytic celiac plexus block. Eighty-nine percent of patients had good to excellent relief for the first 2 weeks after neurolytic celiac plexus block; partial to complete analgesia was maintained in about 90 percent of patients who were alive at 3 months, and 70 to 90 percent of patients surviving longer than 3 months continued to have partial or complete pain relief as well. The complication rate was 2 percent and included such incidents as intravascular injection, epidural or subarachnoid injection resulting in paraplegia, or needle trauma to the kidney, lung, or intestine. Side effects including localized pain at the injection site, diarrhea, and hypotension occurred as well.

There has been an awakening concerning the effectiveness of blocks of the sympathetic nervous system at many levels to provide cancer-related analgesia. An example is superior hypogastric plexus block. [116] [117] [118] This bilateral, retroperitoneal plexus is located at the L5-S1 area (the sacral promontory), close to the bifurcation of the common iliac vessels. It is the continuation of the celiac and lumbar sympathetic chains on each side of the vertebral column, and it innervates the pelvic viscera via the hypogastric nerves. The first description of blockade of this plexus was provided by Plancarte et al in 1990. [117] Twenty-eight patients with

cancers of the cervix, prostate, or testicle who had had a positive response to local anesthetic blocks were given 10 percent aqueous phenol under radiographic guidance. A mean decrease in pain of 70 percent was achieved, and additional therapy increased the analgesia to 90 percent reduction of pain, with these benefits sustained until the patient's death over the ensuing 3 to 12 months in 26 of 28 patients. There were no complications reported, although the potential exists for injury to sacral nerves, bladder or bowel perforation, incontinence, and intravascular injection. Others who have reported benefits with this technique include deLeon-Casasola [116] and Waldman et al. [118]

The union of the bilateral sympathetic chains into a single, retroperitoneal plexus (the ganglion of Walther or the ganglion impar) is located anterior to the coccyx at the sacrococcygeal junction. This can be blocked with local anesthetic and then with neurolytic agents to denervate the lower pelvic structures and the perineum. Plancarte et al [119] presented the first use of this technique in 16 patients with advanced pelvic cancer. From 70 to 90 percent pain relief was achieved in all patients, with a remarkably low incidence of side effects and complications.

Back Pain and Epidural Injection of Steroids

Back pain is a most common and complex type of chronic pain. [14] [15] [16] [29] [77] [120] [121] [122] [123] [124] Many chronic back and extremity pain problems are thought to arise from musculoskeletal sources. A subset of patients with low back pain will have phospholipase A_2 (PLA-2) leaked from the nucleus pulposus as a plausible explanation for their radicular pain. [125] Because it has been shown that corticosteroids can counteract the subsequent inflammatory reaction in the nerve roots and surrounding tissues, several investigators have injected steroids, with or without local anesthetic agents, into the epidural space. [126] The technique consists of injecting 40 to 80 mg methylprednisolone acetate (Depo-Medrol) or 25 to 50 mg triamcinolone diacetate (Aristocort) in 5 to 10 mL of local anesthetic or saline into the epidural space at the level of the suspected pathologic process. In the past, similar doses of steroids, but in smaller volumes of only 1 to 2 mL diluent, had been injected into the subarachnoid space when spinal pain was refractory to epidural administration.

This procedure fell by the wayside years ago when concerns about the tissue toxicity of the corticosteroid preparations was paramount. [127] [128] Subsequent research did not identify that the commercial preparations of corticosteroids are indeed toxic when injected into the subarachnoid space. [129] [130] More to the point, when one understands that radicular pain is believed to originate from inflammatory reactions in the nerve roots in the epidural space, the logic of depositing drugs in the subarachnoid space to manage this pathologic process is lacking.

The significant analgesic effect of epidurally administered opiates in postsurgical and trauma-related pain resulted in their addition to corticosteroids given in the epidural space to treat chronic low back pain more thoroughly. Although initial reports were enthusiastic, subsequent studies were unable to duplicate those results. [131] Intraspinal opiates alone can provide significant pain relief for chronic low back pain caused by nociceptive stimulation from the low back area. [132] Therefore, some patients with chronic low back pain may benefit from ongoing therapy with continuousdelivery systems for administering long-term neuraxial narcotics. The most stable location for the long-term perispinal delivery of opiates is the subarachnoid space, and contemporary therapy includes an intrathecal catheter attached to an implanted pump (after a positive response to a trial of percutaneous intrathecal injections with opiates has been documented). [77]

The true place of steroids in subarachnoid and epidural analgesic blocks is still not completely clarified. [126] Controversy rages with regard to this widely used therapy. Specific guidelines and indications are awaited. Neither the optimal number nor the volume of injections is known, nor is it established whether corticosteroids should be injected with or without local anesthetics or other diluents. Benzon [133] reviewed this controversial topic more than 10 years ago, and many of the essential technique-based queries remain unanswered. Steroids are probably best reserved for instances in which conservative therapy for acute radicular back pain has been ineffective after 4 to 6 weeks or when the patient is suffering a flare-up of chronic back pain that has radicular features. [12] [29] [72] [73] [77] [79] [124] [126] [134] Steroids are used by some clinicians for intra-articular facet joint injections. [77]

Neurolytic Nerve Blocks

Intractable pain of malignant origin may warrant nerve destruction with neurolytic agents by procedures other than those mentioned earlier. [43] [47] This is most commonly considered when life expectancy is short and when chronic pain has a malignant source. It is fair to admit that clinicians still do not have all of the data relevant to deciding the exact indications for nerve blocks or which patients need them and when. Clinicians must carefully select patients for neurolytic procedures, by considering their coagulation and immune status, and must be technically meticulous so as not to obviate the advantages of nerve block therapy (outpatient procedures with less risk than surgery, repeatability, ready availability, and decrease in the need for other therapies [135] [136] [137] [138]). Factors that should influence the decision to use neurolytic regional analgesic techniques include the patient's general medical condition, the location and rapidity of growth of the pain generator, the type of pain, the patient's life expectancy, the risks of the proposed procedure, the patient's tolerance for narcotics and previous conservative therapy measures, the response to a diagnostic block and the tolerance for any related side effects, and access to other specialists. The use of neurolytic blocks represents the ultimate in clinical judgment, rapport, and technical precision. Criteria that must be applied in consideration of such a procedure include a localized source of pain, pain that is diminished with a diagnostic block, pain that is poorly responsive to other more conservative therapy modalities, the absence of coagulopathy, the absence of localized infection or tumor at the proposed site of injection, the patient's tolerance for potential sensory/ motor/continence impairment, and the patient's understanding of the risks. [139]

Because peripheral nerve destruction with alcohol or phenol is frequently followed by denervation/dysesthetic (neuropathic) pain that may be as severe, if not worse, than the original pain, most anesthesiologists access the subarachnoid or epidural spaces for neurolytic injection. [140] The more extensive block provided by these routes of administration is often desirable because of possible growth of the tumor and a subsequent increase in nociceptive stimulation.

The relative merits of the different neurolytic agents are a matter of controversy. Alcohol and phenol are the most widely used agents. [7] The injection of alcohol is very painful, whereas that of phenol, which is usually mixed with saline or glycerin, is painless. The neurolytic effects of alcohol are more intense, and the effect with the block can be evaluated immediately. Phenol has a biphasic action, because it behaves both as a local anesthetic and as a neurolytic agent. Therefore, the extent of the block immediately after the procedure, which may reflect the local anesthetic action, decreases over the ensuing 24 hours to reveal a block of lesser extent. These blocks are not truly permanent; sensation and pain return within weeks or months. Therefore, these procedures are most often suggested to patients whose life expectancy is shorter than this time interval.

Somatic nerve blocks are performed with 50 to 100 percent alcohol, as are blocks of the sympathetic nerves. Alcohol is readily available and is easily stored. For peripheral nerves, 5 to 20 percent phenol is usually diluted with saline or water. For subarachnoid injection of phenol, it is mixed with glycerin (which makes its specific gravity greater than that of cerebrospinal fluid) for use in a hyperbaric technique.

Subarachnoid Neurolytic Nerve Blocks

Neurolytic subarachnoid blocks are best suited for patients with cancers involving the cranial nerves or for tumors involving somatic nerves lying between the limb plexus (i.e., tumors of the breast, chest, abdominal wall, or abdominal viscera). [140] For hypobaric subarachnoid neurolytic nerve blocks, the patient is positioned on the operating room table with the dermatomes to be blocked positioned uppermost. This configuration requires considerable finesse with positioning of the table and appropriate padding and other support to ensure patient comfort and stability during the block. If more than one spinal segment needs to be blocked, needles are inserted at the appropriate spinal levels. Small, discrete

aliquots (0.10-0.25 mL) of absolute alcohol are injected at each level until the desired analgesic effect is obtained. It is usually safer not to try to spread the alcohol over more than a single spinal level. When the desired analgesic effect has been achieved and correlated with appropriate dermatomal analgesia, the patient is left in this position for at least 20 minutes for consolidation of the block.

Hyperbaric subarachnoid neurolytic block is performed with phenol mixed in 10 percent glycerin. This mixture is not commercially available and must be prepared immediately before the block by the hospital pharmacy department. [7] Because glycerin is very viscid, wide-bore needles (18-21 gauge) are used for injection.

Positioning of the patient places the affected side down and the appropriate segmental levels in the most dependent position. The spinal puncture is performed at the appropriate level, and discrete 0.5 mL aliquots of the phenol-glycerin solution are injected until the desired pain relief and dermatomal analgesia have been obtained. As mentioned earlier, treatment of several segmental levels is accomplished more safely by using needles at each level rather than by injecting a larger bolus at a single level.

As an alternative to the traditional neurolytic agents alcohol and phenol, Korsten et al [141] demonstrated, in a small series of 12 terminally ill cancer patients with intractable pain, the effectiveness of a highly lipid-soluble congener of benzocaine, which appeared to afford satisfactory analgesia without creating compromise of motor or bladder/bowel function. Protocols for the clinical use of this agent are in development.

Epidural Neurolytic Nerve Blocks

Epidural nerve block is not widely performed using neurolytic agents. [72] [74] [140] However, epidural injection of 5 or 10 percent phenol in saline has been used successfully for some types of chronic cancer pain. This technique is particularly useful for bilateral pain and is not associated with major motor blockade; it therefore may be appropriate in the region of the limb plexus. It is difficult to detect any evidence of nerve deficits within a day or so of the block, although pain relief often persists considerably longer after this procedure. [7] This is a relatively safe neurolytic procedure, but it carries the theoretical risks of postinjection neuritis, excessive spread, and accidental subarachnoid placement with possible catastrophic paralysis.

Complications

The most frustrating problem with such procedures is usually failure to relieve pain after an apparent satisfactory block. [7] Involvement of nerve structures other than the intended neural elements can lead to unplanned sensory or motor deficits. [7] [74] [78] [107] [108] [109] [116] [140] [142] Thus, establishing the likely diagnosis for the cause of the pain and feeling confident that it can be approached with regional analgesic techniques will go a long way in avoiding these realities. In addition, many cancer pain patients use the intensity of their pain as an index of the activity of their disease. Thus, offers to eliminate the pain must be very clearly understood to guarantee satisfaction on both ends of the needle. Many cancer patients find comfort just in knowing what will be available when needed and will choose not to have all their pain relieved. One must be careful not to exchange tolerable pain for weakness, numbness, incontinence, and/or neuropathic pain. Sphincter disturbance is a very real concern with neurolytic blocks, especially those performed in the lumbar or caudal areas. [7] [140] Retention of urine with overflow incontinence is one of the most common complications. This condition is treated with an indwelling urinary catheter until such time as recovery occurs and the patient can be trained to urinate at regular intervals. These complications usually resolve with days to weeks. Obviously, patients must be thoroughly forewarned of the possibilities, informed consent must be obtained, and preexisting neural deficits must be documented. It is unlikely that a neurolytic block will eliminate all the patient's pain, even when the procedure is performed perfectly. Thus, a compassionate treatment program that blends medication and nonmedication modalities, as in hospice care, will still be needed [135] [136] [138] [143] [144] (Fig. 70-3) .

Neuraxial Administration of Narcotics and Other Drugs

The profound analgesia produced by administration of opioids at spinal cord receptors has led to tremendous interest in the clinical applications of this technique (Ch. 43) . Wang et al [145] initially demonstrated therapeutic feasibility using subarachnoid injections of morphine in patients with terminal cancer. Since then, increasingly sophisticated delivery systems have been used for providing such therapy. [135] [136] [139] [144] [146] [147] [148] It is possible that the patient will have the postoperative epidural catheter left in place so that analgesia can be provided on a continuous basis into the extended in-hospital recovery period or even after discharge from the hospital. [135] [149] [150] [151] Narcotics delivered by indwelling catheters can provide analgesia for patients on an outpatient basis, [152] so patients with terminal cancer can now receive pain relief at home, where home health practitioners provide an increasing array of sophisticated care options. The ability to tunnel these catheters subcutaneously so that they emerge at an anterior abdominal wall site has helped to make this application possible. Automated external and implantable pumps are now also available. [146] [147] [148] Morphine has been the most widely used drug for epidural administration of narcotics for chronic pain. The side effects of its long-term administration (pruritus, urinary retention, mental status change, respiratory depression) occur only rarely and are manageable in patients with terminal cancer. [139] [143] [146] [147] [148]

Hogan et al [153] studied the use of epidural opioids and local anesthetics in referred patients with cancer pain. Of 1,205 patients, these investigators identified 16 who needed perispinal drugs. Six of the 16 patients obtained relief with just morphine, whereas the remaining 10 needed local anesthetic added. Common components of an epidural infusion could include opioids, local anesthetics, clonidine, and, occasionally, steroids. [146] [147] [148] Local anesthetics have been suggested as adjuncts in most infusions for chronic pain because one generally wants to avoid inducing weakness, numbness, and/or postural hypotension, which are the primary pharmacologic effects of the drugs. When patients

Figure 70-3 A daily diary kept by the patient can be very helpful in determining the nature and cause of chronic pain. The patient records all daily activity (sitting, walking/standing, and reclining). The right side of the diary documents the time and doses of medication; and the last column, the level of pain (on a scale of 0 to 10). If pain "switches off" at night, as in this example, pain may well be caused by environmental factors, rather than tissue damage. In this patient, the record of medication does not indicate drug dependence. Also significant is the inordinate amount of downtime. Specifically, the patient is active for only 2¼ hours a day, the rest of the time being spent reclining or sitting. This fact suggests that a behavior-modification program to improve the level of activity would be appropriate.

show refractoriness to the opioid infusion, local anesthetics have been used to "rest" the opioid receptors and to restore their effectiveness during a brief hospitalization.

Detractions from epidural opioid infusions other than tolerance include the lack of expertise for initiation of such treatment and/or its maintenance in the patient's home area, the labor intensiveness of the follow-up care, and the cost. Sjoberg et al [156] [157] provided an important study that addressed the safety of long-term intrathecal injections of drugs for the treatment of refractory cancer pain. They detailed the neuropathic changes in 15 patients with infusions of morphine and bupivacaine for a median of 81 days (range, 4-274 d). [156] No patient had neuropathic changes correlated with the duration or cumulative doses of the intrathecal

therapy. This group also refined the recommendations about specific drugs one could infuse in patients with intractable cancer pain. [157] Fifty-three patients had VAS scores decreased from 6 to 7 of 10 to 0 to 2 of 10 during an infusion duration of 7 to 334 days while receiving a continuous infusion of morphine and bupivacaine in roughly a 1:10 ratio. Reported side effects were associated with bupivacaine and included urinary retention, paresthesias, gait impairment, and, occasionally, orthostatic hypotension.

The search for "new" analgesics will continue. DuPen et al [150] demonstrated the feasibility of combining morphine with low-dose bupivacaine to maximize analgesia even in a home-based setting. Steroids may be beneficial in decreasing the consequences of inflammatory neuropathy, as when cancer invades neural structures in the epidural space. Clonidine, an alpha $_2$ -adrenergic agonist, has become available for general use as a modality in neuropathic pain control. [154] [155] Through actions at presynaptic and postsynaptic alpha $_2$ -receptors of the spinal cord, 30 mug hourly can augment opioid-based analgesia with a low profile of side effects. [146] [147] [148] [154] [155] A central effect of benzodiazepines that is less dramatic for C fiber stimulation than it is for A-delta stimulation has been demonstrated, so these drugs may find utility in the future, as may NMDA antagonists, ion channel blockers, NSAIDs, and cholinesterase inhibitors. [147] Even with these valuable additions to the pharmacologic armamentarium, more modalities must be at hand. Unique techniques for regional analgesia other than neuraxial blockers, [158] [159] neuroablative procedures, [160] and neurosurgical treatments [161] [162] [163] represent such diversity.

Anesthesiologists have guided the subspecialty of pain management for years and have advocated the rational administration of drugs and the performance of nerve blocks to treat chronic pain. They have recognized, too, that other therapies are necessary. Because the treatment of patients with chronic pain has now become the practice of pain medicine, all health care workers must acknowledge the need for a treatment *program,* one that incorporates a number of therapeutic modalities (in addition to medications) used concurrently, regards all the discovered contributors to the "pain," and fosters routine follow-up so that the therapeutic plan can be

modified to include only those treatments that are contributing positively to the patient's quality of life.

/das/book/view/29494766/875/771.html

PSYCHOLOGIC ASPECTS OF PATIENTS WITH CHRONIC PAIN

Patients with chronic pain, who may have had unsatisfactory treatment at the hands of the medical profession, often interpret a referral for psychologic evaluation as an indication that their pain is "all in their head," "imaginary," or "not real." One may ask, how can a patient who is so desperate for improvement be closed-minded about any therapeutic option that has potential for diminishing some of the pain? It is vitally important to introduce patients (and family members) to the idea of psychologic evaluation at a very early point in the comprehensive evaluation scheme. [1] [4] [5] [6] [7] [9] [11] [25] [26] [38] The assessment aims to explore the breadth of the patient's emotional reaction range, identifies behaviors that are being reinforced, and investigates the reality of the patient's expectations about treatment. It may be optimal to accomplish both medical and psychologic evaluations simultaneously, as is most frequently done in contemporary practice. Patients with chronic pain cannot deny the presence of anxiety, depression, or frustration, for example, which they attribute to the agony of their chronic pain. (This testimony fulfills the operative definition of pain, that it is both a sensory and an emotional experience). The incidence of depression in chronic low back pain patients is approximately three to four times greater than in the general population. [164] [165]

Behavioral Analysis

Because of the influential importance of behavioral factors in many patients with chronic pain, a form of behavioral analysis by a clinical psychologist or psychiatrist should be considered. [9] [166] [167] Numerous formalized, standardized tests are used including the classic Minnesota Multiphasic Personality Inventory (MMPI) and the newer Symptom Checklist 90 (SCL-90). Behavioral analysis usually has little application in pain problems caused by acute tissue damage, except when the disruption of the patient's lifestyle provokes excessive anxiety or anger that obstructs therapeutic progress, or it occurs in a patient with preexisting chronic pain whose subsequent symptoms seem disproportionate to the injury or circumstances. The patient should have objective documentation of the relationship between daily activities and pain. This is frequently accomplished with the use of a diary, [26] which lists specific activities such as sitting, reclining, or standing and the accompanying level of pain as well as the nature and timing of medication (see Fig. 70-3) .

Behavioral evaluation should identify those factors that increase or decrease pain behavior. Evidence of how the patient has handled stress in the past and the presence of dependent personalities, external locus of control, or a tendency to misuse substances are established during this interview. Reinforcing factors that enable pain behavior are identified, as are patients who are blatantly psychotic and who thus deserve appropriate therapy directed at this significant aspect of their illness. [168] Patients with neuropsychologic deficits are identified, and proper action is taken.

When environment and behavioral factors are paramount in chronic pain, patients may benefit more from inpatient management, especially if dependence on medications is excessive, family members are strongly reinforcing pain behavior, or structured physical exercise is also necessary. [165] [166] [167] There is no evidence that chronic pain resolves with bed rest. [7] These three factors can be very difficult to attend to consistently on an outpatient basis. The primary goal of inpatient care is to reduce specific pain behaviors. This is a relatively easy goal to reach, particularly over the short term, and therapy often produces extremely effective results. [7]

Reduction of medications and an increase in physical activity are two very important goals of inpatient operant conditioning for behavior modification in patients with chronic pain. [9] [166] The difficult task is to substitute a "well-behavior" lifestyle for the previous pain-oriented lifestyle. A main goal is usually to increase the level of activity, because most people with chronic pain have considerable "down time"; that is, bed rest and inactivity have almost inevitably become part of the problem, rather than part of the solution. Most patients

---

with chronic pain are somewhat more mobile than implicated earlier and can cooperate with a graded aerobic exercise/conditioning program that is an integral part of most pain-management programs. Increasing endurance is a measurable parameter of behavioral change and can, in fact, be quantified. [169] [170]

Retraining the family is also vitally important. The family must learn to not reinforce pain behavior but to encourage nonpain behavior. [9] [166] The patient must be impelled to develop self-care and pain-coping strategies to deal with the pain more realistically. The patient will manifest less reliance on external resources and will begin to retake control of the pain when this is accomplished. Before attempting behavioral modification of a patient's pain problem, one should be sure that the desired behavioral changes are within the patient's capabilities. It is obviously inappropriate to attempt to rehabilitate an individual for a given task or skill if that person would be incapable of that activity even without the pain complaint. [7]

Pain-management programs contribute substantially to the rehabilitation of chronic pain sufferers, and there is evidence that the more intensive the program, the greater the improvement. [171] Objective measures such as activity and work status are desirable, whereas control groups left to rely on conventional medical support "languish or deteriorate." [171] Behavior modification programs using operant conditioning are very effective in reversing pain behavior, reducing dependence on medications, and decreasing use of health care resources. [7] [166] [172]

Disability Associated With Chronic Pain

Physicians who work in pain centers are often asked to rate the degree of disability in the case of injured workers. This is an exceedingly complex and controversial problem without easy solutions and one in which distress between medical and nonmedical issues is often intertwined. [173] One of the strongest predictors of developing disabling back pain on the job is work dissatisfaction. [174] Thus, pain and disability become woven; "it is hard to get well if you have to prove that you are sick." [175] Although often far removed from the anatomy and physiology of nociception, the issues of disability, such as wage replacement and job satisfaction, become pivotal in the assessment and management of disabled workers. [176] Because the data submitted on various physical capability forms are so crucial to the realistic rehabilitation of patients, completing such paperwork should not be done in a cavalier fashion. Many practitioners become certified in declaring disability or use the professional services of colleagues trained in the application and interpretation of functional capacity evaluation methods. Ergonomic evaluation analyzes the patient in his or her total work environment and is an additional, sometimes crucial, but often neglected, arena for investigation.

Biofeedback Techniques

Biofeedback is a self-regulation technique used for controlling normally unconscious or involuntary bodily activity, such as a heart rate, through conscious mental control. [12] [24] In theory, this goal becomes possible when some type of signal is used to make such activity perceptible to the individual's senses. Biofeedback has had its best results in the control of the muscle contraction component of head and neck pain and in migraine headaches. Muscle contractions are recorded with a surface electromyographic electrode, and the patient then learns how to make dial readings or tones change, reflecting a lessening of muscle contraction and, therefore, tension. For migraine headaches, the signal used may be the skin temperature of a digit. The patient learns to improve blood flow to the digits as manifested by a rise in local skin temperature while reducing headache symptoms.

Controversy exists as to whether biofeedback techniques produce better results than simple relaxation training. [12] [24] On the one hand, biofeedback does constitute a safe and benign therapy for muscle contraction conditions, head and neck pain, and migraine headaches and has a success rate of 30 to 60 percent. [7] On the other hand, biofeedback techniques alone are much less successful for low back pain and other pain syndromes, although many pain centers use the method as an adjunct therapy in patients with multiple pain syndromes. A critical review by Zitman [177] described the difficulty of evaluating current studies using this form of therapy and confirmed that relaxation training, because it is most easily applied and is less expensive, is probably the treatment of choice. Further critical evaluation may produce more selective recommendations regarding thermal and electromyographic feedback techniques. [178]

STIMULATION OF THE NERVOUS SYSTEM

Transcutaneous Electrical Nerve Stimulation

When great advances in the understanding of the mechanisms of pain were first being made, one of the earliest applications of this new knowledge pertained to TENS. [23] The use of stimulation techniques for the nervous system was originally based on the reality that hyperstimulation of the nervous system could "drown out" pain. [23] [179] [180] Our contemporary understanding acknowledges that stimulation may also provoke the outpouring of inhibitory neurotransmitters or may manipulate the normal physiologic inhibition or facilitation of afferent input. [179] [180] Stimulators consist of small, battery-powered, portable units that can be worn undetected under clothing (Fig. 70-4) . The corresponding stimuli are administered through flat electrodes applied to the skin. Because TENS has few, if any, side effects, it is highly recommended as an adjunct treatment for patients with chronic pain. The advantages of such therapy are numerous, but the fact that TENS is patient controlled (frequency and strength of stimulation, frequency of use, duration of use), noninvasive, and portable enhances its utility. As with other forms of stimulation-produced analgesia, such as acupuncture and massage, the TENS electrodes are usually placed near the painful area. The stimulators provide low-intensity stimuli of 5 to 200 Hz, which produces a tingling or vibration sensation. Transcutaneous nerve stimulators appear to work best in patients

Figure 70-4 One of the many transcutaneous stimulator units available commercially. Most units use a rechargeable battery pack. The electrodes consist of soft conductive rubber; they conform well to most anatomic sites of application, held in place by tape. Contact is facilitated by conductive jelly placed between the electrode and the skin.

with myofascial syndromes, peripheral nerve injuries, phantom limb pain, and stump pain. [7] These stimulators are less effective in low back pain and cervical spine pain, especially if the patient has had surgery. TENS appears to be unsatisfactory in patients with chronic pain that has no peripheral nociceptive cause (such as central pain states or psychosocial-based pain) and in patients with a physiologic and/or psychologic dependence on drugs. [7]

Many innovative methods to deliver electrical stimulation to the neuraxis and deep brain sites have been tried. [181] [182] [183] [184] The use of deep brain stimulation has been reviewed, and as yet the true place of this invasive technique for controlling chronic pain has not been exactly clarified. [183] Electrical stimulation of central brain-stem sites, such as the nucleus raphe magnus and the periventricular gray matter, can produce profound analgesia in both animals and human beings, but the relation of these findings to TENS is not well defined. Electrical stimulation of the dorsal columns of the spinal cord has now been virtually abandoned as an open, operative procedure. Dorsal column stimulation via percutaneously placed epidural electrodes is a technologic advance that is becoming more popular for patients with chronic spinal pain. [181] [182] [184] Careful selection of patients by their meeting specific criteria for both the implantation procedure and the trial period and by passing psychologic screening [185] can result in an admirable success rate in a group of patients for whom other, more conservative, therapies have not resulted in satisfactory analgesia or adequate return to functional status. North et al [186] established that the trial stimulation should decrease pain by at least 50 percent, decrease concurrent medication use, and result in a very low incidence of side effects. Other reviews echo the experience of most clinicians who use spinal cord stimulation in chronic pain management; mainly, that at best the success rate is approximately 40 percent over the long term. [184] [187]

Acupuncture

Acupuncture is a minimally invasive technique founded in Asian medicine that has neurophysiologic consequences probably related to augmentation of neural input or the provocation of modulating influences. [188] [189] A distracting focus of input is created by the insertion of needles into specific points around the body, as described in historical charts. Newer variations of the traditional technique that use needling of the painful area and sometimes add electrical stimulation through the needles are in vogue. Such treatments do seem to influence pain perception, but they produce relatively weak analgesia and may be more effective in acute pain than in chronic pain. The added expense and the need for a therapist make acupuncture less available than TENS as a therapy for chronic pain, yet the public demand for it and for the many complementary therapies is high. [190] [191] Studies have shown that headache frequency and analgesic consumption are significantly decreased during a course of both acupuncture and placebo treatments. [192] Reviews have been most critical of acupuncture, yet it has been endorsed by the National Institutes of Health for a few, nonpain applications (nausea and vomiting associated with pregnancy, chemotherapy, and the postoperative period) and postoperative dental pain. [193]

Neurosurgical Techniques

Surgery has been performed on almost every conceivable part of the nervous system--from peripheral nerves to the frontal lobes of the brain--in an attempt to control pain. [163] [194] Even though neurosurgical procedures often produce good pain relief on a short-term basis, as with other neurodestructive procedures, pain often returns over time. Therefore, neurosurgical ablation techniques may be best

reserved for patients with terminal cancer and, ideally, those having a life expectancy of only several months. Dorsal rhizotomies, much used in the past, do not consistently provide the desired long-lasting pain relief. Some cranial neuralgias resistant to carbamazepine arise from intracranial arterial compression of the trigeminal or glossopharyngeal nerves, for which operative relief of this compression has been successful in eliminating pain in some patients. [7]

Percutaneous Cordotomy

Percutaneous cordotomy has been used by several practitioners in specialized centers throughout the world. Although it requires special skills and equipment, it appears to be an effective way of interrupting the lateral spinothalamic tract of the spinal cord in which a majority of sensory input ascends to higher CNS levels. Although percutaneous cordotomy initially produces a 95 percent success rate in relieving pain, this rate decreases to 25 percent after 1 year. [7] [194] Therefore, as with most neurodestructive procedures, percutaneous cordotomy is more successful in the patient with terminal illness and a short life-span than in the patient with pain of nonmalignant origin. As with open cordotomy, it is difficult to produce analgesia in the cervical and upper thoracic dermatomes using percutaneous techniques. Postoperative mortality in percutaneous cordotomy, resulting from sleep apnea, occurs in fewer than 1 percent of patients having unilateral procedures but in as many as 10 percent of patients having bilateral procedures. Nashold et al [195] described a new technique for neurosurgical ablation of the dorsal root entry zone (DREZ) in the management of refractory deafferentation pain problems, such as nerve plexus avulsion. [196]

Deep Brain Stimulation

Over the past decade, invasive neurosurgical implantation of electrodes has been used by enthusiasts to treat chronic pain of both malignant and nonmalignant nociceptive origin with mixed success. [163] [194] In a large series of 141 such patients, pain relief occurred in approximately 30 percent. [183] Nociceptive pain is treated usually by stimulation of the periaqueductal or periventricular gray matter, whereas deafferentation pain is treated usually by stimulation of the sensory thalamus. In this series, greater success was achieved in patients believed to have a nociceptive source of pain. Long-term follow-up evaluation of patients undergoing deep brain stimulation indicates that 60 percent of patients with nociceptive sources do obtain pain relief, whereas fewer than 50 percent of those with deafferentation pain achieve lasting results. The rate of complications with this therapy was significant. [183] [194] As experience grows, fewer technical problems should occur while the exact place of this therapy in the armamentarium of pain management is clarified.

Neurolytic Surgical Procedures

Heat lesioning with RF techniques [194] [197] and cold lesioning with cryotherapy techniques [198] have been used to interrupt pain-carrying nerve fibers. Thermocoagulation of the gasserian ganglion has been most effective in the 15 percent of patients with trigeminal neuralgia who do not respond adequately to carbamazepine. [194] Because of its effectiveness and low incidence of side effects, this technique has replaced alcohol block of the gasserian ganglion for these refractory cases. The patient is thereby spared hemifacial numbness, with its conjunctival inflammatory problems. Most series attest to the benign nature of thermocoagulation, which can be repeated if necessary. RF lesions of the DRG of cervical nerves (C4, C5, or C6) in patients with chronic cervical neck pain have the expected 75 percent success during the first month or so after surgery, but pain recurs 3 to 9 months after treatment. [199]

Nerves can be "frozen" with a cryoprobe, [198] [200] the lesion of which disrupts sensory nerve functions for several weeks and may have a lower incidence of denervation neuralgias that often follow the destruction of nerves with neurolytic drugs such as alcohol. Cryoprobes have been shown to control the time-limited pain after thoracotomy. [201] They have also been used for control of chronic pain, mainly on superficial trigeminal nerve branches, and for lumbar facet nerves. [198]

SUMMARY

Because of the tremendous growth in interest in the disease of pain and its subsequent management and the proliferation of facilities for treating patients with pain, the opportunities and demands for clinicians in many specialties to become involved in pain management are increasing. Practitioners need not only technical ability in a variety of nerve blocks, but also the general diagnostic, management, and clinical skills necessary to provide ongoing care for these often complicated and difficult-to-manage patients. Traditionally, these skills have not been part of most anesthesia training programs, although increasing numbers of fellowship positions are now available that permit more formal acquisition of the necessary skills.

Wilson et al [202] stressed the importance of integrating clinical and basic science experience for medical students, but why be so limited in focusing on this group of neophytes? The blending of such data is important for all practitioners, to influence long-term clinical attitudes and to produce lasting changes in practice behavior in a state of affairs whereby health care providers (as well as students) perceive only the negative characteristics of patients with chronic pain, and believe that working with them is "too difficult." By introducing the students at an early stage in their curriculum to the known facts concerning acute and chronic pain and the treatment spectrum, one can develop an understanding that all pain is very real and can also convey the message that working with these patients can be rewarding. [202]

Currently, it seems that pain-management programs are the treatment of choice for those patients disabled by chronic nonmalignant pain. Although added expense is involved, such programs appear to be cost-effective because the alternatives of conventional therapy and repeated operations may be even more expensive. Clinicians' efforts in pain medicine should initially be directed toward prevention. When injury occurs, rapid remobilization of the injured

---

worker and identification of those patients destined to have chronic pain needing the long conservative therapy model are now appreciated. Because so many of the more chronic varieties of pain are accompanied by a significant array of nonphysical influences, it is unlikely that simple therapy for these long-standing entities will be discovered. Anesthesiologists should mobilize the analgesic and anesthetic resources and skills they have to maximize the control of pain at its onset while realizing that a comprehensive, diversified program of therapy is most likely to benefit the patient with chronic pain. Taking this leadership role will honor the rich tradition that anesthesiology enjoys and will propel the fledgling specialty of pain medicine in its natural evolution.

Appendix-GUIDELINES FOR THE USE OF OPIOIDS IN THE TREATMENT OF CHRONIC, NON-CANCER PAIN

THE MEDICAL SOCIETY OF VIRGINIA

Report of the MSV Pain Management Subcommittee

Preface

Recently, there has been increasing interest on the part of physicians, regulatory agencies, legislators, the public and patients for the proper diagnosis, timely workup and state of the art treatment for acute, cancer and non-cancer chronic pain conditions. While there is widespread agreement among health care providers concerning the treatment of acute and cancer pain with opioids (also known as narcotics)--as exemplified by Federal Clinical Practice Guidelines published by the Agency for Health Care Policy and Research, U.S. Department of Health and Human Services--there has been a lack of consensus, misunderstanding and hesitation among health care providers (physicians, nurses, pharmacists), regulatory agencies, patients and third party providers concerning the use of these same agents in the management of chronic, non-cancer pain.

Inadequate understanding about issues such as addiction, tolerance, physical dependence and abuse has led to unfounded stigma against proper opioid prescription. Fears of legal and regulatory sanctions or discipline from local, state and federal authorities often result in inappropriate and inadequate treatment of chronic pain patients. Undertreatment or avoidance of appropriate opioid therapy increasingly has been reported by physicians, patients, and other health care team members.

The discipline of pain medicine has produced a new awareness about the necessity of proper diagnosis, history and physical examination and treatment planning for the patient with chronic pain. Unfortunately, the paucity of specially trained physicians in the field of pain management often precludes patient access to specialized pain treatment facilities. The treatment for these patients will appropriately fall within the realm of the primary care or specialty physician. Until adequate guidelines are made for prescribers of opioids for patients with chronic noncancer pain, episodes of undertreatment of this deserving population will continue.

As a result of the efforts and recommendations of the Governor's Joint Subcommittee studying pain, the Medical Society of Virginia's House of Delegates, at the 1996 annual meeting of its legislative body, recognized the lack of national consensus as well as the need for parameters concerning the proper use of opioids for patients with intractable pain of non-cancer origin within the Commonwealth of Virginia. The following guidelines are presented with the hope that they will attenuate fears about professional discipline, encourage adequate and proper treatment of chronic pain with all appropriate therapies, and educate about and protect patients as well as the general public from unsafe or inappropriate prescribing patterns or abuses.

The Society believes that physicians have an obligation to treat patients with intractable pain and to lessen suffering and that opioids may be appropriately and safely prescribed for many acute, cancer and chronic pain conditions as long as acceptable protocols and standards are closely followed. The Society feels that physicians should be encouraged to prescribe, dispense and administer opioids when there is demonstrated medical necessity and proper indication for these agents without fear of discipline, excessive scrutiny or remunerative or restrictive legal penalties.

These guidelines should not be interpreted as absolute standards of care in the treatment of chronic pain patients, nor are they absolute directives for clinical practice. Rather, they are guidelines by which all physicians may more safely and comfortably evaluate and treat this very problematic and needy group of patients.

Guidelines for the Use of Opioids in the Treatment of Chronic, Non-Cancer Pain

For the purposes of this document the following terms shall have the following definitions:

Addiction is a disease process involving use of opioid(s) wherein there is a loss of control, compulsive use, and continued use despite adverse social, physical, psychological, occupational, or economic consequences.

Substance abuse is the use of any substance(s) for non-therapeutic purposes; or use of medication for purposes other than those for which it is prescribed.

Physical dependence is a physiologic state of adaptation to a specific opioid(s) characterized by the emergence of a withdrawal syndrome during abstinence, which may be relieved in total or in part by re-administration of the substance. Physical dependence is a predictable sequelae [sic] of regular, legitimate opioid or benzodiazepine use, and does not equate with addiction.

Tolerance is a state resulting from regular use of opioid(s) in which an increased dose of the substance is needed to produce the desired effect. Tolerance may be a predictable sequelae of opiate use and does not imply addiction.

Withdrawal syndrome is a specific constellation of signs and symptoms due to the abrupt cessation of, or reduction in, a regularly administered dose of opioid(s).

Opioid withdrawal is characterized by three or more of the following symptoms that develop within hours to several days after abrupt cessation of the substance: (a) dysphoric mood, (b) nausea and vomiting, (c) muscle aches and abdominal cramps, (d) lacrimation or rhinorrhea, (e) pupillary dilation, piloerection, or sweating, (f) diarrhea, (g) yawning, (h) fever, (i) insomnia.

Acute pain is the normal, predicted physiological response to an adverse (noxious) chemical, thermal, or mechanical stimulus. Acute pain is generally time limited and is historically responsive to opioid therapy, among other therapies.

Chronic pain is persistent or episodic pain of a duration or intensity that adversely affects the function or well-being of the patient, attributable to any non-malignant etiology.

Assessment, Documentation and Treatment

A. History and Physical Examination

The physician must conduct a complete history and physical exam of the patient prior to the initiation of opioids. At a minimum the medical record must contain documentation of the following history from the chronic pain patient:

1. Current and past medical, surgical, and pain history including any past interventions and treatments for the particular pain condition being treated.
2. Psychiatric history and current treatment.
3. History of substance abuse and treatment.
4. Pertinent physical examination and appropriate diagnostic testing.
5. Documentation of current and prior medication management for the pain condition, including types of pain medications, frequency with which medications are/were taken, history of prescribers (if possible), reactions to medications, and reasons for failure of medications.
6. Social/work history.

B. Assessment

A justification for initiation and maintenance of opioid therapy must include at a minimum the following initial workup of the patient:

1. The working diagnosis (or diagnoses) and diagnostic techniques. The original differential diagnosis may be modified to one or more diagnoses.
2. Medical indications for the treatment of the patient with opioid therapy. These should include, for example, previously tried (but unsuccessful) modalities/medication regimens, diverse reactions to prior treatments, and other rationale for the approach to be utilized.
3. Updates on the patient's status including physical examination data must be periodically reviewed, revised, and entered in the patient's record.

C. Treatment Plan and Objectives

The physician must keep detailed records on all patients, which at a minimum include:

1. A documented treatment plan.
2. Types of medication(s) prescribed, reason(s) for selection, dose, schedule administered and quantity.
3. Measurable objectives such as:
   a. social functioning and changes therein due to opioid therapy.
   b. activities of daily living and changes therein due to opioid therapy.
   c. adequacy of pain control using standard pain rating scale(s) or at least statements of the patient's satisfaction with the degree of pain control.

D. Informed Consent and Written Agreement for Opioid Treatment

Written documentation of both physician and patient responsibilities must include:

1. Risks and complications associated with treatment using opioids
2. Use of a single prescriber for all pain related medications.
3. Use of a single pharmacy, if possible.
4. Monitoring compliance of treatment:
   a. Urine/serum medication levels screening (including checks for non-prescribed medications/substances) when requested.
   b. Number and frequency of all prescription refills.
   c. Reason(s) for which opioid therapy may be discontinued (e.g. violation of written agreement item(s)).

E. Periodic Review

Intermittent review and comparison of previous documentation with the current medical records are necessary to determine if continued opioid treatment is the best option for a patient. Each of the following must be documented at every office visit:

1. Efficacy of Treatment
   a. Subjective pain rating (e.g. 0 & shy; 10 verbal assessment of pain)
   b. Functional changes.
      i. Improvement in ability to perform activities of daily living (ADLs).
      ii. Improvement in home, work, community or social life.
2. Medication side effects.
3. Review of the diagnosis and treatment plan.
4. Assessment of compliance (e.g. counting pills, keeping record of number of medication refills, frequency of refills and disposal of unused medications/prescriptions).
5. Unannounced urine/serum drug screens and indicated laboratory testing, when appropriate.

F. Consultation

Most chronic non-cancer patients, like their cancer pain counterparts can be adequately and safely managed by most physicians without regard for specialty. However, the treating physician must be cognizant of the availability of pain management specialists to whom the complex patient may be referred. The physician must be willing to refer the patient to a physician or a center with more expertise when indicated or when difficult issues arise. Consultations must be documented. The purpose of this referral should not necessarily be to prescribe the patient opioids.

G. Medical Records

Accurate medical records must be kept, including, but not limited to documentation of:

1. All patient office visits and other consultations obtained.
2. All prescriptions written including date, type(s) of medication, and number (quantity) prescribed.
3. All therapeutic and diagnostic procedures performed.
4. All laboratory results.
5. All written patient instructions and written agreements.

Summary/Concluding Remarks

The treatment of patients with chronic, non-cancer pain should not be limited to pain specialists only. Because of complex social, regulatory, ethical and legal issues surrounding the use of opioids in these patients, the physician who elects to help treat these patients may find it useful to utilize the guidelines and examples outlined in this document. While these guidelines do not define standard of care, it is the hope of the Medical Society of Virginia, working in close conjunction with the Virginia Board of Medicine, and the Commonwealth of Virginia's Joint Subcommittee to Study the Commonwealth's Current Laws and Policies Related to Chronic, Acute and Cancer Pain Management, that physicians who do treat this very difficult and deserving patient population will find significant clinical benefit from this document and will be enlightened by the suggestions offered herein.

This document is the product of the Medical Society of Virginia's Ad Hoc Subcommittee on the Treatment of Chronic Non-Cancer Pain and is the result of many

months of deliberation and study. Members of this committee were Stephen P. Long, MD, Chairman; John Barsanti, MD; Edwin Harvie, MD; Joanne Hudson, MD; Albert Jones, MD; Katherine Maurath, MD; Randolph Merrick, MD; John Rowlingson, MD; Paul Spector, DO; John Tietjen, MD; Thomas Wash, MD. Ex Officio members were Senator Jane Woods; Delegate Vincent Behm; Warren Koontz, MD (Executive Director, Virginia Board of Medicine); Karen Perrine, Esquire (Virginia Board of Medicine); Norma Szakal, Esquire (Division of Legislative Services).

Section 5 - Critical Care Medicine

Chapter 71 - Overview of Anesthesiology and Critical Care Medicine

Robert R. Kirby
Cheri A. Sulek
Michael J. Banner

INTRODUCTION

In October 1979, the Society of Critical Care Medicine listed 882 physician members, of whom 386 (44%) were anesthesiologists. By March 1984, 2,351 physicians were members, 643 (27%) of whom were anesthesiologists. In June 1988, the physician membership had increased to 2,835 and included 679 (24%) anesthesiologists. As of May 1992, the physician membership was 5,411, of whom 916 (17%) were anesthesiologists, and in 1996, physician membership was 6,905, of whom 1,150 were anesthesiologists (17%) (Table 71-1) . Thus, in absolute terms, the rate of increase of anesthesiologists in the Society of Critical Care Medicine slowed, and the percentage of anesthesiologist members declined substantially from 1979 to 1996 (Table 71-1) . At the same time, surgeons (1,850) and internists (2,801) increased their membership and in 1996 outnumbered anesthesiologists by a significant margin. [1]

In view of the illustrious contributions by anesthesiologists to the inception and development of critical care medicine over the past 45 years, the reasons for the decline can only be surmised. The practicalities of modern medicine cannot be ignored. In anything other than an academic setting, anesthesiologists can find employment in an intensive care unit (ICU) but have difficulty being reimbursed. Often, they must work in the operating room, at least on a part-time basis, in order to be able to afford the "luxury" of practicing critical care. Third-party payers seem more likely to reimburse them for administering anesthetics (albeit at an increasingly reduced rate) than for the time they spend in the ICU. This situation seems unlikely to change in the near future and may be the primary reason that fewer anesthesiologists enter critical care medicine than entered a few years ago.

THE ANESTHESIOLOGIST'S ROLE IN CRITICAL CARE

Techniques that anesthesiologists employ daily in the operating room--airway management, including tracheal intubation and manual or mechanical ventilation; intravenous administration of potent and rapidly acting pharmacologic agents; blood and fluid infusion; and cardiorespiratory monitoring--are the mainstays of intensive therapy and critical care medicine. No other specialty provides similar day-to-day experience in these areas, as a result of which anesthesiologists have the oppe the opportunity to become highly proficient and technically competent. They are well suited to assume an important role in critical care if they so choose.

Profound pathophysiologic changes occur in ICU patients, often with little or no warning. Rapid diagnosis and treatment on a minute-to-minute basis are essential if intact survival is to result. Implementation of therapy requires knowledge of physiologic, biochemical, and pharmacologic principles, augmented by sound clinical experience. Critical care medicine represents the ultimate in clinically applied basic science, and no specialty training provides a stronger background in the basic sciences than anesthesiology.

The relationship of the physical and life sciences on the one hand to the art of medicine on the other has been integral to the growth of anesthesiology and to the role of its specialists in the development of techniques including mechanical ventilation, [2] [3] [4] [5] [6] [7] cardiovascular monitoring, [8] [9] positive end-expiratory pressure (PEEP) and continuous positive airway pressure (CPAP), [10] [11] [12] [13] cardiopulmonary resuscitation, [14] resuscitation of the acutely brain-injured patient, [15] and parenteral nutrition. [16] [17] By 1985, noninvasive monitoring techniques, including pulse oximetry and capnography, were commonplace in anesthesiology [18] [19] and are now published standards of care. [20] They are regularly employed in the ICU, augmenting (and often supplanting) more invasive, and hence potentially more dangerous, methods. [21]

TABLE 71-1 -- Membership in the Society of Critical Care Medicine (1979-1996)

YEAR	ANESTHESIOLOGISTS		ALL OTHER PHYSICIANS	
	NO.	*% TOTAL PHYSICIANS*	*NO.*	*%*
1979	386	44	496	56
1984	643	27	1,708	73
1988	679	24	2,156	76
1992	916	17	5,411	83
1996	1,150	17	6,905	83

New methods of ventilatory support were introduced in attempts to improve the outcome and to decrease the untoward effects of mechanical ventilation. [7] [22] [23] [24] [25] [26] [27] [28] [29] Lessons learned in the ICU have been translated into the design of new anesthesia ventilators that are significantly improved compared with their earlier counterparts. [30] [31] This example also highlights the parallel, yet interdependent, development of modern anesthesiology and critical care medicine.

MAJOR PROBLEM AREAS

Problems in critical care medicine are so numerous that one chapter cannot possibly discuss them in any meaningful fashion. However, some, by their ubiquitous nature, impact, and expense, may transcend the rest. Every intensivist can prepare a similar list, and each probably would attach different importance to individual items. Our list is summarized in Table 71-2 . With a few exceptions, it is similar to the one published in the second edition of this text.

Monitoring

Prevention of Cardiac Arrest

Davis [32] addressed the history of intraoperative monitoring. Most of what he said appears applicable to the ICU. In the early 1950s, interest in abrupt and unexpected cardiac arrest was heightened as allegations that it was increased during anesthesia were disseminated. Subsequently, improved methods of resuscitation were developed, [14] culminating in today's well-known basic and advanced cardiac life support. Emphasis was placed on the early detection of circulatory abnormalities and rapid restoration of hemodynamic stability because cerebral damage or death could occur if oxygenation was interrupted for more than a few minutes. In the operating room, this interest translated into increased use of simple physical assessment of heart rate, arterial blood pressure, and skin color.

In 1947, however, Comroe and Botelho [33] described the unreliability of detecting cyanosis visually, even by trained physiologists and anesthesiologists. Similarly, indirect measurements of blood pressure and pulse rate long have been known to be poor indicators of cardiovascular function under many conditions of anesthesia and surgery. As a result, increasing reliance has been placed on electronic surveillance and vascular cannulation to evaluate cardiopulmonary function, with the expectation that improved monitoring will translate into improved patient care. However, this expectation has not been realized.

Taylor et al [34] reviewed 41 cases of intraoperative cardiac arrest detailed in malpractice claims between 1956 and 1971. Thirty-one of the patients were healthy and were undergoing elective surgical procedures. Resuscitation was prompt, yet all but three of the survivors sustained permanent brain damage. In these cases of cardiac arrest resulting from respiratory dysfunction and hypoxemia, the cardiovascular monitoring detected cardiac dysfunction too late to prevent brain damage.

Similar data were presented by Davis. [32] Of 18 cases in which cardiac arrest was the heralding event signaling an intraoperative circulatory catastrophe, 15 patients were resuscitated, but all sustained permanent brain injury. The other three patients died. Nineteen additional cases of unsuspected brain damage occurred, only one of which had any premonitory signs of circulatory inadequacy. Davis concluded that the central nervous system was damaged before recognizable cardiovascular distress signals were detected.

Caplan et al [35] reported similar findings in a study of 14 cases of cardiac arrest in healthy patients undergoing spinal anesthesia for elective or emergency operative procedures. A detailed retrospective analysis suggested that applicable standards of anesthesia care were employed and that observation and monitoring were appropriate. Nevertheless, 10 of the 14 patients never regained consciousness, whereas three of the four who did sustained permanent brain damage. Objective criticism of the techniques of resuscitation, including an inordinate delay in the use of epinephrine, was provided in an accompanying editorial. [36] These observations no doubt played a role in the changes of guidelines and standards for intraoperative monitoring that have been published by the American Society of Anesthesiologists. [20]

Invasive Techniques

The response to this problem was an escalation of invasive monitoring in both the operating room and the ICU (Chs. 30, 31, and 35) . With increased invasive monitoring, however, came new problems. Catheter-related thrombosis, embolization, infection, and sepsis were well known and well documented. More ominous, however, was the possibility of mortality directly related to, or resulting from, the technique employed. Robin [37] suggested that the overall mortality associated with pulmonary artery (PA) catheterization was 1 percent. In 1986, he estimated that 500,000 of these catheters were inserted in the United States. Hence, by his analysis, some 5,000 patients may have died as a result of the monitoring used to assess their well-being.

Some corroboration for Robin's viewpoint was expressed by Connors et al, [38] who studied 5,735 patients, 2,179 (38%) of whom underwent PA catheterization. In this group, 1,354 (62%) were still alive 30 days later, compared with 2,463 (69%) of the 3,566 noncatheterized patients. The two study groups allegedly were similar with respect to age and severity of illness. Of perhaps equal significance was the failure to identify any patients who appeared to benefit from PA catheterization. In this regard, even widely standardized noninvasive techniques have not been demonstrated to reduce morbidity and mortality. [32] [35] [39] In view of the $2 billion estimated cost associated with the use of PA catheters, the findings of Robin [37] and Connors et al [38] warrant further assessment, as suggested in an editorial commentary by Dalen and Bone [40] and a 1997 consensus statement. [41]

To improve the quality and the quantity of information obtained, new technology incorporated a fiberoptic sheath that allows PA catheter reflectance spectrometry determination of mixed venous oxygen saturation (Sv O_2). In general, Sv O_2 correlates directly with cardiac output if oxygen consumption remains unchanged. Continuous monitoring of Sv O_2 in critically ill patients now is thought by many to represent a satisfactory means to assess cardiac outputent a satisfactory means to assess cardiac output that is similar to intermittent Sv O_2 assessment in the past. [11] Other PA catheters utilize a fast-response thermistor and two intracardiac

electrocardiographic electrodes for measurement of cardiac output, right ventricular ejection fraction, right ventricular end-diastolic and end-systolic volumes, and stroke volume in conjunction with a single-purpose ejection fraction cardiac output computer. Efficacy in conjunction with transesophageal echocardiography and radionuclide techniques has been demonstrated.

Two other PA catheters also warrant mention: one incorporates a 10-MHz ultrasound transducer proximal to the catheter tip that measures instantaneous and continuous cardiac output with Doppler-shifted ultrasound [42] ; the other employs a filamentous element in the right ventricle that is heated intermittently in pseudorandom fashion. Heat transfer to the blood results in a downstream temperature change in the PA. [43] This stochastic identification technique thus uses a warm thermal indicator to provide continuous cardiac output data.

Respiratory Care

Basic Concerns

Causes of acute respiratory failure are variable (Table 71-3) , but the acute manifestations are sufficiently similar to be considered as a single entity--the acute respiratory distress syndrome (ARDS) (Ch. 72) . Although simplified, this method of classification has merit. Assuming that a major error in diagnosis has not been made, standardized therapy may be applied. If one accepts the premise that severe, uncorrected cellular hypoxia ultimately is lethal, a simplified concept of therapeutic priorities can be created. These include improvement of gas exchange, particularly oxygen transfer, optimization of oxygen transport from the lungs to the tissues, and enhancement of oxygen use by the cells.

Patients who are unable to breathe spontaneously require some form of ventilatory support. However, many are able to maintain effective alveolar ventilation but are hypoxemic because of ventilation/perfusion abnormalities and intrapulmonic shunting. The primary goal of therapy is restoration of satisfactory oxygenation through the use of PEEP/CPAP. Full support of ventilation (carbon dioxide removal) is not required. Intermittent and synchronized intermittent mandatory ventilation are useful techniques that allow a combination of spontaneous breathing with controlled or assisted mechanical ventilation, respectively. [2] [3] As long as sufficient PEEP/CPAP is used to maintain lung inflation and to increase pulmonary compliance, these techniques work very well. [11] [12]

Large tidal volume (V_T) and high peak inflation pressure are often used to effect adequate ventilation in severe cases of ARDS. Pulmonary barotrauma and depression of cardiovascular function, particularly in hypovolemic patients, may result. Interest has been directed toward low V_T and pressure delivered at a rapid rate (
60 breaths per minute) in an attempt to decrease or eliminate these problems and to improve ventilation and oxygenation. [4] [5] The techniques are referred to collectively as high-frequency ventilation. High-frequency ventilation is useful in diagnostic and therapeutic laryngoscopy and bronchoscopy, some cases of bronchopleurocutaneous fistula, newborn diaphragmatic hernia, and persistent pulmonary hypertension of the newborn. Results

in ARDS are equivocal, and widespread application in adult critical care, despite more than 30 years of development, has not occurred.

To achieve similar goals, permissive hypercapnia has been advocated. [44] A reduction of V_T and minute ventilation delivered by conventional techniques (as opposed to high-frequency ventilation) is deliberately employed, allowing partial pressure of arterial carbon dioxide (Pa_{CO_2}) to increase. Lower peak inflation pressures and V_T are thought to reduce barotrauma (volutrauma) and other complications of conventional therapy. Markedly improved survival in ARDS is reported, [44] but the technique has not been validated in controlled trials. [45]

V/Q Inequalities in Respiratory Failure

Reductions in both partial pressure of arterial oxygen (Pa_{O_2}) and Pa_{CO_2} are characteristic of the early stage of ARDS. Later, Pa_{CO_2} increases, and in the terminal stage of the disease, it cannot be returned to normal by even the most vigorous attempts at mechanical ventilation. Hypoxemia results from continued perfusion of lung regions with decreased-to-absent ventilation.

Poliomyelitis, Guillain-Barre syndrome, and other neuromuscular diseases produce respiratory insufficiency because of a failure of mechanical or neural control of ventilation. ARDS, in contrast, represents a failure of gas exchange that is related primarily to parenchymal involvement. Both neuhough exceptions, such as flail chest associated with an underlying pulmonary contusion, do occur. Even in this case, the musculoskeletal abnormality is of secondary importance to the underlying pulmonary contusion.

A mechanical ventilator is a satisfactory device to sustain ventilation when neuromuscular and musculoskeletal dysfunction predominate. When a decrease in alveolar volume is present--whether associated with surfactant depletion, partial airway obstruction, interstitial and alveolar pulmonary edema, or a combination of these factors--a mechanical ventilator can have salutary effects only during inspiration. During expiration, when airway pressure is reduced, alveolar volume is again decreased, and oxygen exchange is impaired (Fig. 71-1) . Thus, when used alone, a ventilator does not alter the basic pathophysiologic changes of ARDS, and severe hypoxemia frequently persists.

Positive End-Expiratory Pressure and Continuous Positive Airway Pressure

Because decreased lung volume is a predominant feature of ARDS, therapy in most instances includes some form of expiratory positive airway pressure. PEEP maintains an increased volume of gas within the lungs and tends to prevent atelectasis. Improvement in oxygen transfer to the pulmonary capillary blood throughout the entire respiratory cycle usually results, with a concomitant increase in Pa_{O_2}.

Many spontaneously breathing patients with ARDS can maintain satisfactory carbon dioxide elimination; they do not

Figure 71-1 (A) Inspiration. With positive-pressure ventilation, a collapsed or fluid-filled lung area can be inflated following careful adjustment of pressure volume and flow. (B) Expiration. When gas is exhaled and airway pressure decreases, whatever forces predisposed to collapse of fluid accumulation are unopposed; either or both forces then recur.

require intermittent positive-pressure ventilation. CPAP applied through either an endotracheal tube or a face mask is often sufficient in mild-to-moderately severe cases of respiratory distress. In general terms, CPAP maintains a higher mean airway pressure, is associated with less work of breathing, and is potentially more depressing to venous return at a given setting than the same level of PEEP in spontaneously breathing patients. However, the distinctions are not always clear. For example, even though the configuration of a given circuit may suggest that it delivers CPAP, if the gas delivery from the flowmeter and reservoir bag (or demand valve) is inadequate to meet the patient's peak inspiratory demand, airway pressure changes characteristic of PEEP result.

Ventilator Modes

Intermittent Mandatory Ventilation/Synchronized Intermittent Mandatory Ventilation

Intermittent and synchronized mandatory ventilation are commonly used techniques for ventilatory support. Their advantages, although clearly evident in the clinical setting, are difficult to establish on the basis of scientifically valid studies. These techniques have been subjected to rigorous criticism by investigators who allege that significant disadvantages are associated with their use, including increased work of breathing, respiratory muscle fatigue, prolongation of weaning if the intermittent or synchronized mandatory ventilation rate is decreased too slowly, and increasedittent or synchronized mandatory ventilation rate is decreased too slowly, and increased likelihood of cardiac decompensation during weaning. [25] [45] Despite such criticism, they persist as mainstays of respiratory care.

Mandatory Minute Volume

Minute ventilation with intermittent or synchronized mandatory ventilation ventilators is variable because only

the ventilator rate and V_T are programmable. In 1977, Hewlett et al [6] proposed that a preselected minute volume might be more physiologic. The original concept incorporated a known constant flow of gas from which the patient could breathe spontaneously. Any gas greater than that breathed by the patient accumulated in a bellows; when a certain volume was reached, the ventilator cycled, delivering this volume to the patient. If spontaneous ventilation decreased, the bellows accumulated gas more rapidly, and more frequent ventilator breaths were delivered. Conversely, if the spontaneous component increased, gas collected in the bellows more slowly, and the number of mechanical breaths decreased. In both cases, minute ventilation remained constant; only the proportion breathed spontaneously by the patient or provided by the ventilator changed.

Pressure Support Ventilation

Operational Principles

Pressure support ventilation (PSV) is used to relieve the respiratory muscles of their workload in patients with decreased lung and chest wall compliance, increased airway resistance, or both. It utilizes the ventilator to reduce patient work to a more tolerable level, known as partial unloading, [46] [47] [48] [49] or may provide all the work of breathing by total unloading of the respiratory muscles. [46] [47] [48] [49] The technique is useful in overcoming endotracheal tube resistance and that of the ventilator circuitry. [47] [48] When a spontaneous breath is initiated, the ventilator responds to the decrease in airway pressure and delivers a high flow of gas into the circuit, raising the pressure to a preselected maximum level (e.g., 20 cm H_2O). This pressure is maintained until the patient's total flow falls to 25 percent of the initial peak value. At that point, the ventilator cycles off, and circuit flow ceases.

Work of Breathing

Pressure support ventilation levels may be adjusted to provide optimal muscle load, taking into account both the imposed work, caused by the endotracheal tube and ventilator circuitry, and the physiologic work. Until recently, such determinations were difficult or impossible. [49] Conventional methods used to assess respiratory muscle load (e.g., rate of respiration, breathing pattern, and use of accessory muscles) are unreliable and inexact. [50] Today, however, the amount of PSV necessary to achieve graded reductions or increases of spontaneous work can be determined by directly and simultaneously measuring the patient's spontaneous work and the ventilator's mechanical work. [49] A computerized, portable respiratory monitor (Bicore Monitoring systems, Allied, Riverside, CA) provides a real-time display of the pressure-volume (work) loops and calculates the imposed work of the circuit, ventilator components, and endotracheal tube. Differentiation of the physiologic work (related to changes of compliance, resistance, and inertial forces) from the imposed work is thus possible. If imposed work is excessive, an increase of PSV offsets it, thereby reducing the total work of breathing to an acceptable range. Using this approach, one may avoid respiratory muscle fatigue (not enough PSV) on one hand and muscle atrophy (too much PSV) on the other.

Banner et al [46] studied the utility of real-time measurements of work of breathing obtained from the Bicore respiratory monitor to set PSV levels for partial and total

respiratory muscle unloading. Work of breathing was obtained for 30 adult patients with acute respiratory failure. All patients were intubated transorally or had a tracheostomy tube in place and were breathing spontaneously with CPAP. The first measurements were taken while the patients breathed spontaneously with CPAP and PSV set to 0 cm H_2 O. PSV was then increased until the patient's work of breathing corresponded to a normal range of physiologic work (i.e., partial respiratory muscle unloading). Subsequently, it was increased so that the ventilator provided all the work of breathing, thereby totally unloading the respiratory muscles.

Intraesophageal pressure, tidal volume, and airway pressure were entered into the monitor's computer, which constructed a Campbell diagram [46] and calculated the work of breathing performed by the patient and the ventilator. As PSV increased, patient work of breathing decreased, and ventilator work of breathing increased. The respiratory muscles were totally unloaded at PSV of 31 ± 8 cm H_2 O. Investigators concluded that real-time measurement of work of breathing can serve as a goal-oriented approach for applying PSV to decrease the workload to appropriate levels.

Pressure Augmentation

Pressure augmentation provides a guaranteed tidal volume per breath during PSV. This mode is available only with the BEAR 1000 ventilator. When PSV is used as a stand-alone mode or is combined with CPAP, decreases in tidal and minute volume may occur as a result of decreases in the level of consciousness, inspiratory effort, and pulmonary mechanics. Hypoxemia, hypercapnia, acidemia, and their associated sequelae may occur secondary to inappropriately low minute volume.

Operational Principles

Pressure augmentation may be available in the "background" or may be actively operating during PSV to protect the patient from hypoventilation. The PSV level is preselected. Next, a minimum V_T and a back-up inspiratory flow rate are chosen. If the V_T during the PSV breath is greater than the minimum V_T setting, no augmentation of pressure above PSV occurs; the breath is terminated or flow-cycled "off" in the usual manner. If V_T is less than the minimum volume setting after the initial phase of the pressure-supported breath, a constant flow rate of gas (back-up inspiratory flow setting) is directed to the patient until the minimum V_T is delivered. As a result, airway pressure is augmented above the PSV level, and the breath is volume-cycled "off." With pressure augmentation, the breath looks like a conventional PSV breath; the volume feature is activated only when necessary.

Pressure augmentation guarantees V_T during PSV and represents a sensible safety precaution. Future ventilator

designs will, in all likelihood, incorporate pressure augmentation or a similar mode to prevent hypoventilation. In addition to setting a minimum V_T and back-up inspiratory flow rate, a back-up respiratory rate setting is recommended to protect the patient in case of apnea.

Proportional Assist Ventilation

Pressure support ventilation, when properly adjusted, optimizes the relationship between respiratory muscle workloads and ventilatory response. This optimal relationship applies for only one specific set of physiologic conditions. If patient work of breathing changes as a result of changes in airway resistance (Raw), elastance of the respiratory system (E_{RS}), inspiratory flow rate demand (V_T), or V_T, the clinician must increase or decrease the level of PSV to maintain an optimal and nonfatiguing respiratory muscle workload. Because one or more of these parameters may change frequently, maintaining the precise level of PSV required to optimize respiratory muscle workload is sometimes difficult.

Operational Principles

A favorable relationship between respiratory muscle workload and alveolar ventilation is an important therapeutic objective. Proportional assist ventilation (PAV), an experimental technique, [28] [29] may eventually prove superior to PSV in accomplishing this objective. A ventilator capable of PAV continuously manipulates the level of PSV applied to the airway throughout the course of each spontaneous inhalation. In contrast, conventional PSV applies a single rway throughout the course of each spontaneous inhalation. In contrast, conventional PSV applies a single pressure level through the inspiratory phase. During PAV, airway pressure (Paw) varies in response to the patient's respiratory muscle pressure or effort, which is affected by Raw (change in pressure/flow rate), E_{RS} (change in pressure/change in volume), V_T, and V_T. The relationship between these variables and the ventilator's response is described by the following equation of motion for the respiratory system:

To use PAV (and solve the equation of motion), the clinician must first accurately measure the patient's Raw and E_{RS}. Two ventilator controls are then adjusted. One, the resistive gain control, is based on the measured Raw; the other, the elastic gain control, is based on the measured E_{RS}. With this information and real-time feedback from airway pressure, flow rate, and volume sensors positioned in the breathing circuit, the ventilator automatically adjusts the applied PSV up or down to maintain the specific relationship defined by the equation of motion.

Consider an adult whose E_{RS} increases to 50 cm H_2 O/L (normal = approximately 10 cm H_2 O/L) and whose Raw increases to 10 cm H_2 O/L/s (normal = approximately 2 cm H_2 O/L/s). To "normalize" this particular patient, the elastic gain control would be set to 40 cm H_2 O/L (measured E_{RS} - normal E_{RS}), thereby causing the ventilator to assume the extra work resulting from the increase in E_{RS}. The resistive gain control would be set to approximately 8 cm H_2 O/L/s (measured Raw - normal Raw). The total resistive work, or pressure drop, the patient must generate across the airways and breathing apparatus to achieve a desired inspiratory flow rate would thereby decrease.

During PAV, the patient interacts with the pressure-supported breath and retains control over V_T, inspiratory time, breathing frequency, V_T, and minute ventilation. Unlike PSV, the patient regulates the applied airway pressure level as well, thus retaining control over *all* ventilatory parameters during PAV.

Clinical Applications

With PAV, the elastic and resistive gain controls can be set in many different ways, based on a patient's needs. Chronically fatigued respiratory muscles can be totally unloaded to allow a period of rest simply by adjusting the gain controls to assume the total work of breathing. The respiratory muscles may be partially unloaded by adjusting the gain to allow only the work that the patient can tolerate. Finally, the gain can be adjusted to exercise the patient's respiratory muscles by periodically forcing a greater normal work of breathing.

Potential Problems

As with other ventilatory approaches, PAV has shortcomings. It requires real-time airway pressure, flow rate, and volume signals from the "Y" piece of the breathing circuit. Loss or alteration of any or all of these signals can jeopardize the patient. Accurate determinations of Raw and E_{RS} also are necessary. Just as levels must be set for PSV, the gain controls must be readjusted whenever Raw or E_{RS} changes in PAV.

Potential problems include dependence on the patient's spontaneous effort (without spontaneous effort, PAV cannot function) and pressure "runaway" (e.g., a leak in the breathing circuit that causes the ventilator to provide inappropriately high flow rates in response to the leak rather than to patient effort). Finally, PAV controls neither V_T nor breathing rate and, therefore, has no direct control over a patient's breathing pattern.

Airway Pressure Release Ventilation

Airway pressure release ventilation allows spontaneous ventilation with CPAP but differs from conventional ventilatory modes because peak inspiratory pressure never exceeds the level of CPAP. [7] Airway pressure decreases rather than increases when a mechanically controlled tidal volume is delivered (Fig. 71-2) (Figure Not

Available) . The risk of pulmonary barotrauma and adverse hemodynamic effects associated with conventional positive-pressure ventilation may be decreased because of the lower peak inspiratory and mean airway pressures. This technique appears useful for patients who do well at low-rate intermittent or synchronized mandatory ventilation but are unable to effect the transition to totally spontaneous breathing with CPAP.

Figure 71-2 (Figure Not Available) Airway pressure release ventilation circuitry and its clinical application. (A) A high-flow air/oxygen gas mixture passes continuously into a continuous positive airway pressure (CPAP) system, which is bifurcated at its distal end. When the electronically controlled solenoid valve is closed, all gas passes through the CPAP valve, and an airway pressure of 10 cm H_2O results. Typical airway pressure tracings are shown. (B) When the solenoid valve is opened transiently, all the gas flows through the portal, and airway pressure falls to zero. A larger exhalation results. (C) The solenoid valve is again closed, with an immediate restoration of airway pressure back to 10 cm H_2O. Depending on how many times the system is depressurized and repressurized (cycles per minute), an increase or decrease of ventilation can be superimposed on the patient's spontaneous component. Note that the highest pressure is the CPAP value. Other forms of positive-pressure ventilation are associated with an increase of airway pressure above the level of CPAP. *(Courtesy of M.E. Banner, PhD.)*

Resuscitation

Fluid and Electrolyte Therapy

Appropriate intravascular fluid resuscitation (Chs. 45 and 75) in shock and cardiovascular insufe occurs in skeletal muscle cellular transmembrane potential and in peak amplitude of the evoked potential. A progressive increase in intracellular sodium and water and extracellular potassium occurs with an associated decrease in extracellular water (Table 71-4) . The increase in intracellular water occurs at the expense of extracellular fluid, presumably accounting for the loss of functional extracellular fluid volume demonstrated by radioactive isotope dilution techniques.

In severe or long-standing shock, the restoration of intravascular volume alone is insufficient for successful resuscitation. Until restoration of the functional extracellular fluid volume is completed, normal oxygen and nutrient delivery to the cells and removal of waste products from them cannot occur. Provided that cellular damage is reversible, the administration of extracellular fluid substitutes, such as lactated Ringer's solution, is useful.

Critics of such therapy argue that the large volumes of electrolyte solution that may be required to offset a functional extracellular fluid volume deficit of several liters predispose to the formation of pulmonary edema and an increased incidence of ARF. They suggest that dilution of plasma by balanced electrolyte solutions decreases the colloid oncotic pressure and enhances water flux into the pulmonary interstitium. [51] Staub [52] noted, however, that "a decrease in plasma protein concentration, even to low levels, should not produce pulmonary edema because it would be accompanied by similar decreases in perimicrovascular protein concentration of the pulmonary interstitium."

The common practice of administering plasma, albumin, or colloidal suspensions, such as hydroxyethyl starch, to offset possible decreases in plasma oncotic pressure may be deleterious. Holcroft et al [53] reported that the increased albumin extravasation and edema that occur in the lungs, heart, brain, and liver of septic animals cannot be prevented by plasma protein infusion. In septic animals, Sturm et al [54] showed that the administration of plasma solutions is associated with an increased flux of albumin into the pulmonary interstitium compared with that occurring during crystalloid resuscitation. This albumin flux is accompanied by an increase of extravascular lung water (interstitial pulmonary edema).

Colloids and Crystalloids

Much of the controversy concerning the administration of colloid and crystalloid solutions (Ch. 45) to shock/trauma patients appears to be based on misinterpretation or incomplete knowledge of the factors governing fluid exchange in the lung. Absolute values for pulmonary microvascular pressure and plasma colloid oncotic pressure are relatively unimportant in pulmonary edema formation. Rather, as Staub [52] suggested, it is the gradient of hydrostatic and oncotic pressures between the intravascular and pulmonary interstitial spaces that is the important determinant.

Analysis of lung lymphatic drainage showed that normal pulmonary interstitial albumin content is at least 50 percent that of plasma and is altered directly with changes in plasma albumin. [52] [54] An attempt to increase plasma oncotic pressure with colloid solutions in order to prevent pulmonary edema is not based on sound physiologic observations. If an increase in pulmonary capillary permeability occurs, interstitial albumin concentration and oncotic pressure approach that of the plasma.

The most comprehensive assessment of colloid therapy was presented in a workshop on the assessment of plasma volume expanders. [55] All pertinent clinical trials involving albumin, dextran, and hydroxyethyl starch were evaluated in terms of efficacy, cost, indications, and complications. Little evidence supported short-term or long-term benefits associated with colloid administration for burns, blood loss, cardiopulmonary bypass, treatment of pulmonary edema, trauma, or nutritional supplementation. Serum albumin levels as low as 3 g/dL were not deleterious. Even values as low as 2 g/dL were not clearly problematic.

Hypertonic Saline

Therapeutic Implications

Peripheral edema is one of the consequences of balanced electrolyte solutions administered in large quantities. Patients' weight often increases several kilograms during resuscitation. Although adverse cardiopulmonary effects generally do not occur in patients without preexisting cardiopulmonary disease, the edema can cause problems in patients who have sustained major burns and may predispose to anastomotic leaks in general and vascular surgical patients. Here, lesser volumes of hypertonic saline solutions may be of value to reduce or eliminate the requirement for escharotomy; eliminate large, weeping surface areas, which are susceptible to infection; and maintain anastomotic integrity. Renal, cardiovascular, and pulmonary function are supported in a satisfactory manner with such therapy.

Physiologic Effects

Hypertonic saline solutions also have proved to be beneficial in resuscitation from shock/trauma. [56] [57] [58] [59] [60] [61] [62] [63] Compared with isotonic solutions, such as lactated Ringer's, the lesser volumes are associated with equivalent or improved systemic blood pressure, cardiac output, and survival in experimental animals. A positive inotropic effect has been consistently noted. Restoration of normal cellular transmembrane potential is enhanced, indicating a reversal of the cellular abnormalities induced by hemorrhagic shock. As long as 24 hours after the shock episode, blood pressure is maintained more effectively than with lactated Ringer's

solution alone or a combination of lactated Ringer's solution with added mannitol.

Traverso et al [58] found that 7.5 percent saline was more effective with respect to survival than 0.9 percent, 5 percent, or 10 percent saline solutions. They believed that improved tissue perfusion occurred as indicated by reduced lactate values. Improvement in myocardial contractility and reduction in systemic vascular resistance were probably contributory. Early increase in urine output, less fluid retention, and better late pulmonary function are also demonstrable. [59] Hypertonic saline solutions appear equally efficacious, whether administered peripherally (cephalic and femoral veins) or centrally (superior vena cava). Gross and histologic inspection demonstrates no vascular damage. [60]

Infusion of hypertonic lactated Ringer's solution in rabbits was accompanied by a reduction in the percentage of water in all cerebral and extracerebral tissues, an increase in their specific gravity, and a reduction of intracranial pressure (ICP). [61] Cerebral blood flow concomitantly was increased. Although normal animals were studied, the approach may have some advantages over the use of isotonic fluids in the resuscitation of head-injured patients. Similar findings also were reported by Gunnar et al [62] and Suarez et al. [63] In a simulated closed-head injury model, hypertonic saline infusion was accompanied by lower ICP and less cerebral edema than occurred with isotonic saline or colloid. [62]

The findings in experimental animals have been substantiated in humans. Holcroft et al [64] noted that 7.5 percent saline in combination with 4.2 percent dextran 70, administered during air ambulance transport, improved hemodynamic function and appeared to enhance survival in 20 severely injured patients compared with lactated Ringer's solution. The volumes infused were 700 ± 500 mL and 1,300 ± 900 mL, respectively.

Potential Problems

Replacement of the chloride anion with acetate has been suggested to avoid the risk of hyperchloremia and acidosis associated with hypertonic saline. To test this hypothesis, Frey et al [65] compared hypertonic sodium ssed. The study demonstrated that both hypertonic solutions effectively restored cardiac index and oxygen consumption and that sodium acetate dextran offered no advantages over sodium chloride/dextran, although the serum pH was improved.

Despite impressive experimental results, many anesthesiologists seem reluctant to employ hypertonic solutions. Few, if any, studies report deleterious effects, including hyperosmolar states, as long as careful monitoring is employed. Certainly additional experimental and clinical work in this area is warranted. A comprehensive review of the subject has been published by McGough. [66] The composition of various intravenous fluids is summarized in Table 71-5 .

Cardiopulmonary Resuscitation

Historical Considerations

In 1921, Dr. Ralph M. Waters [67] presented the following narrative:

> On November 21, 1920, a woman died during tonsillectomy....
> Forty-five minutes after apparent death I used high pressure (200 mm Hg) in inflating the lungs with pure oxygen .... (using) a McKesson anesthesia apparatus which allows of sudden complete inflation of the lungs....
> Beginning with a dead color of the skin, after fifteen minutes the skin gradually took on a normal color.... This condition was maintained over two hours, in fact until the surgeons convinced me, by opening the diaphragm through the abdomen .... that there was absolutely no heart activity.
>
> By inflating the lungs with oxygen under high pressure .... it would seem reasonable to assume that pressure compression of the heart and large vessels of the chest would result in at least some movement of the bloodstream.

This report predated modern cardiopulmonary resuscitation (CPR) by almost 40 years (Ch. 75) . Since 1961, CPR has been a widely accepted therapeutic procedure. Initially, enthusiasm was high for this new technique that combined artificial ventilation with closed-chest cardiac compression. [68] This noninvasive technique was predicted to replace open-chest cardiac massage as the treatment of choice in cardiac arrest and to improve survival rates. It was estimated that 70 percent of out-of-hospital victims of witnessed primary cardiac arrest in ventricular fibrillation or tachycardia would be saved if effective bystander CPR and paramedic response time were less than 4 minutes. [69] Eighty percent of cardiac arrest patients admitted to a coronary care unit were thought to be salvageable with the immediate availability of a defibrillator and adequately trained personnel.

Survival rates in both prehospital [70] and in-hospital settings have, in fact, been dramatically lower. [71] [72] This discrepancy is due, in large part, to the fact that both prehospital and in-hospital resuscitations are frequently performed on victims with preexisting comorbid conditions and noncardiac causes of arrest. Prehospital survival is determined primarily by the cause of arrest. Critical determinants ofre frequently performed on victims with preexisting comorbid conditions and noncardiac causes of arrest. Prehospital survival is determined primarily by the cause of arrest. Critical determinants of success for ventricular fibrillation or ventricular tachycardia include whether the arrest is witnessed and how much time elapses from arrest to arrival of a defibrillator (Table 71-6) (Table Not Available) . [69] Survival rates for cardiac arrest from other causes (i.e., near-drowning, drug overdose, trauma) remain low and have not changed significantly in the almost 3 decades since the introduction of emergency medical systems. Likewise, survival rates for both noncritically ill (floor) [71] [73] and critically ill (intensive care) [72] hospitalized patients have not improved significantly since the introduction of CPR.

Determinants of Survival

Several factors affect in-hospital survival rates. Rates differ from study to study, depending in large part on the patient population and the diagnostic mix (Table 71-7) (Table Not Available) . Unwitnessed arrest is associated with a dismal outcome. Patients who are intubated, are septic, are in cardiogenic shock, have acute renal failure, have metastatic disease uniformly do poorly, and few survivors are reported. [72] Successful resuscitation must occur quickly; prolonged resuscitation (>30 min) has a similarly poor prognosis. Asystole or pulseless electrical activity usually signifies a delay in identifying arrest and is also associated with poor outcome. Age greater than 70 years has been correlated with poor survival in some studies but not in others. Survival in children generally is no higher than in adults, although some studies suggest that children in ICUs respond more to high-dose epinephrine than do adults. [74] High-dose epinephrine has been shown to be of no value in prehospital pediatric arrest. [75]

Cardiopulmonary arrest is the final pathway to death, and critically ill patients often die. The question is how to identify patients who have a good prognosis for meaningful survival and might benefit from CPR from the considerable number with poor expected outcome in whom CPR can be withheld. Early involvement of the patient's family and, when possible, the patient in decision making precludes unnecessary resuscitative attempts. [76] The neurologic status of successfully resuscitated patients is of predictive value and can be used in decision making about whether further resuscitative efforts will be withheld.

TABLE 71-7 -- Outcome of Inpatient Resuscitation Attempts Reported in the Literature

(Not Available)

Adapted from Landry et al [72]

Cerebral Perfusion

A major determinant of intact survival is the adequacy of cerebral perfusion. Traditionally, carotid arterial blood flow has been used to gauge the adequacy of cerebral blood flow. Various methods to enhance cardiac output and cerebral blood flow include maintenance of positive-pressure inspiration during cardiac compression (using Waters' [67] original observation) and combinations of abdominal thoracic binding to maximize pleural pressure. [77] [78] Significant improvement in blood pressure and carotid flow using these techniques can result compared with conventional CPR. How- ever, only the internal carotid portion of total carotid flow is involved in cerebral perfusion. Hence, overall carotid flow cannot be equated with CBF. This fact is clearly evident in brain-dead patients with good carotid artery pulsation but with absent cerebral blood flow documented by perfusion scans. An increase of pleural pressure to augment forward flow in the arterial system also increases venous and hence ICP by a potentially equal amount. The result can actually be a zero increase in cerebral perfusion pressure, which is equal to the mean arterial pressure minus the mean ICP.

High-Dose Epinephrine

Interest has focused on the use of high-dose epinephrine for CPR. However, in an unpublished trial of doses as high as 0.07 to 0.2 mg/kg in more than 2,450 cases of cardiac arrest, no statistically significant improvement in survival was found when patients who received the high doses were compared with those who were treated with standard doses (i.e., 0.5-1.0 mg). Accordingly, the latest American Heart Association guidelines list higher doses of epinephrine as class IIb (they are acceptable but are neither recommended nor discouraged). [79]

Neurosurgical Critical Care

The scope of neurosurgical critical care has evolved rapidly (Chs. 35 and 52) . Improved outcome can be attributed in part to improvements in initial resuscitation that increase the probability of survival after an acute neurologic insult; advances in microsurgical techniques that allow the surgical treatment of complex disease processes; improvements in neurologic monitoring modalities; and recognition of the role of secondary neuronal injury and treatment directed toward its prevention. Care of neurologically injured patients requires an understoptimize treatment in the ICU and the operating room in order to improve overall patient outcome.

Improvement in initial resuscitative measures; immobilization procedures; acute therapeutic interventions, such as high-dose steroid therapy after acute spinal cord injury; and rapid transit to tertiary care centers has increased initial survival of neurologically injured patients and has contributed positively to final neurologic outcome. The availability of multiple medical disciplines, trained personnel, and advanced imaging techniques in tertiary care centers expedites early diagnosis and acute surgical intervention when warranted and postoperative care after complicated neurosurgical procedures.

Intracranial Contents

The intracranial contents consist of brain tissue, blood, cerebrospinal fluid (CSF), and meninges and communicate with the spinal axis via the foramen magnum. The calvarium is a nondistensible, semiclosed container that limits intracranial volume expansion. Volume of the intracranial contents remains constant unless a pathophysiologic change is introduced. When a new volume is added (i.e., hematoma) or expansion of an existing volume occurs (i.e., tumor), a reciprocal reduction in volume of one or more of the intracranial components must occur to maintain normal ICP. [80] [81] [82]

Intracranial Pressure

Intracranial pressure measurement utilizes subarachnoid bolts, ventriculostomy catheters, and subdural or epidural catheters. Each method has advantages and disadvantages.

Figure 71-3 Intracranial pressure-volume curve. Points A-B represent spatial compensation with expanding intracranial volume. Elastance is low. At C, spatial exhaustion occurs. From C-D, elastance is increased; small changes in volume produce large changes in intracranial pressure.

Normal ICP is less than 15 mm Hg. Values above 29 mm Hg, if sustained, are associated with a reduction in cerebral perfusion pressure and a poor prognosis. An intracranial mass and reduced compliance can be associated with major damage from relatively small changes in pressure. A normal ICP does not exclude a mass lesion.

The intracranial pressure-volume curve (Fig. 71-3) [82] [83] depicts the relationship between intracranial volume expansion and ICP in the presence of a pathologic process. The effect of intracranial volume expansion on ICP depends on the chronicity of the underlying pathologic process and the adequacy of the buffering capacity of the intracranial system. During the period of spatial compensation, even large changes in intracranial volume result in minimal alterations in ICP. Normal ICP is maintained by a displacement of predominantly venous blood from the vasculature, an increase in the rate of CSF absorption, and occasionally by a loss of

water and electrolytes from brain tissue. The greatest buffering capacity is afforded by the CSF; decompensation occurs when maximal CSF absorption occurs.

Cerebral blood volume is the intracranial content most easily manipulated through alterations in ventilation and drug therapy. When the buffering capacity of the intracranial space is exhausted, small increases in intracranial volume result in dramatic rises in ICP. If a mass expands rapidly (i.e., epidural hema most easily manipulated through alterations in ventilation and drug therapy. When the buffering capacity of the intracranial space is exhausted, small increases in intracranial volume result in dramatic rises in ICP. If a mass expands rapidly (i.e., epidural hematoma), compensation cannot occur, and ICP rises abruptly.

Aneurysmal Subarachnoid Hemorrhage

Subarachnoid hemorrhage (SAH) is the result of primary bleeding into the subarachnoid space or direct extension from an intraparenchymal hemorrhage. Intracranial aneurysms are present in over 5 million North Americans, and approximately 28,000 cases of SAH occur each year. [84] The peak age for aneurysm rupture is 40 to 50 years. [84] SAH in patients younger than 20 years is usually secondary to an arteriovenous malformation. The female/male ratio for SAH is 1.6:1 for patients older than 40 years of age. [85] A linear relationship between risk of rupture and aneurysm size appears to exist; however, giant aneurysms (>2.5 cm) do not appear to have a higher risk of bleeding per year, probably because of thrombosis and calcification of the aneurysm wall. [86] Aneurysm rupture also has been associated with the last trimester of pregnancy, excluding delivery; during the postpartum period; and following cocaine use.

Rebleeding

Neurologic complications of SAH include rebleeding, acute hydrocephalus, and seizures. Cerebral vasospasm is a late complication of SAH but warrants early preventive measures in high-risk patients. The risk of rebleeding poses one of the greatest dangers if aneurysm clipping is delayed or conservative management is elected. Fifty percent of patients treated conservatively experience a rebleed within 6 months of initial hemorrhage, ultimately declining to 2 to 3 percent per year. [84] The greatest risk of rebleeding is within 24 hours of hemorrhage (approximately 4% on day 1) and peaks again between days 14 to 21. Aneurysm rebleeding is associated with a 50 percent mortality; of the 50 percent who survive, outcome is often poor.

Hydrocephalus

Acute hydrocephalus is detected by computed tomography (CT) in 15 percent of patients after SAH; of these, 40 percent are clinically symptomatic. [87] Hydrocephalus may contribute to the initial poor clinical grade, or its development may manifest as an acute decline in mental status. The development of hydrocephalus after SAH has been correlated with posterior aneurysms, intraventricular hemorrhage or thick subarachnoid clot, cerebral vasospasm, altered level of consciousness on admission, hyponatremia, advanced age, and hypertension. Acute hydrocephalus manifests with impairment of CSF flow through the ventricular system or impedance of CSF absorption at the arachnoid granulations. CT demonstrates enlargement of the ventricles. Ventriculostomy may be warranted even in the absence of ventriculomegaly if ICP elevation is suspected.

Cerebral Vasospasm

Pathogenesis

The pathogenesis of cerebral vasospasm is poorly understood but is likely complex and multifactorial in origin. It is characterized acutely by smooth muscle contraction, but chronically, structural and morphologic damage to the endothelium becomes evident. [89] Oxyhemoglobin has potent spasmogenic properties and likely plays a vital role in the development of cerebral vasospasm. [89] [90] As oxyhemoglobin is autoxidized, superoxide ion is released and initiates a cascade

of events that lead to endothelial damage, lipid peroxidation, and calcium influx. [88] Superoxide dismutase converts superoxide anion to hydrogen peroxide, and the interaction between the two results in the production of free radicals. [91] Free radicals probably are responsible for the initiation of lipid peroxidation and endothelial damage. Elevated levels of lipid peroxides, which are inherently potent vasoconstrictors, have been detected in animal models and in humans with vasospasm. [88] [92]

Platelet-activating factor, which is produced by inflammatory cells and neurons, may also be contributory via its link to prostaglandins and leukotrienes and by promotion of an inflammatory reaction and platelet aggregation. [93] Under ischemic conditions, glutamate, the predominant excitatory amino acid in the central nervous system, increases platelet-activating factor production. [94]

An imbalance between endothelin-1 and endothelium-derived relaxing factor may play a role in the development of vasospasm. Hemoglobin and oxyhemoglobin stimulate endothelin-1 synthesis and concurrently inhibit endothelium-derived relaxing factor activity. [95] Endothelin-1 is a potent vasoconstrictor that in the absence of endothelium-derived relaxing factor promotes arterial constriction in animal models. [96] Elevated levels of endothelin-1 have been detected in ischemic tissue in animals after global or focal cerebral ischemia; in humans, elevated CSF levels have been documented after stroke and SAH. [96] [97]

Treatment

The primary treatment for established cerebral vasospasm is hypertensive, hypervolemic, hemodilution therapy to augment cerebral blood flow in an effort to reverse or improve isvhemic neurologic deficits achieve a good outcome with this therapy. [98] Intravenous volume expansion is commonly achieved with crystalloid, colloid, or packed red blood cells, if the hematocrit value is low, in conjunction with PA catheter monitoring. Hypertension is induced with fluid infusion, vasopressors, or both, to improve cerebral perfusion and collateral blood flow. In our institution, systolic blood pressure is increased to 180 mm Hg or greater. An optimal hematocrit value is 30 to 32 percent. CBF is increased by a reduction in blood viscosity.

Calcium channel antagonists, specifically nimodipine and nicardipine, are routinely administered from the time of diagnosis and continued for 21 days. Their neuroprotective role may be the result of prevention of calcium influx and cell death. Clinical trials utilizing nimodipine or nicardipine report a decreased severity of symptomatic vasospasm but no difference in overall outcome at 3 months when compared with placebo. [99] [100] [101]

Tirilazad (U74006F or Freedox) is the most promising investigational drug in large clinical trials worldwide for the prophylactic treatment of cerebral vasospasm. It inhibits iron-mediated lipid peroxidation and in animal models attenuates chronic vasospasm after SAH. [92] [102] [103] Patients receiving tirilazad (6 mg/kg/d) had a reduced mortality and an increased frequency of good neurologic outcome compared with their counterparts receiving placebo or lower doses of drug. [104] Men appeared to benefit more than women in this trial.

Superoxide dismutase, platelet-activating factor antagonist, and anti-platelet-activating factor immunoglobulin M for cerebral vasospasm have been investigated in animal models only, with promising results in some trials and no benefit in others. Aspirin use before or after SAH was correlated with a decreased incidence of permanent neurologic deficits and cerebral infarction detected by CT. [105]

Head Injury

Glasgow Coma Scale

The Glasgow Coma Scale (GCS) [106] is used to evaluate level of consciousness after head injury (Chs. 35 and 52) and is not designed to assess focal neurologic deficits (Table 71-8) (Table Not Available) . A separate scale should be used to evaluate children younger than 4 years of age (Children's Coma Scale). The maximal obtainable score is 15, and a separate notation (t) is designated for intubated patients. Severe head injury is commonly defined as a GCS of less than 8. The initial GCS is used to determine the need for ICP monitoring and has been used to predict outcome in head-injured patients.

Radiographic Presentation

Computed tomography is the radiographic imaging study of choice for the diagnosis of acute intracranial pathology associated with head injury. It is a highly sensitive study for the detection of acute hemorrhage, mass lesions, or osseous injury and is ideal for hemodynamically unstable patients who benefit from rapid imaging time. CT documentation of midline shift and compressed ambient cisterns strongly correlates with ICP el sensitive study for the detection of acute hemorrhage, mass lesions, or osseous injury and is ideal for hemodynamically unstable patients who benefit from rapid imaging time. CT documentation of midline shift and compressed ambient cisterns strongly correlates with ICP elevation. [107] Magnetic resonance imaging can be employed to detect subacute collections of blood and to evaluate chronic intracranial pathology; it is more sensitive than CT scanning for the diagnosis of diffuse axonal damage.

TABLE 71-8 -- Modified Glasgow Coma Score

(Not Available)

Adapted from Jannett and Teasdale, [106] copyright by The Lancet, Ltd.

Indications for Intracranial Pressure Monitoring

The need for ICP monitoring is dictated by a combination of factors, including severity of head injury, age, neurologic examination, hypotension, and CT findings. Patients with severe head injury (GCS of 3-8) and abnormal CT scan require ICP monitoring. Monitoring also should be initiated in severely head-injured patients with a normal CT scan if two of the following conditions are also present at admission: age greater than 40 years, unilateral or bilateral motor posturing, or systolic blood pressure less than 90 mm Hg. Eisenberg et al [107] documented intracranial hypertension in 10 to 15 percent of patients with evidence of severe head injury and relatively normal admission CT scan. O'Sullivan et al [108] also documented intracranial hypertension during hospitalization in seven of eight severely head-injured patients (GCS
8) with normal admission CT scan.

Clinical Diagnosis of Brain Death

The diagnosis of brain death is made by assessment of brain-stem reflexes and is often corroborated with radiologic findings, electroencephalography, transcranial Doppler studies, multimodality-evoked potential monitoring or ^{99m}Tc blood flow scans. The diagnosis of death requires the irreversible cessation of cardiopulmonary or brain function (including the brain stem). [109] A recent history of severe brain injury must be deemed irreversible, and the clinical picture must not complicated by hypothermia, severe hypotension (systolic blood pressure <90 mm Hg), metabolic abnormalities, or medications that may confound the neurologic examination. Medications such as barbiturates, atropine, and narcotics preclude the diagnosis of brain death until drug levels are subtherapeutic. After prolonged administration of barbiturates (i.e., treatment of refractory intracranial hypertension), elimination may take several days.

The following conditions must be met for a diagnosis of brain death to be made: (1) pupils fixed and dilated with absent light reflex, (2) absent corneal reflexes, (3) absent oculocephalic or oculovestibular reflexes, (4) absent gag reflex, (5) apnea, and (6) absent motor response to deep central pain [109] (not to be confused with spinal cord-mediated reflex movements).

OUTCOME

Predictive Indices

A laudable, but thus far unattained, goal in critical care is the prediction of outcome for ICU patients early in the course of disease (Ch. 21) . In theory, resources could then be directed to those patients with the greatest potential for intact survival and, just as important, would not be spent on those for whom survival is unlikely. This concept originates from mass casualty situations in the military, during which resources are limited.

Predictive indices are based on patient-disease interactions, physician perceptions, and requirements for nursing care (Table 71-9) . The basic goal of each system is to amass

TABLE 71-9 -- Predictive Indices for Patient Outcome in the Intensive Care Unit

Patient-disease interactions	Frequency distribution of cardiorespiratory variables. Results from survivors applied to critically ill patients.
	Complications Impact Index: Age plus observable diagnoses and complications classified by eight organ systems
	Condition Index Score: Weight assigned to each of 225 complications
	Mortality Prediction Model[113] : Multivariate statistical analysis of easily derived admission variables; results expressed as probability rather than score.
Physician perceptions	*Therapeutic Intervention Scoring System (TISS):* Patients classified from I to IV; sickest patients require the most interventions
	Acute Physiology and Chronic Health Evaluation (APACHE): Weighted sum of 34 potential physiologic measurements in the first 24 hours of ICU admission, plus four- category designation of preadmission health status.
	APACHE II: Weighted sum of 12 physiologic measurements, plus age and previous health status.
	APACHE III
Requirements for nursing care	Based on the number of nursing hours per patient per 24 hour period: Class 1 12 hours; class 2 > 13 < 24 hours; class 3 > 24 hours. Generally equivalent to TISS classes II, III, and IV, respectively.

data that when subjected to appropriate statistical analyses, will determine the severity of illness and the prospects for recovery more accurately and precisely than clinical judgment alone.

Severity of Illness

Severity of illness is usually a major consideration in determining the need for critical care. However, patients are often admitted to an ICU for overnight observation after elective surgery and are discharged within 24 hours, whereas other patients who are extremely ill when admitted die within 24 hours. The first group may be "too well" to require an ICU admission, whereas the second group is "too sick" to benefit. In one study, these two groups constituted 34 percent of all surgical ICU admissions but were responsible for only 5 percent of ICU days and 8 percent of the total charges. [110] [111] Thus, the seemingly paradoxical fact is that the sickest and healthiest patients use the same amount of ICU resources. All predictive scoring systems can distinguish between these two extremes, but so can clinical judgment. It is the majority of patients in between that present the major difficulties.

Common Problems

No predictive index score generated at the time of ICU admission improves on the approximately 15 percent misclassification

rate inherent to each scoring system. For long-term patients, the factors that ultimately determine outcome either are not known or are normal on admission. [110] [112] Pneumothorax, myocardial infarctie, or shock that occurs on the sixth ICU day cannot be taken into account on day 1. Yet, that initially unknown event may be the final determinant of survival, independent of all the predictive factors present on admission.

Mortality Probability Models

The problem of mortality prediction for patients in the ICU for more than 24 hours was addressed by Lemeshow et al [113] in 1994. Using data from a prospective, multicenter study, the authors developed models to estimate mortality at 48 and 72 hours. Their models--the MPM_{48} and the MPM_{72} --are based on the Mortality Probability Model (MPM II) system. The MPM II system consists of the MPM_0 and the MPM_{24} models, which are used to estimate hospital mortality probability for patients at ICU admission and at 24 hours. The MPM_{48} and MPM_{72} models contain the same 13 variables and coefficients as the MPM_{24} ; however, the two new models differ from the MPM_{24} in their constant terms.

The authors also tested whether the MPM_{24} could be used to predict mortality beyond 24 hours. They studied 6,290 consecutive admissions to ICUs in Massachusetts and New York. Of these admissions, 4,485 patients were still in the ICU at 24 hours, 3,023 patients remained at 48 hours, and 2,233 patients remained at 72 hours. The investigators first tested the MPM_{24} model to determine whether it could estimate mortality probability for patients remaining in the ICU at 48 and 72 hours. For both time periods, the model consistently underestimated the probability of mortality. In every patient group, the number of deaths predicted by the MPM_{24} model was lower than the actual number.

Taking into account the underestimates produced by the MPM_{24} model for the longer time periods, the authors generated a new $beta_0$ value for the 48- and 72-hour models, using the 13 coefficients from the MPM_{24} model as a fixed offset variable. After the adjustment, both the MPM_{48} and the MPM_{72} provided a validated probability of hospital mortality in the ICU, at 48 and 72 hours, respectively. The investigators concluded that models developed for specific time periods cannot be successfully used for other time periods. They also noted that although the two new models provided a validated index of severity of illness for patients in the ICU for more than 24 hours, they are not appropriate tools for defining guidelines for allocation of limited resources or for transfer of patients out of the ICU.

Intensive Care Unit Discharge

Noting that there has been little study to determine when it is safe to transfer an ICU patient to an intermediate care unit, Zimmerman et al [114] set out to devise a method to assist physicians in making daily ICU discharge decisions for individual patients. They developed a series of multivariate equations to provide daily estimates of the probability that an ICU patient will receive life-support treatment within the following 24 hours. The equations were based on demographic, physiologic, and treatment data obtained at the time of admission to the ICU and during the first 7 days in the ICU. The authors noted that an ICU patient who has a high probability of receiving life-support treatment during the following 24 hours can be given this treatment most efficins were based on demographic, physiologic, and treatment data obtained at the time of admission to the ICU and during the first 7 days in the ICU. The authors noted that an ICU patient who has a high probability of receiving life-support treatment during the following 24 hours can be given this treatment most efficiently in the ICU. On the other hand, a low probability of next-day active treatment is a major indication for ICU discharge.

Among 13,787 ICU patients who remained for 2 days or more, 4,898 were predicted to have a less than 10 percent risk of requiring life support treatment during the second ICU day; 4,648 of these patients did *not* receive next-day life support treatment (Table 71-10) . Of those 8,860 patients in the ICU for 3 or more days, 2,718 were predicted to have a less than 10 percent risk of requiring life support during the third ICU day; 2,579 of these patients did *not* receive next-day active treatment. The study identified two major determinants of next-day risk for life support treatment: the current day's therapy and physiologic abnormalities, as reflected by the Acute Physiology Score of APACHE III.

Limitations

Zimmerman et al [114] acknowledged at least three limitations to these predictions: (1) factors that influence triage decisions are not considered, (2) the predictions are not 100 percent accurate, and (3) some patients predicted to be at low risk actually receive multiple life support treatments. Moreover, the effect of missing physiologic data on predictive accuracy has to be taken into account. Because unmeasured physiologic data generate an Acute Physiology Score of zero, the probability of next-day active treatment is underestimated. The authors concluded that the probability estimates can be used to supplement the physician's clinical judgment, facilitating ICU discharge decisions.

Daily Prognostic Estimates

Wagner et al [115] developed daily prognostic estimates for risk of death during each of the first 7 days of ICU care. Their goal was to create a single probability estimate that would represent the patient's current prognosis. The study was a prospective, multicenter, inception cohort analysis involving 17,440 consecutive ICU admissions. A series of multivariate equations was developed on the basis of primary reasons for ICU admission, age, chronic health status, treatment before ICU admission, Acute Physiology Score on admission, current-day Acute Physiology Score, and change between the current and previous day's Acute Physiology Score. The equations were used to create day-to-day risk predictions.

The percentage of cases with cross-validated predicted risks greater than 90 percent increased from 2.3 percent on day 1 to 8.8 percent (of patients still in the ICU) on day 7. The 1,033 patients who had a daily risk estimate of greater than 90 percent during any of their initial 7 days in the ICU had a 90 percent mortality rate and represented 47 percent of all ICU deaths (Table 71-11) . The authors concluded that daily physiologic measurements provide a high degree of explanatory

TABLE 71-10 -- Classification Tables Using a Cut-Point of 10% for Comparing Predicted and Actual Next-Day Active Treatment

	PREDICTED RISK	
	HIGH RISK (10%)	***LOW RISK (< 10%)***
ICU DAY 1		
Observed Active Treatment		
Actively treated	6,080	250
Not actively treated	2,809	4,648
[a] Sensitivity, 96%; [b] specificity, 62%; predicted to be at low (<10%) risk but received next-day active treatment (false negative), 5.1%.		
ICU DAY 2		
Observed Active Treatment		
Actively treated	4,147	139
Not actively treated	1,995	2,579
[a] Sensitivity, 97%; [b] specificity, 56%, predicted to be at low (<10%) risk but received next-day active treatment (false negative), 5.1%.		
ICU DAY 3		
Observed Active Treatment		
Actively treated	3,100	93
Not actively treated	1,064	1,627
[a] Sensitivity, 97%; [b] specificity, 60.4%; predicted to be at low (<10%) risk but received next-day active treatment (false negative), 5.4%.		

Data from Zimmerman et al [114]

[a] Defined as those predicted to be at >10% risk of life support divided by all cases receiving active treatment on target day

[b] Defined as those predicted to be at <10% risk of life support divided by all cases not actively treated on target day

power for hospital mortality rate. They further concluded that these daily prognostic estimates may help improve clinical decision making.

Summary and Critique

Survival, although easy to measure and of fundamental importance, is not the only determinant of outcome. [116] Some patients improve enough to leave the ICU only to die before hospital discharge. Other patients survive hospitalization but require nursing home placement or undergo

TABLE 71-11 -- Hospital Death Rate for Patients Predicted to be at 90% Risk of Death on ICU Days 1 to 7

	PATIENTS		
ICU DAY	***n*** [a]	**%**	**OBSERVED HOSPITAL DEATH RATE(%)**
1	406	2.3	90.6
2	399	2.8	92.5

3	348	3.9	92.8
4	330	5.5	91.8
5	271	6.5	93.0
6	240	7.7	92.5
7	218	8.8	91.7

Data from Wagner et al [115]

[a] Among the 17,440 patients in the APACHE III database, there were 2,212 such predictions in 1,033 patients. These 1,033 patients accounted for 47% of the total 1,681 ICU deaths and 933 (31%) of the total 3,030 hospital deaths.

subsequent long-term hospitalization for severe physical and mental impairments. Thus, life and death are not the only important outcome determinants. Rational choices among treatments depend on patients' and families' personalized assessments of specific risks and benefits.

Three groups of patients need ICU care, each with distinctly different goals: physiologically stable patients who are admitted for intensive observation; physiologically stable patients who require extensive nursing care and monitoring (frequently of an invasive nature); and physiologically unstable patients who need constant nursing and physician care. Patients admitted to most ICUs include those who might otherwise be considered "too sick" or "too well." Those who are too well (could survive without intensive care) often are given observation and intensive nursing care and consume a small portion of ICU bed days. Those who are severely ill often die rapidly and also use few bed days. Some patients, however, may respond favorably to intensive treatment and survive, an outcome that would not be possible if all of them were to be excluded from unit admission. Control can be achieved by evaluating and lowering expenditures while patients are in the ICU.

Quantitative indices are thought by many clinicians to provide more precise and accurate tools to evaluate the degree of illness and the likelihood of recovery. Outcome can be accurately predicted in approximastems that were functioning

normally at the time of ICU admission. Most predictive indices are weighted for acute physiologic changes, predominantly of cardiorespiratory and oxygen transport functions. In multiple organ system failure, these indicators often are close to normal, even moments before death. [117]

Cullen and Chernow [118] commented that society may move toward limiting care for critically ill patients sooner than we can perfect the science of risk prediction. They concluded

> Those persons who now believe that risk prediction models intrude on the many variables that caring clinicians use to make decisions about continuing or discontinuing intensive care may find themselves supporting risk prediction models in order to counter the inevitable drive toward limiting care for purposes of cost containment and rationing.

Chapter 72 - Respiratory Care

Barry A. Shapiro
William T. Peruzzi

Chronic Obstructive Pulmonary Disease

/das/book/view/29494766/875/783.html

INTRODUCTION

The knowledge and skills required to provide safe and effective respiratory care were pioneered and developed by anesthesiologists. Acute respiratory care includes both ambient-pressure and positive-pressure therapies applied via the airway. Appropriate and timely application of ambient-pressure modalities (oxygen therapy, bronchial hygiene therapy, and aerosol therapy) often avoids or shortens the time course of positive-pressure therapy. Ventilator management has become complex as basic knowledge, clinical experience, and technologic capabilities expand. Interestingly, advances in respiratory care have been so successful in supporting cardiorespiratory function that clinicians now must be able to support parenchymal lung disease of such severity that the airway pressure therapy itself must be limited to avoid further lung injury. This situation demands training of intensive care specialists with a sophisticated level of knowledge and skill, much of which is an integral part of anesthesiology.

Anesthesiology is the only medical specialty that requires the consistent application of cardiopulmonary supportive

techniques. The anesthesiologist must be prepared to provide patient care outside the operating room, where cardiopulmonary knowledge and skill are needed for reasons other than induction of the anesthetic state and performance of surgery. This chapter concentrates on the principles of respiratory support in which the anesthesiologist is most commonly involved outside the operating room theater.

OXYGEN THERAPY

Tissue oxygenation is primarily dependent on the milliliters of oxygen per minute delivered to the tissues. This oxygen delivery (D_{O_2}) is usually expressed as follows:

Oxygen content is determined by the concentration of hemoglobin [Hb] in the blood (g/dL), the percentage of the hemoglobin saturated with oxygen [percent S_{O_2}], and the milliliters of oxygen dissolved in 1 dL of plasma:

When fully saturated, 1 g of Hb combines with 1.34 mL of oxygen. The solubility coefficient for oxygen dictates that for each mm Hg partial pressure of oxygen (P_{O_2}), 1 dL of plasma will contain 0.003 mL of oxygen in the gaseous state.

Hypoxemia is clinically defined as a relative deficiency of oxygen in the arterial blood. Assuming normal Hb content,

Figure 72-1 (Figure Not Available) Alveolar oxygen tension (P_{AO_2}) is determined from the dynamic equilibrium established between the alveolar oxygen delivery (arrow A) and the alveolar oxygen extraction (arrow B). Alveolar oxygen delivery is a function of the minute ventilation (V_E) and the inspired oxygen fraction (F_{IO_2}). Alveolar oxygen extraction is a function of the pulmonary arterial oxygenation status (Sv_{O_2}) and the capillary blood flow (Q_C). *(From Shapiro et al [1])*

an arterial P_{O_2} (Pa_{O_2}) measurement of less than 80 mm Hg signifies hypoxemia. Hypoxia is clinically defined as an inadequate oxygen tension at the cellular level and cannot be directly measured.

The physiologic responses to either arterial hypoxemia or tissue hypoxia are to improve Ca_{O_2} by primarily increasing cardiac output and secondarily increasing ventilation. The clinical goal of oxygen therapy is to increase the alveolar oxygen content (C_{AO_2}), which is essentially equivalent to increasing the alveolar P_{O_2} (P_{AO_2}). An increase in the C_{AO_2} may result in an increase in the Ca_{O_2}, thereby decreasing the work of breathing and myocardial work required to attain a given arterial oxygen content. [1]

Oxygen therapy is clinically referred to as the fraction of inspired gas that is oxygen (F_{IO_2}). As schematically illustrated in Figure 72-1 (Figure Not Available), inhalation of oxygen concentrations of more than 20.9 percent will increase the P_{AO_2} because there is an increase in the amount of oxygen delivered to the alveolus per unit time. When hypoxemia is secondary to low P_{AO_2} values, increasing the F_{IO_2} increases the Pa_{O_2}, often diminishing both myocardial and ventilatory work. The clinically effective range of F_{IO_2} for prolonged oxygen administration is from 0.24 to 0.50. Prolonged administration of 1.0 F_{IO_2} to patients with diseased lungs often has detrimental physiologic (denitrogenation absorption atelectasis) and cytotoxic (oxygen toxicity) effects. [2] [3]

Oxygen Delivery Systems

Outside the operating room setting, where gases are administered by rebreathing systems that include a CO_2 absorber, oxygen therapy is provided by either partial rebreathing or nonrebreathing delivery systems that do not require a CO_2 absorber. A partial rebreathing system allows for the initial portion of the expired gases containing little or no CO_2 to be collected in a reservoir while the remaining expiratory gases are vented to the atmosphere. Most oxygen delivery systems are intended to function as nonrebreathing systems in which all exhaled CO_2 is vented to the atmosphere and only fresh inspiratory gases are inhaled. Nonrebreathing systems are divided into *high-flow* (fixed performance) and *low-flow* (variable performance) systems.

A high-flow oxygen delivery system provides the total inspired atmosphere so that a premixed F_{IO_2} is consistently and predictably delivered. To accomplish this goal, the inspiratory gas flows must be three to four times the measured minute ventilation. [4] [5] [6] So-called venturi devices (Fig. 72-2) (Figure Not Available) are the most commonly used high-flow oxygen devices for nonintubated patients. The physical behavior of these air-entrainment devices is best explained by the principle of constant-pressure jet mixing, where viscous shearing forces distal to the orifice entrain room air in a specific ratio. [7] Variation in orifice or entrainment port size changes F_{IO_2}, whereas variation of the oxygen flow rate determines the total volume of gas provided by the device. F_{IO_2} values of 0.24 to 0.40 are readily provided by air-entrainment mask systems, whereas higher F_{IO_2} values are best provided by large-volume nebulizers with wide-bore tubing leading to a mask or endotracheal tube. The intubated patient should breathe close to 100 percent humidified 37°C gas, to avoid drying of the tracheobronchial mucosa. This is safely and

Figure 72-2 (Figure Not Available) Principle of an air entrainment device. Pressurized oxygen is forced through a constricted orifice; the increased gas velocity distal to the orifice creates a shearing effect that causes room air to be entrained through the entrainment ports. The high flow of gas fills the mask; holes allow both exhaled and delivered gases to escape. A and B show that the size of the entrainment ports (EP) determines the amount of room air to be entrained. OS, oxygen source. Large ports (A) result in relatively low inspired oxygen fraction (F_{IO_2}); small ports (B) result in relatively higher F_{IO_2}. For any size EP, the F_{IO_2} is stable; however, the total gas flow varies with the pressurized oxygen flow. *(From Shapiro et al [1])*

economically accomplished by placing a reservoir tubing on the distal limb of the endotracheal T-connection so that inspiring room air is avoided.

A low-flow oxygen delivery system requires that the patient inspire some room air to meet inspiratory demands. These systems are popular because of their simplicity, patient comfort, and economics. The use of a low-flow oxygen delivery system does not imply delivery of low oxygen concentrations. As shown in Figure 72-3 (Figure Not Available), the F_{IO_2} is determined by the size of the oxygen reservoir, the oxygen flow rate, and the breathing pattern. For example, a nasal cannula at an oxygen flow rate greater than 6 L/min accomplishes minor increases in F_{IO_2} because the nasopharyngeal reservoir is filled with 100 percent oxygen at a 6 L/min flow rate. An oxygen reservoir must be increased (placing a mask over the nose and mouth) to achieve an F_{IO_2} greater than 0.40. Assuming a normal breathing pattern, Table 72-1 lists the approximate F_{IO_2} at various flow rates for the common low-flow oxygen delivery systems. With abnormal ventilatory patterns (Table 72-2) (Table Not Available), the larger the tidal volume (V), or the faster the respiratory rate, the lower the F_{IO_2}.

/das/book/view/29494766/875/785.html

BRONCHIAL HYGIENE THERAPY

Mucociliary activity and the cough mechanism are major factors that ensure spontaneous clearance of pulmonary secretions (bronchial hygiene). Bronchial hygiene therapy is primarily intended to mobilize retained secretions and to reinflate atelectatic lung regions. Normal pulmonary secretions form the mucus lining the airways that normally moves toward the larynx at 1 to 2 cm/min propelled by ciliary activity. This normal mucus blanket is capable of transporting a foreign particle from a respiratory bronchiole to the larynx in 20 minutes. When the properties of the mucus blanket and ciliary activity become abnormal, the cough mechanism is invoked to mobilize secretions. An effective cough mechanism requires an intact glottis, functional abdominal and intrathoracic musculature, and an adequate inspiratory capacity.

Table 72-3 provides an overview of the goals of bronchial hygiene therapy. Although the maintenance of bronchial hygiene is of recognized importance, the criteria for application of bronchial hygiene therapy are controversial. [8] The essential factors involved in bronchial hygiene therapy can be discussed in five general categories: (1) humidification of the airways, (2) incentive spirometry, (3) chest physical therapy, (4) positive-pressure techniques, and (5) invasion of the tracheal tree.

Humidification

Absolute humidity is the weight of water vapor in 1 L of gas (mg/L). Relative humidity is the absolute humidity expressed as a portion of the maximum absolute humidity. Table 72-4 lists the relationships between absolute and relative humidity at body temperature and at room air temperature.

Figure 72-3 (Figure Not Available) Reservoirs in low-flow oxygen therapy. The anatomic reservoir consists of the nose, the nasopharynx, and the oropharynx. This reservoir is estimated to be approximately one-third of the anatomic dead space. The appliance reservoir consists of (1) the mask: 100- to 200-mL volume, depending on the appliance; and (2) the reservoir bag: 600 to 1,000 mL of added volume. *(From Shapiro et al [1])*

Alveolar air is normally 100 percent humidified at 37°C, having a water vapor content of 44 mg/L and exerting a partial pressure of 47 mm Hg. Standard "room air" conditions (21°C, 50% relative humidity) have water vapor contents of less than 10 mg/L. The difference between alveolar water vapor content and that of room air is termed the *humidity deficit.* The nose normally restores most of the humidity deficit; however, the tracheobronchial mucosa must warm and humidify the inspired gas when the nose is bypassed. The tracheobronchial mucosa is more readily dehydrated than the nasal mucosa, a feature resulting in impairment of mucociliary activity and mucosal inflammation.

F_{IO_2} , inspired oxygen concentration

From Shapiro et al [1]

[a] Normal ventilatory pattern is assumed

The administration of dry oxygen lowers the water content of the inspired air, and placement of tracheal airways bypasses the nasopharynx and oropharynx, where the humidification of inspired gases primarily takes place. If adequate humidification of inspired gases is not provided prior to gas entry into the trachea, the deficit of humidity is provided by moisture from the mucus blanket of the tracheobronchial tree. This situation can result in drying of the tracheobronchial tree, ciliary dysfunction, impairment of mucus transport, inflammation and necrosis of the ciliated pulmonary epithelium, retention of dried secretions, atelectasis, bacterial infiltration of the pulmonary mucosa, and pneumonia.

To prevent these complications, a humidifier or nebulizer should be used to increase the water content of inspired gases. A humidifier increases the water vapor in a

gas without producing particulate water. A humidifier can prevent water loss from the pulmonary system, but it cannot add water to the system. Humidifiers are designed to increase water

TABLE 72-2 -- Variability in Inspired Oxygen Concentrations With Low-Flow Oxygen-Delivery Systems and Variable Patterns of Ventilation

(Not Available)

TABLE 72-3 -- Goals of Bronchial Hygiene Therapy

I. Goals of aerosol therapy
  A. Aid bronchial hygiene
    1. Restore and maintain mucus blanket continuity
    2. Hydrate dried, retain secretions
    3. Promote expectoration
  B. Humidify inspired gases
  C. Deliver medication
II. Goals of intermittent positive-pressure breathing
  A. Improve and promote cough mechanism
  B. Improve distribution of ventilation
  C. Deliver medication
III. Goals of chest physical therapy
  A. Aid bronchial hygiene
    1. Prevent accumulation of bronchial secretions
    2. Promote mobilization of bronchial secretions
    3. Improve cough mechanism
  B. Improve efficiency and distribution of ventilation
IV. Goals of sustained maximum inflation therapy
  A. Optimize lung inflation
    1. Prevent atelectasis
    2. Prevent accumulation of bronchial secretions
  B. Optimize cough mechanism
  C. Detect acute pulmonary disease early

vapor by passing gas over heated water (heated-passover humidifier), by fractionating gas into tiny bubbles as gas passes through water (bubble humidifiers), by allowing gas to pass through a chamber that contains a heated, water-saturated wick (heated-wick humidifier), or by vaporizing water and selectively allowing the vapor to mix with the inspired gases (vapor-phase humidifier). A nebulizer increases the water content of the inspired gas by generating aerosols (small droplets of particulate water) of uniform size that become incorporated into the delivered gas stream and then evaporate into the inspired gas as it is warmed in the respiratory tract. Pneumatic nebulizers operate from a pressurized gas source, and electric nebulizers are powered by an electrical source and are referred to as "ultrasonic." There are several varieties of the foregoing nebulizers that depend more on design differences than on power source.

Incentive Spirometry

The incentive spirometer is an effective and inexpensive prophylactic bronchial hygiene tool that provides a visual

TABLE 72-4 -- Relationships of Humidity and Temperature

21	18	100
21	9	50

goal or "incentive" for the patient to achieve and sustain a maximal inspiratory effort. When performed on an hourly basis, this modality provides optimal lung inflation, distribution of ventilation, and an improved cough. The hope is to prevent atelectasis and the retention of bronchial secretions. Incentive spirometry can also be helpful in the diagnosis of acute pulmonary disease in that a sudden decrease in the ability of a patient to perform at a previously established level may herald the onset of severe atelectasis, pneumonia, or other pulmonary disorders. For incentive spirometry to be effective, the patient must be cooperative, motivated, and well instructed in the technique (by the respiratory therapist, nurse, or physician); a vital capacity of more than 15 mL/kg or an inspiratory capacity of more than 12 mL/kg should be obtainable; the patient should not be tachypneic or receiving a high F_{IO_2} .

Chest Physical Therapy

Chest physical therapy techniques can be classified into those that promote bronchial hygiene, those that improve breathing efficiency, and those that promote physical reconditioning. The techniques considered here are those concerned with bronchial hygiene.

Postural drainage is a technique that utilizes different body positions to facilitate gravitational drainage of mucus from various lung segments (Fig. 72-4) . Common diseases that are amenable to postural-drainage therapy include cystic fibrosis, bronchiectasis, chronic obstructive pulmonary disease (COPD), acute atelectasis, and lung abscess. In hospitalized patients, the basilar lung regions can often benefit from postural drainage because most hospital bed positions do not permit adequate drainage of these lung segments. Of course, patients with increased intracranial pressure or congestive heart failure may not tolerate head-down positioning. In patients with unilateral lung disease, it is best also to provide drainage of the contralateral lung because cross-contamination of the nondiseased lung is always a possibility.

External manipulation of the thorax, in the form of percussion and vibration, is a technique used to loosen and mobilize secretions that are adherent to bronchial walls. [9] The percussion is intended to apply kinetic energy intermittently to the chest wall and lung. This is accomplished by rhythmically striking the thorax with cupped hands or a mechanical device placed directly over the lung segment to be drained. This procedure generates a mechanical energy wave that is transmitted through

the chest wall to the lung tissue and loosens adherent mucus. [9] [10] Mechanical percussion devices are available and have some theoretic advantages in that they apply vibratory/percussive forces in a more consistent, uniform fashion, and they are not subject to fatigue. However, no convincing evidence demonstrates the superiority of one method over the other. [11] Vibration normally follows percussion and involves the application of a fine tremorous action that is manually performed by pressing in the direction of the patient's ribs and soft tissue of the chest. Chest vibration is accomplished by placing the hands on the patient's chest wall and generating a rapid vibratory motion in the arms, from the shoulders, and gently compressing the chest wall in the direction in which the ribs normally move during

Figure 72-4 Common postural drainage positions for (A) posterior basilar segments; (B) middle lobe and ligula; and (C) apical segments of upper lobes.

exhalation. [9] [12] [13] Vibrations should be delivered during expiration over the draining area for optimal effect.

Positive-Pressure Techniques

Compared with spontaneous efforts in a patient with compromised pulmonary function, intermittent positive-pressure breathing (IPPB) can provide a significantly larger V_T and a physiologically advantageous inspiratory-to-expiratory pattern. IPPB therapy is most useful when inspiratory capacity is limited. Although widely applied in the past, this type of therapy is very expensive and should only be utilized when reasonable alternatives are not available. It is suggested that the patient's vital capacity (VC) should be less than 15 mL/kg, the IPPB treatment should augment this by at least 100 percent, and there is an identifiable end point for the therapy. The use of IPPB should be limited to patients with a reversible disease process.

Invasive Tracheal Techniques

Tracheal suction can be accomplished safely through endotracheal or tracheostomy tubes because adequate preoxygenation can be provided. Most commonly, the patient is hyperventilated with a high F_{IO_2} for three to five breaths to minimize the hypoxemia induced by removal of the patient from an oxygen source and the application of suction to the airways. A sterile suction catheter less than half the diameter of the tracheal tube should be advanced without the application of a vacuum until it can no longer be easily advanced. The catheter should then be withdrawn slightly, and intermittent suction should be applied while the catheter is withdrawn with a rotating motion. The duration of the entire procedure should not exceed 20 seconds. The patient should be immediately ventilated with an oxygen-enriched atmosphere to ensure adequate lung reexpansion and oxygenation. The patient must be closely observed for signs of distress, bronchospasm, hemodynamic instability, or cardiac arrhythmias throughout the entire procedure. In conjunction with a ventilator, a closed-system suction catheter may be of benefit to minimize contamination of both patient and health care professional. [14] [15]

Suctioning of the tracheobronchial tree without an established tracheal tube (i.e., nasotracheal suctioning) is common, but it is associated with significant risk because the patient cannot be adequately ventilated and "preoxygenated" prior to the procedure. [15] [16] In addition, passing the suction catheter through the vocal cords can result in laryngospasm or vocal cord injury with subsequent airway obstruction. Nasotracheal suction should be limited to patients who have reasonable ventilatory reserves and are free of coronary artery disease. "Routine" suctioning of the airway should be discouraged, except in neonates, whose small airway diameters can be acutely obstructed by a small accumulation of secretions.

Bronchoscopy for removal of secretions and reinflation of atelectasis is indicated when there is radiographic evidence of segmental or lobar atelectasis and the patient's clinical condition requires urgent intervention, or the atelectasis is persistent despite aggressive postural drainage, percussion, and vibration, and it is likely to result in detrimental sequelae such as pneumonia and lung abscess.

AEROSOL THERAPY

An aerosol is a suspension of fine particles of a liquid in a gas. Particle size should be 5 mum or less for deposition in the pulmonary tree. [17] Aerosols are used in respiratory care to aid bronchial hygiene, to humidify inspiratory gases, and to deliver medications.

Bland Aerosol Therapy

Aerosols of water or salt solutions are considered "bland" if they do not contain medications. Bland aerosol therapy can be used in the hydration of dried, retained secretions and the restoration and maintenance of the mucus blanket. However, bland aerosols are known to increase airway resistance (bronchospasm) or to cause dry secretions to swell, resulting in clinical deterioration that worsens hypoxemia. [18] These detrimental effects may be ameliorated by the administration of a bronchodilator. Although bland aerosol therapy is widely used, the practice is controversial because clear scientific evidence to support the utility of such therapy is not available. [19] [20] The administration of high-volume aerosolized saline (hypertonic, isotonic, or hypotonic) for 30 minutes via a continuous ultrasonic aerosol is appropriate to achieve sputum induction, provided the patient has a strong, effective cough and there is sputum in the airways that can be mobilized and expectorated. Complications associated with ultrasonically nebulized aerosols are wheezing or bronchospasm, infection, overhydration, patient discomfort, and the potential for exposure to droplet nuclei of *Mycobacterium tuberculosis* or other airborne contagion produced as a consequence of coughing, particularly during sputum induction.

Medication by Aerosol

Numerous drugs have been investigated for delivery by aerosol. In most instances, the drug was intended to have a topical or direct effect on the airways or lung tissue while minimizing its systemic effects.

Several antibiotic agents are currently used. There is a high incidence of bronchospastic reactions associated with the administration of aerosolized antibiotics. Either pretreatment or concurrent treatment with an aerosolized beta-agonist is recommended. Aerosolized pentamidine has been shown to be effective for *Pneumocystis carinii* pneumonia. [21] [22] However, pentamidine must be administered with an aerosol device that produces particles with a mass median aerodynamic diameter of less than 3.0 mum to ensure adequate penetration to the lung parenchyma and to minimize bronchospasm. Aerosolization and inhalation of amphotericin B have been investigated as a method to provide prophylaxis against pulmonary fungal infections while minimizing the adverse side effects of the drug. [23] The best reported results are against pulmonary aspergillosis. [24] Aerosolized antibiotic therapy for infections associated with cystic fibrosis was also explored, but it was found to be of equivocal efficacy. [25] Ribavirin has been recommended for the treatment of respiratory syncitial virus in children, especially those with congenital heart disease, immunodeficiency, or bronchopulmonary dysplasia. [25] The U.S. Food and Drug Administration (FDA) recommends an aerosol device that will generate particles with a mass median aerodynamic diameter of less than 1.5 mum.

Table 72-5 (Table Not Available) lists the most commonly used aerosolized pharmacologic agents. The beta-agonists and anticholinergic agents act primarily by enhancing bronchodilation through increases in intracellular cyclic adenosine monophosphate (cAMP) levels or decreases in intracellular cyclic guanosine monophosphate (cGMP) levels. The anti-inflammatory agents have gained popularity in the treatment of bronchospastic disorders because the disease processes have been demonstrated to be of an inflammatory nature.

Small-Volume Nebulizers

The delivery of medications via small-volume nebulizers (SVN) is the standard in clinical practice for aerosol medication delivery. Although the SVN is small and relatively easy to use, it requires a gas source that can produce a flow of 5 to 10 L/min. Either a respiratory therapist or a nurse must spend significant time for the aerosolized medication to be administered via a SVN, thus making these processes expensive and inefficient. [26]

Metered-Dose Inhaler

A functional alternative to the SVN is the metered-dose inhaler (MDI). The MDI is a device that permits rapid, self-administration of an inhaled drug by the patient. With appropriate use, delivery of drug to the lower airways has been demonstrated to be approximately 10 percent of the total dose and is comparable to that attained with the SVN. [27] [28] However, in contrast to the SVN, with which 66 percent of the drug is deposited in the apparatus, MDI administration results in only 5 to 10 percent of drug deposition in the apparatus. [27] [29] MDI and SVN modes of therapy have been clinically compared with respect to bronchodilator administration, and no differences were found between peak expiratory flow rates or severity of symptoms in stable patients treated with either modality. [30] In addition to equal clinical efficacy, administering bronchodilator therapy with MDI devices requires less personnel time and offers significant cost savings to the hospital. [31]

The effective use of an MDI requires that the patient meet certain clinical criteria. The patient must be able to position and actuate the device appropriately, to inspire deeply, and to coordinate the inspiratory effort with the device actuation. [32] [33] To ameliorate some of the problems associated MDI use, "spacer devices" have been developed. As shown in Figure 72-5 , a spacer acts as a reservoir into which the drug is discharged, and the device eliminates the need for significant coordination of hand, mouth, and breathing functions and improves delivery of the drug to the airways. [34] Patients can be expected to benefit from MDI-spacer therapy if they meet the following criteria: [35]

1. Respiratory rate less than 25 breaths/min.
2. Ability to breath-hold for 5 seconds or more.
3. VC greater than 15 mL/kg.
4. Ability to understand verbal and visual instructions.
5. Appropriate hand-mouth-inspiratory coordination.
6. Peak expiratory flow rates greater than or equal to 150 L/min for females and greater than or equal to 200 L/min for males.

Bronchodilators and Ventilators

The use of SVN to deliver bronchodilation during mechanical ventilation can result in bacterial contamination of

the ventilator circuit, alteration in the delivered V_T, increased work of breathing during patient-initiated modes of ventilation, and damage to flow-measurement devices incorporated into some ventilator circuits. [34] Administration of aerosols via an endotracheal tube is known to reduce penetration to the lower airways. [36] MDI have been shown to be comparable to SVN delivery systems without the associated problems in ventilator-dependent patients. [34]

PRINCIPLES OF POSITIVE-AIRWAY PRESSURE THERAPY

Positive-airway pressure therapy refers to the application of higher than ambient airway pressures during inspiration and/or exhalation for the purpose of improving pulmonary and respiratory function. Positive pressures applied during inspiration are usually referred to as positive-pressure ventilation (PPV). Positive pressures applied during exhalation are usually referred to as positive end-expiratory pressure (PEEP). Positive airway pressure is an essential component of critical care medicine and represents the single most important area demanding the unique skills and knowledge of the anesthesiologist.

The application of positive-airway pressure therapy to critically ill patients is confusing and controversial because of the following: (1) the physics, physiology, and technology are complex; (2) the terminology is inconsistent and at times contradictory; and (3) prospective conclusive human studies are rare because of multiple variables and the multidisciplinary clinical setting. This discussion is intended to provide a cohesive overview for all anesthesiologists irrespective of involvement in critical care medicine. Table 72-6 lists the definitions used in this chapter. These definitions are as acceptable as any others and are compatible with the published standards of the American College of Chest Physicians, the American Thoracic Society, and the American Association for Respiratory Care.

Physiology Associated With Positive-Pressure Ventilation

The need for PPV arises when one of three abnormal cardiopulmonary conditions is clinically evident: (1) apnea or any ventilatory pattern inconsistent with sustaining life; (2) acute ventilatory failure (acute respiratory acidosis), which is a condition in which the lungs fail to excrete adequate volumes of CO_2 [37]; and (3) impending ventilatory failure, in which clinical assessment of cardiopulmonary work suggests that the work of breathing is detrimental to maintaining respiratory homeostasis. [38]

Pathogenesis of Ventilatory Failure

Respiration is the exchange of oxygen and CO_2 across permeable membranes. Respiratory failure traditionally refers to inadequate molecular gas exchange at the pulmonary level. Because pulmonary gas exchange involves both bulk flow of gas in and out of the lungs (ventilation) and molecular gas exchange across the alveolar-capillary membrane (external respiration), ventilatory failure is a component of respiratory failure. Acute respiratory failure (ARF) can be conceptualized as resulting from either lung or pump failure (Fig. 72-6) .

Figure 72-6 Schematic representation of the pathogenesis of acute respiratory failure (ARF). The ventilatory pump is composed of the chest cage, the ventilatory muscles, and the nervous system elements involved in respiration. The pump primarily affects carbon dioxide excretion (CO_2). The lung involves the elements that allow inspired gas to exchange with pulmonary blood flow and primarily affects blood oxygenation (O_2). The large arrow from lung to pump represents the finding that lung disease often increases the work of the pump.

TABLE 72-6 -- Definitions

TERM	DEFINITION
Positive-airway pressure therapy	Positive pressure applied to the airway during any phase of the breathing cycle for the purposes of supporting or improving respiratory function
Positive-pressure ventilation (PPV)	Positive pressure applied to the airway for the purpose of providing or augmenting inspiratory tidal volume
Full ventilatory support (FVS)	Provision of PPV in a manner ensuring that the patient is *not obligated* to contribute to the work of breathing required for maintenance of CO_2 homeostasis
Partial ventilatory support (PVS)	Provision of PPV in a manner that *obligates* the patient to provide some of the work of breathing required for maintenance of CO_2 homeostasis
Ventilator mode	A combination of mechanisms that governs the ventilator's function and determines the potential interactions between patient and ventilator
Inverse-ratio ventilation (IRV)	PPV intended to result in an inspiratory time equal to or greater than the expiratory time
Volume-preset modes [a]	
Control-mode ventilation (CMV)	A volume-preset mode in which the patient is not allowed to participate in any phase of breathing cycle (time initiated, volume limited, volume/time cycled)
Assist-mode ventilation (AMV)	A volume-preset mode in which the ventilator frequency is determined by the patient's inspiratory efforts (pressure initiated, volume limited, volume/time cycled)
Assist/control mode ventilation (A/CMV)	Assist mode in which the ventilator frequency is determined by the patient's inspiratory efforts only when the patient's respiratory rate exceeds a preset control-mode rate (pressure or time initiated, volume limited, volume/time cycled)
Intermittent mandatory ventilation (IMV)	A ventilator system that allows spontaneous breathing via a continuous-flow device. Machine breaths are delivered at preset time intervals (time initiated, volume limited, volume/time cycled + spontaneous breathing)
Synchronized IMV (SIMV)	A ventilator system that allows spontaneous breathing via a demand-flow device. Machine breaths are delivered in synchrony with a spontaneous inspiratory effort occurring within a preset time interval (time/pressure initiated, volume limited, volume/time cycled)
Volume variable modes [b]	
Pressure-support ventilation (PSV)	A volume-variable mode in which the ventilator frequency is determined by the patient's inspiratory efforts; a preset system pressure is rapidly achieved and is maintained throughout inspiration by adjustment of machine inspiratory flow, and inspiration ends when the inspiratory flow falls below a preset minimal value (pressure initiated, pressure limited, flow cycled)

Pressure-control ventilation (PCV)	A volume-variable mode in which inspiration is time initiated; a preset system pressure is rapidly achieved and is maintained throughout inspiration by adjustment of machine inspiratory flow; and inspiration ends at a predetermined time (time initiated, pressure limited, time cycled)
Airway pressure-release ventilation (APRV)	A volume-variable mode in which inspiration is time initiated; a preset system pressure is maintained throughout inspiration by a continuous flow (threshold-resistor device), and inspiration ends at a predetermined time (time initiated, pressure limited, time cycled + spontaneous breathing)
Positive end-expiratory pressure (PEEP) [c]	
Continuous positive-pressure ventilation (CPPV)	PEEP in conjunction with positive pressure breaths (CMV + PEEP, A/CMV + PEEP)
Continuous positive airway pressure (CPAP)	PEEP in conjunction with a spontaneous breath through an apparatus designed to maintain airway pressure fluctuations above and below the baseline to no greater extent than would be present with normal spontaneous breathing
Expiratory positive airway pressure (EPAP)	PEEP in conjunction with a spontaneous breath through an apparatus designed to allow inspiratory flow only when inspiratory airway pressures descend below atmospheric

[a] Positive-pressure modes that deliver a specified tidal volume unless predetermined safety limits are exceeded--volume-limited modes
[b] Positive-pressure modes that deliver varying tidal volumes determined both by preset ventilator limits and patient factors--pressure, flow, or time limited
[c] Maintenance of a positive airway pressure at the end of exhalation

Ventilation is the movement of gas in and out of the pulmonary system. The pulmonary system is a to-and-fro valveless pump consisting of the chest cage, ventilatory muscles, and those nervous system components that regulate and influence muscular performance. Failure of the ventilatory pump occurs secondary to (1) fatigue of the ventilatory muscles (primarily the diaphragm); (2) abnormalities or major infringement on chest wall movement (e.g., flail chest, kyphoscoliosis, peritonitis, hemothorax, or after thoracoabdominal operations); (3) myoneural junction abnormality (e.g., myasthenia gravis, pharmacologic blockade); (4) motor nerve deficits (e.g., spinal cord trauma, poliomyelitis, polyneuritic diseases [Guillain-Barre syndrome], amyotrophic lateral sclerosis); and (5) central nervous system (CNS) depression or dysfunction. Acute or impending ventilatory failure is a consequence of a compromised ventilatory pump. The most common clinical manifestation of impending ventilatory failure is respiratory distress due to ventilatory muscle fatigue.

Ventilatory Muscle Fatigue

The energy required for muscle contraction is largely determined by the combination of workload and system efficiency; ventilatory workload is determined by minute ventilation, airway resistance, and lung compliance; and system efficiency is determined by such factors as stability of the chest wall, freedom of movement of the chest wall and abdomen, intrathoracic gas volume, nutritional status, and energy storage within the muscles. For any required degree of muscular work, onset of fatigue is best conceptualized as a situation in which energy demand exceeds energy supply.

Figure 72-7 (A) The work of breathing in relation to the minute volume. Solid line, normal; dashed line, lung disease. (B) The work of breathing in relation to vital capacity. Point "a" represents a tidal volume of 500 mL with a vital capacity to 5 L; point "b" represents a tidal volume of 500 mL with a vital capacity of 1 L.

Increased energy demand is a common reason for ventilatory muscle fatigue. The efficiency of ventilatory muscle activity is the primary determinant of energy demands. In healthy persons at rest, oxygen utilization of the ventilatory muscles (O_{2ven}) accounts for 2 to 5 percent of the total body oxygen consumption (O_{2tot}). Even in this optimal physiologic condition, the efficiency with which energy is transformed into mechanical work is astoundingly poor. [39] As minute ventilation increases, O_{2ven} increases at a faster rate than the increase in O_{2tot}, [40] resulting in the relationship depicted in the solid line in Figure 72-7 A.

In patients with cardiorespiratory disease (see Fig. 72-7, dashed line), resting O_{2ven} is 20 to 25 percent of O_{2tot}. [41] This increased resting O_{2ven} is only partly due to recruitment of postural and synergistic accessory muscles that do not directly contribute to ventilation. Because minute ventilation is increased in patients with cardiopulmonary disease, the O_{2ven}/O_{2tot} ratio has been reported to increase at an exponential rate. [42] It is reasonable to conclude that as ventilation increases, an ever greater proportion of the additional oxygen uptake is diverted to the ventilatory muscles. If this is at the expense of oxygen available for nonventilatory work, further increases in ventilation may be detrimental to vital tissue oxygenation.

In severe cardiopulmonary disease states, the ventilatory pump may become so inefficient that any oxygen potentially gained from increased ventilation is completely consumed by the increased work of the ventilatory muscles. This situation may progress to the point at which the work of breathing is so costly that an increase in ventilation results in a net oxygen loss to the patient.

Decreased oxygen supply is another common reason for ventilatory muscle fatigue. Energy substrates such as glucose are stored within skeletal muscle, so that during limited periods when demand increases over supply (e.g., during exercise), the muscles consume stored energy substrates to avoid fatigue. However, skeletal muscles have no significant ability to store oxygen, so that decreases in oxygen delivery may result in anaerobic metabolism that adversely affects the biochemical reactions involved in muscle contraction.

In the absence of hypoxemia, the oxygen supply available to ventilatory muscles is essentially related to blood flow, which is capable of increasing in proportion to O_{2ven} over a wide range of minute ventilation. [43] [44] Although it has been suggested that the diaphragm may differ to some degree, [45] most investigators agree that the respiratory rate and inspiratory/expiratory (I:E) ratio have potential implications for ventilatory muscle perfusion, because anything that significantly shortens expiratory time potentially diminishes blood flow to the muscles. In either case, a normal cardiopulmonary system is capable of increasing both cardiac output and ventilatory muscle blood flow to allow 3- to 4-fold increases in minute ventilation without fatigue.

When blood flow is limited, increased ventilatory demands may result in anaerobic metabolism of the ventilatory muscles, creating a lactic acidosis. [46] Under these circumstances, a significant portion (25-30%) of the limited cardiac output perfuses the ventilatory muscles, resulting in even lesser flow to other skeletal muscles and vital organs, which may result in a further increase in blood lactate. [47] When diminished arterial oxygen availability exists (e.g., hypoxemia or anemia), as much as 30 to 40 percent of the cardiac output may perfuse the diaphragm at the expense of brain, kidney, and other essential organs. [48] [49] The increase in O_{2tot} is almost entirely due to increased O_{2ven}. If possible, the cardiovascular system increases cardiac output above normal to satisfy total body oxygen requirements.

The clinical relevance of this physiology is that PPV ablates or diminishes detrimental work of breathing. In hyperdynamic states, application of ventilatory support significantly reduces O_{2ven}, and thereby O_{2tot}, resulting in a diminishing cardiac output toward normal and often an improvement in the arterial oxygenation status. It is suggested that such beneficial physiologic responses to PPV are due to decreased ventilatory muscle oxygen demands. [50] Allowing the patient to breathe to whatever extent the ventilatory

muscles can efficiently function, while providing the remainder of the work of breathing with a ventilator, is the best means of eliminating the detrimental work of breathing while optimizing hemodynamic function. [51]

Lung Failure Versus Pump Failure

Lung failure results from pathologic processes that cause inadequate exchange between alveolar gas and pulmonary blood, usually manifested clinically as an arterial oxygenation deficit. Increased work of breathing invariably accompanies lung failure secondary to one or a combination of (1) hypoxemia resulting in increased ventilatory drive, (2) increased airway resistance, (3) decreased lung compliance, or (4) increased physiologic dead space. Pump failure occurs when the work of breathing exceeds reserve capability, usually manifest clinically as respiratory distress and/or hypercapnia. As illustrated in Figure 72-6 , a reasonable generalization is that lung disease primarily results in oxygenation deficits and secondarily may cause inadequate CO_2 elimination; ventilatory pump failure primarily threatens CO_2 excretion and secondarily oxygenation.

Oxygenation

Hypoventilation creates arterial hypoxemia during breathing of room air. Such hypoxemia is reversed when adequate ventilation is restored spontaneously or with a ventilator. Hypoxemia coincident with adequate alveolar ventilation (hypoxemic respiratory failure) is seldom improved by the institution of PPV, except when decreasing O_{2ven} will significantly diminish O_{2tot} , as with impending ventilatory failure.

Most primary arterial oxygenation deficits are best supported by means of oxygen therapy, cardiovascular therapy, bronchial hygiene therapy, PEEP therapy, or combinations of these techniques. Although any or all of these therapies may be administered in conjunction with the ventilator, none of them requires the use of a ventilator. PPV must be considered a tool for directly relieving or diminishing the work of breathing, while indirectly having the potential to improve oxygenation in some clinical circumstances.

Increased Physiologic Dead Space

Minute ventilation is the sum of alveolar ventilation (V_A) and dead-space ventilation (V_D). The adequacy of V_A is clinically reflected by measurement of the Pa_{CO_2} . Normally, ventilation/perfusion relationships (V/Q) are largely determined by pulmonary blood flow preferring gravitydependent lung and spontaneous inspiration favoring similar distribution of ventilation. PPV tends to result in non- gravity-dependent gas distribution in part because of a lack of decreased pleural pressures during inspiration. Additionally, non-gravity-dependent lung normally has less airway resistance and higher compliance than that of gravity-dependent lung, which also favors gas distribution to areas with less perfusion. The resultant increase in V/Q with PPV is generally referred to as an increase in V_D (ventilation in excess of perfusion). This is the major reason why a greater minute ventilation is usually required to maintain a normal Pa_{CO_2} with a ventilator than with spontaneous ventilation.

Decreased Cardiac Output

Diminishment of cardiac output due to embarrassment of venous return to the right heart was the first documented disadvantage of PPV. [52] Appropriate vascular space expansion with intravenous fluid administration restores the cardiac output to pre-PPV levels. Too often, hypotension following the establishment of an airway and PPV is assumed to be due to such factors as (1) stress of intubation, (2) delay in accomplishing successful intubation, (3) use of pharmacologic agents to facilitate intubation, and (4) inappropriate support of ventilation. Although any of these factors is possible, hypotension often occurs in their absence.

Increased sympathetic activity is common in patients requiring initiation of ventilatory support because of factors such as hypoxemia, hypercapnia, acidemia, and increased work of breathing. This sympathetic activity causes contraction of the venous space (venoconstriction) and myocardial stimulation. Initiation of ventilator support usually relieves the work of breathing and reverses hypercapnia, acidemia, and hypoxemia, thereby decreasing sympathetic activity. Most often, the hypotension seen with initiation of PPV is secondary to a decrease in sympathetic tone, creating a relative hypovolemia with resultant decreases in venous return to the right heart. When hypotension is severe, the patient should immediately have both lower extremities elevated 20 to 30 degrees from the horizontal position. The transient increase in "core" blood volume should improve venous return to the right heart. The eventual correction of the relative hypovolemia is accomplished by appropriate intravenous fluid administration. The patient must not be allowed to "fight" the positive-pressure breath to avoid unduly increasing intrathoracic pressures.

Spontaneous Breathing

In the process of initiating PPV, the first priority is to establish the airway and manually to support ventilation, to take over ventilation gradually and to vary the breathing pattern in conjunction with patient efforts. This technique should allow a smooth transition to the ventilator. It is not uncommon for patients to demonstrate cardiovascular instability during this process. Often, delays in establishing the airway, stress of intubation, sedative drugs, and inappropriate support are condemned for this occurrence. However, such instability often occurs in the absence of any of the previously mentioned factors, as a result of the following: (1) the relief of respiratory distress, causing a decrease in circulating catecholamine, with subsequent vasodilatation and decreased cardiac output; (2) decreased venous return related to the positive airway pressure; or (3) a combination thereof.

Principles of anesthesia care apply outside the operating room and must be followed. Vascular access and appropriate monitors must be established as soon as possible. Appropriate analgesia and sedation are necessary to achieve a comfortable and stable patient on a ventilator.

Modes of Positive-Pressure Ventilation

The functions of a positive-pressure ventilator must involve four physical factors: volume, flow, pressure, and time. As shown in Figure 72-8 , three mechanical factors regulate the inspiratory phase, and each must be governed by a physical factor: (1) a mechanism to begin the inspiratory cycle (initiation) must be governed by a physical factor; (2) a generator provides the driving force, and the power of the generator must be governed by a physical factor (limit); and (3) a mechanism for ending inspiration (cycle off) must be governed by a physical factor. Positive-pressure ventilators are traditionally classified by the physical factor that ends the inspiratory cycle.

Volume-Preset Modes

Volume-preset modes are either time initiated (controllers) or pressure initiated (assisters). Volume-preset modes possess several advantages: (1) the volume of gas delivered to the patient is reliably controlled; (2) volume delivery remains constant despite pathophysiologic changes in the patient's condition; (3) reliable monitoring devices are readily adaptable; (4) variations in airway pressure waveforms are readily accomplished; and (5) a consistent oxygen atmosphere can be easily maintained.

Figure 72-9 illustrates the airway pressure curves for the four common volume-preset modes. Control mode delivers positive-pressure breaths to the patient at predetermined time intervals. In the conscious patient, lack of available gas for spontaneous breathing between ventilator cycles may create a sensation of breathlessness and may result in "fighting

Figure 72-8 Airway pressure curves illustrating the three mechanical functions: IN, initiation of the cycle; LIM, a preset limit imposed on the positive-pressure cycle; CYC, ending the cycle. Each mechanical function is preset to be governed by one of three physical factors: volume, pressure, or flow time. (A) Time-initiated, volume-limited, volume-cycled mode. (B) Pressure-initiated (intended to be a sub-baseline pressure secondary to the patient's effort to initiate a breath), volume-limited, volume-cycled mode. (C) Time-initiated, volume-limited, time-cycled mode that extends inspiration

beyond the time the volume is delivered.

Figure 72-9 Airway pressure tracings of the four standard volumepreset modes. Thick solid lines represent ventilator breaths and thick dotted lines represent spontaneous breaths. The thin dotted lines refer to what the spontaneous pattern would have been without the ventilator breaths. IMV, intermittent mandatory ventilation; SIMV, synchronized IMV.

the ventilator." The control mode is seldom used outside the operating room. Assist/control mode initiates a positive-pressure cycle when the ventilator senses a circuit pressure lower than baseline. Because there is no source for fresh gas flow between cycles, circuit pressure must decrease when the patient initiates a spontaneous breath. A minimal back-up rate is set below which the ventilator will initiate breaths at an assigned time interval independent of patient effort. Assist/control mode eliminates the sensation of breathlessness often observed with control mode and usually diminishes requirements for sedation and paralysis. Although respiratory alkalemia may complicate assist/control mode in some patients, generally assist/control greatly improves clinical care when compared with the control mode. It has been shown that the energy expenditure required to initiate the ventilator cycle with assist/control continues throughout the entire inspiratory cycle. [53] [54] This energy expenditure may be significant in patients with extremely limited cardiopulmonary reserves.

Intermittent mandatory ventilation (IMV) is essentially a control mode in conjunction with circuitry that provides a fresh gas flow for spontaneous breaths. The positive-pressure cycle is completely independent of the patient's spontaneous ventilatory pattern. An adequate fresh gas source at least four times the patient's spontaneous minute volume is required to minimize the work of breathing imposed by the ventilator circuit. An appropriately functioning continuous-flow system providing the inspired gas for spontaneous breathing should cause inspiratory airway pressures to drop no more than 2 to 3 cm H_2O below baseline. [55] [56]

Synchronized IMV (SIMV) is essentially an assist/control mode in conjunction with a demand-valve system that provides a fresh gas flow for spontaneous breaths. Originally described as intermittent demand ventilation, [57] SIMV allows spontaneous breathing with positive-pressure cycles triggered by the patient's inspiratory effort at predetermined intervals. The patient will be mechanically ventilated at a

Figure 72-10 Schematic representation of a demand-flow system. DV, demand valve device; EXV, exhalation valve; Initial Spon Inspiration, gas flow at the moment the demand-valve mechanism opens; OWV, one-way valve to minimize tubing that must be decompressed to create sub-baseline pressure; PPV, gas flow during positive-pressure ventilation; PSD, pressure-sensing device that cycles ventilator and demand-valve mechanism; Spon Inspiration, gas flow after the flow has reached the patient; VOWV, ventilator one-way valve.

preset rate if insufficient spontaneous efforts are absent within a prescribed period. The resultant airway pressure pattern synchronizes spontaneous and mechanical breaths (see Fig. 72-9) .

Figure 72-10 schematically illustrates a ventilator demand-flow system. A pressure-sensing device is located near the patient's airway and detects a fall in baseline pressure, activating either the positive-pressure cycle or the demand-flow device. The major disadvantage of demand-flow systems is the delay in providing adequate inspiratory gas flow to the airway, especially when reasonably large V_T or rapid inspiratory flow rates are required. These factors result in an imposed work of breathing significantly greater than that associated with continuous-flow systems. [58] When spontaneous breathing is providing most of the required minute ventilation, the imposed work of breathing coincident with demand-flow systems may be detrimental in patients with significantly limited ventilatory reserves. [59]

Volume-Variable Modes

Pressure-limited ventilators were widely used during the 1940s and 1950s because they confined the pressure applied to the airway. They were clinically unacceptable for ventilator support because they did not provide consistent V_T, and

TABLE 72-7 -- Modes of Mechanical Ventilation and the Factors Controlling the Ventilatory Cycle

VENTILATOR MODE	INITIATED	LIMITED	CYCLED
Control-mode	Time	Volume	Volume/time
Assist/control-mode	Pressure	Volume	Volume/time
Intermittent mandatory	Time	Volume	Volume/time
Synchronized intermittent mandatory	Pressure	Volume	Volume/time

Pressure-control	Time	Pressure	Time
Airway pressure-release	Time	Pressure	Time

monitors to ensure consistent ventilation were not available. Such technologic limitations led to the preference for volume-preset ventilators in acute respiratory care. The availability of microprocessor technology in the 1980s allowed development of pressure-preset (volume-variable) modes with finite inspiratory flow variability, finite control of the preset airway pressure, and extensive monitor and alarm systems. This technologic advance has led to a general acceptance of volume variable modes.

Pressure-preset modes are initiated by time or pressure. Table 72-7 compares currently available volume-preset modes with the standard volume-variable modes. Figure 72-11 schematically illustrates the mechanics of the pressure-support mode. A sub-baseline pressure near the proximal airway activates the demand-flow system. A rapid flow enters the circuitry and continues until a predetermined pressure is achieved. Constant microprocessor analysis of the delivered flow and circuit pressure determines the required variation of flow necessary to maintain the predetermined circuit pressure. Assuming that no leaks are present in the system, the flow entering the circuitry to maintain the preset pressure should be the same as that entering the patient's pulmonary system. When the delivered flow reaches some predetermined minimum set by the manufacturer, flow stops entering the system, and the exhalation valve is opened.

Pressure support was initially developed to surmount the imposed work of breathing associated with demand-flow systems. [60] Three to 8 cm H_2O pressure support has been shown comparable to a continuous-flow system in reference to imposed work of breathing during spontaneous ventilation. [61] Using the continuous positive-airway pressure (CPAP) mode of a demand-flow ventilator imposes work of breathing. Provision of 3 to 5 cm H_2O pressure support allows the CPAP mode to impose no more work of breathing than a continuous-flow CPAP system. [62]

The routine use of 3 to 5 cm H_2O pressure support with SIMV should be considered no different from IMV with a properly functioning continuous-flow system. [63] Combining SIMV with pressure support higher than 10 cm H_2O constitutes the simultaneous application of two ventilating modes. Pressure support greater than 10 cm H_2O should be considered an independent mode for positive-pressure support. Most patients demonstrate an increase in V_T when the pressure-support level

exceeds 10 cm H_2O, and most demonstrate a decrease in respiratory rate by 20 cm H_2O. [64] Despite claims of shorter ventilator time and faster weaning, [65] there are no prospective studies comparing pressure-support

Figure 72-11 Schematic illustration of pressure-support mechanics. IN, initiation; LIM, limit; CYC, cycle; EX, exhalation.

Figure 72-12 Airway pressure tracings of (A) pressure support and (B) pressure control. IN, initiation; LIM, limit; CYC, cycle.

systems with other modes. Observations of lower peak airway pressure, higher mean airway pressure, and subjective comfort during pressure support as compared with SIMV appear valid. [66]

The pressure-control mode is schematically illustrated in Figure 72-12 . The inspiratory gas flow is determined in the same manner as pressure support, but the pressure-control mode is initiated by time and is cycled off by time. The number of ventilatory cycles per minute is preset and determines the time intervals at which a new inspiratory cycle will begin. The positive pressure is cycled off when a predetermined time has elapsed from the start of inspiration. Therefore, the mode allows for any desired inspiratory/expiratory ratio.

The pressure-release mode (Fig. 72-13) consists of a continuous-flow system with a release valve situated in the expiratory limb that determines which of two paths will be open to the gas flow. The release valve is driven by a timing device that allows adjustment of the extent, length, and frequency of pressure release. Closing of the release valve by a timing mechanism initiates the inspiratory phase. During this phase (Fig. 72-13 A), the continuous gas flow exits through a threshold resistor with a preset pressure greater than that during expiration. Opening of the release valve by a timing mechanism cycles the mechanism from inspiration to expiration. This process allows the continuous gas flow to exit through a threshold resistor with a lower preset pressure (Fig. 72-13 B). Thus, airway pressure falls rapidly, and gas exits the lungs. The lung volume at end-inspiration is primarily determined by the preset pressure and the pulmonary compliance. The end-exhalation lung volume is determined by lung compliance, airway resistance, release time, and the gradient between the inspiratory and expiratory preset pressures. Unlike pressure-control mode, the pressure-release mode allows spontaneous breathing without imposed work of breathing.

High-Frequency Ventilation

High-frequency ventilation (HFV) provides V_T less than the anatomic dead space at rates significantly more rapid than normal. Frequencies are stated as cycles per minute or cycles per second (Hz). For purposes of simplicity and clarity, only the three major techniques with the greatest potential for clinical applicability are discussed. More complete discussions are available. [67] [68]

High-frequency positive-pressure ventilation refers to the delivery of small V_T through an insufflation catheter or endotracheal tube with circuitry having a minimal internal compressible volume. The characteristic rate is 60 to 100 per minute, with inspiration taking 20 to 30 percent of the cycle. [69] High-frequency oscillation delivers gas to a reciprocating pump that actively transports the gas both into and out of the lungs. Oscillators are distinct from other high-frequency

Figure 72-13 Schematic representation of airway pressure-release ventilation. (A) Inflation pressure generated by a continuous-flow system with a threshold resistor set at +30 cm H_2O. Flow into the lungs is determined by the inflation pressure and the forces impeding flow (resistance and compliance). The inspiratory lung volume is determined by the inflation pressure and the pulmonary compliance. (B) Release valve positioned to allow flow through the threshold resistor set at +10 cm H_2O. The resultant release pressure in the circuit allows exhalation.

devices because active expiration is an intrinsic part of their design, and oscillators are much less likely to result in hyperinflation because the device actively pulls gas out of the system during the expiratory phase. [70] Commonly used frequencies of 10 to 15 Hz have evolved empirically. High-frequency jet ventilation is the technique most widely used in North America. The technique refers to the delivery of a pulse of gas from a high-pressure source (5-50 psi) through a small-bore cannula with an interposed cycling mechanism allowing high frequencies. Gas entrainment can occur around the jet and may contribute significantly to inspiratory flow. The optimal catheter gauge and positioning within the endotracheal tube have not been established. [71] Inadequate humidification of delivered gas remains a major problem during high-frequency jet ventilation, resulting in tracheal mucosal damage and thickened secretions blocking the airways. Attempts at humidification have included nebulization of a saline infusion by the jet stream, entrainment of humidified gases, and humidification of the jet gases. [68]

Despite numerous anecdotal reports of clinical utility, there is little evidence that HFV has distinct advantages over more traditional approaches. The least controversial indication for use of HFV is with massive air leaks through fistulous tracts. [72] [73] [74] Because the fistula effectively represents a region of high compliance, much of the V_T is lost through the fistulous tract during conventional ventilation. At higher frequencies, the distribution of ventilation depends more on resistance, whereas compliance becomes relatively unimportant. [68] [75] Patients with a massive air leak from a fistulous tract can be ventilated and oxygenated with HFV when conventional techniques have failed. [72] [73] Although randomized prospective studies comparing conventional ventilation with HFV in the management of patients with airway rupture are lacking, crossover animal studies support these clinical observations. [74]

Any purported advantages of HFV must be considered in relation to the potential hazards of massive barotrauma, injection injury, and alveolar overdistention. Injection injury occurs when a high-pressure jet of gas is directed against the tracheal mucosa and results in submucosal dissection and even perforation of the wall. Tension pneumothorax occurs more readily with HFV than with conventional ventilation, owing to the "stacking" of breaths that so rapidly occurs if insufficient time or space for gas escape is allowed.

Positive End-Expiratory Pressure Devices

The safety and efficacy of adult CPAP/PEEP therapy are greatly dependent on the appropriate technical application of threshold devices to avoid increased expiratory airway pressures, increased work of breathing, diminished cardiac output, and an increased incidence of barotrauma. An ideal threshold resistor exerts a constant force that will not impede flow in any way until the system pressure is less than the pressure at which the constant force will completely stop flow. When placed in the exhalation limb of an adult breathing circuit, a threshold resistor stops exhalation at a preset pressure higher than ambient pressure. There are no commercially available threshold resistors that are totally free of flow-resistive properties that increase pressure when flow is high. Additionally, if the cross-sectional area available for gas to exit the device is smaller than the cross-sectional area of the expiratory circuit, or if gas is routed through a convoluted path, flow resistance is created.

Gravity-dependent threshold-resistor devices demonstrate the lowest degree of flow-resistor characteristics, but they require an upright and stable position that severely limits portability and safety. The water-column threshold resistor, very popular before the microprocessor-driven ventilators were introduced, is now only of historical importance. The weighted-ball valve device creates a threshold resistance by the weight of a precision-ground ball atop a calibrated orifice; the heavier the ball, the greater the expiratory pressure. These devices are so gravity dependent that even a 10-degree tilt from vertical may cause changes in end-expiratory pressure level.

Non-gravity-dependent devices are the most popular type of threshold resistors. Spring-loaded valves are available in which expiratory pressure is maintained by the

compression of a spring below its no-load length. The flow-resistance properties of these valves depend on the surface area available at the point of seating of the valve diaphragm. Balloon-type devices (Fig. 72-14) establish PEEP by maintaining a force in the balloon that must be exceeded in order for exhalation to occur.

Continuous Positive Airway Pressure Systems

The application of positive airway pressure at end-exhalation, in conjunction with PPV, is referred to PEEP therapy. [76] When used in conjunction with spontaneous ventilation, the designation CPAP is applied. [1] [77] A CPAP system must provide inspiratory gas flow sufficient to meet the patient's spontaneous inspiratory flow demands. As discussed earlier, the inspiratory gas flow can be provided by either a continuous-flow or a demand-flow system (see Fig. 72-10) . The considerable manufacturing advantages of a demand-flow system are offset by the clinical problem of the imposed work of breathing. [58] [59] As schematically illustrated in Figure 72-15 , changes in pressure during spontaneous ventilation are reflections of the work of breathing. Normal work of breathing causes fluctuations of approximately 2 cm H_2O from baseline (Fig. 72-15 A). Fluctuations of greater magnitude during inspiration (Fig. 72-15 B) may be corrected by increasing system flow in a demand-flow system or increasing the size of the circuit reservoir in a continuous-flow system. Changes in baseline pressure during exhalation (Fig. 72-15 C) are primarily affected by the flow-resistance properties of the threshold resistor employed to produce the end-expiratory pressure.

Physiology Associated With Continuous Positive Airway Pressure/Positive End-Expiratory Pressure

PEEP exists whenever the airway pressure is greater than ambient pressure prior to the next inspiratory cycle. The

Figure 72-14 Schematic representation of a balloon-type exhalation valve, with balloon connected to ventilator pressure line. (A) Pressure (+10 cm H_2O) is applied to the balloon during exhalation. When the exhalation line (EL) pressure exceeds +10 cm H_2O, the balloon will be displaced and gas will flow to the outlet port (OP). There is a potential restriction to flow resulting from the partially expanded balloon. This may be a clinically significant factor at relatively greater flow rates. (B) When the exhalation line pressure is equal to or less than +10 cm H_2O, the balloon will occlude the exhalation line and will stop flow.

acronym PEEP generally refers to positive end-expiratory pressure in conjunction with a positive-pressure inspiration; the acronym CPAP usually refers to PEEP in conjunction with a spontaneous inspiration. To avoid controversy and confusion, we use the acronym CPAP/PEEP in reference to the end-expiratory phenomena independent of the inspiratory dynamics.

Pulmonary Effects

Two universal pulmonary effects of CPAP/PEEP are redistribution of extravascular water and increased functional residual capacity (FRC). Several other mechanisms have been proposed to explain the beneficial pulmonary effects of

Figure 72-15 (A-C) Continuous positive-airway pressure (CPAP) airway pressure curves.

CPAP/PEEP, but these appear to be important only when specific pulmonary disease is present. For example, CPAP/PEEP has been shown to have a favorable effect on the relationship between the closing volume (lung volume at which dependent small-airway closure occurs) and FRC, thereby decreasing the degree of low V/Q that occurs in anesthetized human patients with severe COPD and morbid obesity. [78] The extent to which this phenomenon is clinically significant in nonanesthetized human patients with acute restrictive lung disease is, at best, marginal.

Redistribution of extravascular lung water is a major mechanism by which CPAP/PEEP improves lung function. It has been established that CPAP/PEEP therapy does not decrease total lung water [79] [80] ; on the contrary, it appears that CPAP/PEEP directly increases the accumulation of extravascular lung water. [81] [82] However, the application of CPAP/PEEP to patients with either cardiogenic or noncardiogenic pulmonary edema improves oxygenation and pulmonary mechanics largely because of the effects on the distribution of lung water. As shown in Figure 72-16 , the application of CPAP/PEEP to the edematous lung decreases intra-alveolar fluid volume and facilitates the movement of water from the less compliant interstitial spaces (between the alveolar epithelium and pulmonary capillary endothelium) where gas exchange occurs to the more compliant interstitial spaces (peribronchial and hilar regions). [83] [84] [85] This

Figure 72-16 (A and B) Redistribution of extravascular lung water with positive end-expiratory pressure.

Figure 72-17 (A-C) Increasing alveolar volumes with +10 and +20 cm H_2O positive end-expiratory pressure. Black arrows represent elastic forces; white arrows represent distending forces.

redistribution of interstitial water improves oxygenation, lung compliance and V/Q matching.

CPAP/PEEP results in an increased FRC by two distinct mechanisms: (1) 10 cm H_2O or less is primarily responsible for increasing the volume of patent alveoli, and (2) 10 cm H_2O or more is generally responsible for alveolar recruitment. [86]

As schematically illustrated in Figure 72-17 , incidence light photomicrography studies on normal lung demonstrate that (1) alveolar diameters increase linearly with 0 to 10 cm H_2O CPAP/PEEP; (2) end-expiratory diameters increase to a greater degree than end-inspiratory diameters; (3) at levels higher than 10 cm H_2O CPAP/PEEP, increases in alveolar diameters progressively diminish and reach a plateau at approximately 15 cm H_2O; and (4) at levels higher than 15 cm H_2O CPAP/PEEP, alveolar pressure increases without measurable increase in alveolar diameters. [87] These data suggest that there are upper limits to the distensibility of normal alveoli and that, within these limits, the application of CPAP/PEEP can increase FRC simply by increasing alveolar size. Increased alveolar volumes result in a greater surface-area exposure of alveolar gas and capillary blood secondary to elongation of juxta-alveolar vessels (see Fig. 72-17) . This has been proposed as the primary mechanism by which CPAP/PEEP affects gas exchange in the normal lung, a hypothesis consistent with available clinical data. [86] [88]

Alveolar recruitment is a term commonly used to refer to

Figure 72-18 Schematic representation of alveolar recruitment at +10 cm H_2O positive end-expiratory pressure. External arrows represent elastic forces; internal arrows represent distending forces.

an increase in FRC secondary to inflation of previously collapsed alveoli (Fig. 72-18) . [89] [90] Studies of the effects of CPAP/PEEP on volume-pressure curves during ARDS have demonstrated an inflection point that is thought to represent the critical pressure necessary to reopen or "recruit" closed peripheral airways and/or collapsed alveolar units. [91] [92] [93] Computed tomography (CT) scanning techniques have been applied to correlate the physiologic changes observed in volume-pressure relationships with morphologic changes noted on CT scans in ARDS patients during PEEP therapy. [94] [95] Using this technique, Figure 72-19 (Figure Not Available) B demonstrates a classic inflection point (P_{flex}) in the gas-to-tissue (g/t) ratio curve, at a critical PEEP level, which is consistent with alveolar recruitment; Figure 72-19 (Figure Not Available) C demonstrates no increase in the g/t ratio with increasing PEEP, a finding that indicates no additional lung inflation and is consistent with a consolidative process.

The response to CPAP/PEEP titration varies not only with the type of lung disease, but also in relation to gravity. [94] [95] More gravity-dependent lung regions appear to undergo greater degrees of alveolar recruitment, whereas less gravity-dependent lung regions tend to experience greater increases in alveolar volume without recruitment. It has also been radiographically confirmed that the application of PEEP to ARDS-affected lungs results in a redistribution of tidal ventilation from the less dependent (upper) regions of lung to the more dependent (lower) regions of the lung. [96] Further, the cyclic alveolar collapse and recruitment that occur with normal tidal ventilation, primarily in the middle lung fields, is reduced with the application of PEEP. [96]

Intrapulmonary shunting (Q_{SP}/Q_T) is a mathematic reflection of all lung factors affecting arterial oxygenation and is often used as a means of quantifying the lung response to CPAP/PEEP therapy in terms of arterial oxygenation. Oxygen tension indices, such as Pa_{O_2}/F_{IO_2}, are popular, but they are sometimes misleading in reflecting the status of Q_{SP}/Q_T. [97] Comprehending the importance of the intrapulmonary shunt is important because whenever perfusion exceeds ventilation to an alveolus (low V/Q), the blood leaving that alveolus has a lower oxygen content than blood leaving a well-matched alveolar capillary unit. The resultant hypoxemia is responsive to oxygen therapy, because the increased F_{IO_2} increases the Pa_{O_2}. Perfusion to a collapsed alveolus (0 V/Q) is termed a true shunt unit, and the hypoxemia it creates is not responsive to oxygen therapy because the blood does not come in contact with alveolar gas. The application of CPAP/PEEP therapy to a lung with appropriate pathologic

Figure 72-19 (Figure Not Available) Curves of gas-tissue ratios at various positive end-expiratory pressure (PEEP) levels as determined by computed tomographic scanning. (A) linear gas-tissue ratio curve indicative of alveolar expansion; (B) biphasic gas-tissue ratio curve with classic inflection point (P_{flex}) indicative of alveolar recruitment; (C) insignificant or unchanging gas-tissue ratio curve indicative of alveolar consolidation. *(From Gattinoni et al [88])*

features may result in alveolar distention of poorly ventilated alveoli and the recruitment of collapsed alveoli. As a result, the Q_{SP}/Q_T is decreased, leading to a hypoxemia that is more responsive to oxygen therapy. [98]

V_D is defined as the portion of ventilation that does not respire with pulmonary capillary blood. The application of excessive CPAP/PEEP to lungs with nonuniform pathologic features can overdistend normal alveoli, compressing surrounding capillaries and diminishing perfusion to those alveoli (increased V_D). When the appropriate level of CPAP/PEEP is applied to a relatively diffuse disease, alveolar recruitment and distention should improve V/Q without a significant increase in V_D.

Cardiovascular Effects

A diminishment in cardiac output with CPAP/PEEP therapy is attributable to at least three mechanisms: (1) decreased venous return to the right heart, (2) right ventricular dysfunction, and (3) alterations in left ventricular distensibility. Because oxygen delivery to the tissues is determined by the arterial oxygen content and the cardiac output, oxygen delivery may be compromised if reductions in cardiac output occur to a greater degree than improvement in arterial oxygen content.

The primary mechanism responsible for reduction in cardiac output appears to be decreased venous return resulting from increased intrathoracic pressure. The increase in mean airway pressure associated with CPAP/PEEP increases the pleural and pericardial pressure, decreasing the cardiac transmural pressure, which may significantly decrease the end-diastolic volume and stroke volume of both ventricles. [99] [100] This reduced stroke volume can be restored by preload augmentation. [101]

A secondary mechanism responsible for reduction in cardiac output is right ventricular dysfunction. CPAP/PEEP increases right ventricular afterload because of increased pulmonary vascular resistance. In the normal heart, this results in a diminished right ventricular end-diastolic volume (RVEDV), whereas the right ventricular ejection fraction (RVEF) remains unchanged. [102] [103] At higher levels of CPAP/PEEP, a greater increase in RVEDV results, which may reduce RVEF if myocardial contractility is less than optimal. In patients with preexisting right ventricular dysfunction, even small amounts of CPAP/PEEP have the potential to cause significant changes in RVEDV and RVEF. [104]

Alterations in left ventricular function during CPAP/ PEEP appear to be ventricular septal shifting and cardiac compression. Increases in RVEDV have been associated with a leftward shift in the intraventricular septum, [105] thereby limiting the distensibility of the left ventricle. Decreased distensibility of the left ventricle during CPAP/ PEEP is directly related to the transmission of elevated pressures to the heart from the lung. [103] [106] [107]

In patients with underlying left ventricular dysfunction and elevated filling pressures, CPAP/PEEP may improve cardiac function by improvement in coronary arterial oxygen content, by augmentation of systolic contraction, or by reduction of venous return. [108] The reduction in venous return may actually produce a salutatory effect by shifting the end-diastolic volumes to a position on the Starling curve associated with improved myocardial function.

Application of CPAP/PEEP is known to have effects on hemodynamic measurements because the intrapleural and mediastinal pressures are increased. Normally, more than one-half the elevated alveolar pressure is dissipated by the lung's elastic forces. [109] Less than one-half the elevated alveolar pressure is transmitted when the lungs are poorly compliant; conversely, extremely compliant lungs transmit a greater degree of pressure, which can lead to significant adverse hemodynamic consequences. Pulmonary venous pressure affects pulmonary capillary pressure and is therefore a major factor determining fluid flux in the lung. The pulmonary artery occlusion pressure (PAOP) is commonly used to reflect pulmonary venous pressures. Although acceptable correlation between PAOP and left atrial pressures up to 10 cm H_2O CPAP/PEEP has been demonstrated, at higher levels of CPAP/PEEP, the PAOP may bear no correlation to the actual left atrial pressure. [110] There is no advantage to removing CPAP/PEEP before measuring PAOP because that maneuver has been demonstrated to give consistently unreliable data. [111]

The reduction in aortic blood flow that occurs within one respiratory cycle after applying CPAP/PEEP [112] is related to a decrease in pulmonary flow during exhalation. The reduction in pulmonary blood flow is considerably less with spontaneous breathing (CPAP) than with positive-pressure ventilation (PEEP), and this finding explains why CPAP requires less fluid loading to maintain cardiac output and enhances the transpulmonary pressure gradient resulting from any level of end-expiratory pressure.

Physiologic Alterations due to Airway-Pressure Therapy

Undesirable physiologic alterations attributable to a therapeutic entity are not necessarily complications because they may not contribute directly to mortality or morbidity. In addition to the pulmonary and cardiovascular factors just discussed, there are physiologic alterations attributable to positive airway pressure that affect renal function and water metabolism, hepatic and gastrointestinal function, and psychologic changes.

Positive airway-pressure therapy affects renal function by reducing urine volume, glomerular filtration rate, sodium excretion, and free water clearance. [113] The direct effects on renal function appear to be due to a decrease in renal perfusion, although redistribution of intrarenal blood flow has also been suggested as a mechanism. [114] There appears to be a significant relationship between the degree of renal dysfunction and the intravascular volume, because volume replacement returns renal

function to baseline before the cardiac function returns to baseline. [115] The direct renal effects of positive airway pressure can be minimized with prior intravascular volume expansion or the administration of low-dose dopamine. [116] Positive airway-pressure therapy causes antidiuresis and antinatriuresis by increasing renal sympathetic activity and by increasing release of antidiuretic hormone and renin and angiotensin. [117] [118] Clinical observation and available data suggest that there is increased water retention with increased levels of positive airway pressure.

Gastrointestinal bleeding is common in all critically ill patients. It has been estimated that without prophylactic therapy, as many as 40 percent of patients requiring airwaypressure therapy for more than 3 days would manifest gastrointestinal bleeding; one-half of these patients would require blood transfusion. [119] Most gastrointestinal bleeding in patients receiving airway-pressure therapy is due to multiple acute ulcerations of the gastric and bowel mucosa. [120] The institution of antacid regimens that maintain the gastric fluid pH higher than 5.0 was demonstrated essentially to abolish major gastrointestinal bleeding caused by multiple acute ulcerations. [121] Histamine (H_2) blockers and other agents that reduce secretion of gastric acid appear to be equivalent to traditional antacid regimens in preventing gastrointestinal bleeding. Ileus is common in patients receiving airway-pressure therapy. Although narcotic sedation is often implicated, there is little evidence that nonnarcotic sedation regimens decrease the incidence or severity of ileus.

There may be a higher incidence of liver dysfunction in patients receiving airway-pressure therapy than other critically ill patients, a circumstance widely attributed to the decreased portal blood flow associated with airway-pressure therapy. [122] The decrease of mesenteric blood flow appears to be greater to the stomach than to the small intestine.

Critically ill patients are often conscious, apprehensive, depressed, and exposed to a significant amount of emotional stress. Dependence on mechanical breathing devices limits self-sufficiency and self-image. The concerns of dependency and the threat of machinery malfunction are a constant source of fear for the ventilator-dependent patient. If a mishap occurs, this fear is magnified dramatically. A concerted effort by the staff is necessary to enhance the limited lines of communication. Calm explanations of all interventions help to meet the intellectual and emotional needs of the patient.

CONVENTIONAL VENTILATOR MANAGEMENT

The basic principles of PPV were first developed in the operating room to facilitate anesthesia and thoracic surgery. When postanesthesia recovery rooms began to develop and evolve into intensive care units (ICU) in the 1950s, anesthesiologists' concepts of PPV, endotracheal intubation, sedation/analgesia, and neuromuscular blockade were introduced and accepted. By 1960, there was widespread acceptance that the delivery of a preset V_T was the safest and most predictable means by which to support patients with respiratory failure. [123]

Initiation of Positive-Pressure Ventilation

As all anesthesiologists know, the first priority must be to establish a patent and protected airway through which PPV can be readily administered. It is not uncommon for patients with respiratory failure to demonstrate cardiovascular instability when tracheal intubation is accomplished and PPV is applied. It is common for other physicians to attribute the cardiovascular instability to delays in establishing the airway, stress of intubation, and sedative drugs. However, such instability often occurs in the absence of any of the previously mentioned factors for the following reasons: (1) relief of respiratory distress, causing a decrease in circulating catecholamine, with subsequent vasodilatation and decreased cardiac output; (2) decreased venous return related to the positive airway pressure; or (3) a combination thereof.

Initiating ventilator management in a critically ill patient is no different from the process of induction of anesthesia. Principles of anesthesia care apply outside the operating room and must be followed. Vascular access and appropriate monitors must be established as soon as possible. Vascular volume resuscitation must be timely. Appropriate analgesia and sedation must be instituted at the earliest possible time consistent with patient safety.

Sedation and Analgesia

Increases in intercostal muscle tone, abdominal muscle tone, or abdominal pressure or contents decrease chest compliance. In conjunction with PPV, any factor that decreases chest compliance results in higher intrathoracic pressures, diminished venous return to the right heart, and

diminished V_A. When a ventilated patient actively attempts to impede flow during the inspiratory cycle, the process is referred to as fighting the ventilator. Patients often make breathing efforts during the ventilator's expiratory cycle, a phenomenon that has little detrimental effect in most patients. The most common reasons for fighting the ventilator are (1) inadequate ventilation (hypercapnia), (2) acidemia, (3) inadequate oxygenation, (4) CNS dysfunction, and (5) pain or anxiety. Assisting the patient with a hand ventilator for a short time often "settles the patient down." However, these maneuvers should not replace adequate evaluation and treatment of the underlying cause of fighting the ventilator.

Sedation and analgesia are necessary for more than human compassion. It is well known that the neurohumoral response to stress can be detrimental in critically ill patients. [124] [125] The anesthesiologist is often consulted in these matters and must appreciate how the ICU milieu differs from the operating room. It is important for anesthesiologists to remember that, unlike providing anesthesia in the operating room, they are not going to be in constant attendance. Therefore, anesthesiologists must work within the established protocols of the ICU. They must be flexible and accommodating to the medications and philosophies that are familiar to the health care personnel caring for the patient.

The Society for Critical Care Medicine (SCCM) published practice parameters for intravenous sedation and analgesia in adults in the ICU. [126] Although there are many acceptable ways to accomplish adequate analgesia and sedation, it is helpful to be familiar with these national guidelines. They recommend that morphine sulfate should be the basic analgesic agent because it is an effective analgesic, reasonable sedative, good euphoric, familiar to nursing staff, and inexpensive. Relatively large doses of morphine have little cardiovascular effect other than venodilation in the well-ventilated, well-oxygenated, acid-base-balanced patient. [127] The patient should have reasonable arterial blood gas values, and the airway should be established prior to administration of large doses of morphine. In adults with adequate vascular volume, up to 80 mg may be administered intravenously during the first hour, and up to 20 mg/h thereafter without untoward effects. Fentanyl is recommended [126] if there is concern about the patient's cardiovascular stability.

A benzodiazepine is recommended to provide anxiolysis, sedation, and amnesia: midazolam is suggested for patients in whom less than 24 hours of PPV support is anticipated; lorazepam is recommended for longer-term use. Propofol in subanesthetic doses may replace the benzodiazepine as long as it is anticipated the drug will not be used for longer than 36 hours. [126]

Neuromuscular blocking agents are often the only alternative when preventing a patient from fighting the ventilator, ablating the work of breathing, or protecting the patient from harm and allowing necessary care. Muscle relaxants are required for the low-volume techniques that are becoming widely used for patients with severely diseased lungs. Neuromuscular blockade should be a last resort rather than a first-line alternative. Sedation, analgesia, and amnesia must be provided for paralyzed ICU patients. The SCCM practice parameters [128] recommend pancuronium as the agent of choice. They recommend atracurium for patients with cardiovascular instability; however, cisatracurium [129] became available since the guidelines were published and is less expensive than atracurium while possessing all the same pharmacokinetic advantages.

Traditional Goals of Positive-Pressure Ventilation

Eucapnic ventilation was universally accepted as a basic goal of ventilator management. In a previously healthy patient, eucapnia means maintaining a Pa_{CO_2} between 30 and 50 mm Hg consistent with an arterial pH between 7.30 and 7.50. [130] A patient who chronically retained CO_2 would be considered eucapnic at the established hypercapnic baseline. The reasons for maintaining eucapnea are primarily acid-base and electrolyte considerations. Acute deviation from a baseline Pa_{CO_2} results in alkalemia or acidemia, to which the kidneys respond by retaining or excreting bicarbonate ion. Healthy kidneys can compensate for a Pa_{CO_2}-induced pH change in 24 to 36 hours. This altered acid-base status can be responsible for difficulties in weaning the patient from the ventilator.

In adults with normal or mildly diseased lungs, the clinical propriety of relatively large V_T (10-15 mL/kg), [131] [132] delivered within 1 second, [133] [134] at rates of 8 to 12 per minute, was reinforced by data showing that: (1) consistent use of large V_T maintained near-normal compliance and arterial oxygenation without intermittent larger sigh breaths [135] [136] ; (2) large V_T reduced the incidence of atelectasis when compared with smaller V_T [137] ; (3) large V_T were advantageous in compensating for the increased V_D caused by positive-pressure ventilation [138] [139] ; and (4) large V_T were better tolerated by the conscious and mildly sedated patient. [140] It is important to note that there are no data refuting the safety and efficacy of relatively large V_T (10-15 mL/kg) at relatively slow ventilator rates (8-12/min), except when severe restrictive or obstructive pulmonary disease exists.

End-inspiratory pause (inflation hold) is a ventilator maneuver in which exhalation is delayed for a specific period after the preset inspiratory volume has been delivered. The longer the time from gas delivery to end-inspiration, the greater will be the distribution of gas to areas of low V/Q because of regional airway-resistance variance. [141] Manual inflation hold has long been used by anesthetists to reexpand retracted lung at the end of an open chest procedure. This principle was first applied in respiratory care following suctioning procedures to ensure expansion of a collapsed lung. Whether the naturally occurring yawn has a similar function is still being debated; however, many investigators believe that the constant-volume hypoventilation of the sleep state leads to miliary atelectasis that is reexpanded on awakening by a "natural inflation hold," the yawn. [142] This reasoning led to applying intermittent larger V_T ("sigh breaths") with the earlier volume-preset ventilators.

Appropriate Levels of Continuous Positive Airway Pressure/Positive End-Expiratory Pressure Therapy

The level of CPAP/PEEP required is primarily determined by pulmonary pathology and secondarily by cardiac

pathology. Although a major effect of CPAP/PEEP therapy is to improve lung compliance, the most readily identifiable goal is to achieve adequate arterial oxygenation with an F_{IO_2} of 0.5 or less without impairing tissue perfusion. The degree of CPAP/PEEP therapy that provides the greatest benefit while producing the fewest nonbeneficial effects is difficult to define and complex to monitor clinically. Proper interpretation of the available information necessitates consideration of the data on which various concepts of clinical end points have been based.

Seven factors are commonly considered when monitoring CPAP/PEEP therapy:

1. Pa_{O_2}.
2. Cardiac output.
3. Arteriovenous oxygen content difference: This calculation represents the volume of oxygen extracted from 100 mL of blood and is not necessarily reflective of total body oxygen extraction per minute (V_{O_2}). Normal ($Ca\text{-}VO_2$) values are 4.5 to 6.0 mL/dL; however, acute stress has been demonstrated to result commonly in cardiac output increases in excess of increased oxygen demand, producing ($Ca\text{-}VO_2$) values of 3 to 4 mL/dL. [143]
4. Oxygen delivery (D_{O_2}): This calculation is cardiac output multiplied by the arterial oxygen content multiplied by 10. It is expressed as milliliters per minute and represents the total oxygen volume presented to the tissues per minute.
5. Intrapulmonary shunt fraction (Q_{SP}/Q_T): This calculation requires blood gas analysis of both arterial and pulmonary artery blood samples, and the F_{IO_2}.
6. V_D: This parameter can be quantified by calculation of V_D/V_T or monitored by noting changes in the difference between the arterial and the end-tidal P_{CO_2}.
7. Lung compliance (C_L).

Extrapolation of available data in both animal and human studies allows for the foregoing seven factors to be placed in the general schema depicted in Figure 72-20. The graphs represent pre-lung injury levels, post-lung injury stabilized levels, and levels after incremental applications of CPAP/PEEP therapy. It is assumed that the F_{IO_2} remains at 0.5, the pH and P_{CO_2} remain acceptable, and appropriate fluid therapy is administered.

Optimum PEEP (most commonly referred to as "best PEEP") was defined in the animal model as the level at which the Q_{SP}/Q_T is lowest without a detrimental drop in cardiac output. [144] Because cardiac output increases and $Ca\text{-}VO_2$ decreases in humans, a $Ca\text{-}VO_2$ of less than 3.5 mL/dL under most circumstances should reflect an adequate cardiac output for the oxygen demands. Optimal PEEP was defined as that which provided maximum oxygen delivery and the lowest V_D/V_T. [145] This was found to be coincident with significant improvement in lung compliance and prior to a decrease in lung compliance. Figure 72-21 illustrates that these commonly used end points were simply different ways of looking at the same circumstances.

It is reasonable to state that expansion of collapsed alveoli and avoidance of alveolar hyperoxia create an advantageous milieu for lung repair. These factors must be accomplished while maintaining adequate perfusion and adequate oxygen content. It has been suggested that, regardless of the specific factors measured to make the assessments, the clinically appropriate level of CPAP/PEEP is the least amount

Figure 72-20 Graphic depiction of seven factors used as clinical monitors to determine the required level of positive end-expiratory pressure (PEEP) therapy in humans with acute respiratory distress syndrome. Although anesthetized animal models show a decreased cardiac output (Q_T) postinjury, available data and clinical experience demonstrate that humans respond with a significantly increased cardiac output. A-V, the arterial mixed-venous oxygen content difference. The horizontal gray band represents 3 to 4 vol%. O_2 Del, oxygen delivery expressed as milliliters per minute (cardiac output × arterial oxygen content × 10). C_L, lung compliance; Q_{SP}/Q_T, physiologic intrapulmonary shunt; V_D, deadspace ventilation.

that will result in adequate perfusion and a Pa_{O_2} of 60 mm Hg or greater with adequate Hb concentration at an F_{IO_2} of less than 0.5. [86]

Barotrauma and Airway Pressure

Pulmonary barotrauma is classically defined as extra-alveolar air from lung damage secondary to changes in intrathoracic pressure. The common clinical manifestations of pulmonary barotrauma are listed in Table 72-8 (Table Not Available). [119] Tension pneumothorax refers to pleural air under greater than ambient pressure, displacing mediastinal structures and potentially decreasing venous return to the heart. In the extreme, tension pneumothorax can cause cardiovascular collapse and inability to ventilate. Pneumothorax in conjunction with PPV necessitates decompression because 60 to 90 percent of these conditions are radiologically reported to be under tension. [146] Although a needle inserted into the chest confirms the diagnosis, it may not adequately decompress the

Figure 72-21 Graphic depiction of the factors governing best positive end-expiratory pressure ("best PEEP") and "optimal PEEP." Definitions of abbreviated terms are as in Figure 72-20.

tension immediately. Tube thoracostomy is the recommended therapy for decompression and lung re-expansion.

Bronchopleural fistula is suspected when there is persistent air leak for more than 24 hours after tube thoracostomy. [147] This can be due to several conditions in addition to airway-pressure therapy, but management is greatly compromised by the continued application of positive airway pressure. Efforts to minimize airway pressure without compromising gas exchange should be attempted. HFV can be used for this purpose, but it has not been associated with improved outcome. The same is true of independent lung ventilation.

Barotrauma is associated with a significant increase in morbidity and mortality. Because high airway pressures correlate with the incidence of barotrauma, most practitioners assume a cause-and-effect relationship. The incidence of pulmonary barotrauma is unclear, with reports ranging from 0.5 percent to more than 50 percent. [148] [149] Discrepancies are attributable to differences in patient populations, retrospective

TABLE 72-8 -- Manifestations of Pulmonary Barotrauma

(Not Available)

From Vender [119]

versus prospective studies, and diagnostic methods. Most centers report a 7 to 10 percent incidence of barotrauma in ICU patients receiving positive-airway pressure therapy; the incidence is higher among patients with severe lung disease.

Peak inspiratory pressure (PIP) greater than 60 to 80 cm H_2O is associated with an increased incidence of barotrauma. [150] A prospective study evaluating the effect of high-frequency jet ventilation on the incidence of barotrauma showed no significant reduction despite low PIP and low mean airway pressure. [151] Another study comparing various modes of ventilation showed the group with the highest PIP to have the lowest incidence of barotrauma. [152] A higher incidence of barotrauma has been demonstrated with CPAP/PEEP levels greater than 15 mm Hg (18 cm H_2O), [153] [154] yet there are no data to suggest that limiting PEEP to 15 mm Hg decreases or changes the incidence of barotrauma. [155] It appears that the high-airway-pressure therapy observed to correlate with barotrauma reflects the severity of lung disease and has no direct effect on the incidence of barotrauma.

The association of barotrauma and positive airway pressure is an obvious concern. Available data overwhelmingly favor the concept that when eucapnia is maintained, the risk of barotrauma increases as the severity of lung disease increases, regardless of the ventilator technique applied. [156] [157] The observed correlation between high airway pressures and barotrauma incidence is due to the common denominator of the severity of lung disease; the nature and degree of lung disease appear to be the most significant factors in the genesis of barotrauma (Fig. 72-22) . There is no conclusive evidence that manipulating airway pressures while maintaining eucapnic ventilation diminishes the incidence of barotrauma.

Figure 72-22 The relationship between barotrauma and the severity of lung disease is direct; the relationship between barotrauma and airway pressures is indirect. MAP, mean arterial pressure; PEEP, positive end-expiratory pressure; PIP, peak inspiratory pressure.

Full and Partial Ventilator Support

As listed in Table 72-9 , full ventilator support infers that all the work of breathing necessary to maintain eucapnia is provided by the ventilator; partial ventilator support infers that both the patient and the ventilator provide essential portions of the required work of breathing to maintain eucapnia. [158] The concept of partial ventilator support is predicated on the finding that spontaneous breathing is normally beneficial for cardiopulmonary homeostasis, whereas energy expenditure that exceeds cardiopulmonary reserves is detrimental work of breathing and should be avoided. [38]

Ventilator modes designed to provide partial support permit the patient to breathe spontaneously to whatever extent desirable without physiologic detriment, whereas the ventilator supplies the remaining work of breathing. [56] The first mode capable of providing partial support was IMV, which provided a continuous-flow system to allow spontaneous breathing between the volume-preset cycles. [159] Because of difficulties in manufacturing continuous-flow systems, SIMV was introduced. Essentially, SIMV is an assist/control volume-preset ventilator in conjunction with a demand-flow system for spontaneous breathing. The major disadvantage of demand-flow systems was a delay in providing adequate inspiratory gas flow to the patient, resulting in an imposed work of breathing that was significantly greater than that associated with continuous-flow systems. However, SIMV became almost universally utilized because demand-flow systems

TABLE 72-9 -- Definitions of the Three Levels of Ventilator Support

LEVEL	DEFINITION
Total ventilator support	Patient rendered unable to contribute work of breathing for the purpose of avoiding ventilator-induced lung injury
Full ventilator support	Patient not obligated to contribute work of breathing for the purpose of maintaining eucapnic ventilation
Partial ventilator support	Patient obligated to contribute work of breathing for the purpose of maintaining eucapnic ventilation

were preferable to continuous-flow systems from a manufacturing viewpoint.

In comparison with full ventilator support, techniques of partial ventilator support have been demonstrated to enhance cardiac output in patients with normal left ventricular function, [160] to cause less hemodynamic compromise in conjunction with CPAP/PEEP therapy, [161] and to allow for significantly greater urine output and renal blood flow. [162] However, not all patients do better with partial ventilator support. For example, patients with severe ventilatory muscle fatigue, usually those with COPD, may be treated more successfully with full ventilator support. [163] Another example is a patient with cardiogenic shock and poor left ventricular reserve, who maintains better left ventricular function and has improved peripheral perfusion when all the work of breathing is supplied by the ventilator. [164]

Guidelines for Conventional Ventilator Management

Although there are many acceptable ways to provide conventional ventilator care, it is always helpful to have a "prototype" approach that is consistent with the preponderance of available data and has been time tested in clinical practice. The following suggestions are intended to provide such a prototype and are not intended to define a standard of care or to describe the only way to accomplish good care.

Simply stated, the primary purpose for utilizing conventional ventilator management in the ICU is to provide all or a portion of the work of breathing for maintenance of adequate respiratory gas exchange. The challenge is related to how that support can be provided in a manner that minimizes physiologic insult and avoids lung injury. Conventional ventilator management encompasses all matters pertaining to the safe and effective application of positive-airway pressure therapy. Assuming due diligence is provided to essential factors such as airway management, cardiovascular support, Hb content, analgesia and sedation, we submit that the following guidelines represent a scientifically justified and clinically practical approach to ventilator management in the surgical ICU.

Most ventilator-dependent patients in the surgical ICU require oxygen supplementation and CPAP/PEEP therapy. Inspired oxygen concentrations greater than 50 percent are best avoided for more than several hours. CPAP/PEEP levels of 5 to 20 cm H_2O seldom interfere significantly with cardiovascular function when the therapy is titrated to the minimum level that accomplishes redistribution of extravascular lung water and alveolar recruitment.

1. When the primary concern is diminished arterial oxygenation, one should apply the minimum level of endexpiratory pressure that provides a Pa_{O_2} greater than or equal to 60 mm Hg at a nontoxic F_{IO_2} (0.5).
2. When the primary concern is diminished lung compliance, one should apply the minimum level of end-expiratory pressure that provides optimal V_T delivery.

Full ventilator support connotes an approach in which the patient is *not obligated* to contribute work of breathing to maintain eucapnia (see Table 72-9 ; Table 72-10) . With most patients, it is prudent to initiate full ventilator support and then to consider either partial or total support when the patient

TABLE 72-10 -- Essential Factors Differentiating the Three Levels of Ventilator Support

	FULL	PARTIAL	TOTAL
Clinical goal	Eucapnia	Eucapnia	Avoidance of volutrauma

Recommended modes	SIMV	SIMV or pressure-support	Pressure-control or pressure-release
Neuromuscular blockade	Usually not	Never	Required

SIMV, synchronized intermittent mandatory ventilation

is stabilized and the circumstances are better appreciated.

1. The use of the SIMV mode with 10 to 15 mL/kg V_T and rates of 8 to 12/min in conjunction with 5 to 20 cm H_2O CPAP/PEEP is the most predictable and versatile approach to full ventilator support. In conjunction with appropriate sedation and analgesia, spontaneous breathing efforts should be ignored unless the patient is fighting the ventilator to a degree that there is (1) interference with the distribution of ventilation, (2) cardiovascular instability, or (3) significant expenditure of energy.
2. The assist/control mode in association with appropriate levels of PEEP is usually acceptable, but ventilator rates greater than or equal to 16/min are associated with auto-PEEP and are best avoided. Further, unlike SIMV, theassist/control mode necessitates changing to another mode when partial support is required.
3. Pressure-support mode at 30 to 50 cm H_2O in conjunction with appropriate levels of CPAP is acceptable if the patient's breathing rate is less than 20/min. However, we prefer volume-preset modes for full ventilator support because they allow greater latitude for deep sedation and analgesia without undue demands on nurses, therapists, and physicians.

Partial ventilator support connotes an approach in which the patient is *obligated* to contribute some work of breathing to maintain eucapnia (see Tables 72-9 and 72-10) . This approach is appropriate for relatively stable patients who are capable of providing a significant portion of the work of breathing without physiologic detriment, and for patients requiring a prolonged weaning process. The advantages to this approach are that spontaneous breathing improves V/Q, increases venous return to the right heart, improves cardiac function, diminishes CPAP/PEEP requirements, decreases intravenous fluid and vasopressor requirements, and reduces the need for sedation requirements.

1. Partial ventilator support is easily and effectively provided for most patients with the SIMV mode. V_T of 10 to 15 mL/kg with 5 to 15 cm H_2O CPAP/PEEP at rates of 2 to 8/min are recommended unless the patient has significant permanent lung volume deficits (partial or total pneumonectomy, pulmonary fibrosis), in which case smaller V_T may be indicated.
2. SIMV should always be administered in conjunction with 3 to 5 cm H_2O pressure support to ensure that the work of breathing imposed by the demand-flow system is sufficiently compensated. SIMV rates of 2/min or less with 5 cm H_2O CPAP/PEEP and 5 cm H_2O pressure support are almost always compatible with spontaneous breathing after extubation.
3. Pressure support may be the best available mode for providing partial ventilator support in those patients in whom a difficult or prolonged weaning process is predicted. Pressure support, in conjunction with appropriate CPAP/PEEP levels, should be titrated between 10 to 30 cm H_2O to attain breathing rates less than 20/min with V_T of 8 to 12 mL/kg. Rapid breathing rates should initially be assumed to reflect the patient's inability to provide the required work of breathing rather than anxiety or inadequate sedation. As the patient improves, eucapnia and breathing rates lower than 20/min can be maintained at lower levels of pressure support (usually, 2.5-5 cm H_2O increments are best).
4. A pressure-support level of 5 cm H_2O in conjunction with 5 cm H_2O CPAP/PEEP is usually compatible with spontaneous breathing after extubation.

ACUTE LUNG INJURY

Conventional volume-preset techniques for ventilator management are undeniably appropriate for most surgical patients requiring ventilator assistance. Nonetheless, volume-preset modes have not been judged favorably for patients with severely diminished pulmonary compliance resulting from acute restrictive lung disease. New technologies and more complete knowledge of alveolar pathophysiology make it mandatory to consider approaches to ventilator management that are specifically oriented to patients with severe acute restrictive lung disease.

Pathogenesis

Critically ill patients commonly manifest a diffuse cellular malfunction of lung parenchyma secondary to primary pulmonary disease as well as severe systemic insults such as sepsis, [165] hypoperfusion, [166] and multiple trauma. [167] This pathologic process was first described as the adult respiratory distress syndrome (ARDS) [168] [169] manifesting a clinical picture of hypoxemia, decreased lung compliance, increased work of breathing, bilateral and diffuse pulmonary infiltrates on chest radiograph, and pulmonary hypertension. It is now agreed that ARDS is part of a clinical and pathologic spectrum termed acute lung injury (ALI) with noncardiogenic pulmonary edema at the least severe end of the spectrum and ARDS at the more severe end of the spectrum (Fig. 72-23) (Figure Not Available) . [170] [174] It has been suggested that the term "acute" replace "adult" in the ARDS acronym, [172] to reflect the severe manifestations of ALI more appropriately. Regardless of the acronyms used to refer to this pathophysiologic spectrum, specific therapy must be directed at underlying disease processes because there is currently no direct therapeutic

---

Figure 72-23 (Figure Not Available) Major pathophysiologic manifestations comprising the spectrum of acute lung injury (ALI) from mild to severe disease. *(From Shapiro and Peruzzi[174])*

means by which to reverse the lung parenchymal dysfunction. [172] Although there is ample evidence that appropriate application of conventional ventilator-management techniques improves survival in patients with mild to moderate ALI, [157] [175] [176] these techniques have not changed the outcome in patients with severe ARDS. [176] [179] [182]

Prevailing knowledge of ALI supports the concept of a spectrum of disease as depicted in Figure 72-23 (Figure Not Available) . [171] [172] [178] *Mild ALI,* often referred to as "noncardiogenic pulmonary edema," involves diminished lung volume and compliance secondary to vascular endothelial cell damage. The subsequent changes in endothelial permeability increase water and colloid transductance from blood to interstitium that results in accumulation of extravascular lung water. At this stage of the pathologic spectrum, there is little alveolar epithelial cell abnormality and therefore minimal accumulation of alveolar fluid. Although abnormalities in endothelial permeability occur early in the ALI process, metabolic endothelial dysfunction occurs and progresses at later stages of the lung injury process. This partially accounts for the association of multiple organ system failure seen with ALI because the pulmonary vascular endothelium is normally responsible for production and metabolism of numerous circulating substances essential for appropriate immune responses and tissue repair. [179] [182]

Moderate ALI, often referred to as "early ARDS," entails significant diminishment of lung compliance secondary to both the sloughing of type 1 alveolar epithelial cells, resulting in diminished hysteresis, and hypermitosis of type 2 cells, resulting in insufficient or abnormal production of the surfactant complex. [183] [185] Because the interstitial edema accumulates in gravity-dependent lung, the geometrically unstable alveoli in those areas more readily collapse. [95] These atelectatic alveoli are potentially recruitable with appropriate CPAP/PEEP therapy. In addition to alveolar collapse and interstitial edema, the disorder includes some accumulation of alveolar fluid and an inflammatory response. [183]

Severe ALI, often referred to as "late or severe ARDS," involves extensive atelectasis and consolidation secondary to dysfunctional type 2 epithelial cells. [183] The consolidated lung is not recruitable and results in a significantly diminished number of alveoli that can be ventilated. This disorder has been described as the "baby lung syndrome" [95] because the adult patient has no more lung tissue available for ventilation than a small baby. The severity of type 2 cell dysfunction appears to be correlated with the extent of lung consolidation and fibrotic repair. [183]

The original concept that ARDS was a homogeneous pathologic process has been refuted by CT studies demonstrating gravitational distribution of disease and heterogeneous involvement of alveoli. [94] [95] [96] The anatomic evidence of a heterogeneous distribution of pathologic features ranging from overdistention to collapsed and consolidated alveoli is supported by multiple inert gas studies showing a mixture of high, low, and normal V/Q matching. [186] The recognition of this unique pathologic heterogenicity underscores the complexities inherent with the achievement of optimal distribution of V/Q in such a diseased lung.

Oxygen-Induced Lung Injury

High concentrations of oxygen have long been known to be toxic to cells and tissues. Oxygen toxicity is believed to be in part related to the generation of oxygen-derived free radicals, which are extremely reactive and can cause severe cellular injury. [187] The toxicity is related to both the oxygen concentration and the duration of exposure. It has been demonstrated that diffuse alveolar damage results when healthy mice breathe 100 percent oxygen for several days. [187] Animal and human data demonstrate that high alveolar oxygen concentrations can aggravate and accelerate a preexisting lung injury process. [188] It is now generally agreed that inspired oxygen concentrations of less than 50 percent are reasonably safe and concentrations of more than 60 percent are potentially deleterious. [89] [157] [189]

Although it is debatable whether high inspired oxygen concentrations are toxic to patients without lung injury, the data supporting the statement that patients with ALI are oxygen sensitive and should not receive an F_{IO_2} greater than 0.6 are overwhelming. It is known that lung injury causes release of oxygen-derived free radicals at rates that exceed the ability of the lung to reduce or scavenge them, resulting in cellular destruction, increased permeability, and organ dysfunction. [190] Further, there is evidence that depletion of the pulmonary antioxidant abilities reduces survival in animals exposed to increased oxygen concentrations, [189] increasing antioxidant potential appears to prolong survival despite high oxygen concentrations, [38] [158] and antioxidant therapy can blunt these responses and may minimize tissue damage. [56] In light of such data, inspired oxygen concentrations should be minimized as much as possible in patients with ALI.

Ventilator-Induced Lung Injury (Volutrauma)

LaPlace's law dictates that when the alveolar gas volume falls below some prescribed limit (hypodistention), elastic forces become overwhelming, and alveolar collapse ensues. The same physical law states that above the critical volume, as volume increases, the elastic forces diminish. As the alveolar volume approaches the limit of distensibility (hyperdistention), the contiguous epithelial, interstitial, and endothelial structures are subject to mechanical distortions and stresses that may

induce or exacerbate lung injury. [183] [191]

Pathologic features associated with alveolar hyperdistention are referred to as ventilator-induced lung injury. As illustrated in Figure 72-24 (Figure Not Available) , hyperdistention-induced lung injury can be produced in baby pigs or rats with normal lungs when they are mechanically ventilated at tidal volumes that generate alveolar pressures greater than 40 cm H_2O. [191] [192] In young rabbits and rats, artificial restriction of the chest cage and ventilation at nonhyperdistending V_T results in alveolar pressures greater than 40 cm H_2O but does not result in hyperdistention-induced lung injury. [191] [193] Although high alveolar pressures may not always be associated with alveolar hyperdistention, tidal volumes that produce hyperdistention of alveoli are always associated with high airway pressures when delivered with positive-pressure ventilation. [191] [194]

Figure 72-24 (Figure Not Available) Illustration of animal data indicating that it is hyperdistending alveolar volumes rather than airway pressure that are responsible for ventilator-induced lung injury. A shows animals (pigs, rabbits, rats) ventilated with low airway pressures and normal or low tidal volumes. B shows animals (pigs, rabbits, rats) ventilated with high airway pressure and high tidal volumes without chest wall restriction. C shows animals (rabbits, rats) ventilated with low tidal volumes resulting in high airway pressure attributable to chest wall restriction. D shows animals (rats) ventilated with low airway pressures (negative pressure ventilation; i.e., iron lung) and high tidal volumes. *(From Peruzzi WT, Franklin ML, Shapiro BA: New concepts and therapies of adult respiratory distress syndrome. J Cardiovasc Anesth 11:771, 1997)*

In addition, hyperdistending alveolar volumes in subatmospheric conditions also produce ALI. [194]

Alveolar hyperdistention has been termed "volutrauma," [195] to emphasize that the damage is directly attributable to excessive alveolar volume rather than to excessive alveolar pressure. Preset-pressure modes ordain that alveolar gas volumes are determined by the preset airway pressure and the compliance of individual alveoli, thereby providing the technical means to apply a concept of ventilator management in which the primary goal is the avoidance of ventilator-induced lung injury.

ASSESSMENT OF AIRWAY AND ALVEOLAR PRESSURES

Because one must be concerned with alveolar volume and pressure, it is essential to interpret the available airway-pressure measurements correctly.

Physical Principles

The pressures measured at the Y-piece resulting from a positive-pressure inspiration delivered through the tracheal tube, tracheobronchial tree, and lung parenchyma are determined by inspiratory flow rate, airway resistance, and the compliance factors (lung and chest wall) that impede the flow. For any given V_T delivery, the pressure resulting from compliance factors is essentially independent of flow (static), whereas the pressure resulting from resistance factors is directly dependent on flow (dynamic). Under dynamic conditions, upstream pressures are greater than downstream

---

pressures, and this difference is augmented by increases in either resistance or flow. Under static conditions (essentially zero flow), pressures must be essentially equal throughout the pulmonary system and the ventilator circuit.

Dynamic Airway-Pressure Measurement

Airway-pressure measurements coinciding with high inspiratory gas flows, such as PIP, provide little information concerning alveolar pressures. [196] In fact, the point of greatest resistance and lowest compliance in the entire ventilator-patient circuit is the tracheal tube. The PIP can increase with increased flow rates, increased V_T, airway secretions, or tracheal tube narrowing without any predictable relation to changes in alveolar pressure.

Static Airway-Pressure Measurement

When near zero flow conditions exist, a pressure measurement anywhere in the ventilator-patient circuit should bear a predictable relationship to alveolar pressures. Figure 72-25 (Figure Not Available) illustrates delivery of a fixed V_T in 1 second followed by the inflation-hold (or inspiratory pause) maneuver in which exhalation is delayed for 1 second. During the inflation-hold maneuver, the pressure gradient between the proximal airway and alveoli results in continued flow toward the alveoli, resulting in a *plateau* pressure in the proximal airway. * When near-zero flow exists for at least 0.5 second, usually requiring at least a 1-second inflation-hold, the plateau pressure should reflect the average peak alveolar pressure. [157] [197] It is common practice to measure the inspiratory plateau pressure at the end of a 0.5-second inflation-hold maneuver, a circumstance that *approaches* zero flow (see Fig. 72-25) (Figure Not Available) but still somewhat overestimates the average peak alveolar pressure.

Assessing Alveolar Pressures

It is reasonable to infer from numerous animal studies that *alveolar* pressures exceeding 35 cm H_2O may induce or proliferate lung injury. [157] [172] [191] When applying volume-preset modes, one must develop a scheme to utilize the inspiratory plateau pressure as a means by which to assess the alveolar pressures and thereby to assess the risks of volutrauma.

Clinical observations demonstrate that when delivering 12 to 15 mL/kg V_T, neuromuscular blockade often reduces the plateau pressure by 5 to 10 cm H_2O simply by diminishing the chest wall and abdominal muscle tone. Because inspiratory plateau pressure measurements commonly overestimate alveolar pressures, concern for potential volutrauma is likely justified when the inspiratory plateau pressure approaches 40 cm H_2O in the paralyzed patient or 50 cm H_2O in the nonparalyzed patient.

Figure 72-25 (Figure Not Available) Schematic illustration of inspiratory cycle for volume preset (1,000 mL) tidal volume delivered by square wave generator in 1 second, followed by a 1-second inflation-hold maneuver. The inspiratory cycle is 2 seconds, although tidal volume is delivered by ventilator in 1 second. Normal compliance and resistance are assumed. Proximal airway pressure is shown as a solid line, alveolar pressure as a dashed line, and gas flow in airways as a dotted line. Peak airway pressure is achieved near end of tidal volume delivery, at which point there is considerable gradient between peak airway pressure and alveolar pressure that results in continued flow to lung. Airway pressure rapidly diminishes as flow continues toward the alveoli. Measurable flow in the system has essentially ceased 0.5 seconds after the ventilator has delivered tidal volume; however, a gradient remains between airway and alveolar pressures. To attain true plateau pressure, at which airway pressure reflects average peak alveolar pressure, an additional 0.5 seconds of inflation hold is required after the absence of measurable flow in the system. *(From Shapiro and Peruzzi [174])*

Patients in the surgical ICU commonly have conditions that decrease thoracic compliance independent of alveolar disease, such as abdominal distention, fractured ribs, and surgical wounds. Such circumstances can result in significantly increased inspiratory plateau pressures without suggesting hyperdistended alveoli.

PRESSURE-PRESET VENTILATION FOR TOTAL VENTILATOR SUPPORT

Table 72-9 defines three levels of ventilator support. As previously presented, the clinical goal for full and partial support is to achieve eucapnic ventilation while minimizing potentially detrimental physiologic alterations.

Defining Total Ventilator Support

The term *total ventilator support* describes the concept of applying pressure-preset modes to establish a constant inspiratory pressure, lower than some crucial level, for the purpose of avoiding volutrauma. Total ventilator support is an appropriate term because total control of the ventilatory pattern (neuromuscular blockade) is imperative to optimize ventilation and oxygenation. Microprocessor-controlled ventilators have provided the capability to establish a constant inspiratory pressure reliably and predictably.

Pressure-control and pressure-release modes have been

* When the airway is occluded at the end of exhalation, any pressure gradient between the alveoli and the proximal airway results in flow, and the proximal airway pressure increases. The difference between the end-expiratory occlusion pressure and the baseline pressure (atmospheric pressure or PEEP) is referred to as auto-PEEP.

discussed previously. Briefly, the pressure-control mode provides inspiratory gas flow in the same manner as the pressure-support mode, but the cycle is both initiated and ended by preset time factors. The pressure-release mode consists of a continuous-flow system with a solenoid valve situated in the expiratory limb that determines which of two paths will be open to gas flow. During the inspiratory phase, the continuous gas flow exits through a threshold resistor with a preset pressure greater than that present during exhalation. As illustrated in Figure 72-26 (Figure Not Available) , both pressure-control and pressure-release modes begin inspiration at preset time intervals, rapidly achieve the preset circuit pressure, maintain the preset inspiratory pressure while inspiratory flow varies, and end the inspiratory cycle at a preset time interval. Assuming an adequate inspiratory time, the delivered V_T will be determined by the preset airway pressure and the pulmonary compliance.

The concept of applying pressure-preset modes for the purpose of avoiding ventilator-induced lung injury is based on data and logic specifically pertaining to patients with severe acute restrictive lung disease. [157] [172] [198] No data exist to justify the application of total ventilator support techniques to patients without severe acute lung disease.

Using Volume Preset Modes?

It has been suggested that volutrauma can be avoided using volume-preset modes by decreasing the V_T so that inspiratory plateau pressures are maintained at 35 to 40 cm H_2O. [199] Although this is a superficially appealing concept, it does not logically follow the dictates of physics and airway mechanics. Because airway pressures exceed 40 cm H_2O during most of inspiration, it is probable that some alveoli achieve higher pressures and are transiently overdistended. Further, distribution of ventilation is unpredictable in a lung that has contiguous alveoli of varying compliances. In other words, suboptimal ventilation is imposed without a reasonable expectation that alveolar hyperdistention will be avoided. This is in contrast to the pressure-preset mode wherein by limiting the airway pressure to 40 cm H_2O throughout inspiration and ensuring a near no-flow state at end-inspiration, not a single alveolar pressure can be predicted to exceed 40 cm H_2O at any time while optimal volumes can be predicted to be delivered to every open alveolus. [174]

Permissive Hypercapnia

Three major clinical liabilities of total ventilator support are as follows: (1) hemodynamic instability is commonly encountered when the technique is initiated; (2) neuromuscular blockade must be initiated and maintained; and (3) eucapnic ventilation may not be maintained. Perhaps the greatest clinical concern related to total ventilator support is relinquishing eucapnia as a clinical goal.

Purposefully permitting an arterial blood gas value to transcend traditional limits of acceptability has been sanctioned for many years in relation to the Pa_{O_2} in critically ill patients. Although an Pa_{O_2} greater than or equal to 60 mm Hg is traditionally considered acceptable in critically ill patients, [1]

Figure 72-26 (Figure Not Available) Schematic illustration of a pressure-preset (40 cm H_2O), time-initiated, time-cycled ventilator mode set to provide a 4-second cycle (rate of 15/min) with a 1:1 inspiration-to-expiration (I:E) ratio. Significantly diminished pulmonary compliance with relatively normal airway resistance is assumed. Proximal airway pressures are shown as a solid line, alveolar pressures as a dashed line, and flow in airways as a dotted line. Inspiration (Inspir.): Proximal airway pressure rapidly attains a preset pressure limit of 40 cm H_2O, which is maintained throughout a 20-second inspiratory cycle. Alveolar pressures equalize with proximal airway pressure before the end of the inspiratory cycle. Flow delivery by the ventilator is variable and rapidly approaches 100 L/min. Flow consistently decreases as alveolar pressures approach airway pressure. Ventilator flow ceases before alveolar pressures equal proximal airway pressure. Expiration (Expir.): Airway pressure reaches baseline and flow ceases before the end of the expiratory cycle. *(From Shapiro and Peruzzi [174])*

when severe lung disease is present, there are few who would argue with tolerating an Pa_{O_2} of 50 to 59 mm Hg to avoid use of a potentially deleterious F_{IO_2} or CPAP/PEEP level. [123] Thus, "permissive hypoxemia" (Table 72-11) has been an acceptable clinical concept for decades. The degree of arterial hypoxemia that is tolerated is determined by each clinician's judgment concerning the risk-to-benefit ratio between accelerating potentially harmful respiratory support and maintaining adequate cellular oxygenation.

Permissive hypercapnia (see Table 72-11) is the purposeful act of allowing the Pa_{CO_2} to increase acutely be-yond the point traditionally considered acceptable for the maintenance of homeostasis. Most clinicians agree that an acute Pa_{CO_2} increase to 60 mm Hg is not life-threatening provided the arterial pH is greater than 7.30; in fact, an arterial pH greater than or equal to 7.25 is usually well tolerated by patients who are free of preexisting cardiac disease. [174]

When lung compliance is significantly diminished, total ventilator support administered with a pressure limit of 40 cm H_2O could be expected to result in an Pa_{CO_2} greater than 60 mm Hg. This hypercapnia may be considered permissible provided the clinician judges that the hazards of volutrauma are potentially more deleterious than the potential hazards of cellular acidosis. Although permissive hypercapnia has been safely applied in limited studies, it is premature to assume that this practice is either beneficial or without risk. Reliable criteria and guidelines for permissive hypercapnia await further investigation.

Inverse-Ratio Ventilation

Pressure-control and pressure-release modes of ventilation can provide any desired I:E ratio because the beginning

TABLE 72-11 -- Demarcation of Permissive Hypercapnia and Hypoxemia

PERMISSIVE HYPOXEMIA	PERMISSIVE HYPERCAPNIA
Pa o_2 60 mm Hg, acceptable (normoxia)	Pa co_2 50 mm Hg, acceptable (eucapnia)
	Pa co_2 51-60 mm Hg, acceptable if increasing tidal volume risks lung injury
Pa o_2 50-59 mm Hg, acceptable if cardiovascular function adequate and advancing F $_{IO_2}$ or PEEP risks lung injury	Pa co_2 >60 mm Hg, acceptable if pH_a 7.25, cardiovascular function adequate, advancing pressure limit risks lung injury
Pa o_2 <50 mm Hg, acceptable if advancing F $_{IO_2}$ or PEEP deemed a greater risk to survival than the risks of inducing tissue hypoxia	Pa co_2 >60 mm Hg, pH_a <7.25 acceptable if risks of inducing lung injury deemed a greater risk to survival than the risks of inducing tissue acidosis

F $_{IO_2}$, inspired oxygen concentration; Pa $_{CO_2}$ and Pa $_{O_2}$, arterial partial pressures of carbon dioxide and oxygen; PEEP, positive end-expiratory pressure

and end of the inspiratory cycle occur at preset time intervals. The use of an inverse I:E ratio (inspiration longer than exhalation) was initially noted to improve oxygenation and ventilation in neonates with severe infant respiratory distress syndrome and was later reported to be useful in ARDS. [200] Figure 72-27 (Figure Not Available) illustrates that a 2-second inspiratory time is usually associated with a near no-flow state at end-inspiration. [201] A ventilator rate of 15/min results in a ventilatory cycle of 4 seconds, allowing for a 2-second inspiratory time while a 1:1 I:E ratio is maintained. As illustrated in Figure 72-27 (Figure Not Available) , a rate greater than 15/min requires an inverse I:E ratio to achieve a 2-second inspiratory time.

Available data suggest that inverse-ratio ventilation serves to enhance alveolar recruitment primarily by creating auto-PEEP, [202] as shown in Figure 72-27 (Figure Not Available) . Those who prefer to avoid prescribing extrinsic PEEP levels in excess of 15 cm H_2O, but who also embrace the concept of inverse I:E ratios for support of oxygenation, must realize that the total PEEP level (auto-PEEP plus extrinsic PEEP) is the determinant of the extent of alveolar recruitment. When applying

Figure 72-27 (Figure Not Available) Schematic illustration of a pressure-preset (40 cm H_2O), time-initiated, time-cycled ventilator mode set to provide a 3-second cycle (rate of 20/min) with a 1:1 inspiration-to-expiration (I:E) ratio. Significantly diminished pulmonary compliance with relatively normal airway resistance is assumed. Proximal airway pressures are shown as a solid line and flow in airways as a dotted line. Inspiration (Inspir.): See Figure 72-26 (Figure Not Available) . Expiration (Expir.): Flow has not reached zero at the end of the expiratory cycle (1 s); therefore, alveolar pressure is greater than baseline. The figure shows an airway pressure greater than baseline, but this may not be the case. To show an airway pressure equal to alveolar pressure may require a delay of next inspiratory cycle (expiratory occlusion pressure). Therefore, auto-positive end-expiratory pressure (auto-PEEP) (intrinsic PEEP) is detected either by measuring airway pressure after an exhalation pause or noting that flow has not ceased at the end of the expiratory cycle. *(From Shapiro and Peruzzi[174])*

total ventilator support, there are no data to suggest that inverse-ratio ventilation has any advantage over a 1:1 I:E ratio (at a ventilator rate 15/min) as long as the appropriate extrinsic PEEP levels are prescribed. There is no evidence to suggest that high Pa $_{CO_2}$ levels are significantly diminished by inverse ratios as compared with 1:1 ratios and appropriate extrinsic PEEP.

Extrapulmonary Gas Exchange

A technique permitting exchange of oxygen and CO_2 at sites other than the lung should allow total ventilator support at 40 cm H_2O while allowing the maintenance of eucapnia. To be considered for routine use, an extrapulmonary gas exchange device should be (1) readily initiated at the bedside by an intensive care specialist, (2) readily maintained by routine ICU personnel, and (3) safe enough to be utilized as an alternative to exposure of the lungs to excessive gas volumes and oxygen concentrations. [203]

Extracorporeal membrane oxygenation (ECMO) is known to be capable of completely replacing the gas exchange functions of the lung. [204] [205] Although ECMO failed to demonstrate a decreased mortality rate in adults with severe ARF in the 1970s, [206] interest in this technique continues as a means of limiting lung damage resulting from airway pressure therapy. The significant costs of personnel and equipment associated with ECMO have prevented widespread availability in this era of cost containment.

Extracorporeal CO_2 removal ($ECCO_2R$) is a simple venovenous technique introduced in 1980 to provide significant CO_2 removal in adults. [207] Although $ECCO_2R$ effectively removes CO_2 so that significantly reduced V_T can be applied while maintaining eucapnia, there is limited evidence suggesting that this technique decreases mortality in adults with severe ARF. [208] Although $ECCO_2R$ requires fewer resources than ECMO, current $ECCO_2R$ techniques still demand facilities and personnel beyond the capabilities of the average ICU.

Inhaled Nitric Oxide

Nitric oxide (NO) is an endogenous substance whose primary function appears to be vascular smooth muscle relaxation. [209] The concept of inhaled NO as a practical means by which to achieve selective and therapeutic pulmonary vasodilation [210]

is based on the presumption that NO is so rapidly inactivated in blood that diffusion into a pulmonary capillary can produce local vasodilation without systemic effects. [211] Available data suggest that inhalation of NO by patients with severe ALI reduces pulmonary artery pressures in ventilated lung areas, improves blood flow to these areas, and subsequently improves arterial oxygenation without producing systemic vasodilation. [212] Although this is a promising concept, further investigation is required to define better appropriate dosage, effect on clinical outcome, and the types and incidence of associated toxicity.

Guidelines for Total Ventilator Support

In total ventilator support, the patient is *rendered unable* to contribute any work of breathing, secondary to neuromuscular blockade, for the expressed purpose of avoiding ventilator-induced lung injury (see Tables 72-9 and 72-10) .

1. Total ventilator support should be considered when volume-preset tidal volumes of 12 mL/kg, in conjunction with appropriate CPAP/PEEP levels, display plateau pressures exceeding 40 cm H_2O in the paralyzed patient or 50 cm H_2O in the nonparalyzed patient provided, of course, that there are no significant extrapulmonary factors decreasing thoracic compliance.
2. It is essential first to establish appropriate monitoring systems, cardiovascular stabilization, adequate sedation/analgesia, neuromuscular blockade, and optimal PEEP/F $_{IO_2}$ levels with the patient on full ventilator support with a volume-preset mode. We suggest initial settings for pressure-control or pressure-release at a 1:1 ratio, a rate of 15/min (4-s cycle); the same PEEP/F $_{IO_2}$ levels as required with full ventilator support, and a pressure limit equal to the plateau pressure exhibited with full ventilator support. Within a reasonable time period and with prudent vasopressor and intravenous fluid manipulation, the patient is usually hemodynamically stable, with arterial blood gases similar to those associated with full ventilator support.
3. The pressure limit is then decreased (usually in increments of 2.5-5 cm H_2O) as rapidly as possible until 40 cm H_2O is achieved. The continuous presence of a knowledgeable and experienced physician is required for the safe initiation of total ventilator support.
4. It is essential that the patient remain deeply sedated with adequate analgesia and a level of neuromuscular blockade that ensures complete absence of chest wall and abdominal muscle tone.
5. The pressure limit of 40 cm H_2O is continued while PEEP is incrementally adjusted (5-20 cm H_2O) to establish the minimum level that produces an optimal V_T

delivery; in most cases, this will also be the PEEP level that provides the optimal P_{O_2} at an F_{IO_2} no greater than 0.5.

6. The use of flow graphics is suggested, especially when inverse I:E ratios are applied, to facilitate detection of a no-flow state at end-inspiration or auto-PEEP. This approach may allow more accurate control of ventilator support, but it must be guided by an experienced physician.
7. Hypercapnia to 60 mm Hg should be readily permitted, provided the pH is higher than 7.25 and cardiovascular stability is present. Allowing Pa_{CO_2} values to rise higher than 60 mm Hg, or the pH_a to fall lower than 7.25, requires a clinical judgment about which situation poses the best risk-to-benefit ratio--worsening hypercapnia/acidemia or escalating alveolar volumes.

Does Total Support Improve Outcome?

There are data showing that patients with severe ALI have improved outcomes when total ventilator support is incorporated within a computerized patient care protocol that includes the availability of $ECCO_2R$ or ECMO. [209] [213] Such information must not be interpreted as testimony that simply replacing volume-preset modes with pressure-preset modes will improve outcome or diminish morbidity. [214] [215] More importantly, there is no evidence to indicate that this approach to ventilator management is appropriate for patients with normal or mildly to moderately diseased lungs or that this approach justifies the abandonment of established principles of CPAP/PEEP and oxygen therapy.

VENTILATOR DISCONTINUANCE AND WEANING

Because PPV ventilation is initiated to normalize acute respiratory dysfunction, it is reasonable that reversal of that acute pathologic process should be the major factor considered prior to discontinuance of the therapy. Although the correct definition of the word wean is simply "to withdraw," the common connotation of the term is "to tease away gradually." This gradual concept is unfortunate when applied to ventilator management because most ventilator-dependent patients can be rapidly removed from the ventilator when the disease process has been adequately reversed. In this discussion, the term weaning is used only in reference to the minority of patients who cannot be discontinued from ventilatory support without gradual maneuvers taking more than 8 hours.

Mechanical ventilation should be discontinued at the earliest time consistent with patient safety. Premature attempts to discontinue ventilator support usually result in unnecessary cardiopulmonary stress without shortening the ventilator course. Ventilator discontinuance should be attempted only when (1) the underlying indication for ventilatory support is reversed or significantly improved, (2) measurements of the cardiopulmonary reserves are judged adequate for spontaneous ventilation, and (3) general clinical examination and laboratory measurements suggest no factors that significantly increase ventilatory demand.

Assessment of Cardiopulmonary Reserves

1. VC greater than 15 mL/kg reflects an adequate ventilatory muscle reserve. One should not rule out a trial of ventilator discontinuance for a patient with a VC of 10 to 15 mL/kg because the VC often improves dramatically over

several hours of spontaneous breathing. Patients with chronic diseases (e.g., COPD, chronic heart failure, quadriplegia) adapt in many ways and can be independent of ventilatory support with an extremely limited VC.
2. V_T: Immediate spontaneous V_T of greater than 2 mL/kg are encouraging. V_T is often difficult to evaluate before the patient is breathing spontaneously for a period of time.
3. Tachypnea: Spontaneous ventilatory rates of less than 25/min are encouraging; tachypnea demands reevaluation.
4. Tachycardia: Significant tachycardia on the ventilator is discouraging because the assumption of the work of breathing demands a significant increase in myocardial work. Partial ventilatory support may prove a helpful step in evaluation.
5. Hypotension/hypertension: Hypotension on the ventilator is discouraging; hypertension must be carefully evaluated.
6. Arrhythmia: Cardiac arrhythmia must be evaluated. The increased myocardial work associated with the work of breathing may be significant.
7. Hb: Oxygen-carrying capacity greatly affects the extent of increased myocardial work resulting from the assumption of the work of breathing.
8. Ventilatory demand: Factors that increase ventilatory demand (e.g., acidemia, hypoxemia, and high metabolic rates) should be corrected.

The respiratory status is best assessed by blood gas evaluation before attempting removal from the ventilator: (1) arterial blood gas measurements must be acceptable on the ventilator; (2) no evidence of acute increased V_D should be present; and (3) intrapulmonary shunt measurement should be less than 30 percent, preferably less than 20 percent (Pa_{O_2}/F_{IO_2} 150).

Ventilatory Challenge

The method of withdrawal from the ventilator support is of little significance in patients with adequate ventilatory reserves. [216] In such patients, ventilator discontinuance is mainly a matter of a smooth transition from PPV to spontaneous breathing.

Following is the scientific rationale for a procedure that makes clinical common sense, the ventilatory challenge. There must be adequate stimulation of central chemoreceptors that are sensitive to decreased cerebrospinal fluid (CSF) pH. Because the CSF does not contain appreciable buffering capabilities, small changes in Pa_{CO_2} will result in relatively large pH changes. In apneic patients who are well oxygenated, anesthetized, and paralyzed, the mean rate of rise in Pa_{CO_2} is 13.5 mm Hg in the first minute and 3.5 mm Hg each minute thereafter. [217] With an initial arterial pH of 7.40 and Pa_{CO_2} of 40 mm Hg, the Pa_{CO_2} can be expected to rise 25 to 30 mm Hg after 5 minutes of apnea, resulting in an arterial pH of approximately 7.25. The CSF pH would be expected to change from a baseline of 7.36 to less than 7.10 in response to an increase in P_{CO_2} from 40 to 70 mm Hg, a change that should provide a maximal stimulus to the central chemoreceptors. [218] When a minimum of two positive-pressure breaths per minute is applied to an apneic patient with a clinically apparent basal metabolic rate, the Pa_{CO_2} rise is seldom greater than 15 to 20 mm Hg in 5 minutes. [219]

Clinical assessment begins with notation of baseline values and a pulse oximeter applied. A positive-pressure breath synchronized with the patient's spontaneous pattern is provided every 30 seconds with a manual ventilator delivering 50 to 80 percent oxygen. If the patient manifests significant detrimental changes in vital signs or clinical appearance, the ventilator is reinstituted. Most patients do not require any positive-pressure breaths after several minutes and make a smooth transition to spontaneous ventilation. Patients with chronic CO_2 retention may require Pa_{O_2} values lower than 70 mm Hg to maintain adequate spontaneous ventilation. In such cases, the manual ventilator should be used with an appropriate F_{IO_2}, to avoid relative hyperoxemia.

The patient is allowed to assume the work of breathing, while the Sp_{O_2}, pulse rate, blood pressure, ventilatory pattern, and breathing efforts are closely monitored. The spontaneous ventilatory rate may dramatically change toward normal as the work of breathing is assumed. Breathing rates approaching 20 to 25/min should not cause concern so long as the rate stabilizes, the pattern is acceptable, and the effort is not distressing to the patient. Spontaneous work of breathing is often accompanied by blood pressure and cardiac rate increases up to 10 percent from baseline; this should not be considered a problem in the absence of dysrhythmia or distress. Mild diaphoresis is a common feature and should not cause concern unless it is accompanied by other signs of increased sympathetic discharge or physiologic stress.

Difficult-to-Wean Patients

A ventilatory challenge is applied to patients deemed capable of maintaining respiratory homeostasis without ventilatory support or to patients who appear borderline. When the ventilatory challenge fails, there must be a complete reevaluation of residual sedation, narcosis, and neuromuscular blockade. Most weaning problems are due to (1) attempts to discontinue ventilation too early in the disease course, (2) improper ventilator maintenance, or (3) preexisting chronic disease or malnutrition that severely limits reserves.

Even though there are no data suggesting that specific weaning techniques have any inherent advantage, [220] biases are rampant. IMV, SIMV with pressure support, and pressure-support modes have the advantage of allowing the patient to assume more work of breathing gradually. However, these modes are misused when they

are routinely chosen to provide a prolonged weaning process to patients capable of spontaneous breathing. Improved knowledge of ventilatory muscle function has led to the development of techniques (isocapnic hyperpnea, inspiratory resistive breathing) specifically designed to increase ventilatory muscle strength and endurance. [221] Further study of these techniques as weaning aids is required.

There are circumstances in which the use of 5 to 10 cm H_2O CPAP aids in the ability to maintain spontaneous ventilation. Theoretic benefits include the maintenance of an improved FRC, improved lung compliance, and a subjective "sensation" of better lung inflation. As a general rule, patients

already receiving CPAP/PEEP therapy should be maintained on 5 to 10 cm H_2O CPAP during ventilator discontinuance and extubated from that level. [222]

An inadequate nutritional status impairs ventilatory muscle efficiency and strength and has been assumed to be a potential cause of failure to wean from the ventilator. Although this assumption remains controversial, it is well documented that parenteral hyperalimentation can significantly increase CO_2 production, which may produce weaning difficulties. [223] Parenteral regimens with high-carbohydrate diets are associated with the greatest increases in CO_2 production; fat energy sources added to the diet are recommended to minimize CO_2 production.

Patients Receiving Long-Term Ventilation

Most patients legitimately requiring lengthy weaning programs are those lacking adequate reserves because of chronic lung or heart disease. Often, inordinate time, energy, and emotion are spent to remove the patient from the ventilator for several days and to discharge the patient from the ICU, only to have the patient return in need of ventilatory support without identifiable acute insult. No one disagrees that all patients deserve reasonable attempts to be free of the ventilator. However, after a reasonable trial period, it becomes evident (although difficult to accept) that patients are at least intermittently in need of prolonged ventilator support. Quality of life is best served by early acceptance of these facts and preparation of the patient and family for long-term ventilator support.

OBSTRUCTIVE DISEASE AND RESPIRATORY FAILURE

Two of the most common respiratory abnormalities encountered by anesthesiologists are COPD and asthma. These disease processes are responsible for significant morbidity and mortality, both in the perioperative period and during acute exacerbations of the chronic disease process.

Asthma

Bronchospasm is the most readily reversible pulmonary pathologic process encountered during the perioperative period. Table 72-5 (Table Not Available) outlines some of the various drugs used for the treatment of bronchospasm. First-line therapy for bronchospastic disease consists of inhaled beta-agonists. These drugs are used differently depending on the severity of the patient's disease. Some patients may use them intermittently depending on symptoms, whereas others may require a regular regimen. However, in the perioperative period, the use of beta-agonists on a regular schedule (i.e., q9h) for prophylaxis is recommended. [224] Anticholinergic agents are also considered first-line therapy, especially in older patients or those with a significant smoking history. [225] Asthma has been recognized as an inflammatory process affecting the airways. As such, inhaled and systemic corticosteroids have become a mainstay of therapy in many patients, [226] and they should be continued throughout the perioperative period. Preventive therapy with cromolyn sodium is most effective in younger patients with a strong allergic basis for their asthma. [227] Although this drug also should be continued throughout the perioperative period, if possible, cromolyn has no place in the treatment of acute bronchospastic episodes.

Second-line therapy for bronchospastic disorders consists of oral theophylline and/or sympathomimetics (i.e., albuterol and terbutaline). [227] The use of theophylline for treatment of bronchospastic disorders is controversial; however, if the patient is already being treated with the drug, and there are no signs of toxicity (i.e., tremulousness, tachycardia, nausea, vomiting, seizures), then it should be continued throughout the perioperative period, and drug levels should be checked as indicated. If the patient is being treated with oral sympathomimetics, they can usually be discontinued in the perioperative period, but inhaled agents should be substituted on a scheduled administration basis.

If general anesthesia is utilized, the choice of anesthetic agents may affect the patient's clinical course. In terms of the effects of intravenous induction agents on reactive airways, ketamine [228] [229] and propofol [230] are the only ones that have bronchodilatory effects; however, virtually any agent is acceptable, provided an adequate depth of anesthesia is obtained prior to airway manipulation. Inhalational agents all have bronchodilatory effects. Although some inhalational agents may be more potent in this regard than others, no clinically significant difference has ever been demonstrated. Histamine release is also a concern in patients with bronchospastic disease processes, and, whenever possible, drugs that cause significant histamine release should be avoided. However, the potential for histamine release is not an absolute contraindication to the use of any specific drug in the appropriate clinical situation.

It is important to restart any aerosolized bronchodilator medications as soon as possible in the postoperative period. Frequently, it is necessary to administer aerosolized bronchodilators via a hand-held nebulizer or a face mask until the patient has the ability to properly use an MDI, with or without a spacer device. Contrary to popular belief, there is no clinical advantage to the administration of bronchodilators with a hand-held nebulizer over an MDI if the patient is able to use an MDI properly. [31] Therefore, it is not surprising that the most cost-effective method of aerosolized drug administration has been demonstrated to be via an MDI. [231]

Acute asthmatic exacerbations are occurring more commonly and with greater severity. The anesthesiologist may become involved in the care of the acutely asthmatic patient when ventilator management becomes necessary. The traditional means of estimating the severity of acute asthma in relation to maintaining respiratory homeostasis is to categorize the arterial blood gases into four stages:

1. Stage 1: Mild hypoxemia with normal pH and Pa $_{CO_2}$.
2. Stage 2: Mild hypoxemia with respiratory alkalosis(pH > 7.45 and Pa $_{CO_2}$ < 35 mm Hg breathing room air.
3. Stage 3: Severe hypoxemia (requires 0.4 F $_{IO_2}$) with normalizing pH and Pa $_{CO_2}$.
4. Stage 4: Acute respiratory acidosis (pH < 7.30, Pa $_{CO_2}$ 55 mm Hg) with severe hypoxemia.

Positive airway-pressure therapy applied to patients with acute asthma is associated with a high incidence of barotrauma,

which is the largest contributor to morbidity and mortality in these patients. [232] [233] The first case reports of permissive hypercapnia were attempts to avoid barotrauma in patients with acute asthma by limiting V_T. Although everyone agrees that alveolar overdistention must be avoided, there is controversy about how this is best accomplished. The traditional approach utilizing volume-preset modes is to deliver reasonable V_T (8-10 mL/kg) at rates of 4 to 6/min, allowing extremely prolonged expiratory times. This requires very heavy sedation (even anesthesia) with neuromuscular blockade to ensure that there is no coughing or ventilatory dyssynchrony. A newer approach is to use pressure-preset modes and airway graphics to avoid hyperinflation and barotrauma. [234]

The anesthesiologist is often consulted to intubate the patient with severe acute asthma. Although there is no clear evidence linking the worsening of bronchospasm to the placement of an endotracheal tube, virtually all anesthesiologists have encountered clinical situations in which this has occurred. The most important factor in dealing with an acute asthma exacerbation requiring intubation and mechanical ventilatory support is to induce an adequate state of anesthesia during airway manipulation and initiation of mechanical ventilation. Following this, treatment of the underlying processes can progress with appropriate medications (i.e., inhaled or parenteral beta-agonists, anticholinergics, steroids).

Chronic Obstructive Pulmonary Disease

COPD is an imprecise term encompassing a wide variety of chronic respiratory conditions, including chronic bronchitis, emphysema, chronic asthma, cystic fibrosis, and bronchiolitis. Regardless of type or degree of underlying disease, all patients with COPD demonstrate several common characteristics: (1) chronically increased airway resistance resulting in increased work of breathing, (2) decreased efficiency of inspiratory muscles secondary to chronic thoracic hyperinflation, and (3) impaired pulmonary gas exchange. Although the incidence of chronic hypercapneia rises as the severity of COPD increases, some patients become hypercapneic with moderate lung disease, whereas others remain eucapnic despite severe obstructive processes. A baseline blood gas analysis can be very helpful in determining the patient's chronic status. This is especially important when mechanical ventilatory support is anticipated during the perioperative period. It is imperative that mechanical ventilation be titrated according to the patient's baseline status if optimal outcomes are to be achieved. This applies not only to patients requiring mechanical ventilation during the perioperative period, but also to those experiencing acute exacerbations of their chronic disease.

Although ARF in a patient with COPD can be a catastrophic event, appropriate therapy is often lifesaving. A 2-year survival greater than 70 percent may be expected when mechanical ventilation can be avoided; these patients have a life expectancy comparable to that of stable outpatients with the same severity of COPD who have not experienced ARF. [235] Immediate therapy to decrease airway resistance and to improve pulmonary gas exchange is essential, regardless of precipitating events. Airway resistance is diminished by bronchodilator therapy and removal of secretions (bronchial hygiene therapy); gas exchange is improved by oxygen therapy and ventilator assistance if required.

Bronchodilators have been demonstrated to be beneficial to most patients with COPD, especially those with impending or respiratory failure or ARF. Optimal bronchodilator therapy has been the subject of much clinical research. Although beta-agonists remain the first-line therapy in asthma, [236] the use of inhaled anticholinergic agents has been demonstrated to have equal efficacy compared with beta-agonists in patients with COPD. [237] The combination of an inhaled anticholinergic compound (i.e., ipatroprium bromide) and a beta-agonist appears to have clinical advantages over the administration of beta-agonists alone in patients with COPD, [238] [239] [240] [241] in critically ill mechanically ventilated patients, [242] and in pediatric patients. [243] Current evidence indicates that anticholinergic bronchodilators have emerged as the treatment of first choice in patients with COPD and as a significant adjunctive therapeutic modality in patients with acute asthma. [244] Fortunately, the arrhythmia potential of ipotroprium bromide in patients with COPD and ischemic heart disease appears to be negligible. [245]

The various agents used to achieve bronchodilation often have beneficial effects other than bronchodilation. For example, theophylline may improve diaphragmatic contractility [246] in patients with COPD. [247] [248] Additionally, inhaled beta-agonists, in addition to causing bronchodilation, may improve the ciliary action in the tracheobronchial tree and may enhance the clearance of mucus. [249] [250]

Corticosteroids have been claimed to be useful in reducing air-flow resistance in patients with COPD with acute exacerbations not caused by pneumonia. Intravenous methylprednisolone sodium succinate (Solu-Medrol), 0.5 mg/kg every 6 hours for the initial 72 hours of hospitalization, has been shown to produce significant improvements in air flow. [251] Interestingly, although these beneficial effects have been noted, questions have been raised regarding the ability of inhaled steroid therapy to improve the quality of life in patients with asthma or COPD. [252]

All patients with COPD and ARF require oxygen therapy. The goal is to restore the patient's arterial oxygenation status to a level that ensures adequate Hb saturation while approximating the patient's stable baseline. This usually requires a Pa_{O_2} of 50 to 60 mm Hg. The classic explanation for CO_2 retention with oxygen administration has been "suppression of the hypoxic drive." In its simplest form, this situation is thought to result from a central CO_2 response that is blunted by chronic CO_2 retention, leaving only hypoxiasensitive peripheral chemoreceptor mechanisms intact to drive ventilation. When an increased F_{IO_2} results in augmentation of the Pa_{O_2}, a decrease in hypoxic stimulation occurs, causing hypoventilation. Experience in acute respiratory care resulted in abandonment of that traditional wisdom in favor of a more complex concept in which additional factors such as changes in the work of breathing, hypoxic vasoconstriction, denitrogenation, and Hb-oxygen affinity relationships are potentially involved. Suffice it to say that oxygen administration, although clinically necessary, has the risk of augmenting CO_2. Thus, it is best to administer precise and consistent inspired oxygen concentrations with high-flow oxygen systems; however, the risk of CO_2 retention

is still present even with precisely controlled inspired oxygen concentrations.

PARENT/FAMILY SUPPORT

/das/book/view/29494766/875/796.html

INTRODUCTION

The major objective of pediatric intensive care is to provide maximum surveillance and support of vital systems in infants and children with acute, reversible, life-threatening disease. In contrast to adult patients, few children admitted to a pediatric intensive care unit (PICU) suffer from chronic or degenerative organ system disorders. Most of these children have a potentially reversible life-threatening illness or injury that, if successfully treated, will restore the child to a normal, productive life. [1]

Although the principles of intensive care for children are similar to those for adult intensive care, the age spectrum from infancy through adolescence requires that the intensive care staff have special expertise in developmental physiology and psychology. The pediatric intensive care team must be familiar with fetal and neonatal cardiopulmonary physiology as well as with the physiologic and psychological aspects of growth and development to adulthood. All critically ill children, regardless of diagnosis or subspecialty category, should be placed in units dedicated exclusively to children, whenever possible. Specific guidelines describing minimum criteria for PICUs and services have been published. [2] Beginning in 1985, the American Board of Pediatrics officially recognized the subspecialty of pediatric critical care medicine.

When matched for severity of illness, there is decreased mortality in pediatric patients cared for in PICUs as compared with those cared for by physicians without pediatric intensive care training in nontertiary care facilities. [3] Hospitals without sufficient numbers of pediatric patients to provide specialized facilities for pediatric intensive care should consider transferring critically ill children to a regional PICU. It is the obligation of regional PICUs to develop

transport systems that will facilitate the safe and timely transport of critically ill children to the referral center. In addition, the regional center should provide medical education in emergency and critical care pediatrics to primary care and referring physicians and nurses.

ORGANIZATION OF THE PEDIATRIC INTENSIVE CARE UNIT

The PICU should be represented in the hospital by a multidisciplinary committee of the professional staff, including the medical and nursing directors, hospital administrators, and representatives from pediatric medicine, anesthesia, surgery, and the pediatric subspecialties. This committee should be responsible for policy and procedures pertaining to the PICU and should make recommendations regarding personnel staffing, equipment purchases, and structural and design changes within the unit.

The PICU staff should include a medical director whose special expertise and training in pediatric critical care qualify that person to oversee the quality of care provided to all patients in the unit. Additional responsibilities include patient triage, implementation of policy and procedures, in-service education, and coordination of multiple consultants. Physician coverage should be full-time geographic at the resident, fellow, or attending staff level. The medical director also functions as arbiter and patient advocate.

The nursing director should have special skills in pediatric intensive care, education, and personnel management. The medical director and nursing director must collaborate as a team. The registered nursing staff must be trained in all aspects of pediatric critical care and resuscitation, and staffing needs to be flexible enough to provide one-on-one coverage when necessary. A multidisciplinary in-service program for continuing education and orientation is essential.

Other team members should include respiratory therapists, physical therapists, nutritionists, social workers, psychiatrists, and psychologists for both patients and staff, as well as laboratory technologists. All support personnel are essential to the team effort and should be included in rounds and team meetings whenever possible.

The physical facility for the PICU should be self-contained and spacious enough to provide adequate work area around each bed space and enough storage to keep life-support equipment within reach. Because the PICU staff practically live in the environment, space for reading, meeting, sleeping, and showering should be available. Parent and visitor space is essential to permit parents to sleep overnight. Facilities should be designed to encourage constant parental participation, because parents are such an essential part of the therapeutic plan of any critically ill child.

Each bed space should be standardized so that the level of support and monitoring can be escalated. Distance between bed spaces should be adequate to ensure privacy and to minimize nosocomial infection. Complete precaution or isolation rooms should be available within the confines of the unit.

Along with life-support equipment, devices for diversion and entertainment should be available for children who are conscious. Children's television programs can often replace heavy sedation when patient cooperation is essential. On the other hand, there is no substitute for parental and nursing involvement at the bedside in preventing accidental self-extubations or other inadvertent, potentially self-destructive behavior. Because of the need for close personal observation, centrally monitored nursing stations have little place in the PICU.

CARDIOVASCULAR SYSTEM

Circulation

Circulatory well-being in infants and children is dependent on the progression of structural and functional maturation (Chs. 58 and 59) . An understanding of this agedependent process is essential for the diagnosis and treatment of circulatory failure in infants and children.

Structural and Functional Development

The external shape of the heart is complete by 6 weeks' gestation, but an increase in myofibrillar density and maturation continues at least through the first year of postnatal life. [4] During this time, myocytes are engaged in rapid protein synthesis and rapid cell growth, which require a high intracellular concentration of nuclei, mitochondria, and endoplasmic reticulum. This greater number of nonelastic and noncontractile elements makes the neonatal myocardium stiffer (less compliant) and less efficiently contractile than the adult. [5] In the fetus and newborn infant, because of this decreased ventricular compliance, even small changes in end-diastolic volume cause large changes in end-diastolic pressure. In addition, augmentation of stroke volume by the Frank-Starling mechanism is less effective in the newborn; this necessitates a greater, but not exclusive, dependence on heart rate for maintenance of cardiac output. [6] [7]

Development of the Circulation

Adult and fetal circulation differ in many ways. Fetal circulation is distinguished by (1) the placenta as the organ of respiration, (2) high pulmonary vascular resistance, (3) low systemic vascular resistance, and (4) the fact that the fetal ventricles pump in parallel with a dominant right ventricle. [8] In addition, the fetus exists in a remarkably hypoxic environment compensated for by a relatively high cardiac output and a hemoglobin with a high affinity for oxygen. [9] The fetus compensates for the placement of the placenta in the systemic circulation by several shunts: the ductus arteriosus, ductus venosus, and the foramen ovale. When the fetus becomes an extrauterine being, the following important changes occur to bring the circulation to an adult form:

1. With the first breath, the increase in oxygen saturation, as well as other potential neurohumoral mediators and nitric oxide (NO), [10] relaxes the pulmonary vasospasm that existed *in utero.* Pulmonary blood flow then increases. [11]
2. The placenta separates from the uterine wall, the placental blood vessels constrict, and systemic vascular resistance

(SVR) and left ventricular afterload increase. As the pulmonary vascular resistance (PVR) decreases and SVR increases, left atrial pressures rise above the right atrium, and the "flap valve" of the foramen ovale [12] functionally closes.
3. The ductus arteriosus closes as the arterial oxygen tension (Pa O_2) increases. Mediators such as the prostanoids and kinins, as well as changes in autonomic vascular tone, promote closure of the ductus arteriosus. The ductus is usually functionally closed during the first 24 to 96 hours of life, and anatomic obliteration follows during the next several weeks. [13] [14]
4. The ductus venosus passively closes with the removal of the placental circulation and readjustment of the portal pressure relative to inferior vena cava pressure. [15]
5. There is a further gradual decline in PVR because of a structural remodeling of the muscular layer of pulmonary blood vessels. During fetal life, the central pulmonary vascular bed has a relatively thick muscle layer. After birth, this muscle coat thins and extends to the periphery of the lung, a process that takes months and years to complete. [16]

Development of Autonomic Control of the Circulation

There is still considerable speculation regarding the functional integrity of autonomic circulatory control during fetal and perinatal development. It has been shown in several species that the fetal heart has a reduced store of catecholamines and an increased sensitivity to exogenously administered norepinephrine. [5] The sympathetic nerves first develop in the atria and grow into the ventricles toward the apex at a variable and species-specific rate. [17]

In fetal lambs, resting alpha-adrenergic tone begins at approximately 0.6 gestation and is nearly complete at birth, but resting beta-adrenergic control does not begin until 0.8 gestation and is incompletely developed at birth. [18] Adrenergic innervation of the human myocardium may be complete between 18 and 28 weeks' gestation. However, low cardiac stores of norepinephrine, as well as a lack of fluorescence of sympathetic nerves, have been demonstrated in humans after birth. Adrenergic responses are apparently present but diminished in the newborn human. [19]

Development of cholinergic (vagal) control of the heart is also variable and is species specific. In human newborn infants, the cholinergic system appears completely developed at birth, and the heart is sensitive to vagal stimulation. [20] This provides for a relative vagal predominance of neural cardiovascular control, making bradycardia a more likely response to any increase in autonomic tone.

The chemoreceptor and baroreceptor reflexes have important developmental implications in the infant and child; the baroreceptor reflex is present but is incompletely developed at term in the human. In preterm infants, postural changes elicit no change in heart rate, but there is an increase in peripheral vascular resistance, illustrating an incomplete and attenuated baroreceptor response. [21] The chemoreceptor response seems to be well developed *in utero.* Fetal bradycardia in response to hypoxia is thought to be mediated through the chemoreceptors and may be similar to the oxygen-conserving mechanisms of diving animals. [22]

Myocardial Metabolism

Adult cardiac muscle is almost exclusively dependent on oxygen for its metabolism, with an efficiency of oxygen extraction greater than in other organs. Anaerobic metabolism is nearly nonexistent in adult cardiac muscle, so that the heart is extremely sensitive to hypoxia or ischemia. Either of these conditions, however brief, alters the energy supply and affects the mechanical response of the adult heart.

The metabolic characteristics of the fetal myocardium are different. Relative hypoxia is normal *in utero,* and the infant's heart has been shown to tolerate hypoxia better than the adult's. [23] [24] This difference may be partly due to high concentrations of glycogen in fetal myocardial tissue and the finding that the hypoxic fetal myocardium produces lactate, suggesting anaerobic metabolism. [25] In addition, fetal hemoglobin is more efficient than adult hemoglobin in hypoxic environments. These mechanisms make the fetal/newborn heart relatively resistant to the destructive effects of hypoxia, provided oxygenation and perfusion are reestablished within a reasonable period of time.

Myocardial demands change significantly in the first month of life. Oxygen consumption increases precipitously after birth, presumably owing to thermogenesis. The full-term infant's oxygen consumption in a neutral thermal setting is approximately 5 mL/kg/min and increases to 7 mL/kg/min and 8 mL/kg/min at 10 days and 4 weeks, respectively. Over the ensuing months, oxygen consumption and cardiac output gradually decline. [26] [27] [28]

Age-Related Circulatory Variables

Common Cardiovascular Disease States

Congenital Heart Disease

Although a complete discussion of congenital heart disease is not possible here, various abnormalities that produce significant alterations in oxygenation, perfusion, and myocardial function after birth are worthy of attention (Table 73-1 (Table Not Available) ; Ch. 50). The more common lesions include obstruction to systemic outflow (i.e., congenital aortic stenosis and coarctation of the aorta) and lesions that alter the adequacy of pulmonary blood flow (i.e., tricuspid or pulmonary atresia or tetralogy of Fallot). Many of these lesions are associated with other abnormalities that facilitate mixing or diversion of blood flow from one circuit to the other, in order to permit even marginal survival. Patent fetal conduits such as the ductus arteriosus or foramen ovale may exist in isolation or in association with other "shunt" lesions, and, in some circumstances, rather than helping survival, they may become a source of cardiac decompensation. [6]

Newborns with significant congenital heart disease commonly present with either cyanosis or congestive heart failure (CHF). It is important to recognize that the degree of dysfunction changes during the first 2 to 3 months of life because the PVR decreases to adult levels. [29] As this resistance falls, left-to-right shunts can increase, and the symptoms of CHF become more apparent. In the newborn, the usual signs and symptoms of CHF include poor feeding, irritability,

sweating, tachycardia, tachypnea, decreased peripheral pulses, poor cutaneous perfusion, and hepatomegaly. Cyanosis may indicate structural cardiac disease; however, respiratory disease, neurologic disease, PVR (persistent pulmonary hypertension), and methemoglobinemia must also be considered [6] (Table 73-2) .

The diagnosis of congenital heart disease can be made on the basis of the physical examination, the electrocardiogram (ECG), chest radiograph, and the echocardiogram. Cardiac catheterization may be performed after initial stabilization and prior to either definitive or palliative cardiac surgery.

The initial medical treatment of congenital heart disease is aimed at relieving CHF, improving systemic perfusion, and maintaining pulmonary blood flow. In some situations (i.e., hypoplastic left heart syndrome, aortic stenosis, or atresia), the patency of the ductus arteriosus may be crucial to provide perfusion to the body. In these cases, prostaglandin E_1 (PGE_1) infusion has proved useful in maintaining the patency of the ductus arteriosus until definitive surgical correction can be performed [30] [31] (see the discussion of pharmacology later in this chapter).

Acute Circulatory Failure in Children

Acute circulatory failure is defined as any clinical condition in which systemic blood flow is inadequate to meet the metabolic demands of the body. [32] The clinical syndrome of shock includes the signs and symptoms of both an inadequate circulation and an attempt to compensate for circulatory failure. The child has a remarkable ability to compensate for an inadequate circulation, with both endogenous catecholamine release and increased peripheral autonomic tone. The signs of compensation are often the earliest clinical clues that a child is in shock. Anxiety or irritability, cool, pale extremities, and unexplained tachycardia are usually the earliest signs. Tachypnea, moderate metabolic acidosis, oliguria, and somnolence are signs of inadequate tissue perfusion, whereas obtundation, periodic breathing, and apnea are signs of impending cardiopulmonary arrest. Arterial blood pressure is not usually a good indicator of the adequacy of perfusion in children. The child's ability to constrict the peripheral circulation is so efficient that central blood pressure may be normal despite impending circulatory collapse. Circulatory failure can result from pump failure or from intravascular hypovolemia. Intravascular hypovolemia is a consequence of either true volume loss (blood, plasma, water) or an alteration in peripheral vascular resistance (Table 73-3) (Table Not Available) .

In children, the most common cause of circulatory failure is hypovolemia from excessive volume loss. This condition produces decreased ventricular preload that reduces stroke volume and cardiac output. The causes of acute hypovolemia are (1) blood loss (trauma, gastrointestinal bleeding), (2) plasma loss (capillary leak syndrome associated with sepsis, hypoproteinemia, burns, peritonitis), and (3) water loss (most commonly vomiting and diarrhea, glycosuric diuresis in diabetic ketoacidosis). Patients with acute hypo-volemia usually have extreme peripheral vasoconstriction with cool, poorly perfused extremities. Peripheral pulses may be thready, and the capillary refill time may be prolonged.

Intravascular hypovolemia can also result from decreased peripheral vascular resistance associated with anaphylaxis, septic or endotoxic shock, and the ingestion of

vasodilating drugs. In these cases, peripheral perfusion is usually maintained with warm extremities. [32] [33]

Cardiogenic shock is a relatively uncommon cause of circulatory failure in the pediatric patient when compared with the incidence in adults. In the neonate, the usual cause is congenital heart disease with outflow obstruction or systemic-to-pulmonary shunting, although viral and bacterial sepsis also is a common cause. In any child, extrinsic inflow or outflow obstruction associated with tension pneumothorax, hemopericardium, or pneumopericardium, as well as pericardial effusion, must also be considered. Last, primary pump failure associated with viral or infiltrative cardiomyopathies,

TABLE 73-3 -- Circulatory Failure: Hypotension

(Not Available)

Modified from Crone [32]

collagen vascular or Kawasaki disease, [31] [32] metabolic derangements such as hypoglycemia, sepsis, or uremia can produce circulatory failure that is refractory to treatment. [34] [35] [36] [37] Arrhythmias such as paroxysmal atrial tachycardia or atrioventricular block can also precipitate circulatory failure in children.

Treatment

The cause and functional physiologic features of shock can frequently be identified from a history and physical examination. Specific therapy may differ in various clinical conditions, but immediate therapy should include assessment of the airway, administration of oxygen, establishment of adequate ventilation, and obtaining vascular access. A peripheral venous site may be cannulated percutaneously, but impaired perfusion may reduce the possibility of success. The intraosseous (IO) route for fluid and drug bolus or infusion is now routine in emergency settings. [38] A stiff, short-beveled trocar needle is placed into the proximal third of the tibia (Fig. 73-1) or the distal femur. Specific needles are manufactured for this purpose, but 18-gauge spinal needles and bone marrow aspirate needles also function well. Care must be given to avoid the epiphysis. When the IO needle is properly positioned, its shaft is anchored in the cortex, with the needle tip in the marrow cavity. The cortex supports the needle solidly, blood and bone spicules can usually be aspirated, and the infusion of fluids is easy without distorting the soft tissues of the leg. The IO line is then used to obtain blood samples for laboratory analysis, to deliver fluids, and to administer all resuscitation medications traditionally given intravenously. The IO line provides rapid, safe, emergent vascular access. Standard intravenous access should be achieved as soon as possible because IO placement degrades with time. Percutaneous cannulation of the jugular [39] and subclavian veins carries the risk of carotid puncture, hemothorax, pneumothorax, and perforation of the superior vena cava or right atrium. The smaller size of the child increases the risks [40] of any vessel cannulation.

Specific therapy for circulatory failure is directed toward increasing cardiac output and normalizing peripheral organ perfusion. Because the determinants of cardiac output are

Figure 73-1 Intraosseous cannulation technique.

heart rate and stroke volume, an increase in either may be beneficial. If tachycardia does not already exist, heart rate may be increased either by vagolysis or by cardiac beta-stimulation (positive chronotropy). The principal vagolytic agent is atropine (0.02 mg/kg), and the most commonly used positive chronotropic agents are isoproterenol or epinephrine. In children, a 30 to 50 percent increase in heart rate over control levels is well tolerated and usually increases cardiac output substantially. [7] [8] Stroke volume is increased by (1) increasing preload, (2) decreasing afterload, or (3) improving contractility.

Because most children in shock are hypovolemic, preload augmentation is the usual initial therapy. Once vascular access is obtained, the blood volume should be augmented with an infusion of isotonic crystalloid or colloid solution. Hypertonic resuscitation fluids have been utilized, but there is inadequate information available to justify their use. The amount and rate of infusion of an isotonic solution depend on the clinical condition. A good starting point is 10 mL/kg of estimated body weight rapidly infused over a few minutes. The bolus should be repeated until improvement in perfusion is observed. If no improvement has occurred by the fourth bolus, ongoing losses or a different cause of shock should be suspected, and further diagnoses should be pursued. [32] [33] Intravascular volume can be assessed by physical examination, chest radiography, echocardiography, or placement of a central venous pressure catheter.

Echocardiography has the advantage of being rapid and noninvasive, but it requires the immediate availability of sophisticated equipment and personnel skilled in interpreting pediatric echocardiograms. In addition, structural cardiac abnormalities can be ruled out, and myocardial function may be qualitatively assessed in real time. [41] Most infants and children who need ongoing assessment and cardiovascular support require a central venous catheter. Although a central venous pressure (CVP) value of 5 mm Hg is a reasonable estimate for adequate intravascular volume, there is no single optimal CVP; only with careful incremental infusions of volume (10 mL/kg per bolus) can the effect on cardiac output be assessed. Several extracardiac factors, including lung compliance, the level of positive end-expiratory pressure (PEEP), peak inspiratory pressure (PIP), and increasing abdominal pressure, affect CVP or right ventricular filling pressure; thus, each patient's optimal CVP may differ considerably. Once a reasonable CVP has been obtained, if there is no improvement in blood pressure, cutaneous perfusion, or urine output, cardiogenic causes of circulatory failure must be considered. Arterial blood gases, hematocrit, serum electrolytes, glucose, and calcium levels should be determined. Correction of acidosis, hypoxemia, or metabolic derangement is essential. Blood and other appropriate sites must be cultured, and broad-spectrum parenteral antibiotic coverage must be begun, if sepsis is a possibility.

Urine output can be an important indicator of the adequacy of the circulation. A urine output of greater than 1 mL/kg/h usually indicates an adequate renal blood flow and cardiac output. Patients with an output less than 0.5 mL/kg/h should be evaluated for circulatory failure, renal failure, or obstruction to urine flow.

Myocardial contractility can be improved by correcting existing metabolic derangements (hypoxia, acidosis, hypoglycemia) and by administering positive inotropic agents

such as sympathomimetic amines (beta-agonists), xanthines, and cardiac glycosides.

In clinical practice, the pulmonary artery catheter is used less frequently in children than in adult patients. In contrast to the adult with preexisting coronary artery disease, most conditions causing circulatory failure in children are associated with biventricular failure. In these cases, left ventricular filling pressures are reflected by the right atrial pressure, and the CVP is an adequate indicator of left- and right-sided filling pressures. The pulmonary artery catheter in children is usually used for continuous measurement of pulmonary artery pressure or for intermittent measurement of cardiac output by thermodilution technique. [42] [43] [44]

Pulmonary artery catheters are available in two sizes: the "adult" 7 French and the "pediatric" 5 French. The CVP port is 30 cm and 15 cm proximal to the tip in the 7- and 5-French catheters, respectively. Children who weigh less than 8 to 10 kg are too small for even the 5-French catheter.

Afterload reduction may be indicated specifically when "pump failure" coexists with an elevated SVR. [45] Under these circumstances, there may be an advantage to reducing afterload and ventricular work in order for the ventricle to pump more efficiently with an increase in stroke volume. Afterload reduction may be effected with a direct vasodilator such as sodium nitroprusside, a beta-agonist (isoproterenol), or an alpha-antagonist (phentolamine or tolazoline). Afterload reduction is frequently unpredictable, and the associated hypotension may reduce coronary perfusion to such a degree that it reduces cardiac efficiency rather than improves it. Vasodilators should be used with extreme caution, and vasoconstricting agents (phenylephrine or norepinephrine) should be available for immediate use.

Pharmacologic vasoconstriction is used when hypotension results from an inappropriately low SVR such as in anaphylaxis and warm septic shock. [32] The major complication of this therapy is that vasoconstricting agents produce an increase in the myocardial work and myocardial oxygen consumption, with the result that any

primary myocardial decompensation may be worsened.

Cardiovascular Pharmacology in Children

Pharmacologic support of the circulation includes positive inotropic and chronotropic agents, vasoconstrictors and vasodilators (afterload reduction), and antiarrhythmics (Chs. 14 and 59). Most drugs currently used have not been adequately studied in children, so that dosage recommendations and anticipated effects are extrapolated from studies in adults, as well as from anecdotal clinical experience in children.

Positive inotropic drugs are often used in children, to augment cardiac output in a variety of situations associated with circulatory failure. Most inotropic agents also affect heart rate and vasomotor tone. Tachycardia is often a deleterious side effect in the adult with limited myocardial oxygen reserve, whereas in the child, an increase in heart rate is usually well tolerated and is often beneficial. [32] Particularly in the neonate, whose ventricles are relatively noncompliant and in whom stroke volume is less variable, [6] tachycardia is an important component of cardiac output augmentation. Because all drugs that increase heart rate or contractility also increase myocardial oxygen consumption, it is imperative to ensure adequate arterial oxygenation and adequate supply of metabolic substrate during their administration. In addition, it is important to note that the cardiovascular response to the sympathomimetic amines is attenuated in the presence of acidosis and possibly sepsis; higher infusion rates of these drugs are required and need readjustment as acidosis improves.

Commonly used inotropes are listed in Table 73-4 . Brief comments regarding their use in pediatric intensive care are provided.

Epinephrine

Epinephrine is primarily used for children with cardiac arrest or children with profound myocardial depression and hypotension. Epinephrine is preferably used for initial stabilization, with the hope of switching to another inotrope with less peripheral vasoconstriction as soon as possible. [46] [47]

Dopamine

Dopamine is the most commonly infused inotrope in pediatrics. The physiologic effects are very dose dependent, with activity in low doses, beta activity in intermediate doses, and some alpha activity in higher doses. Specific doses can be patient dependent, but as a rule, young children require higher doses than an adult to produce the same effect. [48] In one study, an infusion of 15 mug/kg/min was needed to increase the cardiac output higher than control in a group of infants after cardiac surgery. [49] This finding may reflect the decreased releasable stores of norepinephrine in the myocardium of immature ventricles. [50]

Isoproterenol

Isoproterenol is a pure beta-agonist medication with very strong chronotropic effects that are often better tolerated in the child than in the adult. Even though a strong inotrope, it causes vasodilation, which may be problematic for the patient who is volume depleted.

Dobutamine

Dobutamine was designed to provide positive inotropy with afterload reduction, without the chronotropy of isoproterenol. However, clinical experience with this drug has demonstrated an associated tachycardia. [51] [52]

Norepinephrine

Norepinephrine, an alpha- and beta-agonist drug, is rarely used in the child except in situations of near-normal cardiac function and extreme peripheral vasodilation. Examples are warm septic shock, anaphylaxis, and sympathetic blocks associated with regional anesthesia. [46] [47]

TABLE 73-4 -- Vasoactive and Inotropic Agents in Pediatrics

DRUG	EFFECT		DOSE[a]	INOTROPY	CHRONOTROPY	VASODILATION	VASOCONSTRICTION

Amrinone and Milrinone

Amrinone and milrinone are noncatecholamine, nonglycoside inotropes and vasodilators. As phosphodiesterase III inhibitors, they increase cyclic adenosine monophosphate (cAMP). These drugs are frequently used for treatment of CHF and postoperative low cardiac output states. [53] [54] [55] In adults, a serum amrinone level of 4 mug/mL has been correlated with a 50 percent increase in cardiac index. [56] In adults, these serum levels are attained with a 0.75-mg/kg loading dose, and they are maintained with an infusion of 5 to 10 mug/kg/min. In infants and neonates, a higher loading dose is required to reach the same therapeutic levels. Lawless et al [57] suggested that infants receive a loading dose of 3 to 4.5 mg/kg in divided doses followed by an infusion of 10 mug/kg/min. Neonates should receive the same bolus, with an infusion of 3 to 5 mug/kg/min. Milrinone is administered as a loading dose of 50 mug/kg over 10 minutes and a maintenance infusion of 0.375 to 0.750

mug/kg/min. This recommendation is extrapolated from adult data, and initial studies suggest the need for a higher loading dose and lower infusion rate in neonates. [58] Medication risks include hypotension, especially during loading doses, and a dose-related thrombocytopenia that may occur with amrinone.

Digitalis

Digitalis is an excellent medication for the long-term treatment of myocardial failure in children. The long half-life and the unpredictability of digitalis toxicity in patients who demonstrate changing levels of serum potassium, calcium, and pH make this drug inappropriate in the unstable, acutely ill patient. More rapid-acting titratable inotropes should be used. [59]

Calcium

Calcium is an often overlooked inotrope. When serum ionized calcium levels are low, the administration of calcium produces a positive inotropic effect; if ionized calcium levels are normal, however, the inotropic effect is much less marked. Low ionized calcium levels are most commonly documented in patients with DiGeorge syndrome or septic shock, after massive volume replacement with citrated blood, and in neonates with relatively unstable calcium metabolism. [60] [61] Calcium can also have a number of effects on the conduction system. In children with a normal ionized calcium level, the rapid administration of calcium through a central venous catheter can cause severe bradycardia or asystole. This effect can be exaggerated in the presence of hypokalemia and digitalis. There have also been reports of calcium precipitating malignant ventricular arrhythmias in adult patients with coronary artery disease; the relative absence of coronary artery disease in children minimizes this complication in the pediatric patient. The vasomotor effects of calcium are somewhat controversial, but most reports show an increase in SVR. Increased PVR has also been documented. [62]

Bicarbonate Therapy

Acidosis profoundly depresses myocardial function and is a sensitive indicator of inadequate tissue perfusion. Initial correction with 1 to 2 mEq/kg of sodium bicarbonate is indicated for a pH of less than 7.20 after establishment of adequate ventilation (P_{CO_2} < 40 mm Hg). The circulatory system is refractory to sympathomimetic amines in the presence of severe acidosis; thus, inotropic agents, even in massive doses, are rendered ineffective unless acidosis is corrected. After initial correction of the pH, the persistence or reappearance of metabolic acidosis suggests a return to an underperfused state and is cause for immediate alarm and therapeutic action. Sodium bicarbonate therapy can only be used as a stopgap measure to render the circulation amenable to pharmacologic support. Repeat infusions of sodium bicarbonate rapidly lead to hypernatremia and hyperosmolarity and cannot neutralize the ongoing lactic acidosis associated with inadequate tissue perfusion.

Vasodilators

Vasodilators are used in children for four main purposes: (1) to control systemic hypertension, (2) to increase cardiac output by decreasing afterload, (3) to control pulmonary hypertension, and (4) to attempt to control cardiac shunting. The use of vasodilators for control of systemic hypertension and for increasing cardiac output in children with CHF has been quite successful. By contrast, the treatment of pulmonary hypertension and cardiac shunting with vasodilators has shown mixed results. The primary problem is that most available vasodilators work on the systemic circulation as well as on the pulmonary circulation. Systemic hypotension and increases in left-to-right shunting have resulted from attempts to treat pulmonary hypertension with vasodilators. The identification of NO as a selective pulmonary vasodilator shows considerable promise in the treatment of pulmonary hypertension.

Sodium Nitroprusside.

This vasodilator relaxes arteriolar and venous smooth muscle, producing a decrease in the afterload and possibly a decrease in the preload. The half-life is only minutes; as such, it is very safe to titrate infusions of this drug to a desired effect. Most common indications for its use are to control severe systemic hypertension, to precipitate an intraoperative episode of controlled hypotension in an attempt to decrease blood loss, and to increase cardiac output in children with low output syndromes [63] (myocarditis, postcardiac surgery). Sodium nitroprusside can be used for days without problems. Potential difficulties include cyanide and thiocyanate poisoning. Cyanate is an intermediate metabolite of nitroprusside; thiocyanate is the final metabolite and is slowly cleared via renal excretion. Thiocyanate toxicity is more common than cyanate toxicity. Thiocyanate levels of 10 mg/dL are associated with weakness, hypoxia, nausea, muscle spasms, and disorientation. Treatment involves discontinuing the administration of nitroprusside. [46] [64]

Nitroglycerin.

Intravenous nitroglycerin is similar in effect to sodium nitroprusside, except nitroglycerin has a relatively

stronger vasodilating effect on the venous capacitance system than on the arterial bed. [65]

Hydralazine.

This vasodilator is routinely used to control systemic hypertension. It produces vascular smooth muscle relaxation in the arterial system much more than in the venous system. There have also been some preliminary reports of hydralazine therapy for treatment of pulmonary hypertension. [66] [67] Certain unpleasant effects of hydralazine therapy (i.e., headache, nausea, dizziness, sweating, tremors) have been described. The most important acute side effect is the cardiovascular effect of reflex tachycardia, with possible increased cardiac output: a beta-antagonist (i.e., propranolol) is often used as adjunctive therapy to counteract this effect.

Tolazoline and Phentolamine.

These competitive alpha-adrenergic blockers have been used in the treatment of pulmonary hypertension. The success of this therapy is not uniform, and these drugs are now rarely used. [68] Serious side effects of these drugs include tachycardia, ventricular arrhythmias, hypotension, and tissue edema.

Prostaglandin E_1 .

Although classified as a vasodilator, PGE_1 is a unique drug that has greatly improved the care of neonates with heart disease. PGE_1 acts directly on vascular smooth muscle; infused at a rate of 0.1 mug/kg/min, it maintains patency of the ductus arteriosus or even reopens the ductus in neonates. This response is dependent on such factors as age and the state of contraction of the ductus. Side effects of apnea, hypotension from systemic vasodilation, or central nervous system (CNS) excitability should be anticipated. This drug is indispensable in patients with ductus-dependent cardiac lesions such as interrupted aortic arch, critical aortic stenosis, or hypoplastic left heart syndrome, in which systemic flow is supplied through the ductus. [30] It is equally indispensable in pulmonary atresia and critical pulmonic stenosis, in which pulmonary blood flow is supplied by the ductus. [31] It has also been used to treat pulmonary hypertension with varying degrees of success.

Nitric Oxide.

With the discovery of NO as one of the endothelium-derived relaxation factors, it appears that we now have a drug that is capable of selectively vasodilating the pulmonary vasculature. [69] NO can be administered by inhalation to patients with pulmonary hypertension, in whom it reduces PVR. [70] It diffuses across the alveoli, dilates the pulmonary vascular bed, and is inactivated by binding with hemoglobin prior to delivery at the systemic vasculature. Extensive clinical testing of inhaled NO is occurring in PICU and neonatal ICU. NO does not appear to cause systemic vasodilation or clinically significant methemoglobinemia in the doses administered (5-80 ppm). [71] Initial studies have shown it to be effective in reducing PVR and in improving outcome in children with reactive pulmonary hypertension. [72]

Arrhythmias

Arrhythmias are less common in children than in adults, most likely reflecting the relative lack of atherosclerosis in the pediatric age group (Chs. 32 and 50). However, a few categories of arrhythmias should be considered.

Perhaps the most common pediatric arrhythmia is sinus bradycardia caused by hypoxemia. Hence, the primary antiarrhythmic agent of childhood is oxygen. Heart block is seen in children after surgical repair of congenital heart disease. If the block persists for more than 2 weeks postoperatively, a pacemaker is generally indicated. [73] Another cause of heart block is connective tissue disease; in fact, infants born to mothers with systemic lupus erythematosus have been diagnosed with heart block *in utero.*[74]

Sick sinus syndrome is usually associated with surgery, myo-carditis, or myocardiopathy. [75] Prolonged QT syndrome, an abnormality of ventricular repolarization, is a familial disorder that can result in sudden cardiac death. Other than sinus bradycardia, the most common arrhythmia is supraventricular tachycardia (SVT), a narrow QRS complex with a regular RR interval. In infants and neonates, the rate can be 200 to 300 beats/min; in the older child, 150 to 250 beats/min. SVT causes a slow myocardial decompensation. The older patient with SVT will frequently complain of palpitations or a racing heart rate and seek medical care long before CHF ensues. By contrast, the younger child is unable to verbalize the sensation of palpitations and will most likely present with CHF. Treatment includes vagal maneuvers, adenosine (0.1-0.2 mg/kg, with maximum single dose 12 mg) IV rapid bolus and direct current cardioversion (0.25-1 J/kg). [76] [77]

Hypertension

Essential hypertension is not a common problem in children. When hypertension does occur, it is secondary (Table 73-5) and is often more difficult to control. The acute onset of severe systemic arterial hypertension constitutes a medical emergency because of the potential for cardiovascular decompensation, as well as the CNS complications of encephalopathy, seizures, or intracranial hemorrhage. In older children, the neurologic manifestations of hypertension are more likely to precede cardiovascular decompensation. By contrast, severe hypertension in the neonate often presents with the nonspecific cardiorespiratory symptoms of CHF. Treatment of hypertension is tailored to the disease process, the absolute degree of hypertension, and the presence of cardiovascular or neurologic symptoms. [78] [79]

The classes of drugs are listed in Table 73-6 . In the ICU, moderate hypertension often accompanies and complicates other disease processes; therefore, familiarity with all these drugs is necessary. However, if malignant hypertension is the admitting diagnosis, an aggressive approach is mandated. This includes close monitoring with a cardiac monitor and an arterial line. In emergency situations, diazoxide is often given. This potent vasodilator reduces blood pressure rapidly, but it has a short half-life and must be followed by other agents of longer duration. Nitroprusside infusions are also beneficial in the acute setting. [80]

Specific Pediatric Diseases

Kawasaki Disease

Kawasaki disease, also known as mucocutaneous lymph node syndrome, was first described in 1967. This disease is a

TABLE 73-5 -- Causes of Severe Hypertension in Children

Renal
Acute glomerulonephritis (e.g., poststreptococcal, Henoch-Schonlein)
Hemolytic uremic syndrome
Chronic glomerulonephritis (all types)
Acute and chronic pyelonephritis
Congenital malformations (dysplasia, hypoplasia, cystic diseases)
Tumors (e.g., Wilms, leukemic infiltrate)
Postrenal transplantation: also rejection
Oliguric renal failure
Trauma
Obstructive uropathy
After genitourinary surgery
Blood transfusions in children with azotemia
Cardiovascular
Coarctation of the aorta
Renal artery abnormalities (e.g., stenosis, thrombosis)
Takayasu disease
Endocrine
Pheochromocytoma
Neuroblastoma
Adrenogenital disease
Cushing syndrome
Hyperaldosteronism
Hyperthyroidism
Hyperparathyroidism
Iatrogenic
Intravascular volume overload
Sympathomimetic administration (e.g., epinephrine, ephedrine)
Corticosteroid administration
Rapid intravenous infusion of methyldopa
Miscellaneous
Immobilization (e.g., fractures, burns, Guillain-Barre syndrome)
Hypercalcemia (e.g., hypervitaminosis D, metastatic disease, sarcoidosis, some immobilized patients)
Hypernatremia
Stevens-Johnson syndrome
Increased intracranial pressure (any cause)

panvasculitis whose victims are primarily children (>80% < 4 y of age). Kawasaki disease is divided into three stages: the acute febrile stage (1-2 wk); the subacute phase; and finally, the convalescent stage (usually 6 wk after onset). The cause is uncertain but presumed infectious. The diagnosis is made when patients fulfill five of six criteria: (1) cervical lymphadenopathy with one node larger than 1.5 cm; (2) mucosal changes, usually the oropharynx, with red, cracked lips; (3) more than 5 days of fever of 101 to 105°F; (4) conjunctival edema and injection; (5) erythema of the palms and soles, often with desquamation after 2 weeks; and (6) an erythematous rash.

Although the disease affects many organ systems, cardiovascular involvement is the usual cause for an ICU admission. Forty percent of patients have cardiac involvement with myocarditis, effusion, and arrhythmias. Twenty percent develop coronary aneurysms with and without thrombosis. Acute myocardial infarction causes death in 3 to 4 percent of patients.

Laboratory tests reveal an elevated leukocyte count with a left shift, increased acute-phase reactants, and, after the first few weeks, a platelet count that is often grossly elevated. An echocardiogram must be done in any child with this presumed diagnosis for assessment of the coronary arteries.

TABLE 73-6 -- Antihypertensive Medications

I. Converting enzyme inhibitors, decrease angiotensin II
Caution in the face of renovascular disease
Captopril
Enalapril
II. Calcium channel blockers, usually type II blockers
Caution: Myocardial decompensation
Nifedipine
Nimodipine
III. Diuretics, usually as an adjunct
IV. beta-Adrenergic blockers
Caution: Reactive airway disease
Propranolol
Esmolol
V. alpha$_2$ -Antagonists
Prazosin
VI. Central alpha-agonist
Clonidine
VII. alpha- and beta-adrenergic blockers
Labetalol
VIII. Dilators
Hydralazine
Diazoxide

Treatment at present is intravenous gamma globulin, 1 to 2 g/kg administered as a 6- to 8-hour infusion. Some patients require inotropic support, and there is much controversy regarding the use of anticoagulation in the face of thrombosis in coronary aneurysms. Survivors of this disease often have resolution of their aneurysms, although some require coronary artery bypass surgery to maintain adequate myocardial perfusion. [81] [82]

Anomalous Origin of Coronary Arteries

Vascular causes of myocardial ischemia are extremely uncommon in pediatric patients. Anomalous origin of the left coronary artery is one rare exception (incidence 1:300,000). In this congenital disease, the coronary artery originates from the pulmonary artery. During the first weeks to months of life, when the PVR is elevated, there can be adequate coronary perfusion. As the PVR decreases, however, coronary perfusion falls and, in fact, can become retrograde. These infants usually present with overwhelming myocardial failure at the age of 2 to 6 months. In the presence of large collateral vessels, these patients can survive into adulthood. The treatment is surgical. [83]

RESPIRATORY SYSTEM

Age-Dependent Respiratory Variables: Structural and Functional Development

Airways and Alveoli

The main fetal organs, including the lungs, appear in the 4th to 8th weeks of gestation [4] (Table 73-7 (Table Not Available) ; Chs. 58 and 59) . At 4 weeks, the endodermal lung buds have divided into the

TABLE 73-7 -- Age-Dependent Respiratory Variables: Normal Values [a]

(Not Available)

From O'Rourke and Crone [384]

[a] Ch. 59

main-stem bronchi; by 6 weeks, all subsegmental bronchi can be identified, and by 16 weeks, the number of airway generations arising from axial pathways is similar to that in the adult. When this airway development is complete, the terminal airways remodel and multiply to form a cluster of large saccules, which are alveolar precursors capable of supporting gas exchange. True alveoli appear before and after birth, when the respiratory saccules become thinner and septated during postnatal growth. [84]

At birth, children have 24 million alveoli; by 8 years, this number has increased to 300 million. After this age, further lung growth reflects an increase in the size of the alveoli. Collateral ventilation between airways (Lambert canals) and between alveoli (Kohn pores) is not present at birth, but it develops by age 8. [85]

The neonatal lung has a decreased amount of elastic tissue, with elastin extending only to the level of the alveolar duct. Elastin progresses to the level of the alveolus, reaching maximal levels by 18 years of age, then over the next 5 decades, it slowly deteriorates. [86] Lung compliance is integrally related to the amount of elastin, and, hence, compliance peaks in adolescence and is relatively low in the very young and the very old. [87]

Pulmonary Circulation

The main axial arteries are present at 14 weeks' gestation, and by 20 weeks, the pattern of branching is similar to that seen in the adult. By 20 weeks' gestation, collateral supernumerary vessels are present in an adult pattern. During fetal life, additional arteries develop to accompany respiratory airways and saccules. Bronchial arteries appear between the 9th and 12th weeks of gestation. [87] The arterial wall develops a fine elastic lamina by 12 weeks' gestation, and muscle cells develop as early as 14 weeks. [88] By 19 weeks, the elastic structure extends to the seventh generation of arterial branching and muscularization extends distally. In the fetus, muscularization of the arteries ends at a more proximal level than in childhood or adulthood. However, the arteries that are muscularized have thicker walls than the arteries of similar size in the adult. The pattern of development of the pulmonary venous system is similar to that of the arterial system. [84] Studies of blood flow to the lungs of fetal lambs suggest that the pulmonary arteries are in a state of active vasoconstriction until the latter part of gestation. In the fetal lamb, pulmonary blood flow at 0.4 to 0.7 gestation is only 3.5 percent of combined ventricular output, increasing to 7 percent near term. [89]

The pulmonary arteries continue to develop after birth; new artery formation follows airway branching up to 19 months of age, and supernumerary arteries continue to grow until the 8th year. [90] As alveolar size increases, the acinar branching pattern becomes more extensive and complex. [84] The arterial structure also changes, preexisting arteries increase in size, and during the first year of life, the thickness of the muscular arteries decreases to adult levels.

Biochemical Development

In the developing lung, two cellular types become obvious by 24 weeks' gestation as alveolar cuboidal epithelium flattens: type I pneumocytes, which become lining and supporting cells for alveoli, and the larger type II cells, which manufacture and store surfactant. [91] Surfactant initially appears at 23 to 24 weeks' gestation in the human and increases in concentration during the last 10 weeks of gestational life. [92] The maturation of the surfactant system is partly controlled by the neuroendocrine system. [93]

Respiratory Transition: Placenta to Lung

By approximately 24 weeks' gestation, the lungs are capable of extrauterine gas exchange. However, several important circulatory and mechanical changes must occur soon after birth for pulmonary gas exchange to be adequate.

Ventilation begins to match perfusion within the first hours of life. Initially, there is right-to-left intrapulmonary shunting through atelectatic areas in the lung, as well as possible extrapulmonary shunting through the ductus arteriosus and foramen ovale. The resultant Pa_{O_2} of 50 to 70 mm Hg in the newborn infant indicates a right-to-left shunt three times that seen in normal adults. [94] [95]

The transition from fetal to neonatal respiration and circulation is dynamic. Postnatally, the pulmonary vascular bed can continue to constrict in response to physiologic stresses such as acidosis or hypoxia. If constriction does occur, the extrapulmonary right-to-left shunting of desaturated blood through the foramen ovale and the ductus arteriosus increases, thus decreasing pulmonary blood. [96] Persistence of this active pulmonary vasoconstriction is called persistent pulmonary hypertension of the newborn or persistent fetal circulation. This syndrome is an important consideration when treating infants with congenital diaphragmatic hernia, meconium aspiration, and sepsis. [97]

Mechanics of Breathing

In order to ventilate the lungs with fresh gas, the respiratory muscles must overcome static-elastic and dynamic-resistive forces intrinsic to the lungs themselves. Changes in these opposing forces during postnatal development affect lung volume, pattern of respiration, and the work of breathing. [98]

Lung Compliance Versus Age

Lung compliance changes with age, as a function of the changing alveolar structure, amount of elastin, and amount of surfactant. [99] At birth, compliance is low secondary to the presence of thick-walled alveolar precursors and decreased amounts of elastin. A deficiency of surfactant as seen in hyaline membrane disease further decreases compliance. Compliance improves over the first years of life with continuing development of alveoli and elastin.

Chest Wall

The thoracic cage of the newborn is mechanically different from that of the adult. The chest wall in the infant is less rigid because ribs are cartilaginous and not bony. In addition, the boxlike configuration of the infant's thorax permits less elastic recoil than does the dorsoventrally flattened thoracic cage of the adult. [100] There are also age-related differences in the intercostal and diaphragmatic muscle fibers. The adult has a high proportion of slow-twitch, high-oxidative, fatigue-resistant fibers: 65 percent of the intercostal fibers and 60 percent of the diaphragmatic fibers. The neonate has fewer: 19 to 46 percent of the intercostal fibers and 10 to 25 percent of the diaphragmatic fibers. [101] Therefore, the infant is more vulnerable to muscle fatigue, which may further decrease the stability of the chest wall. As a result of all these factors, the infant's chest wall is extremely compliant. The net effect of the compliant chest wall and the poorly compliant lungs should be alveolar collapse with lower resting lung volume or passive functional residual capacity (FRC). Despite this tendency to collapse, the child maintains a larger dynamic FRC by a number of active mechanisms, including incomplete exhalation secondary to a rapid respiratory rate, laryngeal breaking, and stabilization of the chest wall with increased intercostal tone during exhalation. [102] [103] [104] [105]

Upper Airway

There are numerous anatomic differences in the upper airway of the child versus the adult, differences that must be considered before any airway manipulation is attempted. The more anterior and cephalad position of the larynx in the child explains the advantage of the "sniffing position" for either mask ventilation or endotracheal intubation. Extreme neck extension can actually obstruct the airway. In addition, whereas the narrowest part of the adult airway is at the level of the vocal cords, the child's airway is narrowest at the level of the cricoid cartilage. An endotracheal tube (ETT) that passes easily through the vocal cords may cause ischemic damage to the airway more distally. The cricoid narrowing and the very pliant tracheal cartilage provide an adequate seal around an uncuffed ETT. Children younger than 10 years of age rarely require a cuffed ETT. [106]

Closing Capacity

The elastic properties of the lung are also closely correlated with closing capacity. Closing volume is the lung volume at which terminal airways begin to collapse, creating discontinuity between trapped gas and conducting airways. [107] Large closing volumes increase dead-space ventilation and can lead to atelectasis and shunting. It is postulated that the elastic tissue helps to keep the airways open, so that the greater the elastic stroma in the small airways, the lower the lung volume required before gravitational forces can close small, noncartilaginous airways. Therefore, closing volume is small in the late adolescent and relatively large in the elderly and the very young. [108] Children overcome the complications of large closing volumes and secondary atelectasis by keeping their lungs expanded through constant activity and crying. However, closing volume becomes a significant problem in the infant who is inactive or sedated because of illness.

Resistive Forces

Poiseuille's law defines resistance during laminar flow through a tube:

where *l* is the length of the tube, r is the radius, and eta is gas viscosity. Because air flow in the lung is generally not laminar, resistance is underestimated by this calculation. However, the Poiseuille law does emphasize the dependence on the radius of the airway. [109]

Not surprisingly, neonates have small airways with high

resistance or low conductance (conductance = 1/resistance). Of interest, the caliber of the small airways does not significantly increase until after the age of 5 years; hence, young children have elevated resistance at baseline and are particularly vulnerable to diseases that cause further narrowing of the airways (i.e., smooth muscle constriction, airway edema/inflammation). [110]

Control of Breathing

Respiratory control in the newborn infant may be unique. Hypoxia in the newborn produces an initial increase, followed by a sustained decrease in ventilation. [111] This response is more exaggerated in the preterm newborn and disappears rapidly in the full-term infant after several weeks. Irregular respiration, known as periodic breathing, is also more common in infants, particularly in the preterm, a finding suggesting incomplete development of the medullary respiratory centers. [112]

Oxygen Transport: Oxygen Loading and Unloading

Oski and others have shown that fetal hemoglobin does not bind with 2,3-diphosphoglycerate (DPG), so that the P_{50} of fetal hemoglobin is lower than that of adult hemoglobin in the presence of 2,3-DPG. [113] This gives the fetus the teleologic advantage of loading more oxygen at low fetal oxygen tensions (fetal Pa_{O_2}, 20-30 mm Hg). As fetal hemoglobin is replaced by adult hemoglobin, the young infant's P_{50} approximates the adult's, enhancing oxygen delivery. At 3 to 4 months of age, infants have higher levels of 2,3-DPG than do adults. [114] The resultant higher P_{50} may compensate for the relative anemia at this age, when the hemoglobin concentration commonly falls below 10 g percent.

The infant is a very metabolically active organism: oxygen consumption at birth is 6 to 8 mL/kg/min and falls to 5 to 6 mL/kg/min over the first year of life. [115] The decreased ventilation/perfusion ratio, the decreased P_{50} of fetal hemoglobin, and the physiologic anemia characteristic of infants can make adequate oxygen delivery difficult. The infant compensates for this by having a high cardiac output up to 250 mL/kg/min, which remains elevated until 4 to 5 months of age. [116] When oxygen delivery to the tissues is inadequate, the cells shift to anaerobic metabolism through the Embden-Meyerhof glycolytic pathway. Byproducts of this pathway are lactic and pyruvic acid, which produce a net acid load. Thus, the arterial pH (pH_a) becomes a very sensitive indicator of the adequacy of oxygen transport. Particularly in young infants and children, metabolic acidosis indicates inadequate oxygen transport until proven otherwise.

Respiratory Failure

Respiratory failure may be defined as inadequate oxygenation resulting in systemic arterial hypoxemia or as inadequate ventilation resulting in systemic arterial hypercarbia (Ch. 58). Because it is impossible to ascribe specific arterial blood gas (ABG) values to this definition without knowledge of the clinical situation, respiratory failure is best described by an integration of historical, clinical, and laboratory observations. These observations must be tailored to the pediatric patient.

A complete family history and medical history characterizing the severity and chronicity of the respiratory dysfunction help to formulate a differential diagnosis and a therapeutic approach. Specific data should include history of prematurity, previous airway instrumentation, previous mechanical ventilation, nonpulmonary organ dysfunction, and family history of any respiratory disease. A detailed feeding history and up-to-date growth chart can provide valuable information.

The clinical examination of lung function includes close visual observation as well as auscultation. The color of the skin and mucous membranes as well as the frequency, pattern, and depth of respiration should be documented. The presence of any end-expiratory grunting, nasal flaring, and intercostal or subcostal retractions can be used to estimate the work of breathing. The profound compliance of the infant's chest wall can exaggerate the severity of retractions. The symmetry of chest movement should be visually noted: because of the small thoracic volume with easy transmission of sounds, auscultation is not always the best way to ascertain symmetry of air entry. Abdominal distention should also be assessed: because children are abdominal breathers and have very compliant chest walls, abdominal distention can dramatically impede adequate air entry. The sounds produced by air movement through the airways can be examined by naked ear as well as by stethoscope.

Radiologic evaluation of the nasopharynx, neck, and thorax can often provide meaningful information regarding the cause and severity of the respiratory dysfunction. Fluoroscopy can be used as an adjunct in evaluating the uncooperative child.

Pulmonary function tests are frequently useful for assessing respiratory function, but secondary to children's lack of cooperation, these tests are difficult to perform in any child younger than 5 years of age. There are numerous maneuvers for evaluating the unintubated child; most of these require a tight-fitting mask, which in itself can be problematic. [117] In the intubated child, lung volumes, expiratory flow rates, compliance, and inspiratory forces can be measured; in fact, most ventilators routinely provide these measurements.

The measurement of ABG (Ch. 38) is an objective indicator of the adequacy of gas exchange. The Pa_{O_2} is helpful, but it is most useful when considered in relation to the inspired oxygen content. Two ways of evaluating this relationship are the gradient difference between the partial pressure of inspired oxygen and the Pa_{O_2} and the calculation of shunt of desaturated blood across the lung.

The elimination of CO_2 from the arterial blood is another indicator of lung function. The specific importance of the Pa_{CO_2} must always be considered in light of the finding that CO_2 is more diffusible than oxygen and that any increase in minute ventilation can often compensate for inefficiency of CO_2 excretion.

Various invasive as well as noninvasive techniques permit measurement of alveolar P_{O_2} (P_{AO_2}), Pa_{O_2}, P_{ACO_2}, and Pa_{CO_2} in even the smallest infants and children. ABG sampling can be thought of as the gold standard. When numerous or repeat analyses are required, blood sampling can be facilitated by an indwelling arterial cannula.

Umbilical artery cannulation is still a popular technique in the newborn; these catheters are relatively simple to insert and, once in place, are easy to maintain. They are most commonly used in the very-low-birthweight infant of less than 1,000 g or in the larger infant during an initial resuscitation prior to transport to an intensive care nursery. To reduce the risk of thromboembolic complications to the renal and splanchnic circulations, the tip of the catheter should be in the aorta either at the level of the diaphragm or at the level of the aortic bifurcation. Extreme caution must be used because all intra-arterial catheters carry the risk of distal thromboembolic disease, and a catheter in the aorta has the potential for distal infarction of extremities or vital organs. [118] Insertion of an arterial catheter as distal from the central circulation as possible would seem to offer the potential advantage of minimal embolic damage. In fact, peripheral arterial cannulation has become the most common technique for repeat ABG sampling in infants and children. [119] The arteries most commonly used are the radial, dorsalis pedis, and posterior tibialis. These arteries are superficial, are easily palpated, and can be cannulated percutaneously in the smallest of infants.

With proper insertion and maintenance, serious complications of arterial lines can be avoided. Although many arteries cannulated on a long-term basis are occluded after removal of the cannula, these arteries tend to recanalize within a short period. [120]

Less invasive techniques for monitoring gas exchange have also been developed. Transcutaneous electrodes designed to measure oxygen and CO_2 have been in use for more than a decade. The main advantage is the ease of application and noninvasive nature, but there are numerous problems. These electrodes are inaccurate during hypoperfusion states, and transcutaneous monitors require a warm-up time that makes "spot-checks" difficult. They are better used as trend monitors after correlating the value with a measured arterial sample. Absolute values can be misleading; this is particularly true with the CO_2 electrode. [121] [122]

Pulse oximeters have become routine in the care of critically ill children. They are accurate, require no warm-up time, and require no skill for application. Unlike fingertip or toe placement on the larger patient, the probe is usually wrapped around the child's entire hand or foot. [123]

End-tidal CO_2 monitoring allows continuous assessment of CO_2 elimination and the capnogram (CO_2 excretion recorded through time) provides information about gas flow in the small and large airways. There are limitations of this technology in the small child. The dead space is increased. The weight of the monitor on the end of the endotracheal tube can result in accidental extubations. The volume of gas withdrawn for sampling can alter the inspired volume and inspired oxygen fraction (F_{IO_2}) in the extremely small child. [124]

Causes

The cause of respiratory failure can be differentiated by the age of the patient at presentation. Respiratory failure in the newborn often reflects a congenital abnormality or immaturity. Congenital abnormalities can include airway malformations, lung dysgenesis, or nonpulmonary organ dysgenesis or malfunction, all of which impair ventilation. Lesions of immaturity include both apnea of prematurity and hyaline membrane disease, a biochemical immaturity of the surfactant system. In addition, the perinatal period is characterized by specific infections, insults, and stress reactions. One particular problematic reaction is persistent pulmonary hypertension, which can complicate neonatal pulmonary and nonpulmonary problems. These and other important causes of respiratory failure in the newborn are listed in Table 73-8 . A wide variety of disorders can cause respiratory failure in the older child (Table 73-9) . Regardless of specific cause, respiratory failure can be categorized as hypoventilation syndromes in patients with normal lungs, intrinsic alveolar and interstitial disease, and obstructive airways disease.

Hypoventilation Syndromes in Children With Normal Lungs

Clinical conditions that produce hypoventilation include neuromuscular disease, central hypoventilation on the basis of reduced CNS efferent activity, and structural/anatomic impairment of lung expansion (i.e., upper airway obstruction, massive abdominal distention). These clinical conditions are characterized by inadequate lung expansion, which secondarily results in progressive atelectasis (intrapulmonary right-to-left shunt) with systemic hypoxia. Atelectasis and the resultant decreased FRC also increase the work of breathing. The child's response to this increased work of breathing at lower lung volumes is to breathe faster with reduced tidal volume at lower lung volumes, a pattern that causes further atelectasis and shunting. As a result, children with intrinsically normal lungs but with hypoventilation syndromes present with shallow tachypnea and possible evidence of increased work of breathing and cyanosis. Their radiographs reveal small lung volumes with miliary or lobar atelectasis. Lung reexpansion with intermittent positive-pressure ventilation (IPPV) and PEEP quickly reverses the pathologic process.

Primary Pulmonary Alveolar or Interstitial Disorders

Intrinsic lung disease involving alveoli or pulmonary interstitium affects respiratory function by decreasing lung compliance and increasing airway closure, both resulting in an increased work of breathing and atelectasis. Edema or inflammation of the alveoli and edema, inflammation, or fibrosis of the interstitium decrease the compliance of the lung or make the lung stiffer. In a stiffer lung, a greater negative intrapleural pressure is required to generate air movement, thus increasing the work of breathing.

In addition, the normal developmental physiology of large closing volumes with a tendency to airway closure is exaggerated, resulting in airway closure, increasing atelectasis and shunting. The principal pathophysiologic feature in the child with intrinsic alveolar or pulmonary interstitial disease is atelectasis. This child may

clinically and radiographically resemble the child with normal lungs and a hypoventilation syndrome, but with a different response to therapeutic maneuvers.

TABLE 73-8 -- Classification of Causes of Neonatal Respiratory Failure

	CONGENITAL ABNORMALITIES	DEVELOPMENTAL IMMATURITY	SPECIFIC NEONATAL " STRESS"
Impaired control of ventilation	Central nervous system dysgenesis Ondine's curse	Apnea of prematurity Intracranial hemorrhage	Drug intoxication (note maternal drugs) Sepsis Central nervous system infections Seizures
Neuromuscular disorders Structural impairment	Congenital myopathies Thoracic deformities Lung hypoplasia Diaphragmatic hernia Potter syndrome Abdominal malfunction Gastroschisis Omphalocele		High cervical cord injuries Severe abdominal distention Pneumothorax or other air leak
Airway obstruction Upper airway	Choanal atresia Pierre Robin syndrome Laryngeal web/cleft Congenital tracheal/laryngeal stenosis Recurrent laryngeal palsy Hemangioma Lymphangioma		Massive meconium aspiration Vocal cord paralysis secondary to myelodysplasia
Lower airway	Tracheoesophageal fistula Lobar emphysema		Meconium/blood aspiration
Alveolar disorders Cardiovascular disorders	Congenital cardiac malformations Congestive heart failure (critical coarctation or aortic stenosis) Total anomalous pulmonary venous return	Respiratory distress syndrome	Bronchopulmonary dysplasia Persistent pulmonary hypertension

Obstructive Airways Disease

Obstruction of the airways can be extrinsic, such as lower tracheal and upper bronchial compression by vascular structures or neoplasms, or intrinsic, caused by intraluminal obstruction or by the airway wall itself. Intrinsic small airways obstruction is commonly seen in bronchiolitis, bronchopneumonia, asthma, and bronchopulmonary dysplasia.

The decreased conductance or increased resistance increases the work of breathing. The degree of airway obstruction ranges from partial to complete. Partial obstruction impedes air outflow more than air inflow, resulting in trapped gases or regional emphysema. Complete airway obstruction results in atelectasis. In small airways disease, there is usually a mixture of total and partial obstruction throughout the airways that results in an inhomogeneous picture of collapse and overdistention. The areas of collapse contribute to an intrapulmonary right-to-left shunt, and the areas of overdistention contribute to dead space. If overdistention is the predominant feature, overdistention of the entire lung can occur, resulting in decreased compliance and increased work of breathing. The key to small airways disease is the inhomogeneity of the pathophysiology; the clinical and radiographic picture will vary with different degrees of collapse and overdistention.

In summary, all causes of respiratory failure share similar pathophysiology, namely, atelectasis with decreased FRC and intrapulmonary right-to-left shunting and/or alveolar overdistention with increased dead-space volume and decreased CO_2 elimination. The concept of increased work of breathing is important to all causes of respiratory dysfunction: any clinical disease that causes increased work of breathing (i.e., decreased compliance or increased dead-space volume) can result in fatigue and a breathing pattern that further complicates the initial process.

Treatment

The standard therapeutic approach to respiratory failure includes (1) maximizing the child's position, (2) increasing the ambient oxygen, (3) relieving an obstruction by either airway instrumentation or pharmacotherapy, (4) treating infection, (5) correcting fluid overload, (6) maximizing all nonpulmonary systems, and (7) instituting either negative-pressure or positive-pressure mechanical ventilation. More specialized and investigational forms of therapy should also be considered. Exogenous surfactant, high-frequency ventilation, and extracorporeal membrane oxygenation are accepted standards of care, whereas liquid ventilation and inhalation of NO are currently undergoing clinical trials.

The child's position must be guarded. Unlike the adult or older child, the infant may require help maintaining optimal positioning. Specific maneuvers may include keeping the

TABLE 73-9 -- Causes of Respiratory Failure in Children

Impaired control of ventilation
Head trauma
Intracranial hemorrhage
Increased intracranial pressure secondary to tumor, edema, hydrocephalus, Reye syndrome, etc.
CNS infections
Ondine's curse
Drug intoxication
Status epilepticus
Neuromuscular disorders
High cervical cord injury
Poliomyelitis
Guillain-Barre syndrome
Neurodegenerative diseases (e.g., Werdnig-Hoffmann syndrome)

- Muscular dystrophies and myopathies
- Myasthenia gravis
- Botulism
- Tetanus
- Phrenic nerve injury

Structural impairment
- Severe kyphoscoliosis
- Flail chest
- Large intrathoracic tumor
- Pneumothorax or pneumomediastinum
- Large pleural effusion, hemothorax, empyema
- Severe abdominal distention
- Severe obesity (pickwickian syndrome)

Airway obstruction
- Upper airway
  - Congenital anomalies
  - Tumor--intrinsic or extrinsic
  - Epiglottitis
  - Croup (laryngotracheobronchitis)
  - Foreign body
  - Postintubation edema, granulation tissue, or scarring
  - Vocal cord paralysis
  - Burns
  - Vascular ring
- Lower airway
  - Asthma
  - Bronchiolitis
  - Foreign body
  - Lobar emphysema
  - Cystic fibrosis

Alveolar disorders
- Pneumonia
  - Infectious--bacterial, viral, fungal, pneumocystis
  - Chemical--aspiration, hydrocarbon, smoke inhalation
- Pulmonary edema--cardiogenic, near drowning, capillary leak syndrome

Massive atelectasis

Oxygen toxicity

Pulmonary contusion

Pulmonary hemorrhage

---

child in a semi-upright position to avoid aspiration or gastroesophageal reflux as well as to minimize the effects of abdominal distention. At times, the upper airway must be supported by keeping the head in a midline position and minimizing excessive neck flexion.

An increase in inspired oxygen can be accomplished in a number of ways. Tight-fitting anesthesia masks and nasal prongs may agitate the child and may negate any beneficial effects. Blow-by oxygen, space masks, croup tents, and head boxes are alternative, less invasive maneuvers.

Relief of an upper airway obstruction can be lifesaving. Instrumentation of the airway includes placement of an ETT, a tracheostomy, or a nasopharyngeal tube to stent open the posterior oropharynx. Pharmacology can decrease airway obstruction as well: inhaled racemic epinephrine and intravenous steroids decrease subglottic edema, [125] [126] antibiotics decrease infectious swelling, and beta-agonists and inhaled anticholinergic medications relax bronchial smooth muscle. [127] Patients with pneumonitis should be evaluated for bacterial, viral, or fungal pathogens and treated with appropriate antibiotics. Excessive intravascular fluid from inappropriate fluid administration and/or cardiac failure should be corrected by limiting fluid intake and by administering diuretics and cardiotonic or vasoactive drugs. Nonpulmonary systems must also be closely monitored. Good nutrition, fluid and electrolyte balance, and adequate cardiovascular and renal function are required for maximal pulmonary support.

Mechanical ventilation is the mainstay in the treatment of respiratory failure and provides respiratory support for nonpulmonary disease as well. There are several nonpulmonary reasons for instituting respiratory support, as follows:

1. *Resuscitation from circulatory collapse.* In virtually any situation in which the cardiovascular system is unstable, it is safest to support ventilation. In the event of cardiac arrest, respiratory support is mandatory. During the immediate postoperative cardiac surgical period, ensuring stable gas exchange and normal ABG afforded by mechanical ventilation minimizes the risk of untoward cardiovascular decompensation.
2. *Respiratory assistance for supranormal gas exchange.* Intentional hyperoxia or, more commonly, hypocarbia is used primarily to treat disorders unrelated to respiratory failure. One example is persistent pulmonary hypertension in which relative hyperoxia and hypocarbia, with resultant alkalosis, may dilate the pulmonary vascular bed in some newborns. [68] A second example is intracranial hypertension: intentional hyperventilation may reduce increased intracranial pressure (ICP) in some patients by reducing cerebral blood volume (CBV). [128] Postoperatively, some children are at risk of developing respiratory failure because of their underlying disease and the nature of their surgery. Underlying conditions that predispose children to respiratory failure include morbid obesity, sepsis, nutritional debilitation, and kyphoscoliosis with respiratory compromise.
3. *Reduced work of breathing.* In addition, reducing the oxygen cost of breathing in some patients may improve the patient's ability to overcome a major physiologic insult. The child with bronchopulmonary dysplasia may need to conserve the energy expended during breathing on a long-term basis in order to grow. [129]

Ventilatory Therapy

Mechanical respiratory assistance can be given by a variety of methods, including continuous positive airway pressure (CPAP), IPPV, and negative-pressure ventilation [130] (Ch. 72). Positive pressure is applied almost exclusively by way of an intratracheal artificial airway, either an ETT or a tracheostomy tube. Oral intubations are easier to perform than nasal intubations and should be used in emergency situations. Although nasal endotracheal intubations can be

more difficult to perform in children, a nasal tube is more comfortable and more easily secured for long-term management.

The size of the ETT should be carefully selected. One formula that estimates the required size of the tube for children over age 2 years is as follows:

which gives the size by internal diameter. If the ETT size is correct, there should be a slight air leak when a positive pressure of 20 to 30 cm H_2O is applied to the airway. [131] Serious lifelong laryngeal and subglottic damage can result from insertion of an inappropriately large ETT; this is particularly important in inflammatory lesions of the upper airway such as laryngotracheobronchitis. Because of the more flexible tracheal cartilage and the relative subglottic narrowing in children, uncuffed ETTs generally provide an adequate seal in children younger than 8 years of age.

After endotracheal intubation, the position of the tube within the trachea should be assessed. Physical examination should reveal symmetric chest movement and symmetric breath sounds on auscultation. An electronic or colorimetric CO_2 detection system should be available to confirm endotracheal position of the tube. On chest radiography, the tip of the ETT should be midway between the vocal cords and the carina. In small infants, this leaves a very small margin of error before the tube has either progressed down one main-stem bronchus or migrated above the vocal cords; extreme care should be given to verify the position of the tube. It is important to realize that movement of the child's head and neck can affect the placement of the tube. Flexion of the neck advances the tube farther into the trachea, and extension pulls the tube higher into the airway, making it important to avoid extreme flexion or extension of the neck during patient care.

In recent years, ETTs have been left in place in infants and children for increasing periods of time. It is not uncommon to leave a child's trachea intubated for more than 2 weeks and up to 12 weeks without performing a tracheostomy. This approach has been possible because of proper humidification and improved techniques of nursing care in both endotracheal suctioning as well as patient surveillance.

Despite these improved techniques, any child with an ETT in place must be constantly monitored for the complications of ETT obstruction with secretions and accidental extubation or accidental intubation of a main-stem bronchus. Tracheostomy is indicated in those children who require a long-term artificial airway for mechanical ventilation or endotracheal suctioning or to bypass obstruction of the upper airway. A potentially life-threatening complication of tracheostomy is accidental dislodgement of the tracheostomy tube soon after surgery before a well-healed track is formed. Reinsertion of the tube can be very difficult during these first 72 hours after surgery, and forceful blind reinsertion of a tracheostomy tube through a fresh tracheostomy site can result in blunt dissection between the tissue planes. The complications of airway obstruction, pneumomediastinum, and pneumothoraces can result.

Continuous Positive Airway Pressure and Positive End-Expiratory Pressure

With CPAP, the child breathes spontaneously with a constant specified positive pressure applied to the airway. With PEEP, the child is ventilated with constant specified PEEP. Positive pressure during spontaneous inspiration is maintained by either placing a pressurized reservoir bag into the system or increasing the fresh gas flow to exceed the inspiratory flow rates (gas flow rates of at least two to three times the patient's minute ventilation are required just to avoid rebreathing from the circuit). Exhalation occurs against a water column adjusted to deliver the desired pressure resistance.

CPAP is applied by way of an ETT, nasal cannulas, or face mask. Because newborns are obligate nose breathers, relatively low levels of CPAP can be produced with nasal cannulas. This method has had variable success, depending on the size and activity of the infant; crying and mouth breathing reduce the efficiency of the system. Gaseous distention of the abdomen is a common complication, and an orogastric tube is often required as a continuous vent. [132] CPAP via face mask can be applied effectively to adults as well as infants and children for short periods of time. Mask CPAP has also been associated with the complications of gastric distention and pressure necrosis of the face and eyes. [130]

Low to moderate levels of PEEP can be maintained in children with uncuffed ETT. If leakage around the ETT precludes a stable level of PEEP, there are two options: the ETT can be upsized to a larger internal diameter tube, or a cuffed ETT can be used.

The goals and risks of CPAP and PEEP are the same in the child and adult. The optimal level of CPAP or PEEP can be difficult to ascertain for each clinical situation. Too little may afford no beneficial effect, whereas too much may cause overdistention of the lung and dead-space ventilation. Low levels of CPAP or PEEP (2-5 cm H_2O) are often considered homeopathic and have been advocated by some authors for any child with an artificial airway in order to maintain FRC at preintubation levels. [133]

In children with lung disease, the goal of optimal CPAP or PEEP is to maximize improvement while minimizing side effects. A conservative approach to choosing pressure is to limit CPAP to levels sufficient to improve oxygenation, decreasing the F_{IO_2} to 0.6 or less while the patient experiences no cardiovascular changes. A second approach is to increase pressure levels until maximal improvement in compliance is achieved. A bedside measurement of compliance can be calculated in ventilated patients to assess the effect of the PEEP. Airway pressure is measured at the end of a 3- to 5-second inspiratory hold. Compliance is then estimated by subtracting the end-expiratory pressure from this end-inspiratory hold pressure and then dividing by the measured expired tidal volume. End-inspiratory hold pressure is used rather than peak airway pressure because it is a more accurate assessment of inflating pressure, without the influence of mechanical flow characteristics or flow-resistance factors. This calculation can be performed at various end-expiratory pressures in order to determine optimal PEEP. [134]

Suter et al [135] proposed that optimal or best PEEP (or CPAP) is the level of pressure associated with the maximal oxygen transport, defined as the product of cardiac output

---

and arterial oxygen content. This concept accounts for both the beneficial effect of improved oxygenation and the complication of decreased cardiac output. This is important in view of the finding that once a patient is higher than optimal PEEP, airway pressure is more directly transmitted to the cardiovascular system and may decrease the cardiac output and, hence, oxygen transport. To apply the concept of Suter et al of best PEEP, repeated cardiac output determinations are required, necessitating a Swan-Ganz thermodilution catheter. The indications and risks of pulmonary artery catheterization must be weighed against the benefits of accurately determining best PEEP and the risks of high levels of pressure. Most clinicians accept that an approximation of optimal CPAP or PEEP can be safely determined by clinical trial and compliance estimates, as long as the level of CPAP or PEEP is less than 20 cm H_2O. If more than 20 cm H_2O is considered, thermodilution catheters are often inserted.

Another alternative for estimating the CPAP or PEEP level is the use of an esophageal pressure monitor. Ideally, esophageal pressure should change only slightly until optimal intrathoracic pressure is reached. Once the maximal improvement in lung compliance is attained, increasing CPAP will result in greater transmission of pressure to the esophagus.

Positive-Pressure Ventilation

Positive-pressure mechanical ventilators can be classified according to their method of control as (1) volume preset, (2) pressure preset, and (3) time-flow preset. [136] As a general rule, time-flow- or pressure-preset ventilators are more convenient to use in infants and young children (<10 kg), whereas volume-preset ventilators are most commonly used in older children (>10 kg) and adults. The time-flow pressure-preset ventilators have several advantages in ventilatory assistance in infants and young children. Most commonly, infants and young children are intubated with an uncuffed ETT, so a variable amount of leak is produced around the ETT. This leak, along with the relatively large compression volume factor in relation to tidal volume in infants, makes the volume-preset determination on volume ventilators unreliable. [137] [138] The main problem of using any pressure-preset or time-flow-preset ventilator is that delivered volume depends on the child's total thoracic and lung

compliance. This may result in overventilation and an increased risk of alveolar rupture as compliance increases. Alternatively, it may cause hypoventilation should compliance decrease.

Intermittent mandatory ventilation (IMV) is available on pressure-, time-flow-, and volume-preset ventilators. [139] [140] In the IMV system, the child may breathe spontaneously from a fresh gas source at low resistance while receiving active inflations from the mechanical ventilator at preset intervals with the same level of end-expiratory pressure. This allows the child additional breaths at the same F_{IO_2}, and PEEP. IMV is produced either by a continuous-flow circuit or by a series of demand valves. Continuous-flow IMV circuits are simpler and do not require additional patient effort during spontaneous breathing. Thus, continuous-flow circuits may have an advantage over demand-valve systems in children with relatively high respiratory rates, in which valve sensitivity and response time are potentially important during weaning from mechanical ventilation. Pressure-support ventilation is an innovation of the assist/control mode of ventilation. In pressure-support ventilation, each spontaneous breath is augmented by the delivery of gas at a preset pressure. The patient determines the respiratory rate and the inspiratory time. The pressure support increases the delivered tidal volume and may decrease the work of breathing and improve patient comfort. This mode is most commonly used while weaning a patient from mechanical ventilation. Because it depends on the patient's own initiation of a breath, pressure support cannot be used in a patient who has abnormal respiratory drive. [141] [142]

The pressure pattern of ventilation is dependent on the inspiratory and expiratory flow rates, the tidal volume, the duration of inspiration and expiration (I:E ratio), and the respiratory rate. The optimal ventilatory pattern varies from patient to patient from one disease state to another.

Insights into the pathophysiology of pulmonary interstitial or alveolar disease represented by the acute respiratory distress syndrome (ARDS) have led to a better understanding of the implications of ventilator management. Table 73-10 outlines the salient features of the pathophysiology of ARDS. This has led to a change in therapy, using ventilator strategies that employ relatively long inspiratory times, high end-expiratory pressures, and low tidal volumes. This technique results in lower minute ventilation and elevated Pa_{CO_2}. Termed *permissive hypercapnia,* this strategy decreases the shear forces acting on the terminal airways and recruits lung units that have dropped below closing volumes. [143] Acid-base status must be maintained with a compensatory metabolic alkalosis that occurs gradually through renal retention of bicarbonate. This process can be assisted with the administration of sodium bicarbonate or tromethamine, allowing time for equilibration of blood tissue pH.

By contrast, the optimal pattern of ventilation for patients with obstructive airway disease is different. In these patients, using a faster inspiratory flow rate with a shorter inspiratory time and prolonged expiratory time allows for better ventilation of relatively normal parts of the lung while still permitting exhalation of gas in obstructed portions of the lung. Unlike treating patients with alveolar collapse, mechanical ventilation in patients with small airways disease should be considered supportive care only, because it is rarely therapeutic. Pharmacologic bronchodilation is the principal therapy in this disease. Barotrauma and alveolar rupture are common complications of ventilatory support in patients with small airways disease.

TABLE 73-10 -- Pathophysiology of Acute Respiratory Distress Syndrome

Disruption of endothelial barriers with leakage of protein-containing fluids and inflammatory cells into the alveoli
Inactivation of surfactant resulting in increased surface tension of the alveolar lining layer
Atelectasis and lung volume loss
Shunting of blood through nonventilated areas of lung resulting in hypoxemia and tissue hypoxia
Decreased pulmonary compliance

Although there is no specific formula for initiating mechanical ventilation, some general principles can be followed. In our experience, the human hand is still the best mechanical ventilator. After a patient has been intubated and stabilized, hand ventilation with a Mapleson-type anesthesia circuit with an airway-pressure manometer in line is useful in determining the approximate pressures required to inflate the chest. In patients with alveolar or interstitial disorders, a prolonged I:E ratio of 1.51 or 11 is frequently useful, using a relatively slow frequency of less than 24 cycles/min in the infant and less than 16 cycles/min in the child.

When initiating mechanical ventilation with a volume-preset ventilator, choosing an arbitrary tidal volume of 10 to 15 mL/kg (using the higher number in the smaller child) while observing peak airway pressures is commonly employed. Regardless of the type of ventilator, the most important variables in initiating mechanical ventilation are the adequacy of chest expansion and gas exchange by clinical observation and auscultation and the adequacy of alveolar ventilation by measuring the Pa_{CO_2}. The peak airway pressure should be measured frequently as close to the ETT as possible.

PEEP should begin at 3 to 4 cm H_2O until arterial oxygenation is maximized. It is unusual in our experience to require end-expiratory pressure above 20 cm H_2O in pediatric patients.

With the initiation of positive-pressure ventilation, it is not uncommon to see systemic arterial hypotension, which usually responds to a volume infusion of 10 to 20 mL/kg of crystalloid or colloid. However, it is strongly recommended that CVP be measured in any patient requiring mechanical ventilation with a PEEP of 10 cm H_2O or greater. These data are helpful in determining the effects of mechanical ventilation and positive airway pressure on the cardiovascular system.

Adjunctive Pharmacologic Therapy: Sedatives and Analgesics

At least initially, some degree of sedation is required for conscious children to cooperate with mechanical ventilation. The amount of sedation depends on the child's age, size, underlying disease, and degree of respiratory support required. Occasionally, an infant in respiratory failure may be initially severely depressed and may not require any sedation. Sedation facilitates the patient's breathing "in phase" with the ventilator, so that minimum peak airway pressure can be maintained without the child's coughing and straining. It is not unusual to find that once the child accommodates to the mechanical ventilator, the amount of sedation required can be reduced. Various combinations of sedatives have been advocated for children, with probably equal success. The drug we usually administer is fentanyl (1-2 mug/kg/h), given intravenously as a constant infusion after an initial bolus. If additional sedation is required, one may use lorazepam (0.1-0.3 mg/kg), administered intravenously every 4 to 6 hours, midazolam (0.05-0.2 mg/kg/h), given as an infusion, or chloral hydrate (30-50 mg/kg), administered rectally or by nasogastric tube every 4 to 6 hours. These drugs have minimal cardiovascular effects, provided intravascular volume is adequate. [144]

There is no perfect pharmacologic recipe for chronic sedation in the ICU. Unfortunately, because children experience tachyphylaxis to many of these drugs, the dosage is continuously increased and/or other agents are added. The result can be a polypharmacy of extremely high drug doses, and weaning from this sedation adds to the patient's problems. Some children develop symptoms of withdrawal and require very slow drug taper, which is often accomplished by switching to oral agents such as methadone and lorazepam.

Neuromuscular blocking drugs are used to increase chest wall compliance, to reduce oxygen consumption, [145] and more commonly, to facilitate mechanical ventilation by preventing patient-ventilator dyssynchrony. These drugs should always be used in combination with medications that provide amnesia and anxiolysis. Adequate analgesia should be provided to patients to ensure that pain is well controlled.

Pancuronium and vecuronium are employed most commonly in the PICU. The usual dose of pancuronium is 0.1 mg/kg administered intravenously every 1 to 1½ hours, or 40 to 100 mug/kg/h as an infusion. Although tachycardia with pancuronium is an undesired side effect [146] in adults, this is rarely of clinical significance in infants and children. Vecuronium and cisatracurium are competitive blocking agents with shorter durations of action than pancuronium. Vecuronium (0.08-0.2 mg/kg, followed by an infusion of 60-150 mug/kg/h) causes less tachycardia than pancuronium: cisatracurium (0.1-0.2 mg/kg, followed by an infusion of 60-120 mug/kg/h) is not dependent on renal or hepatic function for elimination. Neuromuscular blocking agents need to be titrated using a peripheral nerve stimulator or observing movement with regular drug holidays.

Weaning From Mechanical Ventilation

The criteria for weaning are ill-defined clinical factors. In general, weaning from respiratory support should begin only when the child has a stable cardiovascular system and is awake and alert. It is unwise to begin reducing respiratory support in a child who is still at risk of acute cardiac decompensation. It is also best to wait until other major metabolic abnormalities have been corrected. Severe anemia, hypoglycemia, hypernatremia, hypochloremia, or malnutrition may severely impair a child's ability to be weaned from mechanical ventilation. The chest wall and diaphragm must be intact, and the child should be able to generate at least 20 cm H_2O pressure at the airway (inspiratory force) and be able to move at least 10 mL/kg of air with maximal effort (vital capacity). The parameters that can then be weaned include rate, F_{IO_2}, peak inspiratory pressures, and CPAP/PEEP.

On pressure-limited or time-flow-limited ventilators, the peak inspiratory pressure must be reduced, because compliance improves during the weaning process. The best indicators of a change in compliance are the degree of chest expansion seen clinically and the Pa_{CO_2} decrease as alveolar ventilation increases. If peak inspiratory pressure is not reduced, there is a significant risk of alveolar rupture and resultant pneumothorax and/or pneumomediastinum.

Ventilator rates should not be weaned until the ABG is stable with a required inspired oxygen concentration of less than 0.5, a required PEEP of less than 10 cm H_2O, and a peak airway pressure of less than 30 to 35 cm H_2O.

One must also be certain that all residual effects of neuromuscular blocking drugs have disappeared and that a reduced level of sedation is ordered. Neuromuscular blockade can be reversed with the intravenous administration of neostigmine (0.05 mg/kg) and glycopyrrolate (0.01 mg/kg); a peripheral nerve stimulator can confirm the presence of acceptable neuromuscular function. [147] Weaning is then begun by gradually decreasing the ventilator rate over a period of hours to days.

Weaning should continue as long as ABGs remain within an acceptable range and as long as the child's clinical condition tolerates weaning. As the amount of effective spontaneous ventilation increases, the increased work of breathing may cause the child's overall condition to change before blood gases begin to deteriorate. Tachycardia, hypertension or hypotension, tachypnea and increased work of breathing, and anxiety are danger signs. Weaning should be discontinued, and additional ventilatory support should be reinstated. Frequent assessment of ABGs and observation of the child's clinical condition are essential throughout the weaning process. If a child has any residual lung disease with decreased lung compliance, there may be a tendency for the development of decreased FRC with atelectasis and decreased lung volumes. These potential problems can be minimized by weaning on moderate levels of CPAP or PEEP (5-10 cm H_2O).

Once the child is completely weaned from mechanical ventilation, it is wise to observe his or her spontaneous ventilation on CPAP alone for a period of at least several hours before reducing the level of CPAP. Once CPAP has been reduced in a stepwise fashion to 2 to 3 cm H_2O without a deterioration in the child's clinical condition or ABGs, it is reasonable to extubate the trachea. Extubation should be performed by an individual skilled in laryngoscopy, should gas exchange deteriorate and reintubation be required. Once tracheal extubation has occurred, it is not unusual for the patient to require a 20 percent increase in F_{IO_2} by face mask or Oxy-Hood oxygenator. It is essential that the patient be encouraged to cough and clear secretions, while taking slow, deep breaths as often as possible. Incentive spirometry, early mobilization, and chest physical therapy play a significant part in recovering from respiratory failure. [147] [148]

It should be emphasized that weaning from mechanical ventilation requires close clinical observation, frequent assessment of blood gases, and good clinical judgment. The rate of weaning depends on the child's overall clinical condition, as well as on the underlying pathologic process. The child who is ventilated postoperatively overnight may be weaned very rapidly (over an hour or two), whereas the child recovering from severe interstitial pneumonia may require days to weeks to be weaned successfully. In chronically ventilated patients, meticulous attention must be paid to other system problems. Intravascular fluid balance must be excellent, with the patient kept relatively "dry." Serum bicarbonate and chloride should be kept in the normal range to prevent compensatory hypercarbia. The hematocrit must be maintained in the high-normal range to minimize cardiovascular stress. Caloric intake should be maximized with enteral or intravenous alimentation. Infection must be under control, and it is best if the child can be alert and cooperative. If the weaning process is stressful, rest periods of full-time mechanical ventilation, particularly at night, may be helpful. We all find a difficult task more easily handled after a good night's sleep.

Before tracheal extubation is considered, careful assessment of the quality and volume of endotracheal secretions is essential. Large, thick secretions may cause extubation to fail if the child is unable to cough and to clear them adequately. Extubation should be planned carefully and should preferably be performed in the morning while a full staff is available for careful observation. If the weaning and extubation process has been carefully planned and executed, reintubation should be a very rare occurrence.

Negative-Pressure Ventilation

Body-type negative-pressure ventilators, first described by Drinker and Shaw in 1929 [149] and used extensively during the polio epidemic of the 1950s, [150] have achieved renewed popularity. Reports of these devices in children and adults with chronic respiratory insufficiency have rekindled interest in the mechanics and physiology of negative-pressure ventilation. Patients with severe neuromuscular disabilities, such as Duchenne muscular dystrophy, and those with chronic obstructive pulmonary disease (COPD), such as cystic fibrosis, have been reported to have sustained improvement in their gas exchange and general clinical condition when subjected to chronic or nighttime home ventilation. Measurements of vital capacities, inspiratory force, and force of diaphragmatic muscle contraction suggest in a preliminary way that this therapy will improve gas exchange, reduce the complications of chronic hypoxemia and hypercarbia, and prolong life. [151]

Several negative-pressure ventilators are available commercially. The iron lung is most commonly employed in the hospital setting. Its large size and weight, as well as its cost, are limitations to home use. The portable body cuirass and raincoat have achieved popularity for home use. An intermittent vacuum pump provides suction, producing a negative pressure within the body shell or cuirass. Although portable and reasonably affordable, these devices are less efficient and noisy and require closer attention, owing to the difficulty in achieving a tight seal and the likelihood of developing air leaks with body movement. Continued use and future critical study will be important in determining the role of negative-pressure ventilation in the treatment of respiratory failure.

The main advantage of negative-pressure ventilation is that the airway does not have to be instrumented with an ETT or a tracheostomy tube. Unfortunately, there are numerous serious clinical limitations. For example, patient size and patient deformity can make the patient-machine interface both difficult and uncomfortable, and the ability to provide basic and specialized patient care can be compromised. Any degree of upper airway obstruction (anatomic/structural or massive secretions) decreases the effectiveness of gas flow in negative-pressure ventilation. Finally, negative-pressure ventilation is not effective in patients with very poor lung compliance; maximal respiratory pressure is 30

cm H_2O, and it is not possible to sustain a reliably constant distending airway pressure (CPAP equivalent). The ideal candidate for negative-pressure ventilation is one who is cooperative, who has normal lungs and upper airway, and who needs intermittent support for neuromuscular disability.

High-Frequency Ventilation

High-frequency ventilation describes a pattern of ventilation characterized by smaller than anatomic dead-space volumes delivered at high respiratory rates (>150 breaths/ min). High-frequency ventilation can be generated by a number of different types of ventilators: the high-frequency jet ventilator, the high-frequency oscillating ventilator (HFOV), and the flow interrupter. Each of these machines differs in technical design and in clinical application and most likely differs in the mechanics of gas exchange. [152]

Use of the HFOV has become accepted practice for neonatal patients with respiratory failure. There is impressive evidence that use of the HFOV has successfully supported infants who previously would have required extracorporeal membrane oxygenation (ECMO) or who would have died. [153] [154] The HFOV used for neonates has been approved by the U.S. Food and Drug Administration (FDA) for the support of patients up to 35 kg. There has been success with HFOV to treat children with

acute homogeneous interstitial and alveolar disease. [155] The use of the HFOV in large children and in adults has been less successful to date, because of physical limitations of the equipment; however, ongoing research suggests that the utility of this mode will be expanded. Jet ventilation is used in some centers for multiple causes of respiratory failure, although the main indication remains the patient with barotrauma.

Exogenous Surfactant

The administration of exogenous surfactant is now routine therapy for the surfactant-deficient premature infant. Numerous preparations are available that have clearly improved the survival of these children and decreased their need for aggressive mechanical support. [156] Exogenous surfactant has not enjoyed the same success in older children and adults. The primary problem is the nature of the lung disease. Whereas the premature infant has an inadequate amount of surfactant, the older patient has surfactant dysfunction or inhibition rather than absolute decrease in amount. Therefore, exogenous surfactant is vulnerable to the same inhibition.

Liquid Ventilation

Perfluorochemical (PFC) liquids are clear, colorless fluids approximately twice as dense as water with one-fourth its surface tension, 16 times the oxygen solubility, and 3 times greater CO_2 solubility. PFC liquid was first used as a respiratory medium in the 1960s [157] and was popularized in the 1989 movie *The Abyss.* The first human trials of tidal PFC liquid ventilation involved 3 preterm infants "at the point of death" because of severe respiratory failure. They were successfully ventilated for two 3- to 5-minute cycles using PFC liquid tidal volumes exchanged by gravity. [158]

More recent approaches have employed PFC liquid-filled lungs and gas ventilation using a conventional mechanical ventilator. This therapy is referred to as partial liquid ventilation (PLV) or perfluorocarbon-associated gas exchange. [159] The PLV technique has been shown to produce significant improvements in lung function and viability in numerous animal studies of diseased or injured lungs. The decreased surface tension of the perfluorocarbon gas interface enables recruitment of atelectatic alveoli with lower ventilator pressures. This allows reduced oxygen settings, and the combined effect of lower oxygen toxicity and barotrauma can apparently minimize lung damage. PLV is now undergoing clinical trials in the treatment of pediatric respiratory failure. The first published report of PLV in humans involved six children being treated with extracorporeal live support for respiratory failure. They underwent PLV for periods ranging from 3 to 7 days. All six patients survived to hospital discharge. [160]

Extracorporeal Membrane Oxygenation

ECMO is standard of care for term (34 weeks' gestation) neonates with acute respiratory failure (ARF). More than 11,000 infants with an 80 percent predicted mortality receiving conventional management have received ECMO support, 81 percent of whom survived. [161] Although neonatal ECMO is successful, the technology and the patient populations are constantly changing. The majority of ECMO is venoarterial (VA), in which blood is drained from the venous system and is returned to the ascending aorta, supporting not only respiratory but cardiac function as well. Venovenous (VV) ECMO is less efficient than VA ECMO, but it preserves pulmonary flow and avoids cannulation of the arterial system. VV ECMO is rapidly gaining popularity, and many clinicians believe that VV ECMO will be more commonly used than VA ECMO. [162] In addition to these technical changes, the target neonatal ECMO populations are also changing. Exogenous surfactant and new modes of ventilation such as HFOV are "saving" children from ECMO. In fact, most ECMO centers report that their ECMO candidates are a sicker group of infants, with a greater preponderance of sepsis and multiorgan system failure. ECMO support for premature infants is also being evaluated in some centers with phase I studies. [163]

ECMO support for the older child/adult with ARF continues to pique interest. Approximately 500 pediatric ARF ECMO patients have been reported to the Extracorporeal Life Support Organization. All were patients who had a presumed 80 to 100 percent predicted mortality. With ECMO support, 52 percent have survived. [161] These data are difficult to evaluate in this population because of the extreme heterogeneity of age, diagnoses, conventional management, and criteria for ECMO. In addition, whereas the neonatal causes of ARF generally have reversible pathophysiologic features, reversibility of ARF in the older patient population is uncertain. [164] [165]

Common Respiratory Disorders

Laryngotracheobronchitis (Croup)

Croup is the most common cause of acute upper airway obstruction in the otherwise healthy child (Ch. 59) . This viral infection (parainfluenza, influenza, adenovirus) produces swelling and edema of the tissues in the upper airway, particularly in the immediate subglottic region. Croup occurs most commonly in young infants and children between the ages of 3 months and 3 years. Children usually present with a few days' history of an upper respiratory infection followed by the development of hoarseness, a croupy cough, and possibly stridor. [166] These children are nontoxic. The degree of respiratory distress and the child's ability to compensate for the increased work of breathing are best assessed by clinical examination.

Infants are initially treated with mist and aerosolized racemic epinephrine to reduce local mucosal swelling. [167] The use of steroids is both common and controversial. [125] Intubation is required when the infant can no longer sustain the necessary work of breathing. The child is intubated with the smallest possible ETT (usually 3.0 mm in a child <2 y or 3.5 mm in a child aged 2-4 y) that will permit suctioning of secretions. Spontaneous resolution in 3 to 7 days is common. In our experience, the average duration of intubation is 4 to 5 days. As the trachea grows, laryngotracheobronchitis becomes an uncommon cause of significant airway obstruction in children older than 3½ or 4 years of age.

Epiglottitis

Epiglottitis is an inflammation of the mucosa of the supraglottic structures usually caused by *Haemophilus influenzae* type B. [168] It is a true pediatric emergency: the rapid progression has the potential for unpredictable and fatal airway obstruction. Restoration of a secure airway is the first priority. Epiglottitis is usually easily differentiated from laryngotracheobronchitis in that patients with epiglottitis are usually older (4-6 y), there is rarely an antecedent upper respiratory illness, and the child is quite toxic with the fulminant onset of fever and respiratory distress. Expectant intubation under anesthesia is the most common treatment until antibiotic therapy (ampicillin and chloramphen-icol or ceftriaxone) is initiated and signs of systemic toxicity subside. The incidence of epiglottitis is dependent on contact with *H. influenzae,* which occurs most commonly in the early school-age population. [169] The introduction of *H. influenzae* vaccine has dramatically decreased the incidence of this disease, as well as that of other *H. influenzae* processes. [170]

Bronchiolitis

Bronchiolitis is an acute viral infection of the lower respiratory tract, frequently occurring in the first 2 years of life, when small airways have the lowest specific conductance. The signs and symptoms are air trapping, wheezing, mild to moderate systemic hypoxemia, and a considerable increase in the work of breathing because of increased airway resistance. The cause is viral, usually attributed to respiratory syncytial virus. [171] Bronchiolitis is epidemic in nature and variable in severity.

Although the disease is self-limited, patients at high risk of respiratory failure include the very young and infants with a history of prematurity, chronic lung disease, or congenital heart disease. In the very young, apnea is often the first sign of decompensation, frequently occurring before significant hypercarbia. Clinical signs of fatigue are often more important than ABG sampling in determining whether mechanical ventilation is indicated. Therapy is primarily supportive, with endotracheal intubation and mechanical ventilation when the child can no longer support gas exchange. [172]

Ribavirin is a virostatic drug currently available for use in children with respiratory syncytial viral infection. Infants and young children with complicated congenital heart disease, underlying immunosuppressive diseases, or multiple congenital anomalies who develop respiratory syncytial viral disease and are at high risk of serious complications should be considered for ribavirin aerosol therapy. Because of concerns about its safety, benefit, and cost, definitive recommendations for ribavirin therapy are not possible at this time. [170]

Status Asthmaticus

Asthma, a disease of airway hyperreactivity, is the most common chronic respiratory disorder of childhood and is often the most frequent admission diagnosis to a pediatric medical service. Acute attacks are generally associated with intercurrent viral infections, allergen exposures, stress, or noncompliance of therapy. [173]

The chronic treatment of asthma emphasizes inhaled aerosolized beta-agonists and steroids. [174] Of concern, the number of asthmatic patients and the mortality rate of asthma have been increasing. High mortality is associated with a number of risk factors: teen age, black race, history of previous life-threatening episodes, hospitalization within the last year, poor long-term medical care, and psychologic and psychosocial problems. [173]

Some children with extremely severe asthma are now being treated with methotrexate, with improvement in some. Some pulmonologists and allergists believe that the risk-to-benefit ratio of methotrexate favors the use of this drug in some patients with severe asthma. [175]

Most episodes of status asthmaticus respond to emergency department management with oxygen, nebulized/inhaled beta-agonists, anticholinergic agents, and steroids. A few children, however, fail to improve, or even worsen, despite this therapy. Signs of respiratory failure develop, including tachypnea and tachycardia, very poor aeration with a prolonged expiratory phase, marked retractions, and nasal flaring, increased pulsus paradoxus, anxiety, or depressed mental status. Despite the increased minute ventilation, Pa $_{CO_2}$ is either normal or elevated, and moderate to severe hypoxemia is present. Treatment of this impending respiratory failure is to maximize conservative therapy and to start an intravenous terbutaline infusion, beginning at a rate of 0.1 mug/kg/min and increasing until clinical improvement occurs

or until heart rate exceeds 180 to 200 beats/min. If the patient is being treated with aminophylline, levels should be closely monitored. It is important to note that both phosphodiesterase inhibitors and adrenergic agonists share the serious side effects of increased myocardial oxygen consumption, potential myocardial ischemia, and ventricular arrhythmias [176] ; hence, it is important to prevent hypoxia and to monitor closely with a continuous ECG. Children tolerate these drug groups better than do their adult counterparts, most likely because children have relatively normal coronary arteries and better myocardial reserve.

Tracheal intubation and mechanical ventilation are considered a last resort. Pa $_{CO_2}$ values in excess of 70 or 80 mm Hg are tolerated as long as the patient is cardiovascularly and neurologically stable. [177] Intubation is only rarely required in the pediatric patient with asthma, and intubation is avoided if possible, because the ETT serves as an irritant in the airway and may cause further bronchoconstriction. In addition, mechanical ventilation is usually inefficient in the patient with small airways disease, and the complications of barotrauma in all its forms are common. Inhalation anesthetic agents such as halothane and isoflurane have been used as bronchodilators in mechanically ventilated patients with asthma and with severe respiratory failure who are unresponsive to maximal conventional therapy. [178] ECMO could also be used in these patients if gas exchange cannot be achieved with conventional ventilators.

Cystic Fibrosis

Cystic fibrosis is becoming an increasingly common diagnosis of children and young adults in the PICU. It is a fatal autosomal recessive disease carried on chromosome 7. Although it manifests with pancreatic, hepatic, pulmonary, gastrointestinal, and reproductive abnormalities, 90 percent of the reported morbidity and mortality is pulmonary. [179] The pulmonary pathology is severe obstructive disease with bronchiectasis, emphysema, and, ultimately, terminal respiratory failure.

Survival has improved dramatically over the past 30 years. More than one-third of patients survive beyond the age of 30 years. [180] This change reflects improved antibiotic therapy, nutritional adjuncts, and a more aggressive approach to the complications of the disease. This aggressive approach often involves extensive surgical procedures such as pleural stripping and pulmonary lobectomies. The success of these procedures necessitates a program of careful preoperative, intraoperative, and postoperative pulmonary care. This can often require a lengthy ICU admission for respiratory support and management. Lung transplants are being offered to these patients with chronic respiratory failure. [181]

Bronchopulmonary Dysplasia

Bronchopulmonary dysplasia (BPD) is a form of chronic lung disease seen in young patients who survive severe neonatal lung disease. The etiology is uncertain, but patients usually share the common history of prematurity, hyaline membrane disease, and a requirement of prolonged aggressive respiratory support with high levels of inflating and distending pressures and high F $_{IO_2}$ values. Children with BPD have a decreased dynamic compliance, increased airway resistance, increased physiologic dead space, and a markedly increased work of breathing. On examination, these children are hyperinflated with retractions, nasal flaring, and wheezing. Chest radiographs show large lung volumes, fibrosis, and cystic and atelectatic areas. ABG show a chronic hypercarbia and varying degrees of hypoxemia. [182] [183]

Therapy for BPD includes maximal nutritional supplementation to support the large energy expenditure for the increased work of breathing in addition to varying degrees of respiratory support. Some children have been treated with chronic mechanical ventilation and chronic increased ambient oxygen. Diuretics and bronchodilators are often adjunctive therapies. Most children are long-term survivors with subjectively normal pulmonary function. However, there is evidence [184] [185] demonstrating chronic physiologic changes in this population. During the first years of life, any extraneous pulmonary infection or embarrassment may necessitate acute or chronic intensive respiratory support or may in fact prove to be a fatal event.

Much effort is being made to prevent the development of BPD. Because the trauma of mechanical ventilation on the immature lung is identified as the major cause, alternate modes of ventilatory support are being evaluated. These include exogenous surfactant, high-frequency ventilation (especially HFOV), [153] ECMO, and liquid ventilation. [182] [186]

Sleep Apnea

Normal ventilation during sleep depends on normal upper airway anatomy and a number of intact reflexes, including central response to hypercarbia and hypoxia, response to airway irritation, and dynamic phasic contraction of the pharyngeal and hypopharyngeal muscles, which maintain a patent airway. Sleep apnea usually results from an abnormality of one or more of these normal protective responses.

In infancy, central sleep apnea is not uncommon. Numerous potential causes have been postulated, but perhaps the most attractive is immaturity of the medullary chemoreceptors. Central sleep apnea can be complete, as in the Ondine curse, or it may be some lesser degree of hypoventilation related to the group of disorders causing sudden infant death syndrome (SIDS). Treatment consists of respiratory stimulants (theophylline), cardiorespiratory monitoring during sleep, and, in complete sleep apnea, tracheotomy and nighttime mechanical ventilation. [187]

Obstructive sleep apnea can occur in any age child. It can be associated with an identifiable anatomic disorder (e.g., tonsils, adenoids, and Pierre Robin) or with the more obscure dynamic abnormalities of lax pharyngeal musculature. Signs and symptoms include loud snoring, obstructive episodes with constant arousal, behavior disorders associated with sleep deprivation, and cor pulmonale. Diagnosis is made by history, ECG, and formal sleep studies.

Treatment includes any maneuver that helps to remove or to bypass the obstruction. Tonsillectomy and adenoidectomy are usually performed to maximize the patent airway. Rarely does a child require a tracheostomy for definitive therapy.

Foreign Body Aspiration

Foreign body aspiration is a relatively common and often catastrophic event in children. Although it can occur at any age, the peak incidence is 6 months to 3 years. Materials aspirated range from vegetable matter (peanuts) and other foodstuffs (hot dogs) to coins and small pieces of toys; of interest to the clinician is that most of

these objects are radiolucent. Presenting symptoms are a function of both the location of the foreign body within the airway and the time of presentation. Acute symptoms may include total airway obstruction, stridor, wheezing, or acute onset of cough, whereas more chronic symptoms are bloody sputum, chronic cough, or wheezing. The diagnosis is made on the basis of history and examination. Specific radiologic imaging can be useful (plain films or fluoroscopy).

Treatment is controversial. There is much argument about the comparative efficacy and safety of abdominal thrusts, Heimlich maneuvers, and back slaps, all of which are reserved for the acute upper airway obstruction in which there is no air movement. Treatment of less acute or lower airway foreign body aspiration includes bronchoscopy, postural drainage, chest physical therapy, bronchodilators, and surgical removal. [188]

Upper Airway Obstruction and Meningomyelocele

Stridor from bilateral vocal cord abductor paralysis is a reported complication of myelodysplasia. The vocal cord paralysis is secondary to brain-stem abnormalities. Children with meningomyelocele have associated Arnold-Chiari malformations with a caudally displaced medulla, abnormally long cranial nerve tracts, and abnormal arterioarchitecture of the brain stem.

The vocal cord paralysis may be secondary either to pressure on the brain stem (i.e., with hydrocephalus) or to focal infarcts. Treatment entails decompressing any degree of hydrocephalus and, if the paralysis persists, performing a high cervical decompression. Despite these surgical maneuvers, some children require a tracheotomy for long-term care.

CENTRAL NERVOUS SYSTEM

CNS dysfunction secondary to systemic illness occurs quite commonly in infants and children. Seizures, head trauma, CNS infections, and hypoxic or metabolic encephalopathy are the common causes of acute neurologic dysfunction in the PICU. Assessment of neurologic function depends on an understanding and awareness of the age-dependent progression of motor and cognitive skills. Table 73-11 (Table Not Available) lists the developmental milestones.

Functional Postnatal Neurologic Development

Motor function in the newborn is dependent on gestational, rather than postnatal, age. [189] That is, an infant born at 28 weeks' gestation who is 3 months old exhibits motor responses similar to those of a full-term newborn. Motor function and tone as well as reflex behavior serve as the basis for assessing gestational age in the newborn. Although potentially modifiable by cortical influence, most neonatal motor behavior is subcortically controlled, [190] permitting normal motor behavior in newborn infants with severe cortical damage.

Intellectual development is difficult to assess in the newborn; initially, it is predicated on the loss of some newborn reflexes and on the acquisition of new motor skills. Adaptive

TABLE 73-11 -- Normal Ages for Major Developmental Milestones

(Not Available)

Modified from Crone [30C]

or interactive behavior is first seen with accommodation to repeated stimuli and eye contact. The infant's intellectual development depends on the presence of significant external stimulation and social interaction, preferably from one or a few individuals. This has important implications for the infant and child requiring long-term intensive care.

Monitoring of Neurologic Function

The most important aspect of assessing neurologic function is the clinical examination. In the awake child, interactions with the examiner and caretakers are all sensitive indicators of high or integrative cortical function. When the child's cognitive function is depressed from disease or pharmacologic agents, examinations of gross motor function, general level of activity, and peripheral and brain-stem reflexes become important, albeit crude, measures of CNS function. The Glasgow coma scale (GCS) has been used to quantitate the level of function in neurologically impaired patients [191] (Table 73-12) (Table Not Available) . A pediatric GCS has been developed to obviate the problems in a child without language skills (Table 73-13) (Table Not Available) .

Laboratory Assessment of Neurologic Function

The electroencephalogram (EEG) is useful in identifying seizure activity, in diagnosing isoelectric brain death, and in monitoring therapy during therapeutic barbiturate coma. Otherwise, in most neurologic diseases, the EEG is so nonspecific as to be uninterpretable. Brain-stem-evoked potentials (auditory, visual, and somatosensory) have gained acceptance as a means of neurologic assessment in the comatose patient. Evoked potentials define marginally functioning neurons that cannot be detected by the clinical examination. Asymmetry, abnormality, or absence of conduction of auditory, visual, or tactile stimuli through the brain stem to the cortex can provide useful information regarding the progress of neurologic injury or recovery. Although evoked potentials are only mildly affected by barbiturates, a

flat response during therapeutic coma cannot be used as diagnostic of brain death.

Computed tomography (CT) remains an invaluable tool for rapid evaluation of the neurologically impaired child for surgical lesions, extent of structural injury, and noninvasive assessment of ICP. Cranial ultrasound is an effective bedside method of assessing ventricular size and intracranial anatomy in the infant whose cranial sutures have not yet fused. Magnetic resonance imaging (MRI) plays an increasingly important role in the evaluation of acute brain injury. Qualities that make the MRI invaluable in the examination of intraorbital and ocular injuries and brain-stem and spinal cord disorders are its multiplanar imaging capabilities, exquisite soft tissue contrast resolution, and lack of bone interference. [192] The major drawbacks of MRI are the length of time required to complete the examination and the relative inaccessibility of the patient in the scanner. The logistics of safely obtaining an MRI scan for a patient who has significant cardiorespiratory compromise are formidable.

Doppler ultrasound is gaining popularity as a method of assessing cerebral blood flow velocity in the ICU. Although incapable of measuring cerebral blood flow (CBF) directly, it is proving useful as a noninvasive bedside tool for guiding therapy to effect cerebral perfusion. Cerebral angiography plays an increasingly smaller role with the introduction and development of these less invasive tests. CBF scans remain the gold standard for the diagnosis of brain death during barbiturate coma.

Methods of ICP monitoring include placement of a catheter in a lateral ventricle, a subarachnoid screw, a transducer in the epidural space, or cerebral parenchyma. The ventricular catheter is inserted through a drill hole placed in the area of the coronal suture in line with the ipsilateral pupil. If the ventricle is large enough, a

catheter can be placed easily, by penetrating brain substance. It produces an accurate waveform and has the advantage that cerebrospinal fluid (CSF) can be removed as a treatment of raised ICP.

The subarachnoid screw is placed transcranially via a drill hole through which the dura and arachnoid have been incised. Although placement is technically easier than with the intraventricular catheter, the pressure tracing is easily damped and is possibly inaccurate when the brain is soft and swollen. The subarachnoid screw cannot be placed in children

---

under 1 year of age, because the bony structure cannot support the appliance.

The epidural transducer is placed by way of a bur hole or through a formal craniotomy incision at surgery. It is relatively easy to place and does not require incising the dura; once placed, however, it cannot be recalibrated and is therefore only of relative value.

Pathophysiology of Neurologic Disease

The pathophysiology of critical neurologic disease includes increased ICP, abnormal electrical discharge (status epilepticus), and focal loss of functioning neurons (Ch. 52) .

Increased Intracranial Pressure

Increased ICP has been implicated as a potential source of morbidity and mortality in severe neurologic diseases such as head trauma, Reye syndrome, hypoxic ischemic encephalopathy, metabolic encephalopathies, intracranial space-occupying lesions, and hydrocephalus. Increased ICP occurs with an increase in intracranial volume: CSF, blood, brain, or supporting tissues. An increase in one compartment can only occur at the same ICP by displacing another compartment. When displacement is no longer possible, ICP rises proportionate to volume. [193] In older children and adults with closed sutures and rigid calvaria, the cranial cavity is a closed receptacle whose contents are incompressible.

Intracranial Compliance Curve

Recognition of increased ICP is important. In addition to the underlying pathology, intracranial hypertension causes further neurologic injury by two mechanisms: (1) if ICP is sufficiently high to reduce the arteriovenous pressure gradient or cerebral perfusion pressure (CPP), brain ischemia occurs; and (2) ICP can cause compression and herniation of the brain stem or other vital structures if a pressure differential exists. This compression alters brain function acutely and may cause ischemia or infarction of the brain stem. During the past several years, monitoring of ICP and anticipatory treatment of intracranial hypertension have led to claims of improved outcome, particularly in patients with head trauma.

Head Trauma

Significant percentages of adult patients with head injury and altered level of consciousness have abnormal ICP. In one study of 160 head-injured patients, the ICP on admission was greater than 20 mm Hg in 44 percent of cases and greater than 10 mm Hg in 82 percent. All patients whose ICP could not be reduced by therapy to less than 20 mm Hg died. [194] Other studies have confirmed that sustained intracranial hypertension following head injury is associated with poor outcome. Although these trends are impressive, it is important to recognize that the acceptable upper limit of ICP is unknown and may vary with age and disease. [195]

As many as 50 percent of patients who die of head injury are conscious at admission, yet many succumb as increasing ICP impairs CPP. CBF studies done acutely after head trauma have demonstrated that an increased CBF and CBV (hyperemia) are frequent, although unexplained, findings in children. Thus, this common early increase in intracranial volume is usually due to an increase in blood volume, not cerebral edema. In children who die a few days after sustaining head trauma, the most common neuropathologic finding is a swollen brain with little, if any CSF. CT scans confirm in the first days after injury that ventricular size frequently decreases as cerebral swelling increases. [196]

Adults with head injuries and GCS scores (see Table 73-12 (Table Not Available)) of 7 or less (i.e., not spontaneously verbalizing or responsive to pain) have an approximately 55 percent incidence of significantly elevated ICP. It is noteworthy that the incidence of abnormal ICP is similar in patients following evacuation of a hematoma compared with patients without surgical lesions. [197] In children, intracranial hypertension did not occur with GCS scores higher than 6, but it was present in 81 percent of those with GCS scores of 3 or 4. [195]

It is important to reiterate that intracranial hypertension is frequently not detectable by clinical examination. Although certainly not a substitute for careful neurologic assessment, ICP monitoring may provide evidence that further intervention is necessary. In head-injured patients, intracranial hypertension may occur with or without a surgical lesion, or it may only develop after a hematoma is evacuated. Although children have better outcomes than adults after similar head injuries, significant damage frequently occurs. [198] Evidence is accumulating that prompt recognition and treatment of increased ICP increase survival and improve neurologic outcome. [199]

Hypoxic-Ischemic Encephalopathy

There is little documented experience on the incidence of increased ICP in this group or on the ability to alter outcome. However, general clinical impressions suggest the following: (1) outcome is less favorable in this group than in those with trauma or metabolic encephalopathy; (2) aggressive management of ICP, at best, prevents further damage; and (3) the GCS provides a reasonable assessment of initial neurologic function in these patients.

Hydrocephalus

A massive increase of the CSF component of the intracranial volume can result in increased ICP. The most common causes of hydrocephalus are obstructed ventricular shunts or aqueductal stenosis/compression from congenital malformations, infection, posterior fossa tumors, or intracranial bleeds. Decompression of the system by either external or internal shunts can be lifesaving.

Tumors

Brain tumors in children are common. They are characteristically found in the posterior fossa, which is a relatively clinically silent area. The initial presentation may be focal

---

deficits, ataxia, or symptoms of increased ICP either from tumor mass or from secondary obstructive hydrocephalus.

Guidelines for Intracranial Pressure Monitoring

A patient with a diagnosis of head trauma, Reye syndrome, or metabolic encephalopathy is a candidate for ICP monitoring if the following criteria are met: a GCS score of 7 or less, clinical signs of increased ICP, and evidence of increased ICP on CT scan.

Coagulopathies must be corrected before any ICP monitor is placed.

Treatment of Increased Intracranial Pressure

Once intracranial hypertension is documented, prompt therapy must be initiated. Increases in pressure must be interpreted within the context of the clinical situation. While treating increased ICP, it is important to expedite the treatment of the underlying condition, which may also be therapeutic for the intracranial hypertension (i.e., evacuation of a hematoma, drainage of CSF in hydrocephalus, or antibiotics). The general approach to increased ICP includes the following maneuvers:

1. *Positioning.* The head is elevated to 15 to 30 degrees and is kept in midline position to enhance cerebral venous outflow and to maximize CPP.
2. *Adequate oxygenation.* The airway is secured and oxygenation is maintained with the Pa o_2 at 100 mm Hg or greater. Elevated airway pressures should be avoided if possible.
3. *Hyperventilation.* Elevated Pa co_2 decreases cerebrovascular resistance and increases CBF, CBV, and ICP. Conversely, reducing Pa co_2 decreases CBF, CBV, and ICP. [200] [201] Overvigorous hyperventilation could reduce CBF to such a degree as to produce ischemia; a Pa co_2 of approximately 25 mm Hg is generally effective and safe for the acute management of intracranial hypertension. Prolonged hyperventilation has not been demonstrated effective and may be deleterious in patients with severe head injury. [202] Mild hyperventilation with a Pa co_2 of 30 to 35 mm Hg should be maintained in the child recovering from head trauma.
4. *Osmotic agents and diuretics.* Mannitol reduces ICP by decreasing blood viscosity, transiently increasing CBF and improving oxygen transport, which results in a decreased adenosine level. The drop in adenosine causes cerebral vasoconstriction in areas of the brain that have intact autoregulation. [203] CBF remains constant with a decrease in CBV and ICP. Mannitol will have little effect if autoregulation is impaired or CPP is elevated and cerebral vasoconstriction is already maximal. Mannitol should be administered only when necessary to control ICP. Serum osmolarity should be measured and should not exceed 320 mOsm/L. Furosemide reduces ICP by causing the preferential excretion of water over solute in the distal renal tubule. [204] Serum electrolytes should be monitored, and hypovolemia with decreased cardiac output should be avoided.

Steroids

Steroids have been proven efficacious in decreasing vasogenic edema surrounding a brain tumor and reducing 8th nerve swelling and associated hearing loss from bacterial meningitis. [205] [206] It has become increasingly clear that steroids play no role in the treatment of global cerebral edema. Precautions to avoid gastric ulceration should be undertaken if steroids are used.

Temperature Control

Hyperthermia is to be avoided in all patients with brain injury. Cerebral metabolic rate is proportional to body temperature increasing 5 to 7 percent/°C. Antipyretic agents (acetaminophen) and cooling devices should be employed for temperatures higher than 37°C. By contrast, hypothermia reduces cerebral metabolic rate. At 30°C, the cerebral metabolic rate is 50 percent of control. [207] [208] There is evidence that induction of hypothermia prior to a cerebral ischemic insult can permit prolonged periods of inadequate CBF, but there is no reliable evidence that hypothermia induced after an insult improves neurologic outcome. Theoretically, there may be a rationale for decreasing the metabolic rate with hypothermia of 30 to 35°C. Practically, temperatures lower than 33°C are associated with a number of multisystem complications that may increase morbidity and mortality. Hypothermia should not be induced unless the patient is paralyzed and anesthetized to prevent shivering.

Glucose Control

Poor neurologic outcome has been associated with hyperglycemia following head injury in adults and children. [209] [210] Several investigators have demonstrated in animal models that hyperglycemia in the setting of incomplete cerebral ischemia leads to enhanced anaerobic glycolysis and lactic acidosis. [211] [212] [213] The ensuing acidosis in at-risk tissue results in extension of the initial injury. When insulin is used to maintain normoglycemia during temporary cerebral ischemia in rats, fewer neurologic deficits are seen than in their hyperglycemic counterparts. [214] Blood glucose levels should be checked. Hypoglycemia should be avoided, but the routine administration of dextrose-containing intravenous solutions in the setting of head injury should also be avoided.

Seizure Control

Seizures cause an increase in metabolic requirements, resulting in increases in CBF, CBV, and ICP. In the paralyzed patient, an EEG should be obtained to document any seizure activity, and all seizures should be aggressively treated with anticonvulsants.

Muscle Relaxants

Neuromuscular paralysis may reduce ICP in patients with intracranial hypertension by reducing increased intrathoracic

---

and venous pressure associated with coughing, straining, or "bucking" the ventilator.

Sedation

Fear, anxiety, and response to painful stimuli (surgical procedures, intubation, neurologic examination) increase CBF and ICP. Although sedating unconscious patients may appear incongruous and can even obscure the neurologic examination, under some circumstances the benefits may outweigh the risk. Most intravenous sedatives, including benzodiazepines, butyrophenones, and barbiturates, are efficacious and frequently decrease CBF and ICP. Ketamine increases CBF and should be avoided. Opioids can be used if the patient has responses to painful stimuli and respirations are controlled.

Barbiturates

Barbiturates induce the greatest reduction in CBF and cerebral metabolism. [215] Thiopental, 1 to 5 mg/kg, as an intravenous bolus, acutely reduces ICP for 5 to 10 minutes. For a more prolonged effect, pentobarbital (Nembutal), 3 to 30 mg/kg, as an intravenous loading bolus followed by a maintenance dose of 1 to 2 mg/kg/h, is effective in reducing ICP. Blood levels of 20 to 40 mg/L are generally effective, although higher levels may be necessary to achieve burst suppression on EEG monitoring and lower ICP. In these doses, barbiturate metabolism and excretion may be altered; and levels must be monitored closely. Because myocardial depression and hypotension are significant complications of barbiturate therapy, cardiovascular function must be closely followed with specialized monitoring (e.g., Swan-Ganz catheter), if high levels of drugs (30 mg/L) are required or if cardiac decompensation is evident. [216] Although barbiturate administration decreases ICP, it has not been demonstrated conclusively that barbiturates improve survival or neurologic outcome. [217] [218] [219]

Lidocaine

An intravenous bolus of 1 to 1.5 mg/kg may be helpful in minimizing ICP increases that occur with noxious airway stimulation (i.e., endotracheal suctioning).

Status Epilepticus in Children

Status epilepticus is defined as continuous motor seizure activity for more than 20 minutes or as repeated episodes without intercurrent awakening. [220] It occurs in children with a history of seizures, as well as in children previously thought to be neurologically normal. Although it is not unusual for no cause to be found, the most common identifiable causes are infections such as meningitis or encephalitis, metabolic abnormalities or toxins, head trauma, and hypoxic and ischemic injury. Because seizure activity increases both brain and skeletal muscle metabolism and oxygen consumption, status epilepticus may place the child at risk of cellular hypoxia. During a seizure, airway obstruction and ineffective chest wall and diaphragmatic excursion are common such that arterial hypoxemia and hypercarbia are

the rule.

Treatment begins with reestablishing an airway, administering oxygen, and ensuring adequate ventilation. Specific treatment is aimed at stopping the seizure activity by the administration of anticonvulsant drugs, preferably by the intravenous route. Especially in the newborn, intravenous administration of metabolic substrate, including glucose and calcium, is important specific, as well as supportive, treatment. Commonly employed anticonvulsants include lorazepam, phenobarbital, paraldehyde, and phenytoin.

Lorazepam is a rapid and reliable drug for stopping seizures. It is administered in small intravenous boluses of 0.1 mg/kg, or it can be given rectally if intravenous access is unobtainable. Phenobarbital is also used, 5 to 10 mg/kg, up to a total dose of 20 mg/kg. The main complication is respiratory depression, which can occur with high levels. This respiratory depression is exaggerated when phenobarbital is used in combination with lorazepam. Phenytoin can also be given intravenously in doses up to 20 mg/kg, but it should be given slowly to avoid cardiovascular depression. Paraldehyde may be given rectally in a dose of 0.3 mL/kg. Last, sodium thiopental in an intravenous dose of 1 to 4 mg/kg stops the most intractable seizures; however, apnea almost invariably occurs, and the risk of vomiting and aspirating may be high. Once the seizures are under control, a cause should be established, with care taken to maintain an adequate airway and ventilation.

Brain Death

The longest-standing criterion for death is irreversible cessation of cardiorespiratory function (Ch. 76) . Today, death has become less well defined as modern technology of organ system support allows clinicians to maintain cardiopulmonary function indefinitely, even after brain function has permanently ceased. These medical advances have necessitated a reassessment of the definition of death; brain death is a clinical and legal definition of death that describes a permanent cessation of brain function.

The clinical criteria of brain death include irreversibly absent cerebral and brain-stem functions. Absent cerebral function is recognized when there is no cortically mediated receptivity or responsivity to external stimuli. [221] Absent brain-stem function is recognized when brain-stem reflexes cannot be elicited: absent pupillary response to light, corneal, oculocephalic, oculovestibular, oropharyngeal, and respiratory reflexes.

Irreversibility is determined when the cause of coma is sufficient to account for the loss of brain function and when the possibility of recovery is excluded by clinical observation and/or laboratory studies. Laboratory studies that should be considered include analysis of blood and urine for toxic substances, EEG, radionuclide brain scans, cerebral angiography, and brain-stem-evoked potentials. These laboratory functions should be considered confirmatory in nature and supplementary to the clinical history and physical examination. It is important to identify any factors that can simulate the clinical and/or laboratory criteria of absent brain function; severe hypothermia (core temperature < 30°C) and elevated

barbiturate levels present the most common situation. Both hypothermia and the presence of barbiturates can significantly depress electrical activity in the brain and may render an EEG meaningless. In such cases, the technetium 99m (^{99m}Tc) radionuclide angiogram is useful. In patients with brain death, there is no arterial blood flow to the anterior and middle cerebral arteries and no venous flow in the sagittal sinus; blood flow to the extracranial tissues is preserved. This study is independent of the patient's core temperature or barbiturate level. It is usually helpful to have at least two physicians concur on the clinical and/or laboratory diagnosis of brain death. All evidence must be clearly documented in the patient's record.

Whenever a patient is declared brain dead, the family should be approached for the possibility of solid organ donation. Tissue donation (e.g., eyes and heart valves) can also be offered to families after the child has had a cardiovascular death. Regional procurement agencies can provide protocols and support to the ICU staff as well as to families.

RENAL SYSTEM

Structural and Functional Development of the Excretory System

The embryologic development of the renal system begins in the middle of the third week of gestation with the development of the pronephric tubule, which undergoes further development and regression through the stages of pronephric duct, mesonephros, and ultimately the metanephric kidney. By 10 weeks' gestation, a functioning kidney and collection system exist, and fetal urine is discharged into the bladder. At 32 to 36 weeks' gestation, nephron induction is complete, and the full complement of nephrons per kidney is present. [222] Table 73-14 (Table Not Available) presents the normal values for pediatric renal function.

Functional Development of the Kidney

Because the placenta is the major excretory organ of the fetus, renal growth is not governed by functional requirements. Renal growth during the third trimester increases

TABLE 73-14 -- Normal Values for Pediatric Renal Function

(Not Available)

Modified frin Goldsmith [227]

linearly with body weight and body surface area. [223] Glomerular filtration rate (GFR) increases rapidly from 28 to 35 weeks' gestation--the period of greatest nephron growth and functional maturation. At term birth, GFR is 10 mL/min/m^2 and increases to 20 mL/min/m^2 by 2 weeks of age. Although GFR is lower in the premature infant, the rate of increase is at the same rate as in the term infant. [224] Tubular functions are not fully mature in the full-term newborn at birth. The newborn kidney is sensitive to antidiuretic hormone (ADH), or vasopressin, but the urine osmolarity can only vary from 50 mOsm/L up to 780 mOsm/L. [225] The tubular function of premature infants is less mature; they can concentrate their urine only to 600 to 700 mOsm/L.

The renal threshold for bicarbonate in the newborn is about 20 mEq/L (
4-6 mEq/L less than that of the adult). This means that standard acid-base nomograms do not apply to infants, because a serum bicarbonate concentration of 20 mEq/L is normal and does not indicate metabolic acidosis. The renal tubular glucose threshold is at adult levels in the term infant, but it is reduced to approximately 150 mg/dL in the premature infant. The full-term infant handles sodium well, with 1 percent or less fractional excretion by the third day of life. Fractional excretion of sodium can be as high as 5 percent in the premature infant. [226] Renin, angiotensin, and aldosterone levels are high in the newborn and decrease over the first few weeks of life. Table 73-14 (Table Not Available) presents the normal values for pediatric renal function. [227]

Renal Failure

Acute renal failure is an abrupt, often temporary, loss of renal function following an insult that may or may not be evident on presentation (Chs. 51 and 55) . Oliguria is the rule, polyuria the exception, and anuria uncommon. Urine volume and composition are altered, and fluid, electrolyte, and acid-base disorders are commonly associated. Therapy is directed at maintaining normal metabolic and fluid homeostasis, supporting nutrition, and exhibiting patience. Acute renal failure is caused by prerenal, postrenal (obstructive), or intrinsic renal disorders. Prerenal causes are related to the adequacy of renal blood flow. Reducing systemic cardiac output, or renal blood flow specifically, reduces urine output and ultimately causes azotemia and ischemic renal damage. Measurement of the adequacy of the circulating blood volume by central venous pressure and cardiac output and assessment of renal blood flow with Doppler flow studies or nuclear imaging techniques are useful in differentiating prerenal from renal causes of azotemia. [228]

Postrenal obstruction to urine flow can occur anywhere within the collecting system. Chronic partial obstruction at the level of the bladder neck or the ureterovesical or ureteropelvic junction is a common form of congenital malformation. Posterior urethral valves are frequently demonstrated in males. All these malformations can cause mechanical obstructive nephropathy and renal injury or renal failure. Signs of obstruction may be subtle and may require radiologic, ultrasonic, or endoscopic evaluation. Recurrent urinary tract infections are frequently the clinical presentation of obstructive lesions. [229]

Intrinsic renal failure may be due to disorders of the renal

glomeruli, tubules, or blood vessels. Glomerular diseases include hemolytic uremic syndrome, poststreptococcal glomerulonephritis, Henoch-Schonlein purpura, and other inflammatory and immune complex diseases. Acute tubular injury is most commonly caused by hypoxia and ischemia; other causes are rhabdomyolysis, sepsis, hyperthermia, hemolysis, and myriad nephrotoxins, such as mercury, carbon tetrachloride, and ethylene glycol. [230] Vascular disease, including arterial embolus and venous thrombosis, as well as congenital malformations, can lead to acute renal failure.

Hemolytic Uremic Syndrome

Hemolytic uremic syndrome (HUS) is one of the most commonly acquired causes of acute renal failure in children. This syndrome is characterized by microangiopathic hemolytic anemia, thrombocytopenia, and acute renal injury. In North America, HUS is most often associated with infection by cytotoxin-producing *Escherichia coli* 0157, but other serotypes and other Shiga-like toxin-producing bacteria have been implicated. [231]

E. coli 0157 is an inhabitant of the intestinal tract of cattle and can contaminate the surface of beef during processing. [232] The bacterium is killed on cooking, but it survives in uncooked meat or inside undercooked hamburger. Secondary infections can occur as a result of person-to-person spread in day care centers, institutions, and the military. There also appears to be a familial form of this disease that accounts for a small percentage of the total. [233]

HUS predominates in children from 6 months to 4 years of age, but it ranges from the neonatal period through adulthood. [234] It shares many laboratory and clinical features with the adult disease thrombotic thrombocytopenic purpura. In fact, some investigators consider the two disorders to represent a continuum of the same disease. The abnormalities that develop in HUS are believed to be caused by cytotoxins and lipopolysaccharide, a bacterial endotoxin. The toxins damage endothelial cells in the kidney, vasculature, and other organs directly or indirectly by the activation of leukocytes. [235] Cytokines such as interleukin-1 and tumor necrosis factor, prostaglandin I_2 , thromboxane A_2 , and von Willebrand factor multimeres are also released and probably play a role in the pathogenesis of this disease. [236]

The time from exposure to presentation varies from 3 to 12 days, and symptoms last for about a week. Patients usually present with abdominal cramping, bloody diarrhea, tenesmus, and vomiting. [237] On average, about 10 percent of children with *E. coli* 0157 bloody diarrhea progress to HUS. Mildly affected patients exhibit anemia, thrombocytopenia, azotemia, decreased urine output, and an uncomplicated course. In severely affected patients, anuria is common, hypertension and seizures may occur, and the duration of illness is protracted. A small number of children will exhibit progressive and permanent renal insufficiency, severe and recurrent hemolysis, thrombocytopenia, and neurologic impairment.

Hematologic abnormalities include hemolysis and thrombocytopenia. The Coombs-negative microangiopathic hemolysis can result in hyperbilirubinemia, and, despite reticulocytosis, anemia with hemoglobin concentrations as low as 4 to 5 g/dL can also occur. Thrombocytopenia is caused by platelet destruction and sequestration in liver and spleen. [238] The remaining platelets demonstrate impaired aggregation. [239] Disseminated intravascular coagulation (DIC) is not uncommon. Glomerular capillary endothelial injury is the most consistent renal finding in HUS. Acute renal failure with oliguria or anuria usually lasts less than a week, but it can last more than 10 weeks. [240] Glomerular and/or arterial injury may predominate, depending on the presence and extent of renal insufficiency (glomerular injury) and hemolysis and hypertension (arterial injury). CNS abnormalities are manifested by decreased levels of consciousness, seizures, irritability, ataxia, hypotonia, hemiparesis, hyperreflexia, and hallucinations. CNS complications may be due to severe hypertension, electrolyte disturbances, microthrombi, or cerebral edema and increased ICP. [241] Abdominal cramping is common, and vigilance is required to distinguish colitis from intussusception, intestinal stricture or perforation, colonic gangrene, or other surgical emergencies. [242] Pancreatitis is common in patients with HUS. CHF may be a result of fluid overload, hypertension, anemia, or myocardial depression secondary to circulating endotoxins.

Treatment is primarily supportive, with meticulous attention paid to volume status, electrolyte and acid-base balance, nutrition, antisepsis, and treatment of hypertension and coagulopathies as required. Enteric isolation is mandatory to prevent secondary spread. Accurate fluid intake and output records, weights, and frequent clinical assessments of volume status are the pillars of good management. A central venous catheter can be used for pressure measurements and blood sampling and also as a route for intravenous medications and nutrition. In children with cardiac dysfunction, a pulmonary artery catheter can be useful for assessing changes in volume and function. Nephrotoxic drugs should be avoided if possible, or their dose should be modulated with serum levels closely monitored. [243] Daily fluids should be restricted to replacing insensible losses, urine output, and any ongoing losses. Fluids should be used that reflect the electrolyte content of the losses. Caloric support is essential. Enteral feedings are preferred, but ileus often makes parenteral nutrition necessary. No specific treatment has demonstrated to be effective to date. Antidiarrheal medications prolong the duration of colitis and increase the risk of HUS. [244] Heparin, fibrinolytic agents, aspirin, dipyridamole, corticosteroids, vitamin E, and furosemide are not proven to affect the outcome of HUS. [245] Immunoglobulin therapy and infusions of fresh frozen plasma have had mixed results; no therapeutic benefit has been demonstrated.

Dialysis, improved nutrition, and supportive care have decreased the mortality rate from 100 percent in the original report to less than 12 percent in the last decade. [246] Mortality rates in developing countries and in those children who exhibit a genetic predisposition for HUS remain high.

The technique for peritoneal dialysis includes the placement of a soft catheter with multiple holes into the peritoneal cavity through an anterior abdominal wall incision. This procedure can be performed in the ICU with the use of local anesthesia. Once the placement and patency of the catheter are confirmed, a commercially available dialysate solution is infused into the peritoneal cavity, where it equilibrates with the plasma and extracellular fluids, using the parietal and visceral surfaces as semipermeable dialysis membranes. [247] The period of fluid instillation (dwell time) for equilibration can

be varied, depending on clinical conditions. The composition of the dialysis fluid tends to be similar to that of plasma, containing approximately 130 mEq/L of sodium, 100 mEq/L of chloride, 35 mEq/L of acetate or lactate as a buffer, 3.5 mEq/L of calcium, and 1.5 mEq/L of magnesium. The glucose concentration can be varied to be either isosmotic, with 1.5 percent glucose, or hyperosmotic, with 4.25 percent glucose. The latter concentration allows for additional intravascular and extracellular fluid to equilibrate with the dialysate fluid, so that this fluid, as well as electrolytes, can be removed when the peritoneal cavity is evacuated. Complications occur with peritoneal dialysis. Respiratory compromise from increased abdominal pressure during dwell time may require intubation and mechanical ventilation in children with impaired preexisting respiratory function. Peritonitis from bacterial or fungal agents from contamination of the dialysis catheter or dialysate can occur in a patient whose host defenses are not normal. [248] Severe dehydration, including circulatory collapse and metabolic derangements, can occur if peritoneal dialysis is too rapidly or improperly performed. The principles of hemodialysis are essentially the same as those of peritoneal dialysis, using the blood compartment to interface with a semipermeable membrane rather than the peritoneum. Some investigators argue that hemodialysis is more efficient than peritoneal dialysis and therefore is more appropriate for the acute setting.

More recently, the technique of hemofiltration or ultrafiltration has gained popularity. This is an extracorporeal process in which uremic blood is cleansed by a technique based solely on the principle of convective solute transport. During this procedure, an ultrafiltrate of the plasma is created by hydrostatic pressure exerted across a highly permeable membrane. Simultaneously, the blood volume is replaced by a modified lactated Ringer solution. [249]

Outcome

The prognosis in acute renal failure depends on the patient's age, underlying disease, and the extent of the precipitating insult (Ch. 21) . In general, children tend to have a better outcome than adults; in fact, they usually recover completely from a renal insult of hypoxia or ischemia within a short time, provided other organ systems are not involved. [250] In children who develop chronic renal failure, long-term outpatient peritoneal dialysis or long-term hemodialysis is necessary for survival until a renal transplant can be performed. [251]

ENDOCRINE SYSTEM

Certain endocrine disorders cause chronic disease in the pediatric patient (Ch. 25) . It is beyond the scope of this chapter to discuss these in detail, but some acute disorders frequently encountered in the PICU are highlighted in the following sections.

Adrenal

Abnormalities of the adrenal axis result in either deficient or excessive production of glucocorticoids and/or mineralocorticoids. Many of these disorders are diagnosed and treated as they are in the adult. Special reference should be made to the problems of congenital adrenal hyperplasia, pheochromocytoma, and iatrogenic chronic adrenal insufficiency.

Congenital Adrenal Hyperplasia

Congenital adrenal hyperplasia is an autosomal recessive disorder that describes deficiencies in either 21-, 11-, or 17-hydroxylase enzymes. 21-Hydroxylase deficiency is the most common disorder, causing problems from cortisol and aldosterone deficits as well as from the build-up of active intermediary metabolites. [252] 21-Hydroxylase deficiency found in children can either be partial (simple virilizing form) or more complete (salt-losing form); at birth, affected children demonstrate masculinization of the external genitalia, and those with the more complete deficiency show a progressive salt-losing state (i.e., loss of sodium and elevation of potassium). Presentation is usually in the first few weeks of life, with a history of feeding difficulty, vomiting, and failure to thrive--a clinical and historical course suggestive of pyloric stenosis. If these children are not diagnosed and treated early in life, they can present with severe cardiovascular collapse.

Treatment is aggressive support of the intravascular volume and myocardial function and replacement of the deficient hormones. Cortisol can be replaced with oral administration of hydrocortisone at a dose of 25 mg/m^2 /d divided into three doses; if the child is unable to tolerate oral medication, cortisone acetate can be administered intramuscularly in a dose of 37.5 mg/m^2 /d given every 3 days. For emergency therapy, when the oral route is not possible and the perfusion of the muscle bed is poor, hydrocortisone acetate can be used intravenously at a dose of 1.5 to 2.0 mg/kg bolus, then 25 to 250 mg/d in divided doses. Mineralocorticoid is replaced with fludrocortisone acetate 0.05 to 0.2 mg/d orally; these patients usually require the addition of salt to their daily diet. [253] [254] Deficiencies of 11- and 17-hydroxylase do not result in salt wasting; masculinization and hypertension are the common presenting signs. [254]

Pheochromocytoma

Fewer than 5 percent of pheochromocytomas are diagnosed in children. As a rule, these tumors are more often confined to the adrenal medulla, but they can occur anywhere throughout the sympathetic chain. [255] The clinical signs and symptoms of excessive catecholamines are the same as those in the adult.

Iatrogenic Chronic Adrenal Insufficiency

The long-term daily use of steroids for the treatment of asthma, nephrotic syndrome, and malignancies is common. It is important to remember that a hypoadrenal state can result that produces potential risk during severe illness and stress crises. [256] In children, it is also important to remember

that topical steroids have been reported to depress the production of adrenocorticotropic hormone (ACTH). Replacement of stress-level steroids (three times the daily replacement dose) is required.

Anterior Pituitary

Panhypopituitarism can be a problem in the pediatric patient, usually secondary to tumor or to aggressive dissection of tumor. [257] Acute ICU problems that result include the support of the adrenal axis and abnormalities of ADH.

Diabetes Insipidus

Diabetes insipidus can have a central, renal, or psychogenic origin. The central mechanism is the most common form found in ICU patients. The absence of ADH results in polyuria and polydipsia; the patient with a critical disease may not be able to meet the thirst requirement and may then develop severe hypovolemia. Diabetes insipidus can be precipitated by brain tumor, head trauma, neurosurgery, and clinical brain death. [258] [259] Treatment in the setting of the ICU is fluid replacement, or, if this is unwieldy, replacement of hormone with the following: aqueous Pitressin, 0.1 to 1.0 mL IM (duration, 4-6 h); Pitressin tannate in oil, 0.25 to 1.0 mL IM (duration, 24-72 h); desmopressin acetate intranasal, 2.5 to 10 mug bid (duration, 10-11 h). [260] The clinical syndrome may be transient or chronic, and close supervision of fluid intake and output is essential.

Syndrome of Inappropriate Secretion of Antidiuretic Hormone

The syndrome of inappropriate secretion of ADH describes hyponatremia and hypo-osmolality from inappropriate urinary losses of sodium and free water in patients with normal kidneys. Urine osmolality is greater than serum osmolality. This syndrome can be precipitated by a number of mechanisms, including head trauma, neurosurgery, meningitis, hypoxia, and any major surgical procedure with large volumes of fluid shifts and fluid replacement. [261] [262]

This disease is usually self-limited, and the only real problem occurs if the diagnosis is not considered and the level of hyponatremia is low enough to cause CNS dysfunction. Seizures are rare until the serum sodium is less than 120 mEq/dL. Care should be taken to raise serum sodium levels slowly. This syndrome is treated by fluid restriction and, in severe cases, with the infusion of hypertonic or isotonic saline.

Pancreas/Insulin

Hypoglycemia

Hypoglycemia is routinely anticipated as a potential problem in ICU patients. In children, hypoglycemia has been defined by a number of investigators. The definition suggested by Cornblath and Schwartz [263] is generally accepted: premature infants: blood sugar less than 20 mg/dL; term infants up to 3 days: blood sugar less than

30 mg/dL; and children older than 3 days: blood sugar less than 40 mg/dL.

The usual symptoms of hypoglycemia include the early changes of tachycardia, diaphoresis, and weakness, followed by mental clouding, seizures, and coma. [263] In children, hypoglycemia can be precipitated by a number of specific diseases not commonly encountered in the adult. Causes can be subdivided into disorders of increased utilization and disorders of decreased production. Transient hypoglycemia of the newborn from decreased or immature hepatic gluconeogenesis is a condition that self-corrects within hours to days. If the hypoglycemia persists, hepatic enzyme deficiencies, endocrine problems, or hyperinsulinism (i.e., pancreatic cell abnormalities, infants of diabetic mothers) must be considered. Other causes of hypoglycemia in the neonatal period include sepsis, hypothermia, hypoxia, and transplacental exposure to maternal hypoglycemic drugs.

In the older child, hypoglycemia is associated with ketotic hypoglycemia, [264] hepatic enzyme abnormalities, hyperinsulinism, hepatic failure, and Reye syndrome and as a side effect of certain drugs. [265] Regardless of cause, the initial treatment of hypoglycemia is the administration of adequate glucose. The initial emergency dose is 0.5 g/kg given as 50 percent or 25 percent dextrose in water. This should be followed by a dextrose infusion that meets the metabolic requirements of the child (see the later section on gastrointestinal system).

Diabetic Ketoacidosis

The most serious acute complication of diabetes mellitus is diabetic ketoacidosis (DKA), a syndrome of glucose and ketone overproduction and underutilization that results in hyperglycemic ketoacidosis. The clinical syndrome includes dehydration and hypovolemic shock resulting from the forced hyperglycemic osmotic diuresis, compensatory hyperventilation (Kussmaul pattern), life-threatening electrolyte depletion, and, in cases of severe metabolic imbalance, neurologic obtundation and coma. [266] The laboratory evaluation demonstrates elevated blood glucose concentrations, severe metabolic acidosis despite a compensatory hypocarbia, increased osmolality, hyperlipidemia, and a normal or low sodium level (usually fictitiously low because of the hyperlipidemia). There is total body depletion of potassium and possibly phosphate, but levels may be falsely normal because of the metabolic acidosis.

Treatment of DKA requires careful correction of the metabolic derangements with meticulous monitoring of the multisystem complications of DKA, as well as the complications of therapy. Adequate intravascular volume is restored with the administration of an isotonic glucose-free solution. Regular insulin is given as an intravenous infusion of 0.1 U/kg/h. The goal is to decrease the blood glucose at a rate of 75 to 100 mg/dL/h. This infusion is continued until the blood glucose reaches 250 to 300 mg/dL, at which time D_5 W is added to the infusate. [266] This regimen of simultaneous glucose and insulin infusion can be continued until the patient is able to tolerate oral nutrient intake and routine subcutaneous insulin administration. Most clinicians continue the insulin infusion until the acidosis is nearly corrected.

During any fluid administration, potassium should be closely monitored. These children have total-body potassium depletion, and potassium should be added to any infusion as soon as urine output is demonstrated. The addition of phosphate to the intravenous infusion is controversial. [267] The need for phosphate may be more theoretic than real, but in most situations, one-half the potassium is given as a phosphate salt. The severe metabolic acidosis is usually corrected with volume and insulin administration.

The use of bicarbonate is usually avoided because of concern of precipitating or worsening the patient's neurologic status. [268] In severe DKA, there is a tendency for brain cells to reduce their intracellular volume as the patient becomes dehydrated and hyperosmolar. In an attempt to maintain their normal size, brain cells generate osmotically active idiogenic osmoles. These particles attract more water into the intracellular compartment to help the cells retain their size. As systemic rehydration and correction of the hyperosmolar state begin, the brain cells tend to swell until the added idiogenic osmoles are metabolized or cleared. Consequently, rapid osmolar correction can lead to significant brain edema. [269] In addition, rapid correction of the metabolic acidosis may produce worsening neurologic dysfunction. The pH of the brain is determined by the CSF bicarbonate level as well as by the CO_2 content; the CSF CO_2 content equilibrates much more rapidly than the bicarbonate does with the vascular space. Therefore, with systemic correction of the acidosis, respiratory hyperventilation decreases, causing a rise in the Pa_{CO_2}; if this rise is precipitous, there could be a worsening of the CSF acidosis until the increased bicarbonate equilibrates with the CSF space. Because rapid correction of pH is problematic, bicarbonate administration is not advocated in DKA unless there is cardiovascular instability. Even then, the doses administered are small. Unfortunately, despite very careful and slow correction of the hyperosmolar and acidotic state, hyperosmolar coma with fulminant brain edema can occur. [270] The pathophysiology of brain swelling in DKA is poorly understood. There is radiographic evidence that subclinical brain swelling may in fact be relatively common in children with DKA. [271] If the swelling is significant, the therapeutic approach is to administer mannitol immediately and to begin therapy for intracranial hypertension.

GASTROINTESTINAL SYSTEM

Gastrointestinal (GI) problems in the ICU include organ dysfunction and organ failure from acquired disease as well as congenital anatomic malformations and dysfunction. In addition, delivery of adequate nutrition is perhaps the most critical concern in the care of the critically ill patient.

Structural and Functional Development of the Intestine

An understanding of fetal midgut development makes it easier to understand a number of severe congenital anomalies. Although the intestine begins as a hollow tube that is occluded by rapidly growing epithelial cells by 7 to 10 weeks' gestation, this central lumen is later reconstituted when vacuoles within the epithelial cells coalesce. Some of the neonatal intestinal atresias result from abnormalities of this recanalization process. At 3 to 10 weeks' gestation, the midgut lies outside the abdominal cavity, with only the hindgut fixed in the left side of the abdomen. The gut rotates 270 degrees counterclockwise and reenters the abdominal cavity at 10 weeks' gestation. If the midgut fails to migrate back into the abdominal cavity, an omphalocele results. Abnormalities of midgut rotation result in abnormal intra-abdominal relationships, the most important being malrotation volvulus of the intestine. [272]

Development of the Liver

The liver begins as an outgrowth of the foregut ectoderm at approximately 3 weeks' gestation. During fetal life, the liver is relatively large compared with the adult liver. Although the fetus relies on the maternal liver and placenta for detoxification and excreting function *in utero,* the fetal liver is necessary for both prenatal and postnatal survival. As early as 10 to 12 weeks' gestation, the fetal liver is involved in glucose regulation, protein synthesis, lipid synthesis, and some drug metabolism.

Fetal stored hepatic glycogen is approximately three times that of the adult, but it is nearly completely released within several hours of birth to compensate for interruption of the placental supply of nutrients. [273] It takes several weeks for the newborn to restore the liver's stores of glycogen, thus putting the infant at risk of hypoglycemia if any stressful event occurs during this vulnerable period.

Congenital Malformations

Gross anatomic malformations are usually diagnosed during the first few days of life. Some are apparent on initial physical examination, such as omphalocele, gastroschisis, diaphragmatic hernia, and imperforate anus. Others present in the first few days of life as enteral feeding failures, intestinal atresias, microcolon, tracheoesophageal fistula, and meconium ileus. Other malformations present difficult diagnostic and therapeutic dilemmas after the neonatal period. Specific clinical problems are discussed in the following sections.

Intestinal Malrotation and Midgut Volvulus

Malrotation of the intestine is related to the incomplete rotation of the fetal midgut during migration into the abdominal cavity. This abnormal rotation can lead to either partial or complete duodenal obstruction by peritoneal (Ladd) bands or, more important, to volvulus of the midgut. [274] The midgut (duodenum to transverse colon) and its vascular supply hang on a single pedicle; if this twists, vascular infarction of the entire midgut can result. [275] Infants with omphalocele almost invariably have associated malrotation. Symptomatic infants and children usually present with signs of high intestinal obstruction (bilious vomiting) or signs of an acute abdomen, intestinal perforation, and sepsis.

Treatment is surgical reduction and fixation of the volvulus with resection of nonviable bowel. Postoperative respiratory support and total parenteral nutrition are often required in those infants who were severely compromised before surgery.

Meckel Diverticulum

Meckel diverticulum represents a persistence of the omphalomesenteric or vitelline duct that clinically comes to attention as a cause of painless lower GI bleeding. [276] The site of bleeding is an ulceration in the bowel mucosa caused by secretion of gastric acid. Although these hemorrhages are usually self-limited, massive and life-threatening hemorrhages have been reported. [277] The diagnosis is often one of exclusion and can be difficult to make. The technetium-pertechnetate isotope scan is helpful only if there is gastric mucosa in the diverticulum. Therapy is supportive, with particular attention paid to blood replacement. The definitive therapy is surgical resection.

Hirschsprung Disease

Hirschsprung disease (congenital aganglionic megacolon) is characterized by absence of the parasympathetic ganglion cells in varying distal lengths of the rectum and colon. [278] The lack of these ganglion cells produces a relatively narrowed segment of bowel: the normal proximal bowel becomes distended. The resultant clinical symptoms can be relatively minor, with abdominal distention and stool retention, or severe, with toxic megacolon, peritonitis, and perforation. Toxic megacolon usually presents in the younger child; reported mortality rates are as high as 75 percent. [279]

The diagnosis of Hirschsprung disease can sometimes be made on the basis of history and physical examination. Barium enema should reveal a narrowed segment with ballooning of the proximal bowel. The definitive diagnosis is made by rectal/colon biopsy with observation for the presence or absence of ganglion cells. Treatment of toxic megacolon is both supportive, with meticulous volume reexpansion and antibiotic coverage, and definitive, with surgical decompression by creating a colostomy in the region of normal bowel.

Other Intestinal Disorders

Intestinal disorders can produce bleeding, obstruction, or inflammation with secondary problems of malabsorption and bowel perforation. GI bleeds in children are caused by inflammatory diseases (gastritis), ulcers, varices, or vascular malformations. Although ulcer disease is an uncommon presenting complaint in the pediatric patient, the problem of stress ulcer or stress gastritis must be anticipated in any critically ill child. Prophylactic antacids or a histamine II antagonist should be considered. Bowel obstruction can occur from intussusception, twisting of the bowel around congenital or postsurgical bands, and twisting of the bowel on itself (volvulus). Intussusception is relatively common in the pediatric age group and usually occurs in the distal ileum. Only in a few cases can a leading point be identified, such as a polyp or localized edema, as seen in Henoch-Schonlein purpura. The treatment of intussusception can be surgical, or, if there is no evidence of necrotic

bowel, many lesions can be successfully decompressed with a carefully manipulated barium enema. [280] Inflammatory bowel diseases include Crohn disease and regional enteritis. [281] [282] Infectious agents that must also be considered include *Salmonella, Shigella,* and *Yersinia.*[283] These patients can present with diarrhea, evidence of malabsorption, especially with lactose intolerance, and bloody diarrhea. They can also present with a toxic acute abdomen.

Necrotizing Enterocolitis

A specific disease that merits separate discussion is necrotizing enterocolitis, commonly referred to as NEC. This fulminant neonatal disease is characterized by ulceration and necrosis of the small bowel and colon. It has been reported to occur in 2.4 per 1,000 live births. [284] The cause is unknown, but most hypotheses suggest bowel ischemia as the main precipitating factor. Umbilical artery catheters, perinatal asphyxia, respiratory distress syndrome, and persistent patent ductus arteriosis have all been implicated. [285] Most children have had enteral feedings before clinical NEC develops: some investigators suggest that specific pre-existing bowel flora carries a risk of the disease. [286] Feeding intolerance, abdominal distention, and bloody stools are the most common presenting signs. Intestinal obstruction, perforation, and sepsis may follow. Treatment consists of withholding enteral feedings, administering appropriate antibiotics, and surgical exploration if an acute abdomen with free air is evident. Total parenteral nutrition is often required for several weeks, and intestinal obstruction can occur weeks to months after a relatively benign course. [287] [288]

Hepatic Failure

Hepatic failure can occur in patients with chronic or acute liver disease. The causes and clinical presentations differ: chronic liver failure can be caused by biliary atresia, inborn errors of metabolism (tyrosinosis, Wilson disease, galactosemia, cystic fibrosis), or chronic inflammatory hepatitis. Children with chronic disease often present with the signs and symptoms of synthetic dysfunction (malnutrition, hypoalbuminemia, abnormal coagulation), degradation dysfunction (icterus and hyperammonemia), and portal hypertension (hypersplenism and varices). Acute liver failure is most commonly caused by infectious hepatitis, types A and B. Toxic hepatic failure is a close second. [289]

The physical examination is important for the identification of liver and spleen size and for evidence of bleeding, edema, and other organ dysfunction. The laboratory evaluation should include a screen of the synthetic function (albumin, prothrombin [PT], partial thromboplastin time [PTT]), a degradation screen (bilirubin, ammonia), and values of all the liver enzymes. Hepatic ultrasound, radiographic contrast studies, and liver biopsy are indicated on an individual basis.

The life-threatening complications of liver failure include acute bleeding, cardiovascular compromise secondary to

massive intravascular hypovolemia from fluid shifts, and intracranial hypertension from the toxic encephalopathy. Treatment is expectant and supportive. A 10 percent dextrose infusion is used to guarantee an adequate carbohydrate supply. Low-protein diets tend to minimize ammonia production. Coagulation is supported with the administration of vitamin K, fresh frozen plasma, and platelets as required. Plasmapheresis with fresh frozen plasma and platelets can be used to improve coagulation while maintaining normovolemia. Oral lactulose and neomycin enemas are given in an attempt to decrease the enterohepatic cycle of ammonia production and absorption. [290] Cardiovascular and respiratory function should be closely monitored and supported as required.

It is important to anticipate the complication of intracranial hypertension. Serum ammonia levels are often used to monitor or track the neurologic dysfunction, [290] [291] but it is important to remember that it is unknown whether the ammonia is the primary CNS toxin or is just one of many chemical markers. There are other specific and controversial therapies as well. Steroids have been proposed for some forms of inflammatory hepatitis. Exchange transfusions and plasmapheresis have been advocated to decrease the toxin load, [290] and although they have had variable results, to date no strong evidence indicates that morbidity and mortality are changed with these interventions. Patients with certain forms of acute hepatic failure, including that resulting from toxic as well as infectious causes, may be considered candidates for liver transplantation. [292]

Extrahepatic Biliary Atresia

Extrahepatic biliary atresia occurs once in every 8,000 to 10,000 live births. [293] The atresia differs from patient to patient, involving variable degrees of obstruction or discontinuity of the biliary tree between the duodenum and the proximal branches of the hepatic ducts. The treatment is surgical (jejunal Roux-en-Y, and portoenterostomy) and is tailored to the amount of extrahepatic bile duct architecture present. These Kasai procedures are most successful in patients operated on at an early age (before 6-9 mo). [294] There are many acute and chronic complications of this surgery, including hepatic failure, ascending cholangitis, and cirrhosis with portal hypertension and varices. Despite these complications, the Kasai procedure persists because of the scarcity of suitable donor organs.

Liver Transplants

Improved immunosuppressive drugs and surgical technique have increased interest in and the success of liver transplantation. The perioperative and postoperative periods require a coordinated approach of many disciplines: surgery, gastroenterology, anesthesia, immunology, and ICU staff. Reports to date suggest that although these children are critically ill, they do not pose unique clinical problems. Most of the clinical issues that arise can be anticipated. These children experience large blood losses and require massive replacement therapy in the operating room. Because of this situation, the intravascular volume status, renal status, and hematology/coagulation profiles must be closely monitored, and basic liver failure therapy is indicated. The immunosuppression required for graft survival puts the patient at risk of infection, with both "normal" and opportunistic organisms. Surveillance cultures and early aggressive antibiotic therapy are indicated. Perhaps the only unanticipated complication has been systemic hypertension, which appears unrelated to elevated CVP or pulmonary capillary wedge pressure. Many patients have required aggressive therapy (hydralazine, diazoxide, captopril). [295] [296]

Nutritional Support in the Critically Ill Child

Adequate nutritional support of the child with critical disease is of paramount importance because it can decrease morbidity and mortality (Ch. 74) . It is essential to try to meet the caloric and mineral requirements of these patients. The nutritional requirements for healthy children have been defined, but the requirements of critically ill children are less well understood; the measurements of oxygen consumption and nitrogen balance are not easy bedside maneuvers.

Even when caloric needs can be ascertained, it can be difficult to deliver adequate amounts because of extenuating circumstances, such as bowel compromise, severe fluid restriction for either renal or CNS disease, and glucose intolerance. Therefore, all avenues of nutrition (enteral and parenteral) must be explored, and nutritional intervention must be implemented early, before a catabolic state ensues.

The use of the GI tract for alimentation is usually the safest and most efficient approach. Numerous commercial formulas with variable sources and quantities of protein, fat, and carbohydrate are available. Protein requirements can be met by using whole protein, protein hydrolysates, or individual amino acids. Whole protein, which has the least osmotic effect, allows for greater nutrient density. However, it can only be used in children with normal pancreatic function and no allergy. Children with protein allergy, pancreatic deficiency, or severe intestinal mucosal disease may benefit from a protein hydrolysate. However, these formulas have high osmolarity. Free amino acid formulas are also available and are used in chemically defined diets restricted by specific requirements or intolerances.

The high caloric density of fat makes it an important component in nutritional support. A long-chain triglyceride (LCT) yields approximately 9 kcal/g, whereas a medium-chain triglyceride (MCT) yields 8.3 kcal/g. Although of greater caloric density, LCTs are less readily absorbed. MCTs are hydrolyzed more rapidly and are converted almost exclusively into free fatty acids and glycerol. MCTs are absorbed even in the absence of lipase, because of their relative water solubility and emulsification properties. However, there are drawbacks. For example, MCTs may cause osmotic diarrhea, and they contain no essential fatty acids, so that linoleic acid must be added to the diet separately. [297]

Secondary disaccharidase deficiency is a common carbohydrate absorption problem in the critically ill child. Lactase function is easily impaired by hypoxia and ischemia, as well as by infection and malnutrition. [298] In these situations, lactose should be avoided and replaced with sucrose or polycose,

which have the least osmotic effect. Enteral feedings can be delivered orally, through a nasogastric tube or a gastrostomy tube. Children with ETT in place can be safely fed through a nasogastric tube; the risk of aspiration is minimized by using continuous infusion of formula rather than bolus feedings and by placing the child in an upright semisitting position. Opioid analgesics and muscle relaxants hinder enteral feeding; if possible, these groups of drugs should be avoided.

Parenteral Alimentation

Parenteral nutrition is used in children who cannot tolerate enteral feedings. It is used as supportive therapy in the critically ill child with acute respiratory or GI disease and as primary treatment in children with chronic short bowel syndrome, Crohn disease, and renal failure.

Procedure for Implementation of Parenteral Nutrition in Children

When intravenous alimentation is considered, $D_{10}W$ is administered at 1 to 1.5 maintenance for 24 hours. The patient is closely monitored for glycosuria, hyperglycemia, and edema. If glucose load is tolerated, a $D_{10}W$ solution with amino acids (PN-10) can then be initiated. Administration of $D_{10}W$ with or without amino acids can be done safely through either a central or a peripheral catheter. Any more concentrated formula causes sclerosis of peripheral veins and therefore must be given through a centrally placed line. If a central line has been placed and the patient is tolerating the relatively high glucose loads of 1.5 maintenance with PN-10 or $D_{10}W$, one may switch to PN-20 and simultaneously decrease the fluid rate to maintenance, to permit accommodation to the higher glucose load. The PN-20 is then advanced over 2 days, to the 1.5 maintenance rate. The patient should gain relatively little weight until 1.5 maintenance with PN-20 is achieved. [299] In general, if a patient is malnourished (<0.80 weight for height), fluid rates must be adjusted downward to roughly 80 percent of those for children of the same weight. After 1 week of nutritional rehabilitation, regular maintenance fluids may be used (Table 73-15) .

Often, the physician has determined a different maintenance fluid rate for a particular patient on the basis of previous intake/output data. If this is the case, the patient should be started on $D_{10}W$ at the low side of the maintenance rate and advanced to the maximum tolerable rate. When switching

TABLE 73-15 -- Maintenance Fluid Rates in Pediatric Patients on Parenteral Nutrition

BODY WEIGHT	REGULAR MAINTENANCE (mL/kg/d)	MALNOURISHED MAINTENANCE (mL/kg)
1st 10 kg	100	80-90
2nd 10 kg	50	40
Wt > 20 kg	20	20

to $D_{20}W$, the low rate is again used, and the advance in rates is repeated. Initial fluid and electrolyte deficits and ongoing losses (e.g., diarrhea) should not be repleted with parenteral nutrition solutions. A separate intravenous solution and line should be used for these extra losses. It should be adjusted every 8 hours to equal the patient's output. If a patient has severe hypoalbuminemic or edematous malnutrition, or both, great care must be exercised in the management of fluid status. Edema, hypervolemia, and hypovolemia may develop rapidly in these patients. [300]

Intravenous Lipid Alimentation

Lipid in Central Intravenous Alimentation

With central intravenous alimentation, lipid is necessary only to prevent essential fatty acid deficiency and should be given at 5 to 10 percent of the total calories. [301] The following fluid rate permits rough determination of the lipid rate necessary to prevent essential fatty acid deficiency during central intravenous alimentation: 5 to 10 mL/kg for the first 10 kg, 2.5 to 5 mL/kg for the second 10 kg, and 1.25 to 2.5 mL/kg for weight greater than 20 kg. Lipids are usually introduced a number of days after parenteral nutrition has been started. There are multiple reasons for withholding lipid during the initiation of intravenous alimentation. First, the tolerance of lipid products is improved if the patient has been primed by a period of adequate caloric intake. Second, fatty acids may impair the patient's tolerance of the large dextrose load. When increasing dextrose administration, the simultaneous introduction of fat products may confuse the interpretation and treatment of glycosuria. Lipemia checks should be done whenever lipid is used.

Lipid in Peripheral Intravenous Alimentation

With peripheral intravenous alimentation (10% concentration), the lipid product must constitute a major component of the caloric intake, because it is the only isomolar product of sufficient caloric density to provide significant caloric intake by peripheral vein. Thus, once the patient receiving peripheral alimentation has reached a maximum rate of PN-10, Intralipid may be added at a rate of 10 mL/kg/d and advanced by 10 mL/kg/d, to a maximum of 40 mL/kg/d. However, lipid calories must not exceed 60 percent of the total calories. [302] Lipid clearance may be facilitated by administering lipid continuously over 24 hours. Serum lipemia is monitored daily during lipid administration. For calculations, the caloric densities shown in Table 73-16 may be used.

Peripheral Versus Central Alimentation: Energy Considerations

Peripheral intravenous alimentation is a stopgap measure that rarely permits caloric intakes in excess of maintenance requirements. Therefore, there are few extra calories for growth and repletion. Peripheral intravenous alimentation should be limited to 2 weeks' duration. By contrast, central

TABLE 73-16 -- Calculated Caloric Density of Lipid Products Used in Pediatric Peripheral Intravenous Alimentation

LIPID PRODUCT	CALORIC DENSITY
Amino acids	3.33 cal/g
10% dextrose	0.34 cal/mL
20% dextrose	0.68 cal/mL
PN-10	0.39 cal/mL
PN-20	0.73 cal/mL
Lipid 10%	1.1 cal/mL
Lipid 20%	2.0 cal/mL

alimentation can provide caloric and nitrogen requirements for both growth and maintenance. However, an increased risk of infection is associated with the prolonged use of indwelling catheters. [303]

Caloric requirements represent the energy intake necessary for maintenance, growth, and activity. Whatever net energy is left after allowance for maintenance and activity is available for growth. The caloric cost of growth is at least 5 cal/g weight. Normal growth is approximately 25 to 30 g/d for the first 6 months of life, 10 to 15 g/d for the next 6 months, and roughly 7 to 10 g/d thereafter. Representative maintenance energy requirements for the nonstressed state are listed in Table 73-17 . Using these data, intravenous alimentation can be adjusted to produce normal or moderate catch-up growth rates. Weight gain in the face of inadequate caloric intake

(less than maintenance) inevitably means edema. If the goal of nutritional therapy is merely supportive over 1 to 2 weeks, growth may not be necessary, and peripheral alimentation may therefore be adequate. If significant catch-up growth or long-term support is required, the child's growth and activity requirements should be met. [300]

Monitoring of Children on Total Parenteral Nutrition

Careful assessment of intake, output, and body weight should be made on a daily basis. The site of alimentation, either peripheral or central, should be evaluated regularly for signs of obstruction, extravasation, or occlusion. Skin and mucous membranes should be evaluated regularly for evidence of trace metal deficiency. Liver size and function must be monitored: intrahepatic cholestasis, excessive fat and glycogen deposition, and elevated liver function tests have been documented in patients receiving parenteral nutrition.

TABLE 73-17 -- Maintenance Energy Requirements for Nonstressed Patients

AGE (y)	MAINTENANCE ENERGY (kcal/kg/d)
<2	75-80
2-5	70-75
5-10	55-70
10-17	40-55
Adult	40

Other metabolic studies should include routine screening of electrolytes, glucose, blood urea nitrogen, and creatinine, as well as ammonia. A serum lipemia check should be done daily. Total protein, albumin, hemoglobin, and triglycerides should be checked regularly but less frequently. [302]

Outcome

A child's survival obviously depends on adequate nutritional intake. It has been shown that an infant with a nonfunctioning gastrointestinal tract can survive on total parenteral nutrition for years, but this is clearly a stopgap measure. [304] The risk of complications from central vein cannulation increases with time, and vascular access in the child becomes increasingly limited as sites are used. Attention to alimentation has improved outcome in the ICU. Although difficult to quantify, it is our impression that children with any critical illness benefit from improved nutritional intake, with faster recovery and decreased morbidity.

HEMATOLOGY

Hematologic emergencies in the ICU include abnormalities of coagulation, immunity, and the red blood cell (RBC) mass. These abnormalities can be primary isolated defects, or they can be secondary to multiorgan system failure. The immune system is discussed in the section on infectious disease.

Coagulation System

Normal clotting includes an initial phase of platelet hemostatic plug formation and a second stage of fibrin production that occurs by either the intrinsic or extrinsic pathways (Fig. 73-2) (Figure Not Available) . For both phases to occur, platelets, coagulation factors, and an intact blood vessel are essential. [305] Neonates have a number of measurable coagulation abnormalities that rarely have clinical manifestations. Term infants and most preterm infants show normal platelet-vessel interaction, but platelet aggregation is transiently impaired. In addition, many coagulation factors are decreased in activity or concentration in the fetus and in the newborn. Of greatest importance are the vitamin K-dependent factors: factors II, VII, IX, and X. These are low at birth and fall to even lower levels during the first week of life unless vitamin K is administered. Factors V and VIII are close to adult levels in all but the most premature infants. Although routine screening tests for coagulation activity are prolonged in infants, the newborn's blood clots more rapidly *in vitro,* owing to a deficiency of naturally occurring protease inhibitors, principally antithrombin III. [305]

Diagnosis of Hemostatic Disorders

Coagulation disorders are diagnosed on the basis of history, physical examination, and laboratory data. It is important to elicit any history of easy bleeding, bruising, drug ingestion,

Figure 73-2 (Figure Not Available) Scheme of blood coagulation. The suffix a denotes the activated factor with enzyme activity. PK, prekallikrein; HMWK, high-molecular-weight kininogen. *(Modified from Hathaway [305])*

associated illnesses, or a family history of bleeding. The patient should be closely examined for evidence of petechiae or bruises, bleeding gums, or hepatosplenomegaly. Any sites of bleeding or venipuncture should be observed for fresh clot or oozing. The laboratory evaluation of PTT, PT, thrombin time, platelet count, and bleeding time gives valuable information on the nature of the hemostatic defect.

Specific Coagulation Disorders

Congenital Disorders

Hereditary deficiencies of most of the coagulation factors are described, but classic hemophilia (factor VIII) and Christmas disease (factor IX) account for the majority (Ch. 25) . Since the advent of modern factor replacement therapy, these disorders only rarely cause life-threatening hemorrhage requiring ICU management. [306]

Factor VIII Deficiency or Hemophilia A.

Factor VIII deficiency or hemophilia A is transmitted by sex-linked recessive inheritance and occurs in 1 in 10,000 male infants. The severity of the clinical disease is determined by the amount of circulating factor: severe disease is associated with less than 1 percent of normal levels, moderately severe disease with 1 to 5 percent, and very mild disease with 5 to 30 percent of normal levels. The most common sites of bleeding are the joint spaces, but hemorrhage may also occur in the peritoneal cavity, gastrointestinal tract, muscle, skin, or CNS. Severe trauma or surgery can cause extensive bleeding. The diagnosis is made by demonstrating an elevated PTT and decreased levels of factor VIII. Treatment requires administration of factor VIII in the form of plasma-derived or recombinant proteins. There is a wide variety of products available for the treatment of hemophilia A. [307]

von Willebrand Disease.

von Willebrand disease occurs nearly as commonly as hemophilia A and is transmitted to both sexes by an autosomal dominant inheritance. It is characterized by abnormalities of the factor VIII molecule, as well as by qualitative platelet dysfunction. Skin and mucous membrane bleeding, particularly nosebleeds and menorrhagia, are the most frequent clinical problems. The PTT and bleeding time are prolonged in this disorder, as are some tests of platelet function. Desmopressin can be used to increase plasma von Willebrand factor and factor VIII concentrations 2- to 5-fold. Cryoprecipitate or other plasma derivatives of von Willebrand factor can be used in patients unresponsive to desmopressin and in patients in whom severe bleeding occurs. [308]

Hereditary Thrombocytopenia.

Hereditary thrombocytopenia is an uncommon congenital defect. Most cases are associated with the familial sex-linked immunodeficiency diseases such as Wiskott-Aldrich syndrome. [309] Platelet transfusions are given to control clinical bleeding.

Acquired Disorders

A variety of circumstances can impair the production of coagulation factors. The vitamin K-dependent factors are the most commonly affected. [310] These factors are decreased in the presence of liver disease, warfarin therapy, and malabsorption syndromes secondary to either bowel disease or altered bowel flora with long-term antibiotic therapy. In addition, untreated vitamin K deficiency in the neonatal period results in hemorrhagic disease of the newborn. In these disorders, the PT is prolonged, and specific assays demonstrate low levels of factors II, VII, IX, and X. The administration of vitamin K usually reverses these deficiencies unless synthetic function of the liver is markedly compromised.

Acquired platelet abnormalities include problems of decreased production, increased destruction, and decreased function. Decreased production or hypoproliferative states include marrow diseases such as leukemia and aplastic anemia and, perhaps most commonly, side effect of chemotherapeutic

agents. Increased destruction can be immune mediated (i.e., idiopathic thrombocytopenic purpura [311]) or from consumption (i.e., microangiopathic states, HUS, or thrombotic thrombocytopenic purpura [312]). Finally, platelet dysfunction has been demonstrated in the presence of uremia and chronic polycythemia seen in patients with cyanotic heart disease. [309] [313]

Treatment of all the acquired thrombocytopenias includes platelet transfusions and, if possible, correction of the underlying disorder. Therapeutic splenectomy has been used to increase platelet survival in some of the severe immune-mediated diseases.

DIC is characterized as a consumptive coagulopathy with decreased platelets and fibrinogen, increased PT, PTT, and thrombin time, and an elevation of fibrin degradation products. DIC complicates a number of nonspecific conditions: sepsis, anaphylaxis, shock, acidosis, massive tissue trauma, sickle cell disease, and certain malignancies, particularly acute myelogenous leukemia in childhood. [314] Purpura fulminans is a particularly severe type of DIC associated with ecchymosis and thrombosis of the skin, subcutaneous tissue, and distal extremities. This condition is seen with acute meningococcemia as well as with other bacterial, viral, and fungal septicemias. Purpura fulminans is associated with a high morbidity and mortality; the main morbidity is the ischemic loss of distal extremities. [315]

Treatment of DIC consists of removing the triggering event whenever and as soon as possible. General support of the vascular volume and oxygen transport is essential. When active bleeding is present, transfusion of platelets (0.2 U/kg) and fresh frozen plasma (10 mL/kg) every 4 to 6 hours as a bolus or continuous infusion will replenish platelet and clotting factors, as well as coagulation antagonists such as antithrombin III. Heparin has been advocated by some clinicians; however, it has not been shown to improve outcome and may enhance clinical bleeding. Transfusion with factor concentrates may be helpful when fresh frozen plasma therapy is limited by intravascular hypervolemia. Occasionally, exchange transfusion with fresh whole blood or plasma exchange/plasmapheresis with fresh frozen plasma and platelets may be necessary to treat severe DIC effectively. [316] [317] [318]

Red Blood Cell Abnormalities

RBC abnormalities include either a decrease in the RBC mass or the presence of abnormally functioning RBC. The RBC mass is reduced by either decreased production or increased loss. Decreased RBC production is associated with factor deficiencies (iron, folate, vitamin B_{12}), bone marrow disease (aplastic anemia, leukemia), chronic diseases (infection, neoplasm, renal disease), and rarely, a congenital deficiency of RBC precursors (Diamond-Blackfan syndrome). [319] RBC loss is either extracorporeal blood loss (hemorrhage) or cell destruction (hemolysis). Hemolysis can be caused by intrinsic RBC abnormalities or by extrinsic factors. Intrinsic anomalies include membrane defects (spherocytosis, elliptocytosis), enzyme defects (glucose-6-phosphate dehydrogenase, pyruvate kinase deficiencies), and hemoglobinopathies (hemoglobin S, C, D, E, and thalassemia). The extrinsic abnormalities can be immune mediated or infection and toxin mediated, or they may occur secondary to microangiopathic destruction. [320]

Regardless of cause of RBC mass decrease, the signs, symptoms, and therapy depend on the acuity and severity of the blood loss. The acute loss of massive amounts of blood (hemorrhage) can cause hypovolemic shock. Treatment consists of oxygen and emergency intravascular volume reexpansion and ultimately replacement of RBC. In the absence of hypovolemia, acute and chronic RBC loss is tolerated until there is a critical loss of oxygen-carrying capacity, which results in high-output cardiac failure. Treatment of these severe anemias includes oxygen and replacement of the RBC mass, which should be done cautiously and slowly in an attempt to avoid the complications of fluid overload. Partial exchange transfusions are sometimes necessary to deliver an adequate RBC load safely.

The main functional abnormality of the RBC is an inability to carry oxygen; sulfhemoglobinemia and methemoglobinemia are the most common of these abnormalities. Methemoglobinemia and sulfhemoglobinemia can be either congenital or acquired disorders that produce hemoglobin that cannot bind oxygen. The congenital forms are usually asymptomatic and require no therapy, but the acquired or toxic forms may be fatal. Treatment includes oxygen, intravenous administration of methylene blue, and occasionally exchange transfusion. [321]

Complications of Transfusion Therapy

Although the administration of blood products can be lifesaving, a number of potential complications should be anticipated (Ch. 46) . Whenever massive transfusion therapy is employed, the risks of citrate toxicity, transfusion reactions, and leukocyte and platelet sensitization must be kept in mind. In addition, depending on the age and type of blood component being employed, electrolyte disturbances such as hypocalcemia, hyperkalemia, and hypernatremia can occur. Whenever in doubt, a sample of the infusate should be sent for electrolyte analysis, and the patient's serum values of electrolytes and ionized calcium should be followed during therapy. [322] Transfusion-acquired infections, including hepatitis, cytomegalovirus, and acquired immunodeficiency syndrome (AIDS), have decreased with improvements in the screening of blood donors and extensive testing of units of blood. [323]

Finally, hemochromatosis complicates the care of those patients who require long-term transfusion therapy for the treatment of an RBC abnormality. Efforts designed to decrease this often lethal complication include aggressive iron chelation therapy and the selective transfusion of young RBCs in an attempt to increase the time interval between required transfusions. [324] [325]

In addition to RBC loss and abnormal oxygen binding, grossly deformed RBCs can cause vaso-occlusive disease. Sickle cell anemia is the best example of this pathophysiology. Sickle cell anemia is a hemoglobinopathy. The major ICU complication is vaso-occlusive disease that can present as a painful crisis; if the vaso-occlusion occurs in the cerebral

---

vessels or in another vital organ supply, it can present as a stroke or infarction. [326] Vaso-occlusive disease of the lung is referred to as acute chest syndrome and presents clinically as ARDS. Treatment consists of hydration, oxygen, and, when severe, exchange transfusion and mechanical ventilation. [327] The other potentially fatal crisis of sickle cell disease is splenic sequestration, which occurs in infants and young children who have not undergone autosplenectomy. Splenic sequestration presents with severe anemia and hypovolemic shock. The treatment is aggressive supportive therapy with emergency surgical splenectomy. [328] Other children with sickle cell disease have usually had a functional autosplenectomy from multiple splenic infarcts. These "splenectomized" children are at risk of severe infection from encapsulated organisms. Routine pneumococcal vaccine is administered as a precaution. [329]

ONCOLOGY

Neoplastic disease in the child usually involves the hematopoietic system, the CNS and sympathetic nervous system, and soft tissue, bone, and kidney. Although much of oncology has become an outpatient subspecialty, some clinical situations do require hospitalization and intensive care.

Blast Crisis in Leukemia

Children who present with an initial WBC count of more than 100,000 are at a high risk of two potentially lethal complications: leukostasis and metabolic crisis (tumor lysis syndrome).

Leukostasis

Leukostasis is a syndrome of vascular obstruction caused by the high viscosity of elevated cell counts or by the WBC themselves. This syndrome should be anticipated in acute lymphoblastic leukemia patients with presenting WBC counts of more than 500,000 and in acute myelogenous leukemia (AML) patients with WBC counts of more than 200,000. The leukemic cell in AML is less deformable than the lymphoblast; therefore, in AML, a relatively lower WBC can produce the same syndrome. [330]

The two major target organs for leukostasis are the brain and the lung; the pathophysiologic feature is vascular plugging, causing infarct. Presenting symptoms include tachypnea, cyanosis, increased work of breathing, altered mental status, and focal neurologic deficits. In addition to supportive therapy, the goal is to decrease the circulating tumor load and thereby to decrease the viscosity. Leukophoresis and exchange transfusion transiently lower the tumor mass. Cranial radiation may reduce the CNS load, and chemotherapy interrupts cell production and possibly destroys circulating cells. The initial chemotherapy is aimed at stopping cell production without a large amount of cell lysis; this gives the advantage of halting a continually growing tumor load without causing a huge metabolic crisis before adequate perfusion is reestablished. [331] [332] [333]

Tumor Lysis Syndrome

Tumor lysis syndrome is a metabolic crisis precipitated by acute lysis of a large tumor load. The main abnormalities that result are elevations in uric acid, potassium, and phosphate; the elevated phosphate results in hypocalcemia. The hyperkalemia and hypocalcemia can be life-threatening; the increased uric acid causes acute renal failure, which further exacerbates the other metabolic imbalance. [334]

Specific therapy is anticipatory monitoring with alkalinization of the urine and diuresis. Before any chemotherapy is administered, the patient's renal function should be assessed and allopurinol therapy should begin. In most cases, this conservative approach of a forced diuresis and allopurinol is adequate, but occasionally dialysis must be used. Basic indications at our institution for the initiation of dialysis include the following:

1. Potassium > 6 mEq/L and rising despite resin exchange
2. Uric acid > 19 mg/L
3. Creatinine > 10 mg/L
4. Phosphorus > 10 mg/L or rapidly rising
5. Volume overload
6. Symptomatic hypocalcemia

If dialysis is necessary, it is usually only needed for a few days until tumor lysis is nearly complete.

Respiratory Distress and Mediastinal Mass

Children with a mediastinal mass and respiratory distress present a difficult therapeutic and diagnostic dilemma. These children often complain of cough, difficulty in breathing, stridor, and shortness of breath. They prefer to sit upright and cannot tolerate supine positioning. The chest radiograph usually shows a large mediastinal mass, often with obliteration or obscuring of the tracheal air column. These tumors can be either malignant (87% Hodgkin's and non-Hodgkin's lymphoma) or benign; the prognosis and therapy rely on an adequate diagnosis. The diagnosis is best made by tissue sampling prior to any therapy. [335] However, a problem may result because tissue sampling of a mediastinal mass requires anesthesia and surgery; by necessity, the airway must be manipulated and instrumented.

The obstructed intrathoracic trachea presents a major anesthetic risk; it is often impossible to maintain such an airway with the patient supine, deeply anesthetized, or receiving muscle relaxants. [336] Care of these patients clearly requires individualized and creative approaches. If the airway compromise is severe, blind tumor therapy at the expense of obscuring the tissue diagnosis must precede any diagnostic procedure. Mediastinal radiation and systemic steroids are the two modes of emergency therapy most commonly administered. Sometimes, this diagnostic dilemma can be circumvented; peripheral nodes or masses can undergo biopsy using local anesthesia or, if the tumor mass is very large, some of the tumor may remain outside the radiation field. In summary, although diagnosis is the key to neoplastic disease, mediastinal mass is one situation

in which the risk may far outweigh the benefit of tissue diagnosis.

Fever and Neutropenia

The most common admission diagnoses for children with neoplastic disease are fever and neutropenia. The neutropenic immunocompromised state caused by chemotherapy is a high-risk period for life-threatening infections.

INFECTIOUS DISEASE: LIFE-THREATENING INFECTIONS IN THE INFANT AND CHILD

Infections in the Newborn

The newborn has an increased susceptibility to infection as a result of a number of developmental immunologic deficiencies. Depressed cell-mediated immunity renders the fetus and infant more susceptible to viral and fungal infection. In addition, infants have depressed B-cell function with diminished production of immunoglobulins. One protective compensatory mechanism is the active transplacental transfer of maternal immunoglobulin G (IgG), which gives neonates a reasonable amount of IgG at term. At 2 to 3 months of age, however, the level of maternal antibodies reaches a nadir before the infant adequately assumes antibody production. [337] This time of relatively low levels of circulating antibody is a time of increased risk.

A discussion of perinatal infections can be divided into congenitally acquired and postnatally acquired infections. Congenital infections result from prenatal exposure to viral, protozoal, or, rarely, bacterial pathogens. Common diseases are the TORCH infections: *Toxoplasma gondii* (T); "other" (O) including human immunodeficiency virus (HIV), syphilis, and tuberculosis; rubella (R); cytomegalovirus (C); and herpes simplex virus type II (H). Only rarely do these infections produce a picture of overwhelming sepsis, but they can sometimes be confused with bacterial infection when profound CNS depression, circulatory collapse, or thrombocytopenia are presenting signs. When these infections occur in the first trimester, they can result in fetal wastage or major organ malformations. [338]

The incidence of acute infections in the newborn is highest in the premature child. However, regardless of gestational age, the signs and symptoms of infection are often subtle. Therefore, a very low threshold for diagnosing and treating infection is important. [339] Table 73-18 lists the common signs and symptoms of neonatal sepsis.

The most common acquired pathogens are the organisms that colonize the mother's genital tract, group B *Streptococcus, E. coli, Listeria monocytogenes,* and herpesvirus. Herpes is a particularly fulminant infection in the neonate; the presence of active lesions in the birth canal is an indication for a cesarean birth. The most common bacterial pathogen of sepsis in the neonate is group B *Streptococcus.* During the immediate perinatal period, group B *Streptococcus* presents with severe cardiorespiratory instability and meningitis (in 30% of cases). In contrast, the later presentation of this

TABLE 73-18 -- Common Signs and Symptoms of Neonatal Sepsis

Poor cutaneous perfusion, hypotension
Skin rashes or petechiae
Seizures

pathogen at 2 to 3 weeks of age is associated with a higher incidence of meningitis and a lower incidence of pulmonary disease. [340]

Whenever sepsis is suspected, bacterial cultures should be obtained from blood, urine, and CSF. It is important to perform a complete septic workup because it is difficult for both the infant and the physician to localize an infection. After appropriate cultures are obtained, broad-spectrum treatment with ampicillin and an aminoglycoside such as gentamicin is usually begun until specific bacteriologic information becomes available.

The Older Child: Sepsis and Septic Shock

The infectious diseases that require intensive care include sepsis with organ dysfunction and septic shock. Children can develop sepsis from virtually any bacterial or viral pathogen. Sepsis in the previously well child is often accompanied by an obvious primary local site or source of infection. Although older children can usually localize an infection as well as an adult, the younger child does not localize infections well. Of particular note, CNS infections can be difficult to diagnose in children who are younger than 2 years of age, because they are unable to give an adequate history of headache, and also because meningismus or other signs of meningeal irritation are not reliable findings.

The most common clinical manifestations of sepsis in the neonatal age group include fever or hypothermia, tachypnea and tachycardia, poor cutaneous perfusion, altered level of neurologic function (agitation and irritability followed by apnea or coma), petechiae, purpura or other rashes, DIC, and the metabolic abnormalities of metabolic acidosis, hypoglycemia, and hypocalcemia. Sepsis can also be associated with septic shock. In septic shock, endotoxin, exotoxin, or other endogenously liberated vasoactive substances produce an endothelial lesion that results in a syndrome of increased vascular permeability with resultant ARDS, increased utilization of metabolic substrate, depressed myocardial function, and profound DIC. [341]

The mainstay of therapy for any infection and particularly for septic shock is eradication of the infection. Parenteral broad-spectrum antibiotic coverage should begin according to the specific clinical situation, and any septic foci or abscess should be surgically drained. The child in septic shock requires early, and possibly massive, cardiorespiratory support. Endotracheal intubation and positive-pressure ventilation with increased levels of PEEP are used to support the child with ARDS. Inotropic agents are often needed to

maintain adequate cardiac output and tissue perfusion. A Swan-Ganz catheter can provide useful information in this situation. Because coagulopathies, including thrombocytopenia and generalized factor deficiencies, are common in septic shock, fresh frozen plasma and platelet transfusions may be required. In the past, high-dose steroids, although controversial, were commonly suggested for use in septic shock. [342] Clinical studies have shown steroids to have at the least no effect and possibly a deleterious effect in septic shock. [343] The use of these drugs is not advocated, except in the situation of steroid replacement in purpura fulminans with possible Waterhouse-Friderichsen syndrome.

The immunocompromised host differs from the previously healthy child. These children often lack a specific primary focus of infection; in addition, they suffer from attacks from different pathogens, *Pseudomonas aeruginosa, E. coli, Klebsiella, Staphylococcus aureus,* and coagulase-negative *Staphylococcus,* as well as fungi *(Candida albicans* and *Aspergillus).*[344] Immunocompromised children may also suffer polymicrobial sepsis with bacterial seeding from the GI tract. These children may

have few if any premonitory signs or symptoms before developing septic shock. Fever is probably the most common and often the earliest sign of opportunistic infection. Bacterial, fungal, and viral cultures should be obtained, and broad-spectrum antimicrobial therapy should be started. Antifungal agents should also be considered in these patients. Granulocyte transfusions have been reported in neutropenic patients with overwhelming sepsis--usually with a gram-negative organism. [345] Table 73-19 (Table Not Available) lists the most common predisposing causes of immunosuppression, along with the most commonly associated opportunistic organisms. [346]

Human Immunodeficiency Virus

HIV infections are increasing in the pediatric age group. HIV in the young child is secondary to vertical transmission from a seropositive mother. Adolescents with HIV infection are also increasing in number; unsafe sexual practices and intravenous drug use are the most common causes of infection. The adolescent presents in much the same way as the adult; therefore, this discussion is limited to HIV in the younger child.

Perinatal HIV is the primary issue. A mother with HIV infection has a 25 to 35 percent chance of infecting her child. The diagnosis of perinatal infection is problematic in that most infants have passively acquired maternal IgG antibody, preventing serodiagnosis. With current nucleic acid-based detection methods, a diagnosis can be confidently made by 4 months. The usual clinical presentation in the very young includes failure to thrive, hepatosplenomegaly, and chronic interstitial pneumonitis. The toddler age group has a higher incidence of lymphadenopathy, recurrent bacterial infections, neurologic delay, and progressive encephalopathy. Some children may be asymptomatic for years.

Pneumocystis carinii pneumonia (PCP) is seen in all age groups, but it is more common and is associated with a higher mortality in children younger than 1 year of age. The mainstay of treatment remains trimethoprim-sulfamethoxazole and support care.

Lymphocytic interstitial pneumonitis (LIP) is a slowly progressive interstitial disease with chronic cough and slight to moderate hypoxemia seen more commonly in children older than 1 year of age. The radiographic findings are small nodules and fine reticular densities. Treatment of LIP is supportive; the efficacy of steroids remains uncertain.

Children with HIV infection are most commonly admitted to an ICU for pulmonary disease, usually PCP. At this time, aggressive care is provided in the absence of other organ system failure. Survival after respiratory failure from PCP has improved during the past few years. [347] [348]

PEDIATRIC TRAUMA

Prenatal and Perinatal Injuries

Perinatal trauma is sustained by the fetus or newborn before, during, or immediately after birth. The most common prenatal injuries are due to maternal gunshot wounds and maternal blunt trauma. The fetal mortality in either case is greater than twice that of the mother, [349] with fetal death attributable to maternal shock and fetal oxygen deprivation rather than to direct injury. Birth injuries occur more commonly in large full-term infants and in infants with breech presentation. [350] Injuries to the head include linear or depressed skull fractures, cephalohematomas that result from subperiosteal hemorrhage, subdural or subarachnoid hematomas, and intraparenchymal or intraventricular hemorrhage. Intracranial injuries can lead to increased ICP, cerebral ischemia, neurologic injury, and death. Neck trauma can result in torticollis from injury to the sternocleidomastoid muscle and, rarely, cervical cord transection during a difficult breech extraction. [351] This latter tragedy leads to lifelong quadriplegia. Less devastating nerve injuries, also resulting from cervical traction, are phrenic nerve paralysis and Erb or Klumpke palsies from brachial plexus injury.

Perinatal bone fractures occur commonly in the clavicles and humeri from shoulder dystocia; femoral shaft fractures are more common in breech deliveries. Abdominal injuries to the liver, spleen, adrenal glands, and kidneys can produce life-threatening hemorrhage or thrombosis. [351] Thrombosis can cause vaso-occlusion with distal tissue loss in the cerebral, coronary, or renal vascular beds. Finally, emergency instrumentation of the airway in the delivery room can cause tracheal and esophageal perforations, particularly in the premature infant.

Trauma in Children

The leading causes of death among children aged 1 to 14 years are accidents and trauma. [352] The nature of the trauma is different from that in adults; children are usually victims of drops or falls, drowning, near drowning, motor vehicle accidents (pedestrian), ingestions, and burns. The types of bodily damage a child experiences also differ. Head injuries are more common, especially in younger children, who have disproportionately large heads with relatively poor neck muscle support. [353] Children are less likely to be victims of gunshot or knife attacks, causing penetrating injuries; instead, blunt injuries are more usual. Blunt trauma to the abdomen causes solid organ injury (liver and spleen) rather

TABLE 73-19 -- Opportunistic Infection in Inherited and Acquired Disorders

(Not Available)

From Feigin and Matson [346]

than a perforated viscus. [354] Hypothermia is more frequently encountered as a complication of the initial trauma; heat loss is very rapid in children because of their relatively large ratio of body surface area to volume. Although drowning and near drowning are the prototypical hypothermic injuries, hypothermia must be considered in all pediatric trauma victims.

Similar to adult trauma, the management of pediatric trauma requires an organized approach that combines diagnosis and treatment. Most preventable deaths in pediatric trauma are a result of airway obstruction, pneumothorax, shock secondary to inadequately treated bleeding, or secondary brain injury due to an expanding intracranial hematoma. [355] The American College of Surgeons recommends a four-step approach: (1) the primary survey, (2) resuscitation, (3) secondary survey, and (4) definitive care. [356] The primary survey requires rapid assessment of the airway, breathing, and circulation. A disproportionately large tongue in relation to a narrow oropharynx easily obstructs the airway in an unconscious child. A patent airway can often be established by proper jaw positioning, enabling bag-and-mask ventilation until intubation can be accomplished. Cervical spine injuries are less common in children surviving injuries than in their adult counterparts, but the neck of these patients should be immobilized until spinal damage is excluded. [357] Following establishment of an airway, adequacy of respiration should be verified by observation of symmetric chest wall movement, auscultation of normal and equal breath sounds, and an early chest radiograph. Tension hemopneumothoraces can be diagnosed clinically and treated by needle aspiration at the second thoracic interspace in the midclavicular line. This alleviates the tension and permits stabilization until a chest tube can be placed. The circulation can be quickly assessed in children. Hypovolemia is manifested first by tachycardia, poor peripheral perfusion, weak peripheral pulses, and, finally, hypotension, which may not occur until the child has lost more than 25 percent of the circulating blood volume. [358] The severely hypovolemic child requires venous access quickly. If a peripheral venous catheter cannot be placed expeditiously, an IO cannula should be placed until central venous access is established. [359] The degree of volume resuscitation is dictated by the clinical condition of the child and the estimated volume of blood or plasma loss.

During the secondary survey, a thorough head-to-toe examination is done, and a plan of definitive treatment is developed. Diagnostic measures in the pediatric trauma patient are similar to those in the adult patient with consideration to special problems. Because of the higher incidence of solid organ injury and a more conservative approach to management, diagnostic peritoneal lavage is less helpful in children. Most intra-abdominal injuries that require laparotomy are recognized clinically because they produce peritonitis or involve increasing abdominal girth. [360] Diagnostic peritoneal lavage may be helpful in children who are hemodynamically unstable despite fluid resuscitation with greater than 40 mL/kg of blood. It can be used to locate the site of occult bleeding in a child too unstable to undergo CT scan, or it can be used to evaluate abdominal injury in a child about to undergo emergency nonabdominal surgery. The indications for surgical intervention for abdominal trauma include free peritoneal air, evidence of a ruptured viscus, and acute uncontrolled bleeding greater than 40 mL/kg. A ruptured spleen or liver laceration is not an indication for surgery; preferred treatment is supportive therapy with aggressive blood volume replacement. [361]

A careful head and neurologic examination yields rapid information regarding intracranial trauma. The most important indicator of intracranial bleeding is a decrease in the level of consciousness. Rapid diagnosis and treatment of intracranial mass lesions can reduce ICP and may prevent secondary brain injury.

Child Abuse

Children have been subjected to violence, neglect, abandonment, slavery, and murder since time and events were recorded. Child abuse was brought to medical attention in 1962 by Kempe et al, [362] who coined the term *battered child syndrome.* The diagnosis of child abuse is often supported by the presence of an acute injury that may have a plausible explanation, along with signs of past trauma, including healing bruises, contusions, and fractures. Child abuse may also take the form of psychologic or sexual abuse, as well as the parents' failure to meet a child's need for food, clothing, shelter, hygiene, medical care, education, or supervision. [363] In

the ICU setting, physical abuse is the primary concern; however, emotional abuse and neglect can be independent or contributing factors.

Suspicion of child abuse often begins with a history of inappropriate or inadequate explanations for injuries or when the degree of trauma exceeds the historical cause. Multiple hospital admissions, emergency department visits, doctor or hospital "shopping," and a history of previous trauma are all of potential concern. Often, the story regarding the injury changes over time. [364] Certain clinical features are common to child abuse, but they are by no means pathognomonic. Most abused children are younger than 3 years of age and may have poor hygiene and delayed somatic or psychologic development. Injuries seen most commonly include bruises, welts, lacerations, scalds, and burns from cigarettes, stoves, heating grates, or irons. Long-bone fracture, often of varying ages, and abdominal injuries, signs of smothering, and multiple soft tissue or genital bruises are also common. Head injuries are reported; shaking a crying infant can cause neck injuries and intracranial hemorrhage, without necessarily producing external manifestations of trauma. The approach to a suspected victim of child abuse includes a meticulous and nonjudgmental history, written in detail on the chart, stating all allegations and documenting any change in the reported history. The physical examination should include growth parameters, descriptions of soft tissue bruising or burns, and diagrams or preferably photographs of all injuries. The color, shape, placement, and estimated age of all injuries should be catalogued. Laboratory studies should include the following: a skeletal survey of all long bones, ribs, and skull; a coagulation profile, including hematocrit, platelet count, PT, and PTT; and genital and throat cultures for venereal disease if sexual abuse is suspected.

Ingestion Injury

Despite the success of various preventive public health programs, poisoning in the pediatric population continues to be a common occurrence. Fortunately, the vast majority of presumed poisonings in young children can be managed at home by telephone consultation with a regional poison-control center. In one study, acute poisoning accounted for approximately 5 percent of all medical admissions to a PICU. [365] In this study, approximately one-half were accidental ingestions, and one-half were suicidal overdoses. The median age for the accidental group was 2 years, and for the suicidal group it was 15 years. Although many different toxic substances are ingested by children and adolescents, the approach to therapy is routine. Management has three main goals: (1) identifying, decontaminating, and eliminating the toxic agents [366] ; (2) minimizing the toxic effects to the host; and (3) providing close observation and organ system support until detoxification is complete. Procedures for drug elimination include emesis, gastric lavage, activated charcoal, and magnesium citrate. Minimizing toxic effects can be done with specific antidotes when available, with hemodialysis, or with charcoal hemoperfusion. Examples of specific antidotes are deferoxamine for iron ingestion, ethanol infusion for methanol ingestion, naloxone for narcotic overdose, and *N*-acetylcysteine for acetaminophen ingestion. Because many ingestions, particularly the suicidal ones, include multiple drugs, specific antidote therapy is only occasionally successful. Organ system surveillance and support usually include airway protection and mechanical ventilation, intravenous fluids, cardiovascular monitoring for arrhythmias and myocardial depression, and anticonvulsive therapy when seizures occur. Consultation with clinical pharmacologists or with the regional poison-control center and contacting a social worker or psychiatrist are essential aspects of the care of the acutely toxic child. Common complications of ingestions and their therapy include aspiration pneumonia from hydrocarbon ingestions or loss of glottic function, sepsis, respiratory depression, myocardial depression, arrhythmias, seizures, and coma. Although it is important to treat the specific ingestion, the psychosocial environment that allowed or precipitated the ingestion must also be considered. Families should be counseled about proper supervision and "childproofing" their home. Psychiatric intervention should be introduced early; unsuccessful suicide attempts are often repeated.

Transporting the Critically Ill Infant or Child

With regionalization first of neonatal intensive care and later of pediatric intensive care, emergency interhospital transport systems were developed to provide rapid, safe, and effective transfer of critically ill children from community hospitals to regional intensive care facilities. More recently, *in utero* transfer of women with identifiable high-risk pregnancies to regional obstetric perinatal centers has been instituted to provide maximal surveillance and support at the time of delivery. The philosophy of transport systems is not only to provide a means of transferring a sick patient to a more appropriate facility, but also to institute appropriate intensive care monitoring and treatment to the patient before leaving the referring hospital. This begins as soon as the referring physician telephones the intensive care physician at the referral hospital. The patient is presented to the ICU physician, who offers advice regarding immediate treatment and then mobilizes the transport team and alerts the appropriate consultants and hospital resources required for the incoming patient. The transport team usually consists of a physician and nurse who are specially trained in neonatal or pediatric intensive care and transport. Support personnel may include respiratory therapists, anesthesiologists (particularly in the case of a pediatric upper airway problem), emergency medical technicians, or additional nursing or physician trainees. Portable intensive care equipment must include cardiovascular monitoring devices, an infant transport device to maintain a neutral thermal environment during transport, resuscitation equipment (including airway and breathing devices), and additional equipment to institute intensive care on arrival at the referral hospital.

Problems that may arise during transport must be anticipated and treated before the patient is transported. This usually requires a careful assessment of the airway, breathing, and the adequacy of gas exchange along with monitoring the adequacy and stability of the circulation. Because procedures are so difficult to perform in transit, such interventions as intubation and placement of venous or arterial catheters are completed at the referring hospital if there is any question that they will be required. Possible medications required during transport should be anticipated and made immediately available. Transport can be carried out by ambulance, helicopter, or fixed-wing aircraft, depending on local circumstances. In general, the environment provided by helicopter transport is the most difficult one in which to provide surveillance and treatment because of poor temperature and noise control, as well as limited operating space. Communication with the transport team and regional center is essential in order to facilitate consultation with senior staff members and to help the accepting ICU anticipate the nature and degree of illness. The most serious flaws in the transport system are usually the response time of the transport team once a referral call is made and the availability of on-call transport team members who are adequately trained. An institutional commitment of funds, personnel, and equipment, along with excellent organization, can ensure that neonatal and pediatric transport systems have a significant impact on patient care, community physician education, and regional hospital referrals. [367] [368]

SUDDEN INFANT DEATH SYNDROME

Sudden infant death syndrome (SIDS) describes unexplained and sudden death in an infant younger than 1 year of age. It is a major cause of death and morbidity, with an incidence of 2 to 3 victims per 1,000 live births. The incidence peaks at 3 to 4 months of age and can be temporally, but not causally, associated with an intercurrent event such as an upper respiratory tract infection, recent immunization and, rarely, anesthesia and surgery. [369] Potential causes of SIDS include abnormalities to the cardiac conduction system such as the prolonged QT interval syndrome and Wolff-Parkinson-White syndrome and abnormalities of the respiratory

---

system such as central and/or peripheral chemoreceptor abnormalities, upper airway obstruction, and central hypoventilation associated with sleep. [370] [371] When the publication of epidemiologic studies from New Zealand, Britain, and the Netherlands linked the prone sleeping position to SIDS, the American Academy of Pediatrics issued a statement recommending that infants be placed on their back or side. This "back to sleep" recommendation was associated with a decrease in the SIDS rate in the United States. [372] Southall [373] suggested a syndrome of expiratory apnea characterized by severe hypoxemia in the face of continued respiratory effort. For unknown reasons, these children develop sudden severe intrapulmonary right-to-left shunting. [373] In most cases, SIDS appears to be a "quiet" death, in that breathing appears to stop without evidence of arousal or struggle. Occasionally, an infant is observed to be apneic and cyanotic and responds to tactile stimulation or to more vigorous resuscitative efforts. These near-miss SIDS infants are often admitted to PICU for intensive monitoring and observation. Those infants who are discovered close to death may require treatment for multiorgan system hypoxic-ischemic injury.

Future treatment and monitoring of survivors of near-miss SIDS remain controversial, but most authorities recommend cardiorespiratory monitoring at home and that all caretakers be thoroughly instructed in infant cardiopulmonary resuscitation (CPR) techniques. Families of infants who are monitored at home require a variety of home support services, including technical expertise, constant physician availability, and respite care personnel. In addition, parent groups and the National Foundation for Sudden Infant Death have proved helpful to some families, regardless of outcome.

THE ASPHYXIATED CHILD

The asphyxiated patient, whether an older child or an infant with aborted SIDS or birth asphyxia, poses an important challenge for the intensive care pediatrician. Asphyxia produces injury to a number of target end organs.

Asphyxial Injury to Organ Systems

Cardiovascular System

Asphyxia produces hypoxia with mixed metabolic and respiratory acidosis. The resultant hypoxia produces a fall in cardiac output by depression of the medullary cardiac regulation center, with bradycardia and decreased myocardial contractility. [25] As compensation for this decreased cardiac output, there is preferential blood flow to the cerebral and coronary circulations at the expense of shunting blood away from the kidneys and gastrointestinal tract. Clinically asphyxiated children are cold and mottled, with evidence of a low-output shock state. The specific therapy of cardiovascular dysfunction secondary to asphyxia consists of correction of the respiratory abnormality, correction of the acidosis, and chronotropic and inotropic pharmacologic support. (Appropriate monitoring and general treatment of circulatory failure are discussed in the section on acute circulatory failure in children.)

Respiratory System

Respiratory decompensation following an asphyxiation is commonly characterized by pulmonary edema. This may be secondary to increased microvascular pressure from hypoxic myocardial failure, or it may reflect capillary endothelial damage with a resultant capillary leak. [374] Treatment of both conditions includes cardiovascular support and the use of CPAP or PEEP with positive-pressure ventilation. Respiratory support is effected by the establishment of a patent airway, supplementation of inspired oxygen, CPAP, and mechanical ventilation.

Central Nervous System

CNS complications of asphyxia include intraventricular hemorrhage, cortical infarction, and cerebral edema. Intraventricular hemorrhage is a problem in premature infants and is thought to occur as a consequence of hypoxic-ischemic necrosis of the paraventricular germinal matrix. This area undergoes liquefaction and ruptures into the ventricular system several hours to days after the initial asphyctic injury. [375]

Cortical infarction occurs in children of all ages. This condition usually occurs in a "watershed pattern," affecting the motor cortex controlling the upper extremities and the visual cortex. [376]

Cerebral edema is a relatively late consequence of asphyxia, occurring 8 to 72 hours after injury. Because the ultimate neurologic outcome principally depends on the degree of cortical injury occurring at the time of asphyxia, aggressive management of cerebral edema can only be expected to prevent or reduce the amount of additional damage resulting as a late complication. Measures that ensure adequate oxygenation and hemodynamic stability should be instituted. Patients who demonstrate purposeful movements and normal brain-stem examination 24 hours after their hypoxic insult have a good neurologic recovery. Children without these findings at 24 hours are more likely to suffer severe neurologic deficits or death. [377] (The treatment of cerebral edema is discussed in the CNS section.)

Renal and Metabolic Effects

Asphyxia may cause renal ischemia, producing tubular or glomerular necrosis, as well as thrombosis of the renal vein or glomerular capillary bed. Metabolic complications in the asphyxiated infant and child may include hypoglycemia, hypocalcemia, hypomagnesemia, and metabolic acidosis, all of which produce profound myocardial depression and systemic hypotension. [378] Hypervolemia and hypo-osmolality are common problems associated with fluid resuscitation, water absorbed from mechanical ventilator systems, and syndrome of inappropriate ADH. Every attempt should be made to minimize free water overload.

Hematologic System

The major hematologic complication of asphyxia is the development of DIC. In the newborn, as well as in the older

child, levels of vitamin K-dependent factors (II, VII, IX, X) may be low, related to asphyctic hepatic dysfunction; these conditions may respond to vitamin K supplementation.

Gastrointestinal System

Splanchnic ischemia may produce necrosis of the intestinal mucosa, with ulceration or perforation anywhere within the GI tract. [379] Monitoring is difficult and consists mainly of testing all nasogastric secretions and stool for blood, monitoring bowel sounds and abdominal girth, and evaluating abdominal radiographs for intraluminal, intramural, intraportal, or extraluminal air. NEC is a common postasphyctic consequence in the premature infant. In severe cases bowel perforation, peritonitis, and sepsis can lead to death. Treatment consists mainly of minimizing the osmotic load of feedings until the GI tract has fully recovered. This treatment may require avoiding any oral or gastric alimentation for several days to several weeks after injury. When feedings are initiated, low-osmolality solutions should be used. During GI recovery, intravenous alimentation should be maintained through a central venous catheter. The gastric pH should be monitored and treated with antacids or an H_2-blocker. Hypoxia and hypoperfusion to the liver produce hepatocellular damage. The extent of pathophysiologic injury is a direct function of the duration and severity of the insult. Elevated transaminases, abnormal coagulation, elevated bilirubin, and unstable carbohydrate metabolism may all result, but all functional and laboratory abnormalities should be corrected unless there is underlying liver disease. [380]

Approach to Death Due to Asphyxia

Because the CNS is most sensitive to asphyxia, it is not uncommon to see full cardiovascular recovery in combination with profound CNS damage or even brain death. In situations in which meaningful, neurologic recovery is hopeless or when brain death has occurred, life support may have to be terminated. Parents who have lost a child in such a manner need a great deal of support, counseling, and understanding. Parents often react with guilt, denial, or hostility once confronted with the unexpected loss. Particularly in the case of SIDS, parents may react with guilt for not having been more vigilant. These issues must be addressed directly by trained

professionals.

/das/book/view/29494766/875/810.html

CARDIOPULMONARY RESUSCITATION

Pediatric cardiopulmonary arrests differ from adult arrests in a number of ways. Adults usually experience cardiac arrest secondary to coronary artery disease with severe ischemia and precipitation of a malignant arrhythmia. Children, on the other hand, have relatively normal coronary arteries, and it is uncommon for them to experience a primary arrhythmia. The more usual situation in pediatrics is initial respiratory compromise or arrest followed by secondary cardiac arrest. Another difference is the character of the terminal arrhythmia. Adults generally display ventricular arrhythmias, whereas children are more likely to demonstrate a bradyarrhythmia that degenerates into asystole.

In any PICU, there are patients who were victims of cardiopulmonary arrest and successful resuscitation; the treatment of these patients is described in the section on the asphyxiated patient. In addition to caring for successfully resuscitated patients, the PICU staff must be prepared to provide CPR for their own patients. Identifying patients at risk before they have a full cardiopulmonary arrest is as important as providing good CPR. This requires constant clinical surveillance and identification of risk factors. Critically ill patients are frequently placed at risk at various times during the day. Problems can be avoided by increasing everyone's attentiveness to these high-risk periods--during airway manipulation, during any change of therapy, during patient and bed manipulation, and at the change of doctor and nursing shifts.

The basic ABCs of resuscitation are a sequence that must be so familiar that little or no thought is required to begin the initial resuscitative efforts. Despite the evolving literature regarding new CPR, the standard American Heart Association CPR is still advocated as the appropriate method.

Once ventilation has begun, if there is no evidence of a pulse, external cardiac compressions should be started. (The establishment and maintenance of an airway are discussed elsewhere.) A rhythm is very important: five sternal compressions are given for each breath. A pause is given after each five compressions to allow for adequate lung inflation. The rate of compressions should be at least 100 per minute in infants and 80 to 100 per minute in children and adults. Hand positioning can be done in a number of ways. For CPR in an infant, there are two correct hand placements: (1) both thumbs can be placed over the sternum while the fingers are curved around the back over the spine; or (2) one hand can be placed behind the back for support while sternal compressions are done with two fingers of the other hand. This second procedure can also be used in toddlers. The adult-style two-handed massage is preferable in older children, with the patient placed on a cardiac board. Pressure should always be completely released between forceful compressions to permit filling of the heart chambers, and a pulse should be palpated to assess the adequacy of the compressions.

Vascular access is important, but in the child, attaining it may be difficult or impossible. Although a number of medications (atropine, epinephrine, lidocaine) can be given via the ETT, bicarbonate, calcium, fluid, and pressors require vascular access. New CPR guidelines include IO lines (18-gauge spinal or IO needle inserted in the tibia 2 to 3 cm below the tibial tuberosity). Common drugs used for CPR include the following:

1. *Atropine* is used for treatment of bradycardia; the dose in children is 0.02 mg/kg with a minimum dose of 0.1 mg and a maximum of 1.0 mg.
2. *Sodium bicarbonate* corrects the metabolic component of the acidosis. The recommended dose is 1 mEq/kg, followed by 0.5 mEq/kg. The usual acidosis is primarily respiratory, and in the event of inadequate ventilation, administration of bicarbonate may increase the Pa CO_2 and thereby may decrease the pH. In addition, overzealous use of bicarbonate has complications: lowered threshold for ventricular

fibrillation and left shift of the oxygen dissociation curve. The present guidelines suggest that bicarbonate administration be tailored to ABG values.
3. *Calcium* is a positive inotrope and peripheral vasoconstrictor. Caution should be exercised during the administration of calcium in an adult with cardiopulmonary arrest, because calcium has been implicated in decreasing the threshold for ventricular arrhythmias. In pediatrics, because ventricular arrhythmias are rarely a problem, calcium administration is relatively safer. The dose of calcium is 10 mg elemental calcium per kg. The present recommendation is to use calcium only to treat hypocalcemia, hyperkalemia, and calcium channel blocker overdose.
4. *Dextrose* is given to correct hypoglycemia that may be a precipitating or a complicating feature of the arrest. The dose of dextrose is 0.5 to 1.0 g/kg. It is available as D_{50} W (dose, 1-2 mL/kg) and D_{25} W (dose, 2-4 mL/kg). In cardiovascular arrest, D_{50} W and D_{25} W also act as osmotic diuretics. Dextrose is also used in combination with insulin to treat hyperkalemia: dextrose (0.5 g/kg) and insulin (0.1 U/kg). Hyperglycemia should be avoided during resuscitation for fear of increasing CNS damage.
5. *Epinephrine,* an adrenergic agonist, is usually given by intravenous or IO route, but it can also be administeredvia the ETT. Epinephrine is supplied as a 1:10,000 solution (0.1 mg/mL); the dose is 0.1 mL/kg. There has been some success with "high-dose" epinephrine. The newer recommendations include epinephrine 0.2 mg/kg after failure of two standard doses of epinephrine to increase perfusion pressure satisfactorily within 5 minutes. [381]
6. *Lidocaine* is used to decrease ventricular irritability and to help maintain a normal rhythm following defibrillation. It is also a myocardial depressant that decreases myocardial contractility and should therefore be given only when absolutely necessary (i.e., stable rhythm cannot otherwise be maintained). The dose is 1 mg/kg as a single dose; this may be repeated several times, or it can be given as an infusion of 1 to 2 mg/kg/h.

During resuscitation, a constant infusion of an inotrope or chronotrope is commonly used. Countershock therapy (cardioversion) is indicated if the patient presents with or develops ventricular fibrillation or ventricular tachycardia. The dose used in pediatrics is 1 to 3 W-sec/kg or 10 to 15 W-sec/year of life. The synchronized mode is selected for ventricular tachycardia, and the nonsynchronized mode is used for fibrillation. If small paddles are not immediately available for small children, the adult paddles are most easily used in an anteroposterior placement. If resuscitation efforts prove unsuccessful, the primary event that precipitated the arrest should be evaluated for correctable mechanical and/or metabolic insults. Possible reasons for an unsuccessful resuscitation include tension pneumothorax/hemothorax, disruption of the major vessels, cardiac tamponade, profound hypovo-lemia, profound metabolic imbalance, toxin ingestion, and hypothermia. Hypothermia presents a considerable problem: a patient with a core temperature of less than 30°C may appear dead and/or unresponsive to pharmacologic management, and it is important to rewarm the patient as part of the resuscitation. A hypothermic patient can be pronounced dead only if there is no electrical activity on ECG with a core temperature of at least 30°C, or if the person cannot be warmed to 30°C with aggressive methods (including peritoneal dialysis for rewarming).

There are also iatrogenic complications that may make resuscitation unsuccessful. These include traumatic pneumothorax from attempted vascular cannulation, pericardial tamponade from intracardiac injections, splenic or hepatic rupture from closed-chest compressions, pneumothorax from overzealous positive-pressure ventilation, and placement of the ETT into the esophagus. A patient in cardiorespiratory distress or arrest has excellent chances of full recovery with adequate resuscitation. Speed, orderly direction, cooperation of all personnel, and continuous assessment of the effectiveness of resuscitation are key to the successful restoration of adequate heart rate, blood pressure, ventilation, and, most important, brain function. Keeping the brain alive must be the objective of every resuscitative effort and, with rapid institution and maintenance of ventilation and cardiac massage, patients can be neurologically normal after periods of cardiac arrest.

PARENT/FAMILY SUPPORT

Numerous unavoidable stresses are encountered in any intensive care setting. In a PICU, the difficulty of dealing with the illness and/or death of a child often tends to magnify this normal stress. In order to support the ICU staff, children, and families adequately, these potential problems should be discussed and understood. The population in an ICU includes a permanent nurse, physician, and technical staff, a rotating group of residents, and an ever-changing cadre of patients and families. Together, these people are exposed to extremes of frustration and success; this exposure has an emotional and psychologic impact on everyone. Constantly available support systems for patients, parents, and staff are a necessity.

The pediatric patient ranges from a premature infant to an adult, and each patient must be approached in an age-appropriate manner. Diseases, procedures, and treatments should be discussed with the patient; each child should participate in his or her own care to the degree that limits of age, sedation, and disability permit. Parents of a child with a critical illness often progress through the stages of grief reaction described by Kubler-Ross. [382] Their interaction with the ICU staff and with their child is dramatically influenced by the character of their grief reaction. In addition, the ICU may be very confusing. The hectic pace and the numbers of physicians and nurses often leave parents feeling a lack of control and direction. ICU are also very intimidating and isolating. They are usually geographically isolated with a separate dedicated staff, a level of technology not seen in other parts of the hospital, and a terminology of numbers and abbreviations that can render conversations uninterpretable. All these factors make it difficult for a parent to maintain a parenting role. Too often, parents assume a role of the absent or passive parent, the angry critical parent, or the parent who wants to assume the role of physician. Some parents can never be directed into a more productive role, but often careful explanations of ICU operational procedures and generous use of social and clerical services can help parents to retain their parenting roles. Other members of the family, especially the patient's siblings, should also be

considered. Many parents need help and encouragement before they can involve their children at home in the events taking place at the hospital. Visiting should be encouraged and supported by the ICU staff.

There are numerous potentially troublesome interfaces among various members of the ICU staff. The permanent ICU staff members have developed a credibility of their intensive care skills and knowledge. Often, residents in training have never been exposed to intensive care medicine; these physicians may find the ICU and ICU staff overwhelming and intimidating. For the permanent staff, it is frustrating to have to retrain yet another group of residents. These constantly changing levels of expertise may produce antagonism. It is important for supervisors to be aware of these problems and to address them frequently.

Death is a frequent and complicated subject in the ICU. With the explosive growth of technology, the ability to support life often exceeds the ability to cure diseases. Basic definitions of death are being challenged in the medical, legal, and political arenas. The concepts of irreversible disease, chronic vegetative state, and meaningful versus meaningless life are under constant discussion and consideration. This lack of definitive guidelines increases the stress and frustration of families as well as of ICU staff members. By definition, intensive care is a fast-moving, stressful situation. Psychosocial supports are a necessity for patients and for parents as well as for staff members.

Chapter 74 - Nutritional Aspects

John K. Stene
Thomas C. Vary

INTRODUCTION

Nutrition has an important impact on the quality of human protoplasm and ultimately on a patient's fitness for surgery. Thus, anesthesiologists need a fundamental knowledge of nutritional principles to develop a logical approach to nutritional support for the surgical patient during the perioperative period. Changes in energy use induced by starvation (fasting), trauma, and critical illness also have implications for anesthesia care. Amino acid patterns in plasma that vary with dietary changes and in certain pathologic conditions affect plasma binding of drugs and alter neurotransmitter precursor availability. [1] Furthermore, the choice of anesthetic technique may affect the patient's use of energy substrates and nutritional needs. [2]

This chapter concentrates on the perioperative nutritional care of the surgical patient both in the intensive care unit and in the operating room. Although much of the information in this chapter is derived from studies on centrally administered total parenteral nutrition (TPN), perioperative nutritional support may also be administered by peripheral veins and is increasingly being administered enterally through the gut. Physiologic principles for nutritional support are stressed in the chapter. Such physiologic knowledge will help the anesthesiologist decide who will benefit from nutritional support, whether to provide parenteral or enteral nutrition, how to monitor the patient's response to nutritional support, and what prescription to write for nutritional support.

NUTRITIONAL REQUIREMENTS OF SURGICAL PATIENTS

Knowledge of basic substrate-endocrine relationships is essential for the rational planning of perioperative nutritional support. Failure to consider these relationships leads to the use of empirical therapy, to the use of inappropriate intravenous solutions, and to the development of complications, such as hyperglycemia, hypoglycemia, metabolic acidosis, and fatty infiltration of the liver.

Normal organ function depends on normal cellular function. Proper nutrient substrates must be delivered to the cells to maintain healthy cells and normal organ function. The ultimate aim of guidelines for nutritional support therapy should be to maintain cellular homeostasis. Besides uptake of appropriate nutritional substrates, use by the cells depends on substrate delivery by cardiac output and on microcirculatory blood flow.

The choice of appropriate nutrient solutions depends on the knowledge of changes in the energy substrate-endocrine relationships that occur in the perioperative period. [3] These changes are effected by starvation, trauma, anesthesia, and excess glucose administration.

General Principles

The role of nutrition in the posttrauma or surgical patient is generally overlooked. Often, concern with the physical injuries and surgical procedures causes one to forget what is actually occurring within the individual. Healthy people eat to replenish energy stores and to maintain health and well-being. Although there are charts and suggestions for proper nutrition, most healthy adults consume enough (sometimes too much) food to maintain normal structure and function of their organs. This implies that the nutrients delivered by the circulatory system are sufficient to meet the individual organ's needs. Nutrients provide both structural building blocks for cells and fuels for the production of energy. Both functions are vital to the maintenance of normal cell structure and function.

In the normal individual, a balance between those processes involved in anabolism and catabolism is maintained such that the concentration of plasma metabolites remains fairly constant over a wide range of physiologic insults. After meals, anabolism predominates with the storage of energy substrates, which include glycogen, to sequester excess glucose mainly in liver and muscle, triglycerides from both ingested fatty acids and de novo synthesis from glucose and stored in adipose tissue, and proteins necessary for normal function of all tissues (Fig. 74-1) . Between meals and under pathologic conditions, the body draws on these energy stores to maintain normal structure and function (Table 74-1) (Table Not Available) . The resulting catabolism is a normal response in periods in which nutrient intake could be compromised. However, although it is a normal response to starvation, in trauma and sepsis, this catabolic phase leads to further complications unless it is corrected. Although trace elements, vitamins, and minerals are also nutrients that contribute to the overall well-being of the organism, this discussion concentrates on the macronutrients (i.e., carbohydrate, fat, and amino acids). The state of nutritional assessment is based more on empirical anecdotes rather than on scientific fact. As such, the role of nutritional support in the critically ill patient is evolving rather than static. For an appreciation of the changes in nutritional assessment and required support, a solid understanding of the changes in these nutrients in various

TABLE 74-1 -- Body Fuels in Adult Man

(Not Available)

From Hawkins and Vina [190]

disease states is required. Unfortunately, not all the alterations are well defined. This chapter addresses the metabolic and nutrient requirements of the critically ill patient.

Starvation

A lack of food has profound effects on the normal flow of nutrients in the body. The immediate result of food deprivation is decreased intake of glucose. Glucose is vital to the animal for survival because certain cells, such as erythrocytes, cells of the renal medulla, and cells of the central nervous system, have an absolute requirement for glucose, amounting to approximately 180 g/d (Fig. 74-2) (Figure Not Available) . Despite reduced sugar intake, the circulating blood glucose concentration varies little. This is because humans adapt to decreased glucose intake during starvation by two mechanisms that serve to maintain the plasma glucose concentration. First, fatty acids mobilized from triglyceride stores in adipose tissue are used as an alternative fuel to glucose in those tissues that can oxidize fats. This use of alternative fuel for energy production lowers the requirements for glucose, thereby decreasing the demand for more glucose at a time when input via feeding is not available. Second, several adaptations in intracellular glucose metabolism occur that result in an inhibition of glucose-utilizing pathways and a stimulation of glucose-producing pathways (Fig. 74-3) . Initially, to maintain the plasma glucose concentration, glycogen is broken down. The loss of glycogen is rapid and significant. Within

Figure 74-1 Flow of nutrients in the fed state.

Figure 74-2 (Figure Not Available) General scheme of fuel metabolism in normal fasted humans, emphasizing the central position of the liver as a metabolic transformer. Two primary fuel sources are shown: muscle and adipose tissue, and three types of fuel consumer: (1) nerve (including brain), (2) pure glycolyzers producing lactate (red blood cells and white blood cells), and (3) the remainder of the body (heart, kidney, and muscle) that can use fatty acids and ketones. The brain can also use ketone bodies after injury and starvation. *(Modified from Cahill* [194] *)*

48 hours of starvation, rats show a 99.5 percent loss of liver glycogen and a 70.3 percent loss of carcass glycogen. However, the amount of glucose released by glycogenolysis is insufficient to sustain the energy needs of the whole body for more than a short period of time. The liver, and to a certain extent, the kidneys have the ability to synthesize glucose from different carbon sources via the process of gluconeogenesis (Fig. 74-4) (Figure Not Available) . Glucose is synthesized primarily from glycerol, lactate, pyruvate, and certain amino acids, particularly alanine. Lactate and pyruvate are released by peripheral tissues, particularly skeletal muscle. Lactate provides 60 to 70 percent of the glucose carbon used for gluconeogenesis. Glycerol is derived from adipose tissue after the breakdown of triglycerides. Amino acids are derived from the breakdown of proteins in both liver and peripheral tissues.

More than 35 years ago, an interorgan cycle (Cori cycle) accounting for the flow of glucose carbon during starvation was proposed. Glucose taken up by peripheral

organs is converted to lactate, which enters the blood and is returned to liver. The lactate is taken up by the liver and is synthesized to glucose (Fig. 74-5) .

The amount of lactate that can be produced and cleansed by the liver may be extremely high. The normal liver can clear up to 400 g of lactate per day. Lactate production by skeletal muscle must increase to provide the necessary gluconeogenic precursors for the maintenance of sustained rates of gluconeogenesis in starvation or diabetes. Lactate arises from the reduction of tissue pyruvate.

Lactate production occurs whenever the rate of pyruvate production from glycolysis exceeds glucose oxidation by the mitochondria. Therefore, for increased lactate production to be important physiologically, mitochondrial glucose oxidation must decrease under conditions known to result in increased gluconeogenesis. In humans, whole-body glucose oxidation is inhibited 90 percent in starvation, 70 percent in type 1 diabetes mellitus, and 40 percent in non- insulin-dependent

Figure 74-3 Adaptations in glucose metabolism during starvation. M, muscle; L, liver; K, kidney; AT, adipose tissue; CNS, central nervous system.

Figure 74-4 (Figure Not Available) Diagram of pathway of gluconeogenesis from various precursors. Shown are the stages in which amino acids (alanine), glycerol, and lactate join the pathway of gluconeogenesis. The reactions common to gluconeogenesis and glycolysis are those indicated by the straight arrows; the downward arrows show the direction of gluconeogenesis, the upward arrows the direction of glycolysis. The curved arrows represent the reactions (pyruvate carboxylase, phosphoenolpyruvate carboxykinase, fructose 1,6-diphosphatase, glucose 6-phosphatase) circumventing the energy barriers obstructing the direct reversal of glycolysis. *(Modified from Biebuyck [195])*

(type 2) diabetes mellitus. Each of these conditions is associated with enhanced rates of gluconeogenesis (Ch. 25) .

At the enzymatic level, the pyruvate dehydrogenase (PDH) complex catalyzes the first irreversible reaction in the mitochondrial oxidation of glucose. Pyruvate is oxidized by the PDH complex in the presence of the oxidized form of nicotinamide adenine dinucleotide (NAD^+) and coenzyme A (CoA) to form acetyl-CoA, the reduced form of NAD (NADH), and CO_2 . As such, the PDH complex is the primary regulator of glucose oxidation in mammalian cells. [4] [5] [6] Regulation by this complex is important to glucose homeostasis because the oxidation of pyruvate results in the net loss of body glucose carbon sources since glucose cannot be synthesized from acetyl-CoA and the PDH reaction is physiologically irreversible. Thus, the activity of the PDH complex determines whether pyruvate is oxidized to CO_2 and water or is converted to lactate via lactate dehydrogenase. The decreased activity of the PDH complex is caused by several mechanisms, the most prominent of which is reversible phosphorylation (Fig. 74-6) (Figure Not Available) .. Increased phosphorylation results in a decreased flux of glucose through the PDH complex (Fig. 74-7)

Release of amino acids from skeletal muscle is intimately related to glucose homeostasis because amino acids represent an important precursor for gluconeogenesis. Most amino acids are released from muscle in proportion to their concentration in muscle proteins. [7] However, the exceptions are alanine and glutamine, which are released in excess of their concentration in muscle proteins. These observations implied that de novo synthesis of alanine and glutamine occur in skeletal muscle. Because alanine is utilized by the liver and kidney as a major substrate for gluconeogenesis, Felig et al [8] proposed a glucose-alanine cycle as a means of transferring amino nitrogen from muscle to liver and kidney. According to this hypothesis, glucose taken up by muscle is metabolized to pyruvate. Pyruvate, instead of being oxidized via the PDH complex, serves as a nitrogen acceptor, with alanine being formed through transamination from glutamate. The alanine released from muscle recirculates to the liver, where it is taken up and reconverted to glucose.

Although the proposed glucose-alanine cycle allows for the transfer of nitrogen groups derived from amino acid catabolism to liver, it does not account for a net flow of carbon from protein to carbohydrate. Both alanine and glutamine are also synthesized from other amino acids. In the postabsorptive state, about 40 percent of the circulating plasma alanine is derived from endogenous proteins, whereas 60 percent is derived from de novo synthesis in humans. [9] In addition, at least 20 percent of the nitrogen required for the de novo alanine synthesis comes from leucine. [10] Leucine (isoleucine and valine) nitrogen is incorporated into alanine through a series of reversible transamination reactions involving the nitrogen transfer from leucine to glutamate via the branched-chain aminotransferase and the subsequent transamination of glutamate with pyruvate forming alanine. The rate of alanine synthesis is determined by (1) the rate of leucine appearance and (2) the rate of pyruvate availability.

If requirements for glucose carbon continued unabated, protein breakdown would result in a severe depletion of vital proteins. However, ketone body concentrations rise in long-term starvation or diabetes mellitus. Ketone bodies are derived from the incomplete oxidation of fatty acids in the liver. The brain adapts to using alternative fuels such as ketone bodies as a primary energy source, rather than glucose. Thus, by utilizing alternative fuels, the demand for glucose is further reduced (Table 74-2) (Table Not Available) . An important consequence of this adaptation is that the breakdown of muscle is no longer required to maintain the flow of alanine to the liver for gluconeogenesis (Fig. 74-8) (Figure Not Available) . The net result is that muscle proteins are spared further degradation. The adaptive ability of the organism to use alternative fuels instead of glucose is of fundamental importance to the survival of the animal because otherwise, protein function would eventually be compromised.

These adaptive processes are under hormonal control, which serves to regulate the flow of glucose carbon to ensure adequate levels of glucose in the blood. These hormones can be broadly categorized into two groups: anabolic hormones and catabolic hormones. At any given time, the net effect of the hormones, whether to break down or to store fuels, depends on the ratio of concentrations of each of the hormones to each other, as well as on their absolute concentration. The principal anabolic hormone is insulin. Insulin is of major importance in fuel storage, promoting the deposition of glycogen, triglycerides, and proteins. At basal levels, insulin has an important anticatabolic role in restraining glycogenolysis, gluconeogenesis, and lipolysis. Growth hormone is also anabolic, but only with respect to protein

metabolism, in which growth hormone stimulates amino acid transport and protein synthesis. Some studies have suggested that parts of the anabolic effects of growth hormone are mediated by a faster-term insulin-like growth factor-1. [11] The major catabolic hormones are glucagon, cortisol, and catecholamines. Individually, none of these hormones totally opposes the action of insulin; instead, they act together to counterbalance insulin action. Glucagon has its major effects on the liver, promoting gluconeogenesis, amino acid uptake, ureogenesis, and protein catabolism. Cortisol enhances extrahepatic protein catabolism, thereby increasing the release of amino acids, and promotes hepatic utilization of the mobilized amino acids for gluconeogenesis. Catecholamines stimulate lipolysis and glycogenolysis in both hepatic and extrahepatic tissues.

Stress Response to Surgery and Trauma

The body responds to trauma or surgical stress in a characteristic fashion (Fig. 74-9) (Ch. 10) . Monitoring of the

TABLE 74-2 -- Fuels in Circulation in Man

(Not Available)

Aa, amino acid; ADP, adenosine diphosphate; ATP adenosine triphosphate; FFA, free fatty acid; Glc, glucose; KB, ketone body; RQ, respiratory quotient; Tg, triglyceride. *(Modified from Blackburn and Phinney* [197] *)*

stressed surgical or trauma patient has demonstrated a pattern of physiologic adaptations designed to return the host to normal function. [12] [13] The pattern reflects the adequacy of the host defense system and arises out of the interorgan fuel metabolism and immunologic response mechanisms. The normal stress response is characterized by a neurohormonal sympathetic response mediated by a rise in norepinephrine, epinephrine, glucagon, and cortisol levels. Hemodynamically, heart rate, contractility, and cardiac index increase. Oxygen consumption is augmented. Metabolically, in the first few days after trauma injury, the normal balance between anabolic and catabolic processes is altered in the direction of catabolic metabolism. The catabolic response is mediated primarily by a rise in the catabolic hormones. Glucose turnover increases at least 2-fold. The rate of glucose production can be matched by an increased rate of utilization such that euglycemia is maintained. Within days, this sympathetic stress response abates, and lean muscle mass is restored. This pattern of host response is the normal response to a posttraumatic stress. The failure to achieve this state or to deviate from this course represents an abnormal physiologic response in the posttrauma or surgical patient.

Respiratory Muscle Function After Trauma

Respiratory muscle power is reduced during starvation, and respiratory muscles probably are not preferentially spared in the nitrogen losses after trauma (Ch. 62) . The effects of the prolonged use of muscle relaxant drugs and of the enforced immobilization of respiratory muscles on recovery of ventilatory strength and chest-wall coordination have not been adequately investigated. Specific deficiency states may contribute to reduced muscle power; for example, acute areflexic paralysis with respiratory failure resulting from hypophosphatemia has been described. [14] As the malnourished patient with an associated hypermetabolic disease process becomes more depleted, strength is diminished, which can lead to use of the accessory muscles of respiration as well as compromised pulmonary function (Fig. 74-10) (Figure Not Available) . Minute ventilation and ventilatory response to CO_2 breathing are increased in spontaneously breathing patients who receive an amino acid-enriched nutritional formula. [15] Thus, nutritional support with high nitrogen loads leads to improved respiratory muscle strength and ventilatory response.

GLUCOSE HOMEOSTASIS DURING PARENTERAL NUTRITION

Normally, the concentration of plasma glucose is kept within close limits. There is a constant requirement for glucose by glucose-dependent tissues (brain, erythrocytes). Equally, there are detrimental effects of extreme hyperglycemia (e.g., hyperosmolar coma). [16] [17] The mechanisms responsible for the regulation of plasma glucose levels are of fundamental importance to the entire metabolic response to hyperalimentation. [18]

Figure 74-9 Interorgan substrate fluxes in response to trauma or surgery.

Figure 74-10 (Figure Not Available) Effects of semistarvation on metabolic rate and hypoxic and hypercapnic ventilatory responses. The hypoxic response is quantitated by A, defined in the equation $V_E = V_0 + A/(Pa_{O_2} - 32)$, where V_E is minute ventilation, Pa_{O_2} is alveolar oxygen tension, and V_0 is the asymptote for ventilation obtained by extrapolation. The hypercapnic response is quantitated by S, defined in the equation $V_E = S(Pa_{CO_2} - B)$, where Pa_{CO_2} is end-tidal CO_2 tension, and B is the extrapolated intercept on the abscissa (Pa_{CO_2} axis). V_{O_2} and V_{CO_2} declined, reaching the lowest level by the 10th day, as did the hypoxic response. The hypercapnic response declined slightly but not significantly. Asterisk (*) denotes significantly different from control ($P < .05$). Brackets indicate ± SEM. *(From Doekel et al [145])*

During intravenous infusion of glucose, two processes can minimize changes in plasma glucose concentration: (1) reduction in the rate of glucose production and (2) enhanced ability to clear glucose from the blood stream. Wolfe et al [19] demonstrated that when glucose was infused into normal volunteers at the rate of 1 mg/kg/min (84 mL/h of 5% dextrose in water in a 70-kg patient), endogenous glucose production was suppressed. One of the principal reasons whereby infused glucose is of nutritional benefit is that the suppression of glucose production resulting from glucose infusion spares amino acids that would otherwise be catabolized to provide gluconeogenic precursors. The rate of glucose infusion that provides the maximal benefit depends on the condition of the patient. [20]

From a clinical point of view, the justification for administering glucose at rates in excess of 3 to 4 mg/kg/min must therefore reside in the ability of the body to oxidize the infused glucose. Table 74-3 (Table Not Available) shows that even during a 4-mg/kg/min infusion, less than one-half the infused glucose was directly oxidized, and that at an infusion rate of 9 mg/kg/min, approximately one-third of the glucose was directly oxidized. [21] At this high level of glucose infusion, however, only 61.6 percent of CO_2 was attributed to direct oxidation of glucose. Thus, even at these levels of glucose supply, other substrates are being oxidized.

The percentage of CO_2 from glucose infusion also reaches a plateau at around 60 percent in burn patients, regardless of the infusion rate. [22] Importantly, and against all previous reasoning, apparently, if insulin is infused simultaneously with glucose, the glucose clearance rate increases, but the rate of glucose oxidation is unaltered. Perhaps 22 percent of carbon dioxide that is coming from fat oxidation can be attributed to the conversion of excess infused glucose to fat.

RESPONSE TO SEPSIS

The major cause of an abnormal physiologic stress response in surgical intensive care is sepsis (Chs. 55 and 71) . Sepsis is the host's response to infection, which imposes another stress to the host in addition to the stress imposed by trauma alone. As can be expected, this leads to a continuum of responses with increasing severity. Ultimately, the patient either improves and returns to the normal stress response or continues to deteriorate. The complications of sepsis leads to a condition described clinically as a sequential failure of the major organ systems of the body. [13] [23] [24] [25] [26] In operations for intra-abdominal sepsis, multiple system organ failure (MSOF) occurs in 30 to 50 percent of cases and is the major cause of death in patients with sepsis.

Initially, the conditions leading to sepsis-induced MSOF are clinical episodes of shock, resuscitation, and postresuscitation hypermetabolism. The shock state is usually short lived, and the patient is adequately resuscitated with fluids and cardiotrophic support. Clearly, during the shock episode, alterations in hemodynamics and metabolism are driven by the degree of hypoperfusion. This problem can be corrected by increasing the oxygen delivery via augmentation of fluid resuscitation and cardiac output. The end point for resuscitation should be the absence of flow-dependent increase in oxygen consumption, and this should be the cornerstone of therapy. [27] [28]

Three to 4 days after the septic episode, patients enter a phase characterized by persistent hypermetabolism, which can last weeks. These patients are hemodynamically stable, demonstrating an increased cardiac output at 10 to 12 L/min. In contrast to the stress response, the total peripheral resistance falls, indicative of a hyperdynamic cardiovascular state. The oxygen consumption rises approximately

TABLE 74-3 -- Glucose Oxidation During Total Parenteral Nutrition in Postoperative Patients (*n* = 5)

(Not Available)

From Wolfe et al [191]

2-fold above normal (Fig. 74-11) (Figure Not Available) . The respiratory gas quotient falls to 0.8 to 0.85, indicative of a greater reliance on fats for oxidative energy production. In general, there is marked increase in metabolic demand and work relative to the resting, fasting human. The plasma lactate level is increased

Figure 74-11 (Figure Not Available) Cardiovascular and metabolic responses after trauma and sepsis, in 10 septic and 16 nonseptic patients. Mean values over postinjury course for cardiac index (CI) and oxygen consumption (V_{O_2}) are shown for trauma patients who developed sepsis (ST) and compared to those who had nonseptic courses. Note increase in CI and V_{O_2} in ST patients as sepsis becomes established between 5 and 7 days after injury. *(From Sganga et al, [82] copyright 1985, American Medical Association)*

into the 2 to 3 mg/dL range. However, this rise in lactate is not accompanied by a metabolic acidosis. In fact, the plasma pyruvate concentrations also rise such that the lactate/pyruvate ratio in the arterial and femoral vein plasma is within normal limits, implying a normal cytosolic redox potential. [29] Without any overt injury to specific organ systems, the level of plasma enzymes used as indicators of ischemic injury (serum glutamic oxaloacetic transaminase, creatine phosphokinase, lactate dehydrogenase, and ornithine transcarbamylase) are not increased. Biopsies of skeletal muscle reveal adequate levels of high-energy phosphates, also indicative of adequate blood flow. Under this condition, energy production and utilization are consistent with adequate oxygen supply, and metabolically insignificant amounts of hypoxia-driven metabolic alterations are observed. Instead, other mechanisms or abnormalities besides inadequate oxygen delivery are involved in the regulation of plasma metabolites and fluxes in sepsis.

As the septic processes progress, hemodynamic and metabolic dysfunction are observed. [12] In particular, the increase in oxygen delivery begins to fall such that the hyperlactatemia becomes associated with acidosis. Oxygen consumption decreases as organ systems fail. Respiratory dysfunction at this stage leads to the retention of CO_2 , and respiratory acidosis is observed. Eventually, cardiac organ failure leads to a profound myocardial insufficiency in which the hyperdynamic cardiovascular state develops into a hypodynamic state. At this stage, the alterations induced by profound hypoper-fusion outweigh any changes induced by altered metabolism.

It is in the setting of the stable hyperdynamic cardiovascular condition that patients need the maximal nutritional support to prevent sustained starvation from limiting recovery. [30] The septic insult results in pathologic alterations in glucose, fatty acid, and amino acid (protein) metabolism (Fig. 74-12) . Virtually no organ system is spared from the metabolic alterations in sepsis. The pattern of alterations in the plasma level of these fuels is superimposed on changes in the plasma level of hormones. Changes in carbohydrate metabolism after severe trauma and during sepsis include hyperglycemia, increased gluconeogenesis with an increased output of glucose from the liver, hyperlactatemia, and insulin resistance. The metabolic alterations that occur in sepsis are numerous, and all probably contribute to a cascade of secondary alterations that result from the initial traumatic or septic episode. Collectively, these changes lead to the observed plasma alteration in hormones and substrates in the critically ill patient. The metabolic changes observed are likely to result from changes in hormone concentrations and/or expression of inflammatory or immunologic mediators.

Figure 74-12 Interorgan substrate fluxes in response to sepsis.

Sepsis increases glucose turnover by stimulating hepatic glucose production and by augmenting peripheral glucose utilization. [31] [32] Gluconeogenesis represents the major pathway for lactate clearance, and enhanced rates of gluconeogenesis are associated with a 2-fold to 3-fold increase in net lactate extraction by the liver during sepsis. [33] [34] In injured patients, endogenous glucose production is elevated 2-fold to 3-fold above the normal basal level. Therefore, as much as two or three times as much infused glucose may be required to suppress glucose production in the injured patient. By contrast, sepsis appears to minimize the effectiveness of exogenous glucose in suppressing glucose production. The response to glucose in any patient can be determined by recording the infusion rate at which the glucose level begins to rise rapidly. The ability of tissues to clear glucose increases with time on hyperalimentation (Fig. 74-13) (Figure Not Available) . This increase in clearance apparently is not due to insulin mechanisms. [21]

Sepsis also increases glucose utilization, as measured by lactate and alanine production. However, the increased glucose uptake is not accompanied by a corresponding increase in glucose oxidation. Instead, the glucose carbon is released from peripheral tissues into the venous blood as lactate, pyruvate, and alanine. [31] [34] Because the rates of pyruvate, lactate, and alanine production are normal or increased, it appears that glucose uptake and glycolysis are normal or accelerated

in sepsis. Thus, glucose carbon is conserved by the body because oxidation would deplete the body stores of glucose carbon. The lactate, pyruvate and alanine released by skeletal muscle are returned to the liver and kidney, where glucose is synthesized from these C_3 precursors by the process of gluconeogenesis. This interorgan relationship probably accounts for the increased rate of glucose carbon recycling observed in sepsis (Fig. 74-14) (Figure Not Available) . Furthermore, it is a futile cycle in that the overall process consumes energy with no net energy production. Thus, it is not necessary to invoke an uncoupling of oxidative metabolism to account for the increased oxygen demands during sepsis. In fact, this futile cycle may account in part for the increased hepatic oxygen consumption.

An impairment in glucose oxidation in conjunction with normal or increased lactate, alanine, and/or pyruvate production suggests a specific inhibition of the pyruvate dehydrogenase reaction. This impairment can be due either to the decreased formation of pyruvate or to the entry of glucose carbon into the tricarboxylic acid (TCA) cycle. Estimates of glucose recycling [31] [32] [33] [34] suggest that the rate of pyruvate formation from glucose is probably not rate limiting for

Figure 74-13 (Figure Not Available) Glucose concentration and glucose clearance (glucose uptake/glucose concentration) in postoperative patients on total parenteral nutrition. There is a progressive rise in glucose clearance such that after 6 days of infusion, the glucose concentration is significantly lower than at 2 hours of infusion, even though the infusion rate is much higher at 6 days. Glucose production is suppressed in normal volunteers by exogenous glucose infusion. During the first 2 hours of glucose infusion, suppression of glucose production appears to be of predominant importance in maintaining normal blood glucose concentration. Maximal suppression can be obtained at glucose infusion rates well below rates conventionally administered in total parenteral nutrition. *(Modified from Wolfe [196])*

Figure 74-14 (Figure Not Available) Gluconeogenic response to trauma in 10 septic and 16 nonseptic patients, mean values for plasma glucose and alanine in patients with sepsis after trauma (ST) compared to those with nonseptic post-trauma courses (NST). glucose oxidation. Thus, entry of glucose carbon into the TCA cycle may be limiting for glucose oxidation in sepsis. Some studies have identified a specific inhibition of the pyruvate dehydrogenase complex in sepsis.

Endotoxin administration and bacterial infusions stimulate glucose uptake and phosphorylation in skeletal muscle. [35] [36] [37] The increased glucose uptake and phosphorylation is associated with a 2-fold increase in the glucose 6phosphate content. [38] The mechanisms responsible for these changes are unknown. Glucose entry into muscle is facilitated by specific transport proteins. At least five isoforms of the facultative glucose transporter have been described, of which two of these isoforms, GLUT-1 and GLUT-4, are present in skeletal muscle. The GLUT-1 isoform is present in a wide variety of tissues and mediates basal glucose uptake. [39] In contrast to GLUT-1, the GLUT-4 isoform is expressed only in those tissues in which glucose uptake is facilitated by insulin. [39] In skeletal muscle, glucose uptake is the rate-limiting step in glucose utilization. Sustained increases in glucose transport activity result from an increase in the number of cell surface glucose transporters. [39] Some studies have demonstrated an increased amount (approximately 70%) of GLUT-1 protein in skeletal muscle from septic animals compared with controls. [38] The increased GLUT-1 transporter expression correlates with enhanced basal (non-insulin-stimulated) glucose transport after endotoxin administration or sepsis. [40] [41] The significance of this observation is that non-insulin-mediated glucose uptake accounts for 75 to 85 percent of the total glucose disposal in the basal postabsorptive state. [35] Therefore, the increased glucose transport in sepsis may result in part from an increased GLUT-1 transporter protein content.

There is a specific inhibition of the PDH complex in sepsis, and the degree of impairment is dependent on the severity of the septic episode. [42] [43] Because decreased PDH activity is associated with decreased pyruvate oxidation, the inhibition of the complex during sepsis may provide a biochemical explanation for the shift in skeletal muscle glucose metabolism in sepsis. The inhibition of the PDH complex results from an increased phosphorylation, catalyzed by the PDH kinase. The effect of sepsis to increase PDH kinase activity is mediated by an increase in the acetyl-CoA/CoA concentration ratio. [42] In muscle tissue, the acetyl-CoA/CoA concentration is a sensitive index of the availability of metabolic fuels to be oxidized by the TCA cycle. The ratio is increased when noncarbohydrate fuels are the major oxidative substrate. Because the acetyl-CoA/CoA ratio is increased in skeletal muscle from septic rats, the skeletal muscle may have become more dependent on noncarbohydrate fuels. The net effect of an increased dependence on noncarbohydrate fuels for energy production would be a decreased rate of glucose oxidation and a conservation of glucose carbon. Analysis of respiratory quotients [44] [45] and of indirect calorimetry data [46] in septic patients has demonstrated an increased dependence on fatty acid oxidation, supporting the concept of altered fuel utilization in sepsis. Sepsis also increases the activity of the PDH kinase by mechanisms that are independent of the acetyl-CoA/CoA ratio. Rate constants for PDH kinase activity are increased more than 2-fold in sepsis. [47]

The regulation of the PDH complex makes a significant contribution to glucose homeostasis during sepsis. In experimental septic animal models, activation of the PDH complex with dichloroacetate decreases skeletal muscle, liver, and plasma lactate, pyruvate, and alanine concentrations [48] [49] [50] [51] [52] (Fig. 74-15) (Figure Not Available) . Concomitant with the fall in plasma gluconeogenic precursors, the rates of glucose production and glucose turnover were reduced to nonseptic values. [49]

Hormonal Changes in Sepsis

Typically sepsis is characterized by a decrease in the thyroid hormone, triiodothyronine, whereas the levels of the other stress hormones, namely cortisol, epinephrine, and glucagon, are elevated. Glucagon levels rise to an extraordinarily high level. Although the rise in glucagon is accompanied by a rise in immunoassayable insulin, the insulin-to-glucagon ratio is reversed compared with the postabsorptive state. This reversal of the insulin-to-glucagon ratio may be responsible in part for the accelerated rate of glucose production by the liver in sepsis. Both insulin and

Figure 74-15 (Figure Not Available) Effect of dichloroacetate in skeletal muscle. *(Modified from Vary and Siegal [12])*

glucagon have immediate and delayed effects on hepatic glucose metabolism. The immediate effects of glucagon on hepatic glucose production are seen within seconds and are mediated by alterations in the level of cyclic adenosine monophosphate (cAMP). Somewhat surprisingly, the action of cAMP acts not on the gluconeogenic enzymes directly but rather by restraining phosphofructokinase and pyruvate kinase activity, which are both regulators of glycolysis in liver. Longer-term effects of glucagon on liver metabolism usually appear within hours of glucagon stimulation and involve changes in the synthesis or degradation of enzymes in the metabolic pathway of glucose production. In addition to stimulating the enzymes necessary for gluconeogenesis, glucagon also stimulates the breakdown of intracellular proteins. Although the precise mechanism of action of glucagon responsible for this is unknown, glucagon does enhance the formation of autophagic vacuoles, which engulf and digest intracellular proteins via lysosomes. The stimulation of autophagic vacuole formation occurs secondary to a reduction in the amino acid glutamine levels in the liver, and glucagon reduces hepatic glutamine levels. By increasing the degradation of hepatic proteins, the action of glucagon on protein metabolism ensures that adequate substrate, in the form of amino acids, is available for gluconeogenesis.

Catecholamines also stimulate both glycogenolysis and gluconeogenesis. Plasma catecholamines levels of epinephrine and norepinephrine have been demonstrated to rise progressively with increasing severity of injury. Both epinephrine and norepinephrine rise to levels considered high enough to produce metabolic changes. In this regard, plasma epinephrine concentrations are more important for stimulating hyperglycemia than is the severity of the injury itself. The stimulation of hepatic output of glucose by epinephrine involves the breakdown of glycogen with the release of glucose. It appears that catecholamines activate glycogenolysis more effectively through a cAMP-alpha independent mechanism involving alpha-receptors, rather than through cAMP production by stimulation of beta-receptors. The alpha-adrenergic activation of glycogenolysis is due to an increase in phosphorylase a, secondary to stimulation of a Ca^{2+} -sensitive phosphorylase kinase. However, changes in the hormonal milieu are not solely responsible for enhanced gluconeogenesis in sepsis. Unlike other pathologic conditions, such as starvation and diabetes, in sepsis, gluconeogenesis is not suppressed by infusion of glucose. [31] [53] The failure of glucose to limit hepatic gluconeogenesis has been proposed to occur as a result of enhanced and continual delivery of gluconeogenic precursors from peripheral tissues.

Metabolic Changes in Sepsis

Skeletal Muscle Protein Metabolism

In addition to its role in locomotion, skeletal muscle (by virtue of its mass in relationship to body weight) represents the major reservoir of amino acids. Some of these amino acids, including alanine, serine, and glycine, are important substrates for gluconeogenesis in liver and kidney. Protein wasting is a general feature of trauma, sepsis, and burns. The earliest recognizable disturbance in protein metabolism in the injury process is excessive urea excretion, resulting in a loss of nitrogen from

the body. [12] [30] [31] [54] [55] Much of this nitrogen loss originates from protein in skeletal muscle. This catabolic phase is an intrinsic response to trauma and sepsis, with the loss of muscle protein exceeding that simply resulting from bed rest. In trauma patients, the catabolic phase is short lived, and restoration of normal nitrogen balance and lean body mass follows. In contrast to trauma, the catabolic phase continues unabated in sepsis and accounts for the massive loss of body protein observed in septic patients. [30] The loss of protein arises from an imbalance in protein turnover in skeletal muscle (Fig. 74-16) (Figure Not Available) .

The rate of muscle protein breakdown increases to a greater degree than that of the whole body, with the contribution of muscle proteolysis to whole-body protein degradation nearly doubling. The measurement of nitrogen excretion by the kidney can be used as an estimate of protein breakdown because the nitrogen excreted is derived from amino acids released by proteolysis. The increased proteolysis results in the release of amino acids from structural protein stores, particularly in skeletal muscle. The rate of release of amino acids across the lower extremities increases 2-fold to 5-fold in trauma or septic patients, compared with healthy volunteers after an overnight fast. Although the protein economy of the whole body can be estimated by monitoring the nitrogen balance, the contribution of muscle tissue can be monitored by measuring the rate of 3-methylhistidine production. 3-Methylhistidine is a component of actin-myosin proteins and is released from muscle in proportion to its concentration in muscle protein (both skeletal and smooth). [56] [57]

The increased rate of net catabolism in sepsis can result from a rise in protein degradation, or a decrease in protein synthesis, or both. The relative importance of protein synthesis versus degradation in the induction of the negative nitrogen balance during sepsis is unresolved. The increased net catabolism after trauma uncomplicated by sepsis results from an inhibition of protein synthesis rather than a change in protein degradation. [54] [58] [59] In contrast, sepsis accelerates muscle proteolysis. [56] [60]

The rate of protein synthesis in mixed hindlimb muscles is not altered in nonseptic inflammation, whereas sepsis produces

Figure 74-16 (Figure Not Available) Effect of sepsis on rate of protein synthesis (A), RNA concentration (B), and translational efficiency (C) in gastrocnemius (gastroc), psoas, soleus, and heart. Open bars represent control animals, shaded bars animals with septic abscess (5 days after fecal-agar pellet infected with *Escherichia coli* + *Bacteroides fragilis* implanted intraperitoneally.) *(Modified from Vary and Kimball [61])*

a 50 percent inhibition of protein synthesis. [61] [62] This reduction did not result from a decreased RNA content. Instead, the translational efficiency, expressed as protein synthesis/RNA, was significantly reduced by 50 percent in skeletal muscle of septic animals compared with controls. The effect of sepsis to lower protein synthesis was further examined by use of individual muscles containing different fiber types. [61] Gastrocnemius and psoas muscles were chosen to represent fast-twitch muscles, whereas soleus and heart muscles represented slow-twitch muscles. Sepsis caused a decrease in the muscle weight of all four muscles. Furthermore, both the protein concentration and the protein synthetic rate in fast-twitch muscle were reduced by sepsis, whereas neither of these parameters was affected in slow-twitch or heart muscles. The sepsis-induced inhibition of protein synthesis in fast-twitch muscles resulted from a restraint in peptide-chain initiation because sepsis caused a 1.6-fold increase in free ribosomal subunits. [55] [61]

Amino Acid Metabolism

The net catabolic state in skeletal muscle is characterized by changes in the intracellular amino acid concentrations. Postoperatively, there are rises in the concentrations of branched chain amino acid, phenylalanine, tyrosine, and methionine compared with preoperative values. Although the basic amino acids show small reductions, the overriding feature of injury is a depletion of glutamine concentrations.

The concentration of glutamine in human muscle is extremely high (20 mM) and is equivalent to 715 g of nitrogen in the adult. Glutamine, which represents as much as 65 percent of the total free amino acids in muscle, decreases by up to 50 percent immediately after trauma. [49] [63] [64] The muscle glutamine constitutes a labile pool that could influence changes in whole-body nitrogen balance. Furthermore, this fall in glutamine cannot be rectified by administration of total parental nutrition (TPN) support because most TPN solutions do not contain glutamine. Glutamine is unique among the amino acids because muscle glutamine concentrations are inversely related to rates of protein synthesis. [65] In liver, a decrease in glutamine concentrations is associated with increased rates of protein degradation.

Glutamine arises both from de novo synthesis and from release from protein stores. Glutamine is synthesized from alpha-ketoglutarate, a citric acid cycle intermediate, via glutamate and transamination reactions. Glutamine synthase, a multienzyme complex, catalyzes this reaction, and its concentration is particularly high in skeletal muscle and kidney. After amination of glutamate to glutamine, glutamine is released into the blood stream. It is the most important carrier for removal of nitrogen from peripheral tissues to the splanchnic area.

The role of this labile pool of glutamine in skeletal muscle has not been fully elucidated. Possible functions of increased glutamine release by muscle are to serve as (1) a labile store of fuel for both intestinal cells and lymphocytes and (2) a source of ammonia for utilizing acid-base imbalances. As a fuel, cells use glutamine for two major processes. First, it can be used as an energy source. Cells of the small intestine use glutamine for oxidative energy metabolism. The output of ammonia, protein, alanine, glutamate, and citrulline from gut cells depends on the supply of glutamine to the gut. Second, glutamine is a donor of nitrogen in de novo purine and pyridine biosynthesis. Hence, glutamine is essential for cellular proliferation. Therefore, an intraorgan relationship between glutamine release by skeletal muscle and utilization by splanchnic organs exists.

Decreased skeletal muscle glutamine concentrations postoperatively could result from decreased glutamine synthase activity, decreased release of glutamine from protein stores, increased release of glutamine from muscle through accelerated transport activity, and/or increased breakdown of glutamine via glutaminase. It is unlikely that increased glutaminase activity is responsible for the decrease in muscle glutamine in sepsis because functional hepatectomy

causes a significant accumulation of glutamine in the blood. [51] Furthermore, it argues against decreased glutamine synthase activity. Glutamine synthase activity in skeletal muscle traumatized by 1-carrageenan is markedly increased, not decreased. [66]

Inhibition of glutamine synthase with methionine sulfoximine attenuates glutamine release by 50 percent, suggesting that release of glutamine from protein stores is also an important mechanism in glutamine production. [52] Despite increased production of glutamine by de novo synthesis and increased proteolysis, the skeletal muscle glutamine concentrations are reduced. Therefore, an increase in glutamine transport must also occur.

To determine whether decreased glutamine is critical in posttraumatic skeletal muscle protein catabolism, glutamine has been administered as part of TPN. In this regard, Kapadia et al [67] reduced the postoperative efflux of amino acids from dog hindlimb by infusing an amino acid mixture supplemented with glutamine. However, commercially available amino acid supplements do not contain glutamine, because it is considered a nonessential amino acid and is unstable in aqueous solutions. Consequently, it must be added immediately before use. A more convenient method of supplying glutamine in TPN solutions is to use stable dipeptides, such as alanyl-glutamine and glycyl-glutamine. Both dipeptides are hydrolyzed in the body, releasing glutamine. Furthermore, administration of these dipeptides as part of TPN counteracts the decrease in muscle glutamine and improves nitrogen balance in the immediate postoperative period (Fig. 74-17) (Figure Not Available) .

In addition to provision of dipeptides, plasma and skeletal muscle glutamine concentrations can be augmented by the provision of ornithine-alpha-ketoglutarate or alpha-ketoglutarate. Supplementation of TPN with either of these compounds maintains nitrogen balance and decreases cumulative urea excretion after abdominal surgery. [68] In addition, the rate of protein synthesis is maintained, and the characteristic increase in several essential amino acids in skeletal muscle is also attenuated.

Mediators of Metabolic Changes in Sepsis

The stimulus for enhanced muscle catabolism during sepsis is unknown. A certain amount of catabolic response in trauma patients can be attributed to direct injury to the muscle. However, the enhanced catabolism in the septic patient occurs without any overt signs of direct tissue trauma. The amount of catabolism observed in

septic patients is far in excess of what would be expected simply because these patients are bedridden and inactive.

In burn patients, cortisol is a major determinant of the catabolic response. [69] The catabolic effects of cortisol have been confirmed in healthy volunteers subjected to cortisol infusions to levels seen in burn patients. Cortisol administration in animals reduces the rate of protein synthesis in fast-twitch muscles but not in slow-twitch fibers and heart. The fall in protein synthesis results from a loss of total tissue RNA and to an impairment of translation. [70]

Besides cortisol, epinephrine concentrations are elevated in sepsis. In contrast to cortisol, the catecholamines may not have as a dramatic effect on protein turnover. [71] Isoproterenol does not alter protein synthesis but does reduce protein

Figure 74-17 (Figure Not Available) Day-to-day and cumulative nitrogen balance in patients receiving 1-alanyl-1-glutamine dipeptide-supplemented (black columns) or conventional amino acid total parenteral nutrition (TPN) (open columns). These results clearly illustrate a beneficial effect of increasing glutamine concentration on maintaining nitrogen balance. *** $P < .001$; ** $P < .01$. *(From Stehle et al [199])*

degradation by 20 percent. The decreased proteolysis is sufficient to prevent the release of alanine, threonine, phenylalanine, tyrosine, lysine, arginine, leucine, and valine.

Insulin conserves muscle protein both by stimulating protein synthesis and by inhibiting protein degradation. [72] [73] However, in sepsis, the breakdown of muscle protein, as measured by 3-methylhistidine release, is increased despite increased insulin concentrations. [56] These observations also suggest that additional factors resulting from the septic episode accelerate muscle catabolism or that injury itself renders the muscle resistant to insulin action.

The factors responsible for the septic-induced metabolic alterations are unknown. Although the cause of potential mediators may be multifactorial, a frequent common denom-inator of organ dysfunction and organ failure is alterations in the release of cytokines, particularly by the macrophage. In particular, tumor necrosis factor, interleukin-1, and interleukin-6 have been demonstrated to play a pivotal role in mediating some of the metabolic responses to sepsis. As a mediator of the septic process, tumor necrosis factor triggers neutrophils to degranulate, lymphocytes to divide, and other cytokines (including interleukin-1 and interleukin-6) to be released. The natural induction of tumor necrosis factor during inflammation is protective, but overproduction, as occurs in sepsis, is detrimental to the host. There are essentially two approaches to delineating the role of these cytokines in sepsis. First, several metabolic disturbances present in infectious diseases have been reproduced by administration of recombinant monokines. Second, it is possible to attempt to block the cytokine response to sepsis. There are several potential mechanisms to block cytokine function. Cytokine synthesis or release can be inhibited as well as inhibit the cytokine action by blocking, for example, cytokine receptors.

Branched-Chain Amino Acid Metabolism

In addition to the role of leucine in de novo alanine synthesis, the branched-chain amino acids are of special importance because some reports have suggested that administration of branched-chain amino acids is beneficial in septic patients, improving the survival in surgical patients with multiple organ failure. [74] [75] [76] Administration of branched-chain amino acids as part of the nutritional support in traumatized or septic animals results in decreased weight loss, reduced negative nitrogen balance, decreased protein catabolism, and increased protein synthesis. In surgical patients, nitrogen retention was greater in those patients receiving TPN with 45 percent of the amino acids as branched-chain amino acids than those patients receiving TPN with 24 percent of the amino acids as branched-chain amino acids. One hypothesis for their efficacy is that they provide a fuel for skeletal muscle and liver energy metabolism at a time when glucose oxidative metabolism may be inhibited.

Branched-chain amino acids are among the few amino acids oxidized in muscle tissues. In healthy animals and humans, there appears to be a differential pattern of branched-chain amino acid metabolism in muscle and liver. In muscle tissues, the aminotransferase activity is high, and the oxidative decarboxylation of the corresponding alpha-ketoacid is rate-limiting for leucine oxidation. Only about 50 percent of the leucine undergoing transamination is oxidized. The corresponding alpha-ketoacids are released into the blood. The concentration of all three alpha-ketoacids of branched-chain amino acids in human plasma is approximately 0.1 to 0.04 mM. In contrast to muscle, in hepatic tissue, the activity of the branched chain dehydrogenase is higher than that of the transaminase, and alpha-ketoacids are readily oxidized. The reason for differential pattern may lie in the differential regulation of the branched-chain amino acid dehydrogenase in muscle and liver. The branched-chain alpha-ketoacid dehydrogenase is also regulated by a phosphorylation/dephosphorylation cycle, analogous to the PDH complex. [77] The branched-chain alpha-ketoacid dehydrogenase is inactived in muscle tissue through phosphorylation but is protected in some way from inactivation in liver. This affords a mechanism whereby alpha-ketoacids released by extrahepatic tissues are taken up and used by the liver with the possible formation of glucose and ketone bodies.

The absolute contribution of branched chain amino acids to the overall energy metabolism (adenosine triphosphate generation) is still debatable. In the absence of any other exogenous substrate, leucine oxidation in cardiac muscle could only account for about 5 percent of the total oxygen consumption, even at supraphysiologic levels of leucine. [78] Furthermore, leucine could not provide sufficient energy to maintain normal cardiac function. Hence, it is doubtful that leucine represents a significant energy fuel.

Alternatively, the branched-chain amino acids, and leucine in particular, are unique in that they stimulate protein synthesis. [79] [80] The stimulatory effect of branched chain amino acids on protein synthesis was associated with a facilitated efficiency of translation. However, the response is not as great as that produced by insulin. Therefore, the protein-sparing effects of branched-chain amino acids are more likely a result of modulation of protein metabolism.

Hepatic Protein Metabolism

While it is clear that net proteolysis occurs in skeletal muscle in sepsis, in liver, protein synthesis after trauma or infection is increased (Ch. 17) . The increased rates of protein synthesis coincide with enhanced hepatic uptake (or clearance) of amino acids. Thus, the increased hepatic protein synthesis has been suggested to be caused by or dependent on an increased supply of amino acids from the peripheral tissues. Liver is unique in that it synthesizes proteins for its own use (i.e., structural proteins essential for normal cell function), as well as proteins that are secreted into the blood (i.e., secretory proteins, e.g., albumin). The synthesis of secreted and nonsecreted proteins was stimulated in inflammation and sepsis (Table 74-4) (Table Not Available) . [81] There was a preferential stimulation of proteins destined for secretion, the acute phase proteins.

Distinct and coordinated changes in the concentration of individual plasma proteins, called acute phase proteins, occur within 24 hours after injury. [82] The acute phase proteins maximize immune responsiveness to the foreign body and repair to damaged tissues. These functions include complement activation and opsonization needed for bacterial killing (C-reactive protein), coagulation, surface structure,

TABLE 74-4 -- Effect of Sterile Inflammation and Sepsis on Rates of Protein Synthesis in Perfused Livers

(Not Available)

From Vary and Kimball [81]

and support lattice formations needed for leukocyte entrapment of foreign material (fibrinogen), superoxide scavenging (ceruloplasmin), and inactivation of excess proteases needed to prevent damage to viable cells (alpha $_1$ -antitrypsin) (Fig. 74-18) (Figure Not Available) . A differential pattern in the plasma acute phase protein profile has been demonstrated in trauma and septic patients. The presence of sepsis, whether clinically evident or not, modifies the posttraumatic acute phase protein response, so as to favor the increase of some acute phase proteins, while effecting a decrease in the concentration of other proteins that may not be as critical for survival. In both nonseptic and septic patients during the first 2 to 3 days after injury, there is a rise in C-reactive protein, fibrinogen, alpha $_1$ -antitrypsin, and

ceruloplasmin concentrations. After 3 days, the concentrations of C-reactive protein, fibrinogen, and ceruloplasmin all return toward normal values in nonseptic trauma patients, whereas alpha$_1$ -antitrypsin concentrations remain elevated. In contrast, in trauma patients who show clinical signs of sepsis, C-reactive protein, fibrinogen, alpha$_1$ -antitrypsin, and ceruloplasmin concentrations all remain elevated. There is an early decrease in transferrin, but alpha $_2$ -macroglobulin and albumin

Figure 74-18 (Figure Not Available) Hepatic acute phase (AP) protein response after trauma in 10 septic and 16 nonseptic patients. Mean values for C-reactive protein (CRP) (A), fibrinogen (B), alpha$_1$ -antitrypsin (C), and ceruloplasmin (D). Patients with sepsis developing after trauma are compared to patients with nonseptic post-trauma courses. Note early rise of CRP and alpha $_1$ -antitrypsin in patients who later become clinically septic at 5 to 7 days. The fibrinogen response and ceruloplasmin response tend to be increased in sepsis, but only after the fully developed septic clinical picture is demonstrated. *(From Sganga et al, [82] copyright 1985, American Medical Association)*

concentrations do not change in nonseptic trauma patients. The plasma concentrations of these latter proteins decrease as the septic episode progresses.

Because the liver is responsible for the synthesis of these acute phase proteins, hepatic protein synthesis is accelerated by a wide variety of acute inflammatory insults. Despite the accelerated rate of hepatic protein synthesis during inflammation and sepsis, the mechanisms responsible for this stimulation have not been fully elucidated. The synthesis of specific proteins is probably regulated transcriptionally during inflammation. For example, messenger RNA concentrations for the acute phase proteins are elevated, [83] [84] [85] whereas albumin messenger RNA is decreased. [86] However, increased messenger RNA concentrations may not wholly account for the overall increased rates of protein synthesis. Instead, the translation phase of the protein synthetic pathway is also increased. [81] Interleukin-6 appears to be responsible for the changes in acute phase messenger RNA levels in trauma and sepsis. [87]

Fatty Acid Metabolism

The metabolic course of the traumatized or septic patient shows that fatty acids become the preferred fuel for oxidative metabolism. The same dependence on fatty acid metabolism is observed under conditions of starvation and diabetes, in which the conservation of glucose carbon becomes pathologic (Fig. 74-19) (Figure Not Available) .

The release of fatty acids from adipose tissue in sepsis is variable, with some reports of an increased release and other reports of a decreased release. Despite unaltered arterial fatty acid concentrations, fatty acids are continually released into the blood stream and are delivered to the liver. After removal from plasma, fatty acids may either undergo oxidation for energy and ketone body production, or esterification to triglycerides. Increased hepatic triglyceride levels are a characteristic feature of sepsis, giving rise to the histologic observations of increased lipid droplets in liver tissue at autopsy. The increased triglyceride levels may be partly due to reesterification. This increased reesterification may be responsible in part for the increased secretion of triglycerides as very-low-density lipoproteins. Administration of monokines, either tumor necrosis factor or interleukin-1, increases hepatic lipogenesis in fed rats, but not in fasted rats. [89] [89]

Lipogenesis

Although ketogenesis may be inhibited during sepsis, lipogenesis appears to be accelerated. In septic patients receiving only glucose in excess of 800 cal/m ^{2} body surface area, the respiratory quotient (RQ) rises above 1.0, a value

Figure 74-19 (Figure Not Available) Septic alteration of metabolic regulation of hepatic fatty acid oxidation, ketogenesis, fatty acid synthesis, and carbohydrate metabolism. Malonyl-CoA (...) derived from citrate and cytosolic acetyl-CoA inhibits carnitine:acyl CoA transferase I. (Carnitine:acyl CoA transferases [I and II] are bound to inner mitochondrial membrane in vivo, but for clarity, the reactions are shown away from membrane.) The effects of hormones (insulin or glucagon) and of small and large septic abscesses to increase (+), or inhibit (-) particular synthetic pathways or oxidation of specific substrates are shown. FFA, long-chain fatty acids; FA-CoA, long-chain fatty acyl-CoA; FACarn, long-chain fatty acyl carnitine; CoA, coenzyme A; OAA, oxaloacetate; PYR, pyruvate; LACT, lactate; TCA, tricarboxylic cycle; TG, triglycerides; PL, phospholipids; CAT-1, carnitine:acyl-CoA transferase I; II, carnitine:acyl transferase II; PDH, pyruvate dehydrogenase complex; MITO, mitochondria; HMG-CoA, beta-hydroxy-beta-methyl glutaryl-CoA; cholesterol esters, CE. *(Modified from Vary et al [200])*

that is indicative of net lipogenesis. [44] [45] The capacity to synthesize lipids is increased, suggesting an increased flow of acetyl groups toward fatty acid synthesis and away from ketone body formation. These observations support the concept of a reciprocal relationship between lipogenesis and ketogenesis, thus preventing both fatty acids and ketone bodies from being synthesized simultaneously, which would result in an energy-wasting futile cycle.

The potential site of hepatic fatty acid oxidation regulation, and therefore ketone body formation, is the carnitine:acyl transferase-1. This enzyme is competitively inhibited by malonyl-CoA, resulting in decreased formation of long-chain fatty acyl carnitine. Malonyl-CoA is the first committed intermediate in the conversion of glucose carbon into fat, and its concentration is known to fluctuate in parallel with the rate of fatty acid synthesis. The physiologic role of malonyl-CoA is to provide unidirectional flow of glucose carbon to fatty acid synthesis by preventing the futile oxidation of newly synthesized fatty acids via the carnitine:acyl transferase system to beta oxidation. The malonyl-CoA concentration is elevated 2-fold in livers from septic animals. [90] The rise in malonyl-CoA concentration is in the range reported for maximal inhibition of the carnitine:acyl transferase-1. Therefore, the increased malonyl-CoA concentrations would be expected to inhibit the carnitine:acyl transferase-1 during sepsis.

Progressive sepsis increases plasma triglycerides as the septic process worsens. Besides an increase in hepatic triglyceride synthesis, an impairment in the peripheral triglyceride disposal mechanisms may exist. Lipoprotein lipase activity, the enzyme responsible for clearance of plasma triglycerides, is reduced in both adipose tissue and muscle from septic animals. Concomitant with the lowered lipoprotein lipase activity, plasma triglyceride concentrations are increased. It appears that a monokine or several monkines acting synergistically act to downregulate lipoprotein lipase activity.

Ketone Bodies

The normal response of the liver to increased delivery of fatty acids is the synthesis of ketone bodies (3- $_L$-hydroxybutyrate and acetoacetate). In addition, reversal of the insulin-to-glucagon ratio enhances the ketogenic capacity of the liver. In sepsis, there is a rise in the glucagon-to-insulin ratio, but the plasma ketone body concentrations are lower than expected given the hormonal environment, and septic animals and patients undergoing a total fast do not demonstrate ketonemia. The lack of elevated plasma ketones does not indicate a lack of fatty acid oxidation, because these patients have an RQ of 0.75, which is indicative of fat oxidation. Thus, sepsis appears to induce changes in hepatic fatty acid metabolism that prevent or reverse maximal rates of ketogenesis.

The failure of hepatic tissue to enhance ketogenesis may be important to the clinical outcome of the septic episode, because survival is dependent on normal liver function. A decrease in the circulating ketone body concentrations would be expected to increase the dependence of peripheral tissues on alternative substrates for energy production when cellular metabolism is accelerated by sepsis. The failure of similar increases in plasma ketone bodies in nondiabetic septic patients may be an additional factor in the markedly increased rates of proteolysis in septic patients. Of considerable interest is the observation that enhanced muscle catabolism in response to injury is not observed if the blood concentration of ketone bodies is increased. However, it would be impractical to simply supply ketone bodies as nutritional support. To replace 5 percent glucose, one would require 125 g ketones/d. That amount of ketone bodies presents few problems, because ketone bodies are readily soluble in saline. The problem is that accompanying the ketone body infusion would be approximately 1,200 mEq of a positive ion (Na^+). Such a salt load on the kidneys is certainly not advised in healthy persons and is probably devastating in the septic patient, who may have complicating renal dysfunction.

Insulin Resistance in Sepsis

The effects of sepsis on glucose production in liver are well characterized, but very little information is available concerning the effect of sepsis on peripheral glucose utilization. Abnormal glucose tolerance tests are commonly observed following traumatic injury, burn, shock, or sepsis despite normal or accentuated insulin secretion. Despite the responsiveness of the pancreatic beta cells to secrete insulin in response to a glucose load, glucose intolerance and hyperglycemia persist, suggesting that certain target organs in the injured or septic patient are relatively insensitive to the effects of circulating insulin. Because glucose consumption by central and peripheral nervous tissue, renal medulla, bone marrow, erythrocytes, and leukocytes is not insulinsensitive, the primary sites of insulin resistance are in peripheral tissues, particularly skeletal muscle and adipose tissue, where insulin stimulates glucose uptake. Because only a small percentage (1%) of the glucose load is taken

up by adipose tissue, the major effect of insulin appears to be in muscle tissue.

In the case of sepsis, insulin resistance is manifested by either an abnormal glucose tolerance test or simply an elevated plasma glucose concentration for a given insulin concentration. This insulin resistance could occur by alterations at one of three levels: (1) before the interaction of insulin with the receptor, (2) at the receptor level, or (3) at steps distal to the insulin-receptor interaction, namely, cellular metabolism. Insulin concentration is the same or increased in sepsis, and no anti-insulin antibodies have been detected. At the receptor level, the sensitivity of the receptor to circulating insulin appears to be normal. [91] Hence, it appears that insulin resistance in sepsis may be related to an intracellular defect in glucose metabolism.

MEASUREMENTS OF ENERGY REQUIREMENTS FOR PARENTERAL NUTRITION

Kinney [92] pointed out that surgical weight loss can be rapid and can result in massive depletion of up to 20 percent of normal body weight within 3 weeks of multiple injuries, despite the resumption of some oral intake within the first

week. Surgeons have tried to explain this large tissue loss and increased nitrogen excretion on the following basis: a major injury produces a very large increase in the rate of resting energy expenditure (REE) [a] that exceeds the energy availability from fat mobilization; muscle protein is progressively broken down, the resulting amino acids deaminated, and the carbon chains oxidized for energy. The preceding sections have outlined the theoretical basis of catabolic response to sepsis as attempts to compensate for decreased peripheral oxidation of glucose and the need for increased hepatic protein synthesis. Partial starvation in the perioperative period aggravates the catabolic loss of lean body mass. Therefore, it is imperative to consider a nutritional prescription to the septic or stressed patient.

Nutritional Assessment

Four factors have been used to assess the need for nutritional support: [93] (1) history of unexplained weight loss of 10 percent of body weight, (2) serum albumin concentration of less than 0.34 g/dL, (3) anergy to a battery of four or five standard skin-test antigens, and (4) abnormally low total lymphocyte count. A patient who manifests all four indexes is severely malnourished. However, the efficacy of preoperative parenteral nutrition in reducing operative morbidity and mortality is still open to question. Serum transferrin and prealbumin are better markers than albumin for rapid changes in nutritional status because they have shorter half-lives than albumin. The excretion of 3-methylhistidine (primarily from muscle actin) also has been used as a marker for muscle breakdown. [94] However, the MM band of creatine phosphokinase isoenzyme is also elevated after skeletal muscle trauma.

Estimating Energy Expenditure

For severely ill patients, indirect calorimetry seems the most feasible method. The measurement of four independent quantities is required for this procedure: [95] (1) daily intake of fat, carbohydrate, and protein; (2) daily nitrogen excretion; (3) daily oxygen consumption (DV $_{O_2}$); (4) daily CO_2 production (DV $_{CO_2}$). For bedridden patients who are completely at rest during the entire 24 hours, three to five measurements of REE (40-60 minutes' duration) may be extrapolated to obtain a reasonably good estimate of total energy expenditure (TEE) for the 24-hour period. Van Lanschot et al [96] investigated the Harris-Benedict equation versus the accurate measurement of TEE by continuous indirect calorimetry. Despite the overestimation of TEE when caloric needs were calculated by formula, they remarked that the difficulties associated with continuous indirect calorimetry left "unresolved, whether or not indirect calorimetry is actually to be preferred in daily clinical practice." [96]

The usual approach is to measure DV $_{O_2}$, DV $_{CO_2}$, and nitrogen excretion. Energy requirements must be adjusted for variations resulting from difference in body size. The basal metabolic rate refers to energy expenditure at a specific time in the morning, soon after awakening and approximately 14 hours after the last meal, measured at thermal neutrality. This discussion refers to basal energy expenditure (BEE) instead of basal metabolic rate.

Harris-Benedict Equation

Heat production per square meter of body surface area per unit time decreases steadily as humans approach puberty; then energy expenditure more gradually decreases as age increases. This decrease is approximately 1 to 2 percent per decade in adults (20-75 years of age). [97]

The Harris-Benedict equation is an empirically derived equation with variables that reflect the relative contributions to overall heat production per square meter body surface area of activity, age, sex, and body size:

For males:

For females:

BEE equals basal energy expenditure in kilocalories per day.

To apply this equation to nutritional requirements, the BEE is multiplied by activity and injury factors to arrive at a daily nutrition requirement in kilocalories per day, or TEE. Activity factors vary from 1 for a patient on bed rest to 1.3 for an ambulatory patient. Injury factors vary from 1 to 1.2 for minor surgery to 1.8 for major sepsis (Table 74-5) (Table Not Available) . For each degree above 37.2°C, the daily nutrition requirement is multiplied by 1.07. An important reason for excessive energy administration is using TEE based on weight and on estimates

TABLE 74-5 -- Energy Expenditures Measured in Different Clinical Conditions

(Not Available)

From Popp and Brennan [192]

[a] REE is defined as the mean daily value obtained from measurements of gas exchange at rest. It includes the specific dynamic action of foods and is about 10 percent greater than the basal metabolic rate.

of BEEs rather than on measured metabolic expenditures. [96] [98] Lean tissue repletion is maximal at 4 to 6 g/d of nitrogen in the malnourished, nonstressed patient receiving energy at 1.75 × BEE (estimated BEE) and protein at 1.5 g/kg/d. [99] Any positive energy balance beyond this is used in fat synthesis. In the past, nutritional support was used with very high multiples of BEE to attempt to force positive nitrogen balance. Current practice is to prescribe energy (glucose, lipids) to meet measured energy requirements and separately prescribe proteins (amino acids) to meet measured nitrogen excretion. [100]

Calculation of Energy Metabolism from Gaseous Exchange

Energy expenditure is more accurately assessed by measuring DV O_2 and DV CO_2 (Ch. 15) . When urinary nitrogen (UN) is measured, the formula described by Weir [101] can be used to calculate the amount of nonprotein energy expended in kilocalories: [b]

Energy expenditure/unit of time

where DV O_2 and DV CO_2 are in L/24 h STPD (standard temperature and pressure, dry).

The technique of indirect calorimetry has been used to measure metabolic rate. Furthermore, it has long been recognized that these measurements also can give information on the type and the rate of fuel oxidation within the body. This latter information is based on a number of assumptions, which may not hold in the presence of two metabolic processes: gluconeogenesis and lipogenesis. [102]

Resting energy expenditure includes BEE and the thermal effect resulting from food intake as well as nonshivering thermogenesis in response to environmental temperature alterations. Infusing amino acids increases energy expenditure by 10 percent over 24 hours in normal subjects and in postoperative patients, whereas glucose and lipid infusions have little effect. [103] [104] Increased energy expenditure, however, is noted when carbohydrates are given in excess of energy requirements. REE can be initially estimated from the following formula [105] after indirect calorimetry measurements of oxygen consumption and carbon dioxide production:

Resting energy expenditure can then be adjusted for protein metabolism by measuring the UN in grams per day.

The adjusted metabolic expenditure equals REE - 2.17 × UN. A 2-hour UN measurement can be substituted for a 24-hour collection. [106] UN excretion is calculated from

TABLE 74-6 -- Assessment of Daily Nitrogen Losses and Requirements

(Not Available)

From Lee [193]

measured urinary urea measurements as outlined in Table 74-6 (Table Not Available) .

The REEs of a hospitalized patient are usually a balance between the decrease that normally occurs in association with any weight loss and nutritional depletion from partial starvation and any increase that results from disease or injury. An average increase of 13 percent in energy expenditure is associated with each degree centigrade of fever.

Respiratory Quotient

The RQ is the ratio of DV CO_2 divided by DV O_2 (DV CO_2 /DV O_2). Normally, the RQ ranges between 0.7 (lipid oxidation) and 1.0 (glucose oxidation) and varies with substrate oxidation. The RQ moves toward 1 with dietary carbohydrate loading and decreases to 0.7 with prolonged fasting, demonstrating almost complete fat oxidation during the starved state. With lipogenesis from excess caloric intake, RQ becomes greater than 1.0. The RQ measurement also reflects gas exchange from protein metabolism. UN excretion is therefore determined, and the contribution of protein combustion to gas exchange is calculated. This correction yields the "nonprotein RQ."

Thus, measurement of DV O_2 , DV CO_2 , and UN excretion permits determination of individual fuel sources oxidized as well as calculation of the total quantity of heat produced. [107]

The RQ for metabolism of carbohydrates equals 1:

In oxidation of fat, the RQ is less than 1:

[b] Food energy values are usually given in kilocalories. One kilocalorie is the amount of heat necessary to raise 1 kg of water from 15° to 16°C. Energy conversion factors generally used are 4.1 kcal/g of food protein or carbohydrate and 9.3 kcal/g of food fat. The energy expenditure to nitrogen loss for a 70-kg man receiving no nitrogen intake would be 1,800 kcal/3.7 g/d of nitrogen. The minimal nitrogen intake, however, has been set at 5.2 g/d in the form of high-quality protein.

Cells can oxidize multiple substrates concurrently and can convert glucose into both fat and glycogen. Therefore, an RQ derived from gas analysis cannot provide precise information concerning the metabolic pool. However, the RQ estimates the relative contributions of glucose, lipids, and proteins as well as lipogenesis from overfeeding.

Methods of Measuring Respiratory Quotient

The most common methods for measurement of the respiratory quotient use a closed-circuit or open-circuit technique. The closed-circuit method uses a spirometer, filled with oxygen with a CO_2 absorber placed in the circuit. The rate of disappearance of oxygen from the spirometer equals the oxygen consumption, and mean expired CO_2 concentration times the minute volume equals the CO_2 production. The open-circuit method uses a set of one-way valves to direct expired air into a collecting container (usually a Douglas bag or a Tissot spirometer). At the end of a carefully timed collecting period, both the volume and the composition of the

expired air are measured, and the rate of DV $_{O_2}$ and DV $_{CO_2}$ are determined by the difference between the concentrations of inspired gas and the expired gas collected. A correction (Haldane) is used to account for the difference between inspired and expired volumes. Because the Haldane correction depends on a conservation of nitrogen between inspired and expired gas, it becomes inaccurate at low inspired nitrogen (high fraction of inspired oxygen [F $_{IO_2}$]) levels.

Kinney et al [108] designed a noninvasive system for nonintubated patients that consisted of a clear plastic head canopy (with no attachment to the face or airway) ventilated with air that is continuously analyzed for measurement of DV $_{O_2}$ and DV $_{CO_2}$. REE of hospitalized patients can be determined by obtaining average gas-exchange measurements from five 30- to 45-minute canopy runs during each waking day (Fig. 74-20) (Figure Not Available) .

Commercial instruments with attached CO_2 and oxygen analyzers that have been developed to measure DV $_{O_2}$ and DV $_{CO_2}$ in patients in the operating room and intensive care unit are now available. Several problems are associated with validation of these instruments and in performing gas exchange measurements during mechanical ventilation. [109] [110] The closed-circuit devices function well on mechanically ventilated patients because they are not effected by F $_{IO_2}$. The open circuit devices can be utilized for patients either breathing spontaneously through their native airways or breathing through an endotracheal tube and ventilator but are limited to an F $_{IO_2}$ value of 0.6 or less.

NUTRITIONAL PRESCRIPTION

Prescribing intravenous nutritional support for surgical patients during the perioperative period requires a knowledge of the patient's requirements for calories and protein nitrogen. To accurately predict a patient's protein-calorie requirements, one must know the patient's current state of nutritional health and current predicted calorie requirements. The previous sections discussed the assessment of nutritional defects measuring caloric use with indirect calorimetry

Figure 74-20 (Figure Not Available) Alterations in gas exchange secondary to total parenteral nutrition (TPN) are shown (mean ± SD). Glucose was the primary source of nonprotein calories. Clearly, two different responses are seen. Depleted patients show a respiratory quotient (RQ) above 1.0 with a small increase in V_{O_2}, while hypermetabolic patients have an RQ less than 1.0 with a marked increase in V_{O_2}. Both groups show a large increase in V_{CO_2}. *(From Askanazi et al [126])*

and the calculation of REE and measurement of protein requirements by nitrogen balance studies.

Parenteral Versus Enteral Nutrition

Nutritional requirements for perioperative surgical patients can be administered either enterally through the gut or parenterally via a central or peripheral vein. [111] [112] [113] All three routes have their indications and advocates. Enteral feeding either through a fine-bore nasogastric tube or bypassing the stomach with a feeding enterostomy tube in the distal gastrointestinal tract has the advantage of the use of normal routes for nutrient absorption as well as a decreased risk of infection. Although enterostomy tubes provide a convenient simple route for nutrition, they must be carefully monitored for function. If the stoma breaks down or the tube becomes misplaced, the patient is at risk for peritonitis from leakage of gut contents or tube feedings into the peritoneal space.

It has been demonstrated that enteral feeding decreases the atrophy of the luminal brush border of the gut and may decrease bacterial translocation from the intestinal lumen to the blood stream. [114] However, enteral feeding intolerance was associated with an increased mortality in a study by Chang and colleagues. [115] This complication was aggravated by delayed recognition of enteral feeding intolerance and a period of starvation before the commencement of intravenous nutrition. Enteral feeding intolerance is manifested by diarrhea, bowel distention from unabsorbed feedings, high residual volume aspirated from the catheter, and failure to reverse signs of malnutrition. It is not immediately apparent whether the route of nutrition caused the mortality

noted by Chang et al [115] or merely heralded a more profound systemic disease. Because the efficacy of perioperative nutritional support is generally effective only to reverse specific nutritional deficits, [116] [117] [118] [119] it is unlikely that any route of nutrition would reverse an otherwise inexorable, downhill clinical course.

Perioperative starvation impairs wound healing [120] [121] and causes excessive protein catabolism, but routine TPN to all surgical patients is not cost-effective because well-nourished surgical patients with brief perioperative fasting periods do not demonstrate a therapeutic effect of TPN. [121] [122] [123] [124] Cancer patients frequently represent a group of patients who benefit from TPN [125] [126] to replace specific nutritional deficits. The use of enteral feedings placed through a tube distal to the pylorus allows an increasing use of nutrition support for surgical patients, including cancer patients. Enteral feeding is associated with fewer complications and less expense than TPN, but it must be monitored carefully to avoid the complications noted by Chang et al. [115] Appropriately monitored enteral feedings can be successfully administered into the small bowel of most postsurgical and trauma patients, including those who have undergone abdominal surgery. Parenteral nutrition via a peripheral vein or a central vein provides nutritional support in patients with a nonfunctioning gastrointestinal tract.

Substrate Requirements for Total Parenteral Nutrition

A caloric source and an amino acid source are required for adequate nutrition (Fig. 74-21) (Figure Not Available) . When glucose is given as the sole caloric source, 1 dL/wk of 10 percent fat solution prevents essential fatty acid deficiency. However, a balanced daily energy supply of fat and glucose is commonly used for TPN. This approach may decrease the problems in hepatic and pulmonary function that occur with high glucose loads. [127] [128]

If the total energy requirements are not met with a total dextrose intake of 5 to 6 mg/kg/min (or about 2.5 L of 25% dextrose for a 70-kg adult), consideration should be given to providing extra calories as fat emulsions--not only to prevent fatty infiltration of the liver and glucose intolerance but also to avoid excessive production of CO_2. An excess of CO_2 resulting from administration of too much parenteral glucose can compromise weaning of hypermetabolic patients from mechanical ventilation or can precipitate respiratory failure in patients with severe obstructive pulmonary diseases. Infusion of 1 L of solution containing 4 to 5 percent amino acids and only 15 percent dextrose (1,400 mOsm/L), combined with 5 dL of a 20 percent fat emulsion may be indicated in these situations. [129] This combination provides the same amount of amino acids and calories as regular central formulations; however, 50 percent of the calories are derived from dextrose and 50 percent from fat emulsions.

The provision of 5 dL of a 20 percent fat emulsion has been shown to have no adverse effects on hemodynamic status or pulmonary diffusing capacity in critically ill patients. [130] [131] Medium-chain triglycerides may be substituted for long-chain triglycerides, with improved patient tolerance of fat infusions. [132] [133]

All solutions should contain the daily requirements of essential electrolytes. Zinc, copper, selenium, and chromium are increasingly being used to prevent abnormalities associated with trace-metal deficiency. Daily vitamin supplementation is required. [134] Figure 74-21 (Figure Not Available) illustrates a worksheet/ order sheet for parenteral nutritional support prescription writing.

Administration

Peripheral Administration

When the need for parenteral supplementation is limited (approximately 1,500 kcal/d), TPN may be delivered through a peripheral vein. A solution containing 3 to 4 percent amino acids (e.g., Travasol, FreAmine, or Aminosyn) mixed with 5 to 10 percent dextrose and given simultaneously with fat emulsion (Intralipid or Liposyn) delivers 1,100 to 1,800 kcal and 0.8 to 1 g/kg/d of amino acids. Fat emulsions supply essential fatty acids and a concentrated source of energy (1.1 kcal/mL). With an osmolarity of 280 mOsm, they can be infused through a peripheral vein.

Central Administration

When 2,000 kcal or more is required daily, a central catheter should be inserted (subclavian vein). A 15 percent dextrose (1,400 mOsm/L) solution containing 4 to 5 percent amino acids can be combined with 5 dL of fat emulsion. This provides balanced parenteral nutrition by administration of 50 percent of the nonprotein calories

as fat and 50 percent as dextrose.

Central venous catheter complications (Table 74-7) (Table Not Available) limit the usefulness of intravenous nutrition administered by this method. Catheter-related sepsis is a common complication of any central venous catheter left in place longer than 72 hours. Therefore, a device (Vitacuff) that consists of silver ion-impregnated collagen to seal the subcutaneous and intravascular catheter tract from the environment appears very promising for central vein-administered nutritional support. [135] [136] This device has significantly reduced the number of catheter-related infections for catheter durations of up to 10 days. Multilumen catheters for central venous insertion are also attractive for parenteral nutrition because one lumen may be dedicated to the nutritional media, which is highly bacteriophilic, and other lumens may be used for pressure monitoring or drug administration. The combination of the subcutaneous, sealed cuff with a multilumen catheter is attractive because there is concern that multilumen catheters may lead to an increased incidence of catheter-related sepsis. [137] Other complications of TPN are outlined in Table 74-8 (Table Not Available) .

Complications

Depression of Serum Folate Concentration

Tennant et al [138] reported acute depression of serum folate concentrations in patients fed preoperatively with parenteral nutrition solutions. Their studies seem to indicate

Figure 74-21 (Figure Not Available) Adult total parenteral nutrition order form. *(Courtesy of Pennsylvania State University, Hershey, Pa.)*

that the amino acid component of the solutions may be at least partially responsible for the fall in serum folate level, as suggested by Krebs and coworkers. [139] Tennant and colleagues [140] cautioned that further investigation may be indicated in patients receiving postoperative parenteral nutrition after anesthesia exposure to nitrous oxide, which may alter serum methionine and folate concentrations. [141] [142]

The most common errors are underestimating phosphate needs (40-100 mEq/d) and overestimating calcium requirements (3-8 mEq/d). The most common abnormality in patients receiving TPN is a mild-to-moderate elevation in results of liver function tests. This may be a result of fatty infiltration of the liver that occurs with excess glucose administration. In a patient who begins with normal indexes of liver function, 2-fold elevations in serum glutamic oxaloacetate (SGOT) and serum glutamic pyruvate transaminase (SGPT) levels and a progressive mild rise in alkaline phosphatase level are not uncommon. If an increase in bilirubin

TABLE 74-7 -- Potential Catheter Complications of Total Parenteral Nutrition

(Not Available)

From Dudrick [93]

occurs and SGOT and SGPT levels continue to rise, a cause other than the TPN infusion should be sought. Unfortunately, maintenance or restoration of lean body mass in hypercatabolic patients can be difficult because of the inevitable increased breakdown of muscle protein supplying amino acids for gluconeogenesis. An attempt to induce anabolism by infusing large amounts of carbohydrate increases the metabolic rate, the conversion of carbohydrate into fat, and the rate of DV $_{CO_2}$; it does not promote increased protein synthesis, and thus, it results in self-defeating hypermetabolism. [143] Hypercatabolic patients must be given adequate amino acids to achieve nitrogen equilibrium. Patients with persistent negative nitrogen balance should have the ratio of nitrogen to calories increased without increasing nonprotein calories beyond their use capabilities. [119] [143] [144]

Respiratory Complications of Total Parenteral Nutrition and Relative Starvation

In 1976, Doekel et al [145] reported that normal volunteers fed 400 kcal/d of carbohydrate orally for 10 days experienced a decrease in ventilatory response to hypoxia, a measure of respiratory drive (Fig. 74-10) (Figure Not Available) . Weissman et al [146] observed that 7 days of infusion of 400 kcal/d of 5 percent dextrose resulted in a reduced mean inspiratory flow, another measure of neuromuscular drive.

Arora and Rochester [147] found that chronically ill, nutritionally depleted patients had significant reductions in respiratory muscle strength, as measured by maximal inspiratory and expiratory pressures; endurance, as measured by maximal voluntary ventilation; and vital capacity. High-protein nutritional support improves respiratory muscle strength and ventilatory drive. [118] [148]

Excessive glucose administration leads to an increase in minute ventilation that is proportional to an increase in DV $_{CO_2}$ caused by oxidation of carbohydrate (RQ = 1) or lipogenesis (RQ = 8). [149] Thus, infusion of glucose as a sole energy source can lead to increased respiratory work because ventilation increases in response to added CO_2 .

In summary, Weismann and Askanazi [149] recommended that nonprotein calories be administered as 50 percent carbohydrate and 50 percent lipid. They recommended this balanced supply of energy sources both for patients with poor respiratory function and for those who are septic and hypermetabolic. This approach leads to less DV $_{CO_2}$ than occurs with methods supplying 100 percent of the nonprotein calories as glucose. Furthermore, the combined substrate technique causes less increase in energy expenditure and norepinephrine secretion in the septic and hypermetabolic patient [150] and prevents essential fatty acid deficiency. [116]

Hypoglycemia

The most common cause of hypoglycemia is a slowing or a cessation of infusion. The increased secretion of insulin that accompanies TPN when suddenly unopposed by exogenous glucose results in hypoglycemia. For this reason, TPN solutions should never be abruptly discontinued in the operating room without being replaced with a concentrated glucose solution, such as 10 percent dextrose solution.

Complications of Intravenous Fat Emulsions

Extended TPN using lipid emulsions may injure the bilirubin-transfer mechanism in the liver and lead to progressive

TABLE 74-8 -- Potential Metabolic Complications of Total Parenteral Nutrition

(Not Available)

From Dudrick [93]

cholestasis. This is usually a benign, readily reversible state, but continued TPN without a change in the constituents can cause liver injury with hepatocyte necrosis and periportal fibrous changes. In a study by Allardyce, [151] patients with a high lipid intake had significant elevations of the serum bilirubin and alkaline phosphate levels at the completion of parenteral nutrition. Cholestatic jaundice is associated with administration of lipid emulsion in a dose of 3 g/kg/d in patients fed intravenously for more than 3 weeks. The condition improves, with a return of liver function to normal, when the dose of lipid emulsion is reduced or when intravenous feeding is discontinued. Lipid emulsion might be limited to 1 g/kg/d, and liver function may be evaluated twice weekly. It appears that the dose of lipid emulsion should be reduced if a progressive rise in serum alkaline phosphatase level occurs.

Disorders of Water Metabolism

Bistrian et al [99] pointed out that the tendency to retain water is characteristic of many of the disease states for which TPN is employed, including postoperative states, shock resuscitation, congestive heart failure, oliguric renal failure,

hepatic insufficiency, and severe malnutrition. The antinatriuresis that results from the hyperinsulinemia seen with glucose-based TPN can lead to serious water overload in a brief period. This can be minimized or avoided by matching total fluid losses plus 5 dL, by limiting sodium intakes to less than 40 mEq of sodium beyond loss replacement, and by limiting insulin response by the use of a mixed-fuel system.

EFFECTS OF NUTRITION ON DRUG METABOLISM

Pantuck et al [152] showed that TPN can alter rates of hepatic drug oxidation in divergent ways, depending on the type of nutrition furnished. After six healthy young male volunteers had their total nutrition provided parenterally for 4 days with 5 percent dextrose followed by an isocaloric amount of amino acids (Aminosyn, 3.5%) for 1 day, disposition of the model drug antipyrine changed significantly. Compared with antipyrine clearance values obtained on their home diet, the 4 days on dextrose significantly decreased antipyrine clearance. By contrast, after only 1 day on parenteral amino acids, antipyrine clearance increased markedly. Thus, dextrose retarded, whereas amino acids enhanced, rates of antipyrine elimination. This and other studies led Vesell and Biebuyck [153] to suggest that anesthesiologists should consider that the doses of many drugs given to surgical patients may need to be changed on commencement of TPN. Drugs eliminated primarily by hepatic metabolism may especially require dosage adjustment.

These effects also occur from enteral feeding. In general, high-protein diets significantly enhance drug clearance (Fig. 74-22) (Figure Not Available) . [154] [155] [156] [157] [158] Patients on a low-protein diet had delayed drug clearance, regardless of the lipid/carbohydrate ratio of their diets. These changes occurred without changes in volume of distribution or plasma protein binding. The effect of protein is also seen in vegetarians; high-protein vegetarian diets significantly enhance drug clearance. [159] This effect is so pronounced in experimental studies that variations in dietary protein intake probably explain the otherwise

Figure 74-22 (Figure Not Available) A comparison of theophylline half-life results during test diet periods. Bars represent means ± SD. *(From Feldman et al [201])*

inscrutable interpatient variation in response to intravenously administered anesthetics. Furthermore, starvation during a period of critical illness retards clearance of many intravenous drugs. Enteral feedings directly inhibit the absorption of enterally administered phenytoin; thus, tube feedings must be discontinued for an hour before and an hour after phenytoin dosing. The total volume of tube feedings must compensate for the period of discontinuation.

PERIOPERATIVE NUTRITIONAL SUPPORT IN SPECIAL SITUATIONS

Modifications of the standard adult formula are required for the treatment of patients with congestive cardiac failure, hepatic failure, and renal failure. Modifications of the solution are often necessary, depending on the patient's metabolic response. It is essential for the anesthesiologist to recognize that no single intravenous nutrient solution can be ideal for all situations. Nutritional support services are becoming a feature of modern critical care units. These consulting services, which may employ critical care anesthesiologists among their medical staff, must consider the following special situations for nutritional support.

The Neurosurgical Patient

Three cautions should be remembered when TPN is being considered for the brain-injured patient (Ch. 52) :

1. Severe head injury is associated with hyperglycemia, and administration of large amounts of glucose could worsen this abnormality. [16] [160]
2. Free water administration is usually restricted after brain trauma to prevent severe hyponatremia.
3. The greatest hazard of TPN is sepsis. This risk should not be underestimated in critically ill patients bearing numerous catheters and multiple possible foci for infection.

Animal experiments employing controlled degrees of cerebral ischemia have demonstrated that elevated blood-brain glucose concentrations greatly enhance the extent and the degree of subsequent brain damage. [161] Pulsinelli et al [162] have examined the effect of hyperglycemia versus normoglycemia in nondiabetic patients with stroke. These workers reported that stroke-related deficits among nondiabetic patients appeared to be more severe when the admission blood glucose level was above 120 mg/dL than when it was below this level. The precise mechanism of the adverse effects of hyperglycemia in ischemic brain is unknown. Myers [163] suggested that increased cerebral lactic acidosis, which results from the anerobic glycolysis of increased brain glucose stores, is directly or indirectly responsible for the adverse effect. Because the blood's oxygen reserve is substantially less than its glucose reserve (especially in hyperglycemia), areas of brain experiencing severe but incomplete reduction of blood flow would be particularly affected by such a mechanism. Thus, hypoxic areas of brain receiving continued delivery of glycolytic substrate would be subject to higher levels of accumulation of lactic acid. [164] Pulsinelli et al [162] concluded that hyperglycemia can accentuate ischemic brain damage in humans and suggested that blood

glucose levels be maintained in the near-normal range in diabetic patients with a high risk of stroke. Similarly, they suggest that glucose-containing infusions should be avoided in the immediate treatment of patients with acute or progressive stroke, in patients undergoing surgery that could affect cerebral blood flow (e.g., carotid endarterectomy, extracranial-intracranial bypass, cardiac bypass), or in those who have had a cardiac arrest.

Renal Failure

The principle that endogenous urea can be converted to nonessential amino acids if an adequate amount of carbohydrate is provided underlies one nutritional approach to patients with acute renal failure (Chs. 34 53 and 55) . The Giordano [165] -Giovanetti [166] diet contains a high carbohydrate load with limited protein, abundant in its percentage of essential amino acids. The use of commercially available essential amino acids (NephrAmine) with hypertonic glucose has served to facilitate control of electrolyte balance, to lower blood urea nitrogen levels, to decrease or eliminate the need for dialysis, and to speed recovery of patients with acute tubular necrosis.

Patients with acute tubular necrosis are treated by parenteral nutrition with essential amino acids and hypertonic dextrose, now commercially available as NephrAmine (McGraw Laboratories: 12.7 g of eight L-essential amino acids and 350 g of dextrose, insulin, and vitamins, in a total of 750 mL). The total glucose concentration thus reaches 47 percent, and the osmolarity of the solution is 2,100 mOsm/L. The high concentrations of glucose in a small volume enable even an oliguric patient to receive a substantial amount of calories.

Because urinary glucose is notoriously unreliable in renal failure, the blood glucose level should be checked at least twice daily when therapy is started. Insulin is added to the solution as necessary, according to blood glucose levels. Hypokalemia, hypomagnesemia, and hypophosphatemia occur regularly, sometimes as soon as 8 hours after the initiation of renal failure fluid infusion. Reduced amounts of standard amino acid formula can be utilized just as successfully in most renal failure patients.

Feinstein [167] demonstrated a novel approach to providing amino acids to patients with hemodialysis-dependent renal failure by adding the amino acids to the dialysate. There was a substantial, although slow, uptake by the patient of amino acids from the dialysis bath. Patients with large wounds and acute renal failure require increased protein for wound healing and dialysis for the control of excessive plasma urea.

Hepatic Failure

Nutritional support is highly desirable for many surgical patients with cirrhosis, in the perioperative management of bleeding esophageal varices, and in postshunt encephalopathy. Intravenous solutions for patients with liver failure (Chs. 54 and 55) should essentially fulfill the following requisites [168] :

1. Provide adequate amounts of calories and nitrogen for protein synthesis.
2. Neither produce nor aggravate plasma amino acid imbalance.
3. Do not produce electrolyte or acid/base imbalance.
4. Neither produce nor aggravate neurologic or encephalopathic symptoms.
5. Provide sufficient calories in a volume tolerated by patients with hepatic failure.

Hepatic Encephalopathy

Hepatic disease may lead to symptoms of brain malfunction or encephalopathy ranging from subtle behavioral changes to deep coma (Ch. 54) . Such patients often have shunting of blood around the liver, either produced surgically or occurring spontaneously. Increases in brain ammonia and glutamine have been demonstrated in hepatic encephalopathy. A current hypothesis of the cause of hepatic encephalopathy is that an imbalance of neurotransmitters, specifically monoamines, occurs in the brain. [169] This is based on the finding of an increased content of the amino acids tryptophan, tyrosine, and phenylalanine in the brain [170] ; these are precursors for the synthesis of serotonin and the catecholamines.

In the case of catecholamines, the excess precursor material in the brain in hepatic encephalopathy may cause inhibition of the normal synthetic pathway, leading to a reduced content of dopamine and norepinephrine and to increased amounts of trace amines, such as octopamine and phenylethanolamine.

Plasma amino acid profiles are characteristically changed when hepatic failure is present. A common finding is elevation of phenylalanine and methionine levels. The plasma levels of the branched-chain amino acids leucine, isoleucine, and valine are generally decreased in patients with hepatic failure, possibly because of peripheral use of these amino acids in muscle. The levels of plasma amino acids in liver disease relate to competition between some of the same neutral amino acids--phenylalanine, tyrosine, and tryptophan--and of the branched-chain amino acids in penetrating the blood-brain barrier. The neurotransmitter profile is markedly deranged in hepatic encephalopathy. There is increased serotonin, decreased norepinephrine, and to a lesser extent, decreased dopamine in the brain. Octopamine, a known false transmitter that may replace dopamine and norepinephrine in the central nervous system, is markedly increased in the brains of animals and in the blood of patients in hepatic coma.

Tyrosine is thought to be the normal precursor of the catecholamines dopamine and norepinephrine. Profound depletion of norepinephrine has been demonstrated in hepatic coma. [171] Phenylalanine may compete with tyrosine-3- hydroxylase and decrease the conversion of tyrosine to dopa in hepatic encephalopathy. Tyrosine then accumulates and becomes decarboxylated to tyramine and then to octopamine.

Aims of Total Parental Nutrition in Liver Failure

If the amino acid levels in plasma are abnormal in hepatic encephalopathy, and if these have a role in the pathophysiology

of the disease, a reasonable starting point in therapy would be the normalization of the plasma amino acid patterns (Chs. 54 and 55) . Therapeutic efforts have been directed at attempting to normalize the brain amino acid concentrations during TPN with specific "hepatic failure" solutions. The amino acids tryptophan, tyrosine, and phenylalanine compete with other large neutral amino acids (including the branched-chain amino acids) for passage across the blood-brain barrier. There has therefore been increasing interest in therapeutically altering plasma amino acid concentrations in patients with liver disease by infusing branched-chain amino acid mixtures. The results obtained with these treatments have been ambiguous. Several uncontrolled studies have reported clinical improvement. [172] Controlled studies have not clarified these situations: for example, Wahren et al [173] concluded that no effect on encephalopathy could be attributed to the amino acid infusion.

An experimental solution has been developed that appears to be well tolerated by patients with hepatic insufficiency and encephalopathy. [174] The solution is now commercially available as HepatAmine. The solution with reduced aromatic amino acids and increased amounts of branched-chain amino acids was devised to normalize plasma amino acid patterns and to improve encephalopathy.

Sepsis

The nutritional support of septic patients is designed to reduce glucose administration because plasma glucose levels are high and peripheral tissues cannot use glucose. [175] Lipid emulsions are used to provide calories because fatty acids and ketone bodies are preferred fuel for many organs during sepsis. Amino acid mixtures are enriched with branched-chain amino acids to provide another nonglucose fuel source for skeletal muscle and to prevent extensive muscle autocatabolism. Marked improvement of indexes of nutritional competence has been demonstrated in stressed patients in surgical intensive care units who were given branched-chain amino acid-enriched mixture. [176]

Intraoperative Management for Patients Receiving Total Parenteral Nutrition

Whether TPN is temporarily discontinued or unchanged during the operative period, the anesthesiologist must monitor blood glucose levels meticulously to avoid hypoglycemia or hyperglycemia. Hyperosmolar, nonketotic, hyperglycemic coma has been reported in patients who fail to regain consciousness after anesthesia. [17] [177] [178]

Hagerdal et al [179] pointed out the effect of even 5 percent glucose intraoperatively on the RQ seen in the recovery room in patients after anesthesia. They demonstrated a 20 percent greater DV CO_2 during the first hour in the recovery room in patients who had received 5 percent dextrose intraoperatively compared with those who had received isotonic saline.

The anesthesiologist should also be meticulous about ensuring the presence of normal serum phosphate levels in the patient receiving TPN. Hypophosphatemia has been associated with several clinical conditions of interest to the anesthesiologist. Newman et al [180] described two cases of acute respiratory failure associated with hypophosphatemia. These patients, both with a history of alcoholism, developed profound areflexic muscle weakness such that mechanical ventilation became necessary. Serum phosphate levels were 500 and 400 mg/dL. Muscle strength returned quickly after phosphate administration.

Preoperative Anesthetic Considerations

A preoperative check should include the following evaluations [181] :

1. Serum sodium, potassium, chloride, and bicarbonate levels
2. Chest roentgenogram showing infusion catheter position
3. Serum phosphate level
4. Serum calcium level
5. Serum magnesium level
6. Urinary phosphate and magnesium level
7. Blood urea nitrogen and creatinine level
8. Forced vital capacity
9. Blood and urine glucose levels
10. Blood acid/base status and blood gases
11. Liver function tests
12. RQ (if measured)

Details of the duration and the type of TPN solutions and additives should include the following:

1. Incidence of hyperglycemia or hypoglycemia
2. Addition of insulin to regimen
3. History of chronic alcoholism
4. Presence of sepsis
5. Central catheter functioning
6. Site for additional intravenous infusion during anesthesia

A decision must be made whether to continue TPN [182] or to replace TPN by 10 percent dextrose for the perioperative period. [183] In either event, special precautions and monitoring are essential. In most instances, it is safer to continue the patient's TPN during the operation, especially with mixed glucose/lipid solutions. The anesthesiologist must remember that the TPN volume is added to the total intravenous intake. It is important to monitor plasma glucose level, potassium level, and pH.

Intraoperative Anesthetic Management

In theory, it is possible to lessen the stress hormone response to surgery by using either opioid-based anesthesia or spinal or epidural anesthesia (Chs. 10 42 and 43) . [184] [185] [186] [187] [188] One study could not demonstrate a consistent reduction in stress response to surgery when regional anesthesia was used. [189]

SUMMARY

Perioperative nutritional support is indicated for malnourished patients, severely catabolic patients (trauma, burns, sepsis), cancer patients, and patients with organ failure. Special nutritional support is not indicated for well-nourished surgical patients with uncomplicated surgery who will have a limited period of fasting (2-4 days). If nutritional support is indicated, it should be initiated as soon as possible. Many patients tolerate enteral nutritional support via gastric or jejunal feeding tubes. In the absence of contraindications for enteral feeding, it should be attempted with a willingness to rapidly switch to parenteral nutrition if the enteral route fails. Patients with modest caloric requirements (<1,800 kcal/d) may receive adequate nutritional support through a peripheral vein with amino acid, glucose, and lipid solutions. Central venous administration of nutrition should be reserved for patients with high caloric requirements and a nonfunctioning gastrointestinal tract because of increased complications of central venous catheterization.

The optimal nutritional prescription includes adequate protein intake (as amino acid solutions) in aiming to keep the patient in nitrogen equilibrium as well as calories in the form of glucose and fat (each supplying 50% of the total calories) to meet measured daily energy expenditure. Protein and energy requirements should be considered separately and monitored individually: nitrogen balance for protein, indirect calorimetry for energy. A convenient starting point for protein administration is 1.0 to 1.5 g/kg/d, with glucose and lipids adjusted to each provide 50 percent of calculated or measured nonprotein calories per day. The prescription must also include vitamins, minerals, and trace elements. Markers of muscle protein metabolism, such as serum 3-methylhistidine, transferrin, and prealbumin, are monitored to rule out extensive catabolic activity. Water balance is followed by daily weighing, and serum electrolyte levels, liver enzyme levels, and renal function test results are also monitored frequently. Properly administered, perioperative nutritional support can markedly enhance the care of selected surgical patients.

Chapter 75 - Cardiopulmonary Resuscitation: Basic and Advanced Cardiac Life Support

Roger D. White

INTRODUCTION

Although the history of resuscitation can be dated at least to biblical times, [1] contemporary approaches to cardiopulmonary resuscitation (CPR) go back to 1966, when a National Academy of Sciences National Research Council conference generated consensus standards for the performance of CPR. [2] Since that time, successive conferences have reviewed the practice of CPR in light of available experimental and clinical data and have prepared revisions of previous standards. [3] [4] [5] [6] [7] The most recent such conference was held in 1992, and from it emerged the current guidelines for CPR and emergency cardiac care (ECC). [6] [7] This conference in particular experienced the benefit of considerable information relative to resuscitation, although it was still hampered by a disquieting lack of substantive data. Despite this limitation, both basic life support (BLS) and advanced cardiac life support (ACLS) have been established on credible foundations and have enjoyed widespread acceptance in the ECC community. Indicative of this acceptance is the widespread popularity of the American Heart Association (AHA) BLS and ACLS training programs and related training materials. The intent of this chapter is to review the premise, rationale, and techniques for the performance of both BLS and ACLS in light of current understanding and as incorporated in the 1992 guidelines [6] and AHA textbooks on BLS [8] and ACLS. [9] It is not the intent of this chapter to restate the performance steps and rationale for all the BLS CPR procedures, which can be reviewed in the guidelines and also in the AHA BLS text. [8] Rather, both BLS and ACLS are reviewed within the context of their application by anesthesiologists in operating rooms and intensive care units (ICU) or other in-hospital areas.

BASIC LIFE SUPPORT

It is well accepted that effective CPR is based on the artificial delivery of oxygenated blood to systemic circulatory beds at rates that are sufficient to preserve vital organ function and at the same time providing the physiologic substrate for the rapid return of spontaneous circulation. The mechanisms for provision of this adequate blood flow have undergone intensive scrutiny, and the result has been both insightful and controversial. Both components of CPR (ventilation and perfusion) are reviewed in light of current understanding.

Airway Control and Ventilation

Anesthesiologists know well that ventilation is critical for the restoration of a spontaneous circulation and organ preservation in cardiac arrest (Ch. 39) . The AHA ACLS training program has conveyed effectively this treatment priority. [9] The techniques employed are obviously dependent on the clinical situation. In out-of-hospital or hospital ward settings, initial airway control and ventilation usually are accomplished by mouth-to-mouth or mask-to-mouth techniques. [9] The head tilt-chin lift is recommended for initial airway control. [8] [10] [11] The epiglottis rather than the tongue is the major cause of obstruction of the upper airway in unconscious humans. [12] Because of its ligamentous attachments to the hyoid bone, the epiglottis can be lifted by manual maneuvers that displace the hyoid anteriorly. These observations provide anatomic confirmation of the efficacy of the head tilt-chin lift for opening an obstructed airway. The head tilt-jaw thrust accomplishes the same purpose in restoring airway patency. [13]

In order to minimize high airway pressures and thereby reduce the likelihood of exceeding esophageal opening pressures, [14] emphasis is placed on a slow inspiratory phase

(1.5-2.0 seconds) in the nonintubated patient receiving CPR, and during two-person CPR, a deliberate pause is incorporated after every fifth chest compression in order to provide time for safe and effective ventilation at relatively low inspiratory pressures.

Because anesthesiologists employ advanced life support procedures and devices early in resuscitation, whether in the operating room or elsewhere, these procedures are reviewed here within the context of early control of the airway and ventilation. In the traditional BLS/ACLS format, these procedures are all considered as ACLS techniques and adjuncts.

Endotracheal intubation is the usual and expected standard of airway control in critical care settings. [15] There are alternative devices that may be useful to gain rapid control of the airway and ventilation and to protect the patient at risk of aspiration. These include the esophageal obturator airway, esophageal gastric-tube airway, pharyngotracheal airway, and combination esophageal-tracheal tube. [16] All these devices are classified in the 1992 guidelines as acceptable and possibly helpful. [6] Although they may be helpful as temporizing devices, endotracheal intubation remains the optimal technique for controlling the airway and ventilating the lungs during CPR.

Confirmation of proper placement of an endotracheal tube can be difficult in the patient who has undergone cardiac arrest. Observation of rise and fall of the thorax and auscultation of lung fields in this situation can be misleading. Likewise, because of the very low pulmonary blood flow during CPR, end-tidal carbon dioxide ($E_{T}CO_2$) detection devices may not readily distinguish tracheal from esophageal tube position. For these reasons, esophageal detector devices, based on the description by Wee, [17] have been introduced and advocated for use in emergency situations such as cardiac arrest. Both a syringe and a self-inflating bulb (SIB) have been used. The efficacy of these devices in distinguishing esophageal from tracheal intubation is based on the principle that the trachea remains patent during aspiration of air, whereas the esophagus collapses because of its fibromuscular structure. The effectiveness of the SIB in distinguishing esophageal from tracheal tube position has been documented. [18] [19] [20] It has also been effective in confirming proper position of the esophageal-tracheal tube (Combi-tube, Sheridan Catheter Corp., Argyle, NY). [21] In an emergency patient population, an esophageal detector device as described by Wee was observed to be more accurate than $E_{T}CO_2$ detection because of its greater accuracy in patients in cardiorespiratory arrest. [22] Nevertheless, false-negative results occur with the SIB more frequently in emergency intubations than reported in anesthetized patients undergoing elective procedures. Causes include partial tube obstruction with secretions, atelectasis, bronchospasm, and endobronchial intubation. [23] A high incidence of false-negative results was observed in morbidly obese patients. [24] In these patients, reduced functional residual capacity and large airway collapse secondary to invagination of the membranous posterior tracheal wall with application of subatmospheric pressure with the SIB were identified as the cause of the false-negative results. [24] With these limitations in mind, however, the SIB or syringe-type esophageal detector device should be considered a very useful device in emergency situations such as cardiac arrest.

Despite extensive experience with the laryngeal mask airway (LMA) in fasted patients undergoing general anesthesia, its role during CPR remains somewhat controversial. [25] [26] [27] [28] [29] In anesthetized patients, positive-pressure ventilation with the LMA has been observed to be safe and effective, but concern was expressed that gastric inflation could be a problem in the presence of increased inflation pressures. [30] This, of course, is a common problem in patients who sustain cardiorespiratory arrest, who typically have a full stomach and frequently require high inflation pressures during ventilation. The LMA has been used successfully in arrested patients who have no evidence of regurgitation or aspiration. [31] It may be particularly useful in trauma victims with possible cervical spinal injury in whom direct laryngoscopy and intubation cannot be accomplished; likewise, in arrested patients in whom endotracheal intubation is not possible, the LMA may offer the best available alternative to control the airway and to ventilate the patient. [27]

If these devices and techniques are unsuccessful in securing an airway, an immediate cricothyroidotomy may be necessary. A 12-, 13-, or 14-gauge catheter-over-needle can be inserted quickly into the trachea through the cricothyroid membrane. Equipment permitting transtracheal jet ventilation from a 50-psi oxygen source via such a catheter should be available in the operating room and the ICU. [32] [33] Benumof and Scheller [33] provided specific guidelines for acceptable transtracheal jet ventilation systems. These guidelines should be consulted for the implementation of an effective jet ventilation system in operating rooms or ICUs. Ventilation of the arrested patient can be accomplished with a variety of devices, including anesthesia bags, self-inflating bags, oxygen-powered manually cycled demand valves with peak flow rates of 40 L/min, and time-cycled, constant inspiratory flow rate generators, known as automatic transport ventilators.

Chest Compression

Delivery of oxygenated blood during cardiac arrest and CPR is critically dependent on the effectiveness of chest compressions. The major thrust of current CPR research has been directed toward optimizing blood flow by means of variations in compression techniques. The AHA-recommended chest compression rate is 80 to 100/min with a depth (
1.5-2 inches) sufficient to generate a palpable carotid or femoral pulse. A compression/relaxation ratio of 50:50 is advocated. During one-person CPR, the recommended compression/ ventilation ratio is 15:2, whereas for two-person CPR, it is 5:1. In both instances, the compression rate is 80 to 100/min.

Physiologic Considerations

Since the early 1960s, when CPR became a widespread clinical technique, it has been assumed that blood is ejected as a direct result of actual compression of the heart between the sternum and the vertebral column. This is commonly referred to as the *cardiac pump mechanism.* Echocardiographic and hemodynamic measurements obtained during experimental porcine CPR demonstrated that both mitral and tricuspid valves opened during the upstroke phase of external

Figure 75-1 (Figure Not Available) (A) Schematic representation of the cardiac compression pump. (B) The intrathoracic pressure pump. C, collapse of airways and venous structures; LV, left ventricle; RV, right ventricle. *(Modified from Halperin [274])*

compressions and closed during the downstroke. A reduction in left ventricular area occurred during the downstroke. [34] These observations support direct cardiac compression as the mechanism producing forward blood flow during CPR. Transesophageal echocardiography in arrested humans provides an opportunity to assess changes in cardiac dimensions and valve positions during chest compressions, as well as directional blood flow. Using this method of assessment, it has been confirmed that, at least in some patients, direct cardiac compression is the predominant mechanism of blood flow during external chest compressions. [35] [36] [37] Right and left ventricular compression, mitral valve closure during the downstroke of the compression phase, and opening of the mitral valve during the upstroke or relaxation phase are all consistent with direct cardiac compression, or the cardiac pump mechanism [35] [36] (Fig. 75-1 (Figure Not Available) .A)

The finding that repeated, forceful coughing (cough CPR) can sustain consciousness during ventricular fibrillation (VF) for as long as 100 seconds suggests that mechanisms other than direct compression of the heart may account for forward blood flow during cardiac arrest in some circumstances. [38] Indeed, vigorous coughing produces an arterial pressure pulse associated with forward blood flow and opens the aortic valve during pressure and flow generation. [39] These findings support the proposal that increases in intrathoracic pressure generate forward blood flow. [40] This is commonly referred to as the *thoracic pump mechanism* for movement of blood (Fig. 75-1 (Figure Not Available) B). The increasing intrathoracic pressure during chest compression equalizes intravascular pressures within the thorax. On the venous side, valves and venous collapse at the thoracic inlet limit transmission of retrograde pressure or flow. The arterial system, which is relatively resistant to collapse, transmits pressure and flow into the extrathoracic arterial tree. A peripheral arteriovenous pressure difference is thus established that permits blood to flow forward in the extrathoracic vascular system. Some studies suggest that, during compression or vigorous coughing, the left side of the heart may act as a passive conduit for the transfer of pulmonary venous blood out into the peripheral arterial circulation. During compression, blood flows from the lungs through the left ventricle and toward the periphery. The pulmonary valve is closed and the mitral and aortic valves are open during periods of high intrathoracic pressure when the chest is compressed. [41]

Interposed abdominal counterpulsation (IAC) is a form of CPR in which the abdomen is compressed during the upstroke of the chest compression phase in an attempt to sustain aortic diastolic pressure and thus to improve coronary perfusion pressure, a critical determinant of successful restoration of a spontaneous circulation. There is experimental evidence that carotid blood flow [42] and end-diastolic arteriovenous pressure differences, [43] indexes of coronary perfusion pressure, are increased with this IAC CPR. A randomized controlled trial comparing IAC CPR with standard CPR in humans in asystolic and electromechanical dissociation arrest indicated that IAC CPR conferred a significantly higher rate of return of spontaneous circulation, but no patient in either the IAC CPR group or the standard CPR group survived to hospital discharge. [44]

Active compression-decompression (ACD) CPR accomplishes compression and active decompression of the thorax by means of a device containing a suction header, bellows, and a compression area within the bellows. Preliminary data in arrested humans comparing ACD CPR with standard CPR provided evidence of hemodynamic benefit, with higher systolic arterial pressure and $E_T CO_2$ concentrations

and echocardiographic demonstration of increased velocity time integral, an analogue of cardiac output. Transesophageal echocardiographic imaging during ACD CPR disclosed that the atrioventricular (AV) valves were closed during chest compression but open during active decompression. [45] During the compression phase, direct compression of right and left ventricles occurs, with ejection of blood into the pulmonary artery and aorta, whereas ventricular filling from right and left atria occurs during the decompression, or relaxation, phase. [46] In a study of 16 patients with out-of-hospital cardiac arrest, peak $E_T CO_2$ pressure was significantly higher during ACD CPR compared with that during standard manual CPR (27.6 ± 3 mm Hg versus 15.6 ± 2.2 mm Hg). [47] This finding was interpreted to reflect a higher cardiac output with ACD CPR. In a porcine model of VF arrest, intermittent impedance to inspiratory gas flow during ACD CPR improved coronary perfusion pressure and blood flow to brain and heart. [48] This finding was attributed to enhanced equilibration of the negative intrathoracic pressure generated by active chest wall expansion, with increased venous return the result.

In humans studied during implantation of cardioverterdefibrillators, ACD CPR increased systemic arterial pressure, coronary perfusion pressure, and minute ventilation when compared with standard CPR. [49] Although these observations provided clinical support for experimental studies, indicating improved hemodynamic (and perhaps ventilatory) function with ACD CPR compared with standard CPR, still lacking was evidence of patient outcome benefit. Several studies have been undertaken to address this critical question. In one such study of patients experiencing inhospital cardiac arrest, initial return of spontaneous circulation was higher with ACD CPR compared with standard manual CPR, but there was no statistically significant improvement in survival to hospital discharge. [50]

Several studies of ACD CPR have been carried out in patients with out-of-hospital cardiac arrest. [51] [52] [53] None of these has demonstrated an improvement in patient outcome in terms of hospital discharge when ACD CPR was compared with standard CPR. The largest and most recent study comparing ACD CPR with standard CPR includes 1,784 adults with in-hospital and prehospital cardiac arrest. This study, like its predecessors, concluded that ACD CPR does not improve survival or neurologic outcomes. [54] Thus, despite the earlier experimental and clinical evidence that ACD CPR may confer benefit to victims of cardiac arrest by virtue of enhanced hemodynamic variables, no evidence to date supports the hypothesis that ACD CPR improves outcome from cardiac arrest in humans when compared with standard manual CPR.

Circumferential compression of the chest employing a pneumatic vest (vest CPR) has been described as a mechanism for generating intrathoracic pressure fluctuations and thereby improving blood flow [55] [56] (Fig. 75-2) (Figure Not Available) . The increased intrathoracic pressure fluctuations are apparently mediated through increased chest compression force and increased airway collapse during chest compression, trapping air in the lungs. The latter may also increase the effectiveness of transmission of vest pressure to the intrathoracic space. The increased intrathoracic pressure with vest CPR is the presumed major mechanism of hemodynamic benefit. As with ACD CPR, vest CPR has been shown in a preliminary study to increase both aortic and coronary perfusion pressures, [57] but no data are yet available relative to its impact on survival, the ultimate determinant of benefit.

Much more information is needed before any of these observations can be extended to modification of currently recommended CPR practice as described earlier. It is likely that both direct cardiac compression and intrathoracic pressure changes contribute to forward blood flow and that they are not mutually exclusive. In some patients, the cardiac pump may be primarily operative, whereas in others, the thoracic pump may predominate. [58] [59] Continued transesophageal echocardiographic observations in human victims of cardiac arrest may provide the insight into definition of which mechanism of blood flow is functional in which patients. Most important, until the clinical relevance of any of these observations is established, standard CPR techniques as described earlier are recommended. What is certain is that CPR, regardless of mechanism of blood flow and technique, is only a temporizing procedure in need of rapid supplementation with ACLS, most critically rapid defibrillation of the fibrillating heart.

Monitoring CPR Performance

Until recently, palpation of the carotid or femoral pulse and observation of pupillary size were the standard and very indirect measures for assessing the apparent adequacy of CPR. Obviously, a palpable large-artery pulse indicates only the transmission of a pressure wave into the arterial tree during chest compression and provides no objective evidence of the effectiveness of cardiac output. Initial pupillary size and changes during CPR are of some prognostic value. [60] Persistently contracted or initially dilated but subsequently contracting pupils are associated with a greater likelihood of successful resuscitation and neurologic recovery than

persistently dilated or subsequently dilating pupils. [61]

As already discussed, monitoring the systemic arterial pressure directly, as can usually be done during in-hospital CPR, is helpful. [62] Aortic diastolic pressure in particular, as an index of coronary perfusion pressure, should be monitored whenever possible and optimized with appropriate changes in manual compression technique and with early and repeated injection of epinephrine prior to restoration of a spontaneous circulation.

In 1978 Kalenda [63] described use of the capnogram as a guide to the effectiveness of external chest compressions. He demonstrated the value of $E_T CO_2$ monitoring in three patients in cardiac arrest and confirmed changes in $E_T CO_2$ with changes in external chest compression technique. He also observed a rapid increase in $E_T CO_2$ with restoration of a spontaneous circulation. He proposed that when ventilation is constant, as during controlled mechanical ventilation, "the expired CO_2 is a precise and continuous mirror of lung perfusion and hence of cardiac output." [63]

Despite the potential clinical importance of Kalenda's well-documented observations and conclusions, it was several years before $E_T CO_2$ monitoring during cardiac arrest and CPR was explored further. In 1984, using a porcine model of cardiac arrest, Grundler et al [64] demonstrated the rapid decrease in $E_T CO_2$ with onset of arrest and its immediate increase with resuscitation. Based on these preliminary

Figure 75-2 (Figure Not Available) A comparison of the thoracic vest system (A) for cardiopulmonary resuscitation (vest CPR) with standard manual CPR (B). The vest contains a bladder that is inflated and deflated by the pneumatic system. The lower panels show schematic representations of transverse sections of the midthorax during vest CPR and manual CPR. The thoracic size during chest relaxation is shown by the solid lines. The arrows indicate force applied to the thorax during chest compression. With vest inflation, there is a relatively uniform decrease in the dimensions of the thorax. With manual CPR, the sternum is displaced during compression (arrow) and the lateral thorax can bulge, thereby increasing thoracic volume and reducing the intrathoracic pressure generated during compression. *(Modified from Halperin et al. [57] Copyright 1993 Massachusetts Medical Society. All rights reserved.)*

experimental observations, this group suggested that $E_T CO_2$ monitoring may be a relatively simple and noninvasive guide to advanced life support interventions during CPR. [64] [65] Severe reductions in pulmonary blood flow during cardiac arrest and CPR, and therefore an acute failure in CO_2 delivery to the lungs, explained the observed very low $E_T CO_2$ and the increased venous CO_2 pressure ($P CO_2$) (see the discussion of sodium bicarbonate later). [66] Subsequent studies in dogs provided confirmation of this possible utility of $E_T CO_2$ in that expired $P CO_2$ correlated very closely with coronary perfusion pressure, which itself was shown to be a determinant of survival from cardiac arrest in this model. [67] [68] In a porcine model of VF, onset of VF was associated with a rapid decline in $E_T CO_2$ from a mean (±SEM) of 4.0 ± 0.2 percent to less than 0.7 ± 0.2 percent. [69] With external chest compression and constant-volume mechanical ventilation, $E_T CO_2$ increased to 1.9 ± 0.3 percent, with an immediate increase to 4.9 ± 0.3 percent after successful defibrillation following 12 minutes of CPR. There was a close correlation between changes in cardiac output and $E_T CO_2$ during both closed-chest and open-chest CPR. [69]

$E_T CO_2$ pressure monitoring has been reported in arrested humans undergoing CPR. [70] [71] [72] [73] In a study of ten patients in whom spontaneous circulation returned, the $E_T CO_2$ increased immediately on restoration of a spontaneous circulation, from a mean (±SD) of 1.7 ± 0.6 to 4.6 ± 1.4 percent. [70] The rapid increase in $E_T CO_2$ was often the first clinical evidence of resumption of spontaneous circulation.

In ten critically ill patients, nine of whom were in septic or cardiogenic shock at the onset of cardiac arrest, the $E_T CO_2$ decreased from a mean (±SD) of 1.4 ± 0.9 to 0.4 ± 0.4 percent shortly after the onset of cardiac arrest. [72] The very low prearrest value is indicative of a low cardiac output and therefore low pulmonary blood flow. During external chest compressions, this value increased to 1.0 ± 0.5 percent. In seven patients in whom circulation was restored, the $E_T CO_2$ rapidly increased from 1.3 ± 0.5 to 3.7 ± 2.1 percent, then it declined to a stable volume of 2.4 ± 1.8 percent 4 minutes after resumption of a spontaneous circulation. In patients in whom resuscitation failed to restore spontaneous circulation, the $E_T CO_2$ remained at 0.7 ± 0.4 percent. [72]

There is increasing evidence that $E_T CO_2$ measurements obtained during cardiac arrest and CPR may have predictive value relative to the likelihood that spontaneous circulation will be restored. [71] [73] [74] In one study, patients who later developed a pulse had a mean $E_T CO_2$ of 19 ± 14 (SD) mm Hg at the beginning of resuscitation, whereas those who never regained a spontaneous pulse had a mean $E_T CO_2$ of 5 ± 4 mm Hg ($P < .0001$). [73] Other investigations have observed similar significant differences in $E_T CO_2$ during CPR between those patients who develop spontaneous circulation and those who do not. [74] [75] [76] Two of these studies were conducted in patients in out-of-hospital cardiac arrest. [75] [76] The $E_T CO_2$ was significantly higher during CPR in these patients who subsequently regained spontaneous circulation than in those who did not. For example, 1 minute after initiation of measurement, the $E_T CO_2$ was 23.0 ± 17.4 mm Hg in those who regained pulses and 13.2 ± 14.7 mm Hg in those who did not ($P = .0002$) (Table 75-1) (Table Not Available) . Differences of similar magnitude were noted at 2 minutes as well as with the maximum value observed during the resuscitation. [75] Although more such data are needed to quantitate the predictive power of these differences, it seems certain that $E_T CO_2$ measurements during cardiac arrest and CPR will become an objective index to predict the likelihood that persistent resuscitative efforts will result in restoration of spontaneous circulation.

The major determinants of $E_T CO_2$ are CO_2 production, alveolar ventilation, and pulmonary blood flow. [77] [78] [79] [80] In the presence of constant-volume ventilation and apparently unchanged CO_2 production immediately after cardiac arrest, the changes in $E_T CO_2$ observed both experimentally and clinically during cardiac arrest and CPR and resumption of spontaneous circulatory function indicate that $E_T CO_2$ reflects pulmonary blood flow and therefore cardiac output. [70] [71] [72] [73] [74] Monitoring of both systemic arterial pressure via arterial catheter and $E_T CO_2$ with controlled ventilation should provide optimal hemodynamic assessment of the adequacy of the resuscitative effort and response to interventions such as changes in depth, rate, and location of manual chest compressions, as well as response to drugs such as epinephrine. [62]

ADVANCED CARDIAC LIFE SUPPORT

Although it is commonly understood and accepted that all physicians, regardless of specialty, should be able to perform CPR, it must be emphasized that CPR almost invariably necessitates rapid interventional follow-up care with ACLS procedures. It is essential that anesthesiologists be capable of rendering such follow-up definitive intervention, whether in the operating room, ICU, emergency department, delivery room, or hospital ward. In the operating room, cardiac arrest is rare; during a 15-year period, a cardiac arrest incidence of 1.7 per 10,000 anesthetic regimens was identified. [81] As Vandam [82] stated in an accompanying editorial, the fact that cardiac arrest occurs at all is terrifying. [82] The somewhat reassuring observation that intraoperative cardiac arrest is a rare occurrence does not dismiss the need for anesthesiologists to be thoroughly acquainted with ACLS equipment and interventions, because when these methods are needed, they must be executed skillfully and decisively. The need for skillful and knowledgeable ACLS intervention in intraoperative cardiac arrest is recognized. [83] Failure to intervene rapidly with ACLS pharmacologic therapy was identified as a major cause of poor outcome in these intraoperative cardiac arrests. [83] [84] It is evident that ACLS is a body of knowledge and skill with which anesthesiologists must be thoroughly familiar.

In a study using a computer program that simulates critical patient incidents such as cardiac arrest, it was observed that only 30 percent of participants, consisting of anesthesiology residents, faculty, and private practitioners, managed a simulated cardiac arrest in accordance with AHA ACLS guidelines. [85] Time since the last ACLS training was noted to be an important predictor of proper management of simulated cardiac arrest. Of those trained in ACLS within 6 months preceding the assessment, 71 percent managed simulated cardiac arrests successfully, whereas successful management decreased to about 30 percent by those whose ACLS training occurred from 6 months to 2 years earlier. No participant who had been trained in ACLS longer than 2 years prior to the assessment used ACLS guidelines correctly in simulated cardiac arrest management. [85] This experience supports the position that some form of training and periodic retraining in ACLS are necessary to enable anesthesiologists, as well as other physicians, to maintain the level of knowledge and skill essential for management of cardiorespiratory arrest in accord with contemporary principles as incorporated in the ACLS training program. Because advanced airway control and ventilation have already been discussed, this section presents the remaining components of ACLS as they directly pertain to anesthesiologic practice.

Monitoring and Arrhythmia Recognition

Prompt recognition and treatment of potentially life-threatening (prearrest) cardiac arrhythmias are essential components of ACLS (also see Ch. 32). [86] Early recognition and immediate pharmacologic intervention frequently can prevent the onset of fatal arrhythmias necessitating the full application of BLS and ACLS. In this context, supraventricular arrhythmias that may cause hemodynamic compromise are discussed first, followed by recognition and management of those that are ventricular in origin.

Supraventricular Bradyarrhythmia

Supraventricular bradyarrhythmias may be sinus or junctional in origin, or they may be caused by second-degree (types I and II) or third-degree AV block. Sinus (or junctional) bradycardia and type I (AV nodal) second-degree AV block are usually manifestations of increased vagal tone. Sinus bradycardia and type I second-degree AV block (Wenckebach phenomenon) may be observed during high-dose narcotic anesthesia. During spinal anesthesia, reduced venous return and unopposed vagal tone may produce bradycardia and hypotension of sufficient severity to progress to cardiac arrest. [87] Treatment is indicated whenever the bradycardia, regardless of type, leads to a significant fall in systemic arterial pressure, produces clinical signs of reduced cardiac output (or a fall in measured output), or is accompanied by

ventricular ectopic depolarizations. Any of these signs should be taken as evidence of hemodynamic or electrophysiologic deterioration with the propensity to progress to lethal arrhythmias, either bradyasystole or VF. Initial treatment is with atropine, 0.5 to 1.0 mg intravenously and repeated as needed at 3- to 5-minute intervals to 0.04 mg/kg. [88] If this treatment is ineffective in producing an increase in heart rate and in hemodynamic (increased systemic pressure and/or cardiac output) or electrophysiologic (elimination of ventricular ectopy) improvement, alternatives include external or transvenous pacing or, during spinal anesthesia, small (0.2 mg) intravenous doses of epinephrine. [89] The availability of intraoperative cardiac pacing equipment and techniques has diminished the need for isoproterenol for treatment of brady-arrhythmias. The increase in myocardial oxygen demand imposed by isoproterenol makes its use potentially hazardous in the presence of acute myocardial ischemia. If transvenous or transcutaneous pacing is not available to treat atropine-refractory bradyarrhythmias, an infusion of dopamine (5-20 mg/kg/min) or epinephrine (2-10 mg/min) would be a better choice than isoproterenol.

Pulmonary artery catheters that permit the insertion of ventricular or atrial pacing probes are available. If such a catheter is in place, emergency pacing can be instituted rapidly. Pacing probes can be advanced into position quickly to permit rapid control of cardiac rate via ventricular, atrial, or AV sequential pacing.

External transcutaneous pacing can be used rapidly to treat atropine-resistant symptomatic bradyarrhythmias. The safety and effectiveness of these devices have been described, as has favorable intraoperative experience. [90] [91] Their greatest therapeutic benefit is likely to be in atropine-resistant bradyarrhythmias, and these devices should be available for emergency use along with a defibrillator. External pacing has not yet been shown to be useful in bradyasystolic cardiac arrest.

Transesophageal atrial pacing has been shown to be effective in treating intraoperative supraventricular bradyarrhythmias such as sinus or junctional bradycardia. [92] [93] In its present configuration, it cannot be used to pace the ventricles, and therefore it is not useful in the management of any form of bradycardia caused by AV conduction disturbances. An esophageal pacing probe modified to enable ventricular pacing has been described, but it is not available for clinical use. [94]

Supraventricular Tachyarrhythmia

Supraventricular tachyarrhythmias include atrial flutter, atrial fibrillation, AV junctional tachycardia, multifocal atrial tachycardia, paroxysmal reentrant tachycardias, and other much less frequent arrhythmias. Paroxysmal supraventricular tachycardia (PSVT), atrial fibrillation (or flutter) with rapid ventricular rates, and multifocal atrial tachycardia are discussed here because not only can they produce hemodynamic compromise, but also they can present diagnostic and therapeutic challenges.

An example of PSVT is shown in Figure 75-3 . If such a tachyarrhythmia produces hemodynamic deterioration, cardioversion is the treatment of choice, beginning at 50 joules (J) and progressing to 100, 200, 300, and 360 J if needed. If the patient is hemodynamically stable, vagal maneuvers can be tried (e.g., Valsalva maneuver in awake patients). Adenosine is the drug of choice for termination of such arrhythmias, for which it is highly effective. [95] [96] [97] The drug is also of diagnostic usefulness in revealing the underlying mechanism in tachyarrhythmias of uncertain origin by inducing transient block of AV nodal conduction [98] [99] [100] (Fig. 75-4) . Adenosine can be used initially in a dose of 6 mg given rapidly through an antecubital venous catheter; if necessary, a second dose of 12 mg can be given in 1 to 2 minutes. If a central venous catheter is used, these doses can be reduced to 3 and 6 mg, respectively. [101] Because of rapid cellular uptake and metabolism, adenosine must be injected rapidly into a venous catheter proximal enough to the heart to ensure delivery of a sufficient concentration of the drug at the AV node to

induce AV nodal conduction block. If the drug is injected more distally and slowly (e.g., into a small-bore dorsal hand vein catheter), not only may therapeutic failure result, but also transient acceleration of the tachyarrhythmia may occur [102] (Fig. 75-5) (Figure Not Available) . This paradoxic acceleration of the rate is a manifestation of the increase in sympathetic venous traffic induced by adenosine in the presence of inadequate AV nodal blockade. Likewise, conversion of 2:1 to 1:1 conduction in atrial flutter has been observed. [103] [104] [105] This adverse effect indicates that an attempt to establish the diagnosis of atrial flutter should be made electrocardiographically, using vagal maneuvers if necessary to unmask the flutter waves. Rate acceleration also has been observed after adenosine administration in patients with atrial fibrillation and preexcitation (Wolff-Parkinson-White syndrome). [106] As with verapamil in this setting, the rate acceleration is a result of the AV nodal block with diversion of fibrillation wavefronts through the accessory connection. Even though the short half-life of adenosine may reduce this hazard, it seems prudent to avoid adenosine as well as other AV nodal-blocking drugs in patients with atrial fibrillation and preexcitation.

Adenosine induces slowing of AV nodal conduction and prolongation of refractoriness and therefore is very effective in terminating PSVT, the most common cause of which is reentry within the AV node. [107] [108] [109] Its very short half-life

Figure 75-3 Paroxysmal supraventricular tachycardia. The rate is 250 beats/min with no clearly identifiable P waves.

Figure 75-4 A supraventricular tachycardia at a rate of 180 beats/min is present; the origin of the tachycardia is not evident (A). Following injection of 6 mg adenosine, atrial flutter waves are clearly visible, establishing the diagnosis (B).

Figure 75-5 (Figure Not Available) (A) Atrial fibrillation with a ventricular response of 190 beats/min. (B) Following injection of 6 mg adenosine, the ventricular response increased to 240 beats/min. *(From White [102])*

(<5 seconds) is both advantageous and disadvantageous: side effects such as flushing, dyspnea, and chest pain are short-lived, but the tachyarrhythmia may recur, necessitating use of another drug. The AV nodal-blocking action of adenosine is antagonized by theophylline or related methylxanthines and is potentiated by dipyridamole and carbamazepine [95] [96] [97] [110] [111] (Fig. 75-6) (Figure Not Available) . A suggested scheme for the use of adenosine, including dosage adjustments, is shown in Table 75-2 .

Bronchospasm also has been described after injection of adenosine, including intraoperatively. [112] [113] [114] [115] This complication has occurred in patients with bronchial asthma or chronic obstructive pulmonary disease (COPD). The mechanism is unknown, but it may result from stimulation of bronchial smooth muscle adenosine receptors or stimulation of mast cell-derived mediators of bronchoconstriction. Aminophylline, an adenosine receptor antagonist, has been used successfully intraoperatively to treat adenosineinduced bronchospasm. [115] In light of this experience, adenosine should not be used, or used with caution, in patients with a history of bronchial asthma or COPD with a bronchospastic component.

If the PSVT does not respond to adenosine, or if it recurs, verapamil is the drug of choice. A dose of 5 mg produces a more sustained block of AV nodal conduction. Verapamil can also be used to slow the ventricular response in atrial fibrillation or flutter. [116] However, it should not be used in patients with Wolff-Parkinson-White syndrome who develop atrial fibrillation or flutter. In this setting, verapamil-induced increases in conduction over the accessory pathway may produce alarming acceleration of the ventricular rate or VF. [117] [118] [119] If atrial flutter or fibrillation results in hemodynamic deterioration because of the rapid ventricular response, cardioversion is the treatment of choice. Atrial flutter

Figure 75-6 (Figure Not Available) The cardiac adenosine system is composed of three components: (1) formation; (2) receptor complex effects; and (3) degradation. (1) Adenosine (ADO) can be formed intracellularly via the adenosine triphosphate (ATP) or *S*-adenosylhomocysteine (SAH) pathway, or extracellularly via breakdown of adenosine nucleotides. (2) The adenosine receptor (ADO-R) is coupled to ion channels via the guanine binding regulatory proteins (G i). Theophylline (THEO) derivatives act as competitive antagonists for the adenosine receptors. (3) ADO can be transported into the cell and then degraded via deamination to inosine or phosphorylated to adenosine monophosphate (AMP). Dipyridamole can block the cellular uptake of ADO, thus prolonging its effect. ADP, adenosine diphosphate; cAMP, cyclic AMP; GTP, guanosine triphosphate. *(Modified from Bertolet and Hill [275])*

TABLE 75-2 -- Administration of Adenosine

Peripheral (antecubital): 6 mg, then 12 mg if needed
Central: 3 mg, then 6 mg if needed
If taking theophylline-containing drugs: 9 mg peripherally, 6 mg centrally
If taking dipyridamole: 2 mg peripherally, 1 mg centrally
Use with caution in asthmatic patients
Caution in patients taking carbamazepine

can be terminated with low-energy synchronized shocks (e.g., 25-50 J).

Atrial fibrillation or atrial flutter with rapid ventricular response can cause rate-related hemodynamic compromise, manifest perioperatively as hypotension and/or decreased cardiac output. In hemodynamically unstable patients, cardioversion should be used. Recent-onset atrial flutter is typically very sensitive to low-energy shocks (e.g., 50 J) (Fig. 75-7) (Figure Not Available) . For atrial fibrillation, the initial energy dose should be 100 J and increased as needed to 200, 300, and 360 J. Atrial flutter also can be terminated by overdrive pacing using external generators with this capability.

In hemodynamically stable patients with rapid ventricular rates secondary to atrial fibrillation or flutter, treatment is pharmacologic. With recent onset of these tachyarrhythmias (<45 days), ibutilide given intravenously has been successful in restoring sinus rhythm. [120] Ibutilide is a recently approved class III antiarrhythmic drug that prolongs action potential duration and effective refractory period without effects on action potential upstroke. The dose is 1 mg over 10 minutes. A second dose can be given 10 minutes after the first, if necessary. Conversion of atrial flutter is more frequent in atrial flutter than in atrial fibrillation (63% versus 31%), and more frequent in atrial fibrillation with shorter arrhythmia duration. [120] Prolongation of the QT interval reflects the pharmacologic action of the drug; polymorphic ventricular tachycardia accompanied by increases in the QT interval has been reported in 8.3 percent of patients receiving ibutilide, so clinicians should be prepared to manage this arrhythmia [120] (see the discussion of ventricular tachyarrhythmias).

Alternative options include diltiazem or verapamil to control ventricular rate or digoxin for rate control and procainamide for conversion of the tachyarrhythmias. Diltiazem is given as a loading dose of 0.25 mg/kg over 2 minutes, followed, if needed, in 10 to 15 minutes by 0.35 mg/kg. An infusion at a rate of 10 mg/h can be used to maintain rate control. If verapamil is used, 5 mg can be given initially, then 7.5 to 10 mg in 15 to 30 minutes if needed. Rate control also can be achieved with beta blocking drugs such as esmolol or propranolol if there is no contraindication to their use.

Multifocal (multiform) atrial tachycardia (MAT) is a quite common tachyarrhythmia often misdiagnosed as atrial fibrillation. [121] [122] [123] It is usually described as occurring in patients with COPD, especially during exacerbations necessitating ICU management. However, it occurs in other settings as well, such as hypokalemia, catecholamine administration, and acute myocardial ischemia. [124] [125] MAT is diagnosed by observing the presence of at least three morphologically different P waves in the same lead with a rate greater than 100 beats/min (Fig. 75-8) . Misdiagnosis as atrial fibrillation is a concern because it can lead to ineffective and even hazardous therapy. Digitalization and cardioversion, both useful in management of patients in atrial fibrillation, are ineffective in MAT. Digitalis toxicity or repeated and

futile attempts at cardioversion can follow misdiagnosis. Verapamil has been useful in rate control and in some cases in termination of MAT while the underlying cause, such as hypoxia or hypokalemia, is corrected if possible. [126] [127]

Ventricular Bradyarrhythmia

Within the setting of ECC, the bradyarrhythmia arising within the ventricles in need of urgent treatment is complete heart block with a very slow idioventricular escape rhythm (e.g., 15-30 beats/min) (Fig. 75-9) . In this situation, atropine can be tried, but the treatment of choice is external or transvenous pacing as soon as it can be accomplished. If an external pacemaker is available, pacing can be instituted quickly.

Figure 75-7 (Figure Not Available) Electrical cardioversion algorithm (with the patient not in cardiac arrest). *(Modified from American Heart Association, [6] copyright 1992, American Medical Association)*

Ventricular Tachyarrhythmia

In this category of potentially life-threatening, and sometimes prearrest, arrhythmias, ventricular tachycardia (VT) (Fig. 75-10) is commonly in need of urgent intervention. VT that produces cardiac arrest (pulseless VT) is discussed with VF. Treatable causes of VT should always be sought before or during pharmacologic or electrical interventions. Hypoxemia, hypercarbia, hypokalemia and/or hypomagnesemia, digitalis toxicity, and acid-base derangements are obvious considerations.

Treatment of VT is dependent on the degree of hemodynamic compromise induced by the tachycardia. If a patient remains stable, lidocaine is the drug of choice. [128] It is given initially in a dose of 1.0 to 1.5 mg/kg and is repeated in a dose of 0.5 to 0.75 mg/kg every 5 to 10 minutes, until the arrhythmia is suppressed or a total of 3 mg/kg has been given. If this treatment is ineffective, procainamide can be administered in a dose of 20 to 30 mg/min until the tachycardia is controlled or a total of 17 mg/kg has been injected. With constant monitoring of systemic arterial pressure and the electrocardiogram (ECG) for QRS widening more than 50 percent of control width as an end point, procainamide can be used very safely and effectively. If these measures fail to control the arrhythmia, bretylium can be administered in a dose of 5 to 10 mg/kg over 8 to 10 minutes. [128] If a conversion is effected with this drug, an infusion at a rate of 1 to 2 mg/min can be started.

For VT refractory to this approach, intravenous amiodarone may be effective, providing a new therapeutic option.

Figure 75-8 Multifocal atrial tachycardia. P waves with several different morphologic identities are evident.

Figure 75-9 Slow (14 beats/min) idioventricular escape rhythm in a patient with carotid sinus hypersensitivity. External or transvenous pacing is the treatment of choice for bradyarrhythmias such as this.

Figure 75-10 Ventricular tachycardia. The rate is 280 beats/min, QRS width is 160 ms, and three consecutive capture/fusion beats are seen.

[129] [130] [131] [132] The mechanism of action is unclear, but it probably includes antisympathetic and calcium channel blocking actions. It exerts antiarrhythmic action within an hour of intravenous administration. The initial dose is 150 mg in 100 mL dextrose in water given over 10 minutes, followed by a loading infusion of 1 mg/min for 6 hours. The loading infusion is prepared by adding 100 mg to 500 mL dextrose in water. If breakthrough VT/VF occurs, supplemental 150-mg infusions over 10 minutes can be given. Because the intravenous form of amiodarone has only recently become available, it is not included in the AHA ACLS algorithms.

In unstable patients (e.g., in the presence of systemic hypotension, pulmonary edema, or clinical or ECG signs of acute ischemia or infarction), cardioversion is the treatment of choice, with energy doses of 100, 200, 300, and 360 J in progressive increments as needed. An algorithm for cardioversion of a variety of tachyarrhythmias, including VT, is shown in Figure 75-7 (Figure Not Available) .

There is an atypical form of VT known as *torsades de pointes* ("twisting of the points") originally described in 1966, characterized by a twisting of the QRS axis around the baseline and a polymorphic appearance. [133] [134] [135] [136] [137] The underlying electrophysiologic derangement in this arrhythmia is a marked and nonuniform delay in repolarization, manifested as a prolonged QT interval on the ECG. It typically begins with a characteristic long-short initiating sequence (Fig. 75-11) . It can be induced by drugs such as quinidine, procainamide, disopyramide, and phenothiazines and also by bradycardia, hypokalemia, hypomagnesemia, or acute ischemia or infarction. [138] Even though amiodarone produces marked prolongation of repolarization, it rarely causes torsades de pointes. This may be because the drug-induced prolonged repolarization is uniform (nondispersed), in contrast to the repolarization abnormality induced by other drugs. [139] Closely related to torsades de pointes is polymorphic ventricular tachycardia (PVT) (Fig. 75-12) (Figure Not Available) . The description of the tachycardia as PVT rather than as torsades de pointes implies that there is no evident cause of prolonged repolarization and the QT interval is not prolonged. [140] [141] [142] [143] Because both PVT and torsades de pointes can be life-threatening, a correct diagnosis is required. The critical therapeutic distinction is based on the presence or absence of QT-interval prolongation. If QT prolongation is present, therapy is directed toward shortening the repolarization time (after withdrawal of offending drugs listed earlier or correction of abnormalities such as hypokalemia). In the past, drugs such as isoproterenol were used for this purpose, but definitive short-term therapy is overdrive ventricular

Figure 75-11 Torsades de pointes ventricular tachycardia. The Qtc interval is 450 mg during the sinus rhythm preceding the tachycardia. This arrhythmia occurred in a patient expressing an acute myocardial infarction.

Figure 75-12 (Figure Not Available) Polymorphic ventricular tachycardia. The QRS complexes have varying morphology, but without the "twisting of the points" torsades morphology seen in Figure 75-11 . The tachycardia terminated spontaneously. *(From White and Wood [143])*

or atrial pacing, preferably the latter, if AV conduction is intact. Magnesium sulfate has also been used successfully in the treatment of torsades de pointes, and some clinicians recommend it as the first line of emergency treatment. [144] [145] [146] [147] If PVT is present (i.e., without evident QT prolongation), standard antiarrhythmic therapy as outlined earlier for VT can be tried, although magnesium sulfate should be considered early in the treatment of this form of PVT as well, particularly if torsades de pointes is suspected by history but QT prolongation cannot be confirmed on the ECG. In fact, a 12-lead ECG is often needed to identify QT lengthening. If hemodynamic deterioration occurs with PVT, defibrillation should be used as initial treatment.

An algorithm for the treatment of tachyarrhythmias, encompassing those of supraventricular and ventricular origin, is shown in Figure 75-13 (Figure Not Available) . This algorithm makes provision for intervention in a patient with a wide-QRS complex tachycardia of indeterminate origin, beginning with lidocaine, then, if unresponsive, moving to adenosine for either therapeutic or diagnostic purposes. Catecholaminemediated VT sensitive to adenosine is well documented, [148] [149] [150] including an intraoperative event [151] (Fig. 75-14) (Figure Not Available) . If a wide-QRS complex tachycardia is accompanied by clinical evidence of catecholamine

excess, adenosine should be considered as a possibly therapeutic drug after a trial of lidocaine, as recommended in the section of the tachycardia algorithm for wide-complex tachycardia of unknown origin (see Fig. 75-13 (Figure Not Available) .)

Verapamil should be avoided in any wide-QRS complex tachycardia, unless it is known with certainty that the tachycardia is supraventricular in origin; if VT is present, verapamil can induce severe hypotension or cardiovascular

Figure 75-14 (Figure Not Available) Wide-QRS complex tachycardia at a rate of 160/min. (A) Precordial lead 5; (B) lead 2. Atrioventricular dissociation is present, evident by the P wave preceding the third QRS complex, confirming this to be ventricular tachycardia. *(From Wagner et al [151])*

Figure 75-15 Adverse response to verapamil. Tachycardia thought to be atrial flutter was present initially (A). After injection of 5 mg verapamil, the rate accelerated, and the patient became unresponsive, necessitating cardioversion (B). The first rhythm was ventricular tachycardia. Cardiovascular collapse is a potential complication of verapamil injection when the tachycardia is ventricular in origin.

collapse in as many as 87 percent of such misdiagnosed episodes (Fig. 75-15) . Any wide-complex tachycardia of uncertain origin (despite careful scrutiny of the ECG for all helpful clues) should be assumed to be VT and treated accordingly. If the patient is hemodynamically deteriorating, cardioversion should be used initially, without a prior trial of drug therapy.

Management of Cardiac Arrest

This section reviews the interventions, both electrical and pharmacologic, utilized in the treatment of the various forms of cardiorespiratory arrest. Included is a discussion of the major beneficial and adverse actions of the drugs used in ACLS. Clinical applications of some of these drugs have already been presented in the review of recognition and management of "prearrest" or potentially life-threatening events.

Pulseless Ventricular Tachycardia or Ventricular Fibrillation

For therapeutic purposes, it is reasonable to consider pulseless VT and VF as the same entity in need of the same interventions. It is fortunate that this is the most common form of cardiac arrest because it is the most treatable one, and it is the arrhythmia that yields the greatest likelihood of immediate and long-term survival, both in hospital and out of hospital. [152] This finding has accelerated the extension of early intervention in VF to levels of out-of-hospital emergency care lower than emergency medical technicianparamedics to basic emergency medical technicians and even first responders with minimal training. [153] This likelihood of significant salvage by early defibrillation also accounts for the growing interest in, and application of, automated external defibrillators [6] and the rapid increase in implantation of implantable cardioverter-defibrillators [154] [155] [156] [157] [158] [159] in patients at risk of cardiac arrest from VF. It is obvious that physicians involved in caring for patients in hospital are assumed to know how to intervene in the event of cardiac arrest, how to operate defibrillators, and how to administer drugs rationally, especially in the presence of VT/VF, when survival is likely with rapid and correct treatment.

Despite rare reports of apparently spontaneous termination of VF, the required and definitive intervention is rapid defibrillation. Two practical and important considerations enter into every attempt to defibrillate patients in VF. The first is the energy output of the defibrillator. [160] Termination of VF is critically dependent on the amount of energy available from a defibrillator, and therefore it is necessary that output be checked at regular intervals. Guidelines for proper maintenance of defibrillators are available. [161]

The second practical consideration is the resistance to current flow during shock delivery. Current flow is inversely related to resistance; excessive resistance because of poor technique can impede the transthoracic flow of adequate current to permit defibrillation to occur. [160] The major operator-controllable variables that can reduce impedance during defibrillation are proper electrode position, firm pressure against each hand-held paddle, and an optimal electrode-chest wall coupling medium such as electrode paste or the use of self-adhesive electrode pads. [160] Preapplied electrode pads are particularly advantageous in the operating room when patient position precludes rapid access to the chest for standard paddle placement.

In the operating room or ICU, in which the cardiac arrest is witnessed and a monitor reveals the mechanism to be pulseless VT or VF and where a defibrillator is immediately available, a 200-J shock should be delivered immediately; if this shock is unsuccessful, a second shock of 200 to 300 J, and, if necessary, a third shock of 360 J should be administered. Thus, for persistent VF, a series of three shocks (200, 200-300, and 360 J) should be delivered in rapid succession. If a cardiac arrest is witnessed but not monitored and a defibrillator is not available, a single precordial thump can be applied before beginning CPR and while awaiting the arrival

of the monitor-defibrillator. If at any time VF recurs following successful conversion, the series of up to three shocks should be repeated. This sequence of rapidly repeated defibrillatory shocks for persistent VF underscores the primacy of this treatment of VF over all other interventions. If VT persists despite this initial treatment, pharmacologic therapy becomes necessary. It is assumed that the airway and ventilation are already controlled by the anesthesiologist with endotracheal intubation and ventilation with 100 percent oxygen.

Drug therapy at this point begins with epinephrine. Assuming that a peripheral intravenous line is present, initial drug injections can be given by this route, but if cardiac arrest persists, a central venous catheter should be inserted to ensure more rapid drug delivery and attainment of higher peak arterial concentrations more quickly than with peripheral injection. [85] Because of evidence that glucose administration during global cerebral ischemia can worsen neurologic outcome in survivors, [162] [163] [164] [165] lactated Ringer's solution or normal saline should be used instead of glucose-containing solutions. If for some reason an intravenous line is not pres-ent or cannot be inserted promptly, epinephrine can be injected into the tracheobronchial tree, a site from which it is absorbed rapidly to produce prompt pharmacologic effects. [166] [167] [168] If this route is used, a dose of 2 to 2.5 times the intravenous dose is recommended. [85]

Previous clinical impressions regarding the beneficial effects of epinephrine during cardiac arrest, regardless of the underlying rhythm, have been substantiated. [169] [170] [171] [172] [173] The drug increases both cerebral and myocardial blood flow in experimental cardiac arrest. [169] [170] [171] The mechanisms responsible for enhanced cerebral and myocardial blood flow appear to be based on prevention of arterial collapse and intense vasoconstriction in other vascular beds, thus preventing runoff of blood into noncritical tissues and preferentially increasing cerebral and myocardial perfusion pressures and flow. [169] Because of the critical role of potent vasoconstriction in the beneficial action of epinephrine, phenylephrine has been studied as well. [170] [174] [175] Comparison of phenylephrine and epinephrine in experimental cardiac arrest has shown no evident benefit gained from using phenylephrine in terms of changes in blood flow, [170] [175] somatosensory evoked potentials, [170] or neurologic or cardiovascular outcome. [172] In human victims of cardiac arrest, epinephrine has been shown to produce increases in both peak aortic and coronary perfusion pressures, further attesting to its vasoconstrictive properties in a clinical setting. [176] Thus, epinephrine remains the drug of choice at this time.

The recommended dose of epinephrine is 1.0 mg (10 mL of a 1:10,000 dilution). This dose should be repeated every 3 to 5 minutes as long as cardiac arrest persists to ensure sustained blood flow benefit.

Based on experimental observations of apparent hemodynamic benefit from large doses of epinephrine (up to 0.2 mg/kg), [177] [178] numerous clinical reports and studies have assessed the impact of high-dose epinephrine (HDE) on such end points as restoration of a spontaneous circulation (ROSC) and discharge from the hospital. [179] [180] [181] [182] [183] [184] [185] Although some investigators have observed an increased frequency of ROSC after HDE compared with standard 1-mg doses, [183] most have not, and no study has yet confirmed benefit in terms of discharge survival. Therefore, the currently recommended (standard) dose is 1 mg given every 3 to 5 minutes. Alternative doses are considered acceptable and possibly helpful if an initial trial with standard doses is not effective. These additional dosing regimens are intermediate (2-5 mg every 3-5 minutes), escalating (1 mg, 3 mg, 5 mg at 3-minute intervals), and high (0.1 mg/kg every 3-5 minutes). [186]

Following the initial injection of epinephrine after the third shock, defibrillation should be attempted again, using 360 J. If VF persists, it is necessary to use a drug with antifibrillatory actions. Lidocaine is the drug of choice for this purpose. [128] Lidocaine has been shown to enhance intraoperative ventricular defibrillation in cardiac surgery, permitting defibrillation with fewer shocks of lower energy and current. [187] This concept is controversial, however, because other investigators have observed an elevation of defibrillation threshold with blood concentrations of lidocaine that may occur during cardiac arrest and resuscitation. [188] [189] [190] In persistent pulseless VT and VF, lidocaine is given initially in a dose of 1.5 mg/kg, followed by a 360-J shock. If VF persists, lidocaine can be repeated in a dose of 1.5 mg/kg in 3 to 5 minutes, with a total loading dose of 3 mg/kg. Lidocaine, like epinephrine and atropine, can be injected into the tracheobronchial tree via an endotracheal tube, but data on absorption from this site in cardiac arrest are not available. [85] Until this issue is resolved, it is not certain that therapeutic benefit can be expected from endotracheally administered lidocaine in human victims of cardiac arrest.

If lidocaine is apparently ineffective in terminating VF, bretylium can be used. It has been shown to possess both antiarrhythmic and antifibrillatory properties. [191] [192] [193] In acute ischemia, depressed conduction and shortening of the refractory period are electrophysiologic substrates for reentrant excitation and thus to both VT and VF. Bretyliuminduced improvement in conduction along with prolongation of the refractory period would tend to extinguish these reentrant mechanisms during ischemia. [193] The drug also elevates the VF threshold. [191] Bretylium can be given in a dose of 5 mg/kg, followed by a 360-J shock. If VF remains, a second dose of 10 mg/kg can be given in 5 minutes, followed by another shock. If necessary, a third dose of 10 mg/kg can be given.

VF or pulseless VT that remains refractory to repeated shocks, epinephrine, lidocaine, and bretylium poses a major therapeutic dilemma. If an electrolyte disorder, such as hypokalemia, hyperkalemia, or hypomagnesemia, is suspected or documented, correction may permit shocks to restore a sustained conversion (Fig. 75-16) . There is increasing evidence that magnesium plays a critical role in maintenance of a stable cardiac rhythm. [194] [195] [196] [197] [198] [199] [200] Hypomagnesemia should be suspected and treated when refractory VT or VF is present. Even in the absence of documented hypomagnesemia, magnesium sulfate, 1 to 2 g over 1 to 2 minutes, can be used to treat refractory VT or VF. [201] [202] Its benefit in terminating torsades de pointes has already been discussed. Procainamide, 30 mg/min to a total of 17 mg/kg, can also be used in refractory VT or VF. Intravenous amiodarone is likely to become a part of the therapeutic approach for refractory VF as well as for refractory VT, as discussed earlier. The same dosage scheme can be used for VF as that outlined for VT.

Figure 75-16 (A and B) Hyperkalemic ventricular tachycardia with a sine-wave morphologic pattern. The serum potassium was 7.8 mEq/L.

In cardiac arrest that does not respond to the initial measures (intubation, ventilation with 100% oxygen, defibrillation, epinephrine, and antiarrhythmic drugs), sodium bicarbonate can be considered. If hyperkalemia is known or suspected to be present, sodium bicarbonate should be administered promptly. Recommendations for the use of this drug in cardiac arrest have changed substantially. Despite its long history of early and frequent administration in cardiac arrest, there is still no convincing evidence that it confers any benefit in survival from VF. [203] [204] By contrast, its adverse effects are well documented, including severe plasma hyperosmolality, [205] [206] paradoxic cerebrospinal fluid acidosis, [207] and CO_2 generation. [205] [208] It is this last effect that has been primarily responsible for renewed concern.

During cardiac arrest, with severely reduced pulmonary blood flow and therefore CO_2 transport and elimination, CO_2 is retained in mixed-venous blood and tissues, producing a disparity between pH and P_{CO_2} in arterial and mixed-venous blood. [208] Sodium bicarbonate is a rapid and potent CO_2 generator, which can be observed in arterial blood, as well as in expired air, after intravenous injection. Sodium bicarbonate would only add to the CO_2 load and could worsen mixed-venous (and presumably tissue) acidosis. Myocardial hypercarbic acidosis has been confirmed to exist during experimental cardiac arrest and resuscitation, [209] and it is not reversed with sodium bicarbonate or other buffer agents. [210] At least with regard to the heart, increases in tissue P_{CO_2} produce progressive decreases in the performance of ischemic myocardium. Clinically, one may infer that intractable electromechanical dissociation (EMD) could be a consequence, even if VF were removed. Myocardial hypercarbic acidosis decreases the success of restoration of spontaneous circulatory function and survival. [211]

In light of all these observations, sodium bicarbonate should not be used routinely in the treatment of cardiac arrest. It can be considered after the foregoing electrical and pharmacologic measures have been instituted, if preexisting metabolic acidosis is present, or if severe documented metabolic acidosis develops during the arrest. [212] A review of acid-base derangements during cardiac arrest [213] [214] suggests that sodium bicarbonate may be beneficial in restoring spontaneous circulation after prolonged (15 minutes) VF cardiac arrest, based on experimental observations. Clinically, if this drug is used, an initial dose of 1 mEq/kg can be given, followed at 10-minute intervals by 0.5 mEq/kg. Of course, if a base deficit is documented on blood gas analysis, the drug can be given based on that measurement. Other antacids, such as sodium carbonate, [212] carbicarb, [212] [215] and tribonat, [212] [216] have been studied, but none has been shown to be superior to sodium bicarbonate in clinical cardiac arrest. Monitoring both arterial and mixed-venous blood gases and pH during cardiac arrest helps to define the derangements in acid-base equilibrium occurring in arrested humans and thereby leads to more rational antacid therapy.

Pulseless Electrical Activity

The term "pulseless electrical activity" (PEA) is now applied to a heterogeneous group of cardiac rhythm disorders, all characterized by pulselessness in the presence of some type of electrical activity other than VT or VF. Thus, included in this designation are the traditional EMD, in which pulseless but organized electrical activity is present; idioventricular rhythms, ventricular escape rhythms, postdefibrillation idioventricular rhythms, and bradyasystole.

High priority must be given to identification of a possibly correctable cause of any form of PEA. For example, when EMD is present, the clinician should immediately consider severe hypovolemia. In a traumatized patient, in addition to hypovolemia, cardiac tamponade and tension pneumothorax with hypoxemia are possible causes. Intraoperatively or postoperatively, acute massive pulmonary thromboembolism should be considered. Idioventricular rhythms may accompany such derangements as severe hyperkalemia, acidosis, hypothermia, or overdose with such drugs as digitalis, beta blockers, calcium channel blockers, and tricyclic antidepressants.

In any of these forms of PEA, the most important point is that although initial temporizing measures such as injection of epinephrine or pacing may be needed to "tide the patient over," an immediate diagnostic assessment and redirection of treatment in a disorder-specific direction may permit salvage of many patients with PEA.

Asystole

The complete and sustained absence of electrical activity is most often an irreversible and therefore terminal event, caused by such derangements as uncorrected persistent hy-poxia, severe hyperkalemia, massive drug overdose, myocardial infarction, or hypothermia. In most of these conditions, asystole is irreversible and terminal, but at least a brief trial of intervention may be warranted in some patients. In specific instances, such as hyperkalemia, known metabolic acidosis, or tricyclic antidepressant overdose, sodium bicarbonate should be administered early in the effort. Pacing has not been shown to improve survival from asystolic cardiac arrest, but if it is tried, it should be done as early as possible in the attempted resuscitation.

Outcome Following In-Hospital Resuscitation

Discharge survival rates following in-hospital cardiac arrest and resuscitation range from 8 to 21 percent, with most reports demonstrating an average survival rate of approximately 14 percent. [217] [218] [219] [220] [221] [222] [223] [224] [225] [226] [227] These reports usually include cardiac arrests in both ICUs and general wards. In a retrospective review of 668 cardiac arrests over a 3-year period, discharge survival was 3.3 percent in ICU patients and 14.0 percent in non-ICU patients. [225] In a small retrospective study of 24 consecutive patients who had an intraoperative cardiac arrest between 1986 and 1994, the survival rate was 38 percent. [228] A primary cardiac event was presumed causative in 50 percent. An accompanying invited commentary pointed out that much of the credit for these favorable outcomes is attributable to advances in intraoperative management by anesthesiologists. In any case, it is certain that anesthesiologists well trained in resuscitation can play a

decisive role in the management of patients with intraoperative cardiac arrest.

The most favorable outcome, as in out-of-hospital cardiac arrest, is observed with VF or VT. [217] [219] [220] [222] [223] In a study comparing CPR techniques in 143 hospitalized patients experiencing asystolic or EMD arrest, there were no survivors to hospital discharge with intact neurologic function. [44] Duration of resuscitative attempts is a determinant of survival [222] [224] [225] [226] [227] [228] ; in one study, none of 179 patients in whom resuscitative efforts lasted longer than 30 minutes survived to be discharged. [222] Other variables that limit survival from in-hospital cardiac arrest include unwitnessed arrest, [224] sepsis, [224] cancer, [222] [224] renal failure, [222] and prearrest hypotension. [217] [222] Age is a major determinant of outcome. [224] In one study, no patients 70 years of age or older who experienced cardiac arrest and resuscitative attempts survived to discharge. [224] These data were obtained in a hospitalized population of relatively sick, aged, male patients, and it is not possible to extrapolate these observations to a different hospital population. Nevertheless, these observations have provoked open and candid discussion and reappraisal in an attempt to define the appropriate application of CPR in hospitalized patients as well as in patients in long-term care institutions. [229] [230] Certainly, age alone should not preclude patients from receiving CPR. [222] [230] At the same time, the presence of sepsis or cancer in an elderly patient who experiences an unwitnessed bradyarrhythmic cardiac arrest would be an example of a clinical circumstance in which resuscitative efforts would be unwarranted. As CPR becomes increasingly available, sophisticated clinical and ethical discussions and decision-making must assume a more dominant role in defining the appropriate application of resuscitation in hospitalized patients.

Do-Not-Resuscitate Orders

The increasing application of do-not-resuscitate (DNR) orders in hospitalized patients has necessitated development of specific guidelines for the management of such patients. The CPR and ECC guidelines [6] addressed this issue in a section entitled "Ethical Considerations in Resuscitation," and the American Medical Association Council on Ethical and Judicial Affairs developed guidelines for use of DNR orders. [231] These documents provide helpful assistance in the utilization of DNR orders in hospitalized patients and should be consulted.

In an analysis of DNR orders in ICUs comparing practice in the period 1988 to 1990 with that in 1979 to 1982, it was observed that DNR orders were written earlier and more frequently in the more recent time period. [232] These practice changes preceded implementation of the Patient SelfDetermination Act, a finding suggesting that improved understanding and acceptance of the limitations of treatment by both physicians and families resulted in more frequent and earlier application of DNR policies.

A unique aspect of application of DNR orders is posed by the patient with such orders who comes to the operating room, for example, for a palliative procedure. Should DNR orders be suspended for this period, or should they be modified in some way? These are difficult questions with no definitive answers that can be applied uniformly to all patients in the same manner. Many authors have addressed these issues and have proposed approaches that give due consideration to patients' wishes and ethical concerns of both anesthesiologist and surgeon. [233] [234] [235] [236] [237] [238] [239] [240] Some investigators have recommended continuing all DNR orders during the perioperative period after discussion of this option with the patient. Guidelines published by the American Society of Anesthesiologists in 1993 recognize that automatic suspension of DNR orders may not honor a patient's rights to self-determination, but that such a suspension is respectful of a patient's wishes if it is explicitly discussed with the patient or surrogate. [241] For the anesthesiologist, an immediate question in such a setting is what constitutes resuscitation, because the monitoring and life support measures accompanying the administration of anesthesia could be taken to be a component of resuscitation in another context. An institutional policy that uniformly suspends all DNR orders for the intraoperative period would seem to be unduly restrictive and probably not respectful of a patient's wishes. The most acceptable position for such a patient coming to the operating room is to engage the patient or designated surrogate in a detailed and explicit discussion that assesses the patient's wishes after he or she has been informed of the usual interventions taken in the administration of anesthesia and what therapeutic options are available in the event of cardiorespiratory failure. Suggested guidelines for the acquisition of this type of informed consent have been proposed. [233] One specific focus of this patient-physician discussion should be whether or not an effort should be made to restore spontaneous circulation in the event of cardiac arrest in any of the forms discussed earlier, such as VF, asystole, or any type of pulseless electrical activity. In this context, attempted restoration of spontaneous circulation from pulselessness in any form would be the ultimate criterion of application of a DNR order intraoperatively. All other forms of life support interventions would be applied as in any other circumstance. Whatever decisions are made during the patient-physician discussion must be documented by the physician in the patient's record.

PEDIATRIC RESUSCITATION

It is now well understood and accepted that pediatric resuscitation is an area of knowledge and skill with specific diagnostic

and therapeutic considerations. No longer is it acceptable to treat pediatric patients as "little adults." [242] [243] Recognition of this change is evident in the new guidelines and in the AHA BLS instructor's manual [8] and the ACLS textbook, [9] both of which devote specific sections to pediatric BLS and ACLS. In addition, training programs incorporating this body of knowledge and skill have been developed with *Textbook of Pediatric Basic Life Support,*[244] *Instructor' s Manual for Pediatric Basic Life Support,*[245] and *Textbook of Pediatric Advanced Life Support.*[246] This discussion highlights the major areas of essential information, again, as in the previous portion of this chapter, with specific regard to application by anesthesiologists in the operating rooms or ICU settings. The AHA textbooks should be consulted for further specific details.

Basic Life Support

Primarily for convenience and uniformity in teaching, infants are considered to be 0 to 1 years of age and children are aged 1 to 8 years. Table 75-3 (Table Not Available) depicts similarities and differences in the performance of CPR in these two groups. In infants, the brachial pulse is often more easily located and palpated than the carotid, and therefore it is recommended for assessment of pulselessness. The tips of two fingers can be used for chest compressions over the lower half of the patient's sternum, with a compression depth of one-third to one-half the depth of the chest (
0.5-1.0 inch), a compression rate of at least 100/min, and a compression/ventilation ratio of 5:1. The 5:1 ratio is used whether one or two rescuers are performing CPR. In children, the heel of one hand can be used to deliver chest compressions over the lower half of the patient's sternum at a rate of 100/min, a depth of one-third to one-half the depth of the chest (
1.0-1.5 inches), and a compression/ventilation ratio of 5:1. Chest radiographs and right heart angiograms in infants, children, and young adults ages 1 day to 19 years have confirmed that the heart lies under the lower sternum in all age groups [247] [248] ; therefore, this is the proper location for external chest compression.

Advanced Cardiac Life Support

Generally speaking, unlike adults, infants and children predominantly experience cardiorespiratory arrest secondary to respiratory arrest, rarely secondary to a primary cardiac event. [6] [242] [243] [249] [250] [251] [252] This is a critical observation because ACLS interventions directed primarily toward the restoration of cardiac function may cause the physician to delay properly directed therapy. For example, a progressive decline in cardiac rate leading to bradycardiac arrest is likely to be an ominous sign of hypoxia in infants and children. Treatment with atropine in a futile attempt to increase heart rate would be tragically misdirected therapy. Furthermore, VF and VT, so common in adults, are uncommon cardiac arrest arrhythmias in infants and small children, [249] [250] although there is evidence that VF is not rare in children and adolescents experiencing prehospital cardiac arrest. [253] Thus, the application of ACLS is indeed different in this patient population. Because the cause of cardiac arrest in children is most commonly respiratory and not cardiogenic, the ensuing pathophysiologic events and mode of presentation of the cardiac arrest state are different, and the subsequent initial efforts at resuscitation must be directed toward respiratory support maneuvers. In addition, of course, equipment, techniques, and drug dosages are of necessity different. All these facts mandate that physicians caring for infants and children have a clear understanding of the role of ACLS interventions in these patients.

Airway Control and Ventilation

The foregoing discussion underscores what is well known to anesthesiologists: definitive control of the airway and oxygenation and ventilation are the most decisive, pivotal, and critical ACLS interventions in pediatric cardiac arrest. As in adults, anesthesiologists ordinarily intubate the trachea for this purpose, then ventilate with such devices as anesthesia bags or bag-valve units with supplemental oxygen. [254] It should be noted that alternative devices such as esophageal obturator airways, esophageal gastric-tube airways, or

TABLE 75-3 -- Summary of Basic Life Support Maneuvers in Infants and Children

(Not Available)

From the American Heart Association, [6] copyright, American Medical Association.

esophageal-tracheal Combitubes referred to earlier for use in adults are not available in sizes for pediatric application. [254] It should also be noted that with the evolution of experience with LMAs, these devices have been successfully utilized for neonatal resuscitative efforts in the delivery room setting. [255] [256] [257] However, as with the esophageal adjuncts mentioned earlier, the LMA should be viewed as an adjunct in this setting, with a secured airway via an endotracheal tube the gold standard during resuscitation.

Monitoring and Arrhythmia Recognition

ECG monitoring permits immediate recognition of the arrest rhythm or, more likely in infants and children, the "prearrest" rhythm. Prompt intervention and correction in the latter event prevent cardiac arrest that, if induced by unrecognized hypoxia and manifested by progressive bradycardia, may be irreversible. With this in mind, potentially life-threatening arrhythmias are discussed first, followed by cardiac arrest.

Supraventricular Bradyarrhythmia

As already discussed, the appearance and progression of slowing of the heart rate in infants and children demand immediate assessment of the cause, ruling out first the most likely culprit--hypoxia. The bradycardia at this point (before cardiac arrest) is most commonly sinus or junctional in origin. Second- or third-degree heart block may ensue if corrective treatment is not applied. If hypoxia has been ruled out and if the bradycardia is accompanied by clinical evidence of impaired perfusion, usually with systemic hypotension, the patient should be treated with epinephrine in a dose of 0.01 mg/kg intravenously, repeated if necessary every 3 to 5 minutes. The 1:10,000 dilution of epinephrine is used for intravenous injections. If the drug is injected into the tracheobronchial tree via an endotracheal tube, 0.1 mg/kg

(1:1,000 dilution) is recommended. The intraosseous route also can be used if necessary (see later).

Epinephrine is the first choice in treating bradyarrhythmias in infants and children. If the rate does not increase with this drug, atropine can be used in a dose of 0.02 mg/kg and repeated once. An algorithm depicting recommended interventions in pediatric bradyarrhythmias is shown in Figure 75-17 (Figure Not Available) .

Supraventricular Tachyarrhythmia

In infants and children, supraventricular tachycardia (SVT) may represent ectopic atrial rhythms, atrial flutter or fibrillation, or paroxysmal reentrant tachycardia. [258] Standard pediatric cardiology texts should be referred to for specific diagnostic and therapeutic details. Although SVT is usually well tolerated in most infants and older children, immediate cardioversion may be necessary when heart rates in the range of 240 to 300 beats/min are reached, rates that may result in severe and rapid hemodynamic compromise. In this emergency setting in which rapid SVT causes cardiovascular instability, [259] synchronized cardioversion is the treatment of choice. The initial energy dose is 0.5 J/kg body weight; if necessary, the energy dose is doubled. [246] If conversion to sinus rhythm still does not occur, the diagnosis of SVT should be reconsidered.

In hemodynamically stable children with SVT, adenosine is the drug of choice, as with adults. The drug can be given as a rapid bolus in a dose of 0.1 mg/kg intravenously, ideally injected into the closest port to the hub of the catheter and flushed with 2 to 3 mL of saline. If the SVT persists or recurs, a second dose of 0.2 mg/kg intravenously can be given in 1 to 2 minutes. [6] [246] [260] [261] [262] The maximum single dose should not exceed 12 mg.

Verapamil is not recommended for SVT in an emergency setting because it may induce systemic hypotension and a state of depressed myocardial contractility. [263] [264] [265] Specifically, it is not recommended in this setting for infants less than 1 year of age, for children with congestive heart failure or myocardial depression, for children receiving beta-adrenergic-blocking drugs, or for children who may have a bypass tract. [246]

Ventricular Bradyarrhythmia

As with supraventricular bradyarrhythmias, a slow idioventricular rhythm that has not yet produced pulselessness must be considered indicative of severe hypoxia (Fig. 75-18) (Figure Not Available) , and treatment must be directed accordingly. Only after this condition has been addressed should rateaccelerating therapy as discussed for supraventricular bradycardia be invoked.

Ventricular Tachyarrhythmia

Despite a common misconception, VT is not always associated with severe hemodynamic compromise. Slow ventricular rates (e.g., 150-200 beats/min) may be well tolerated, as defined by the presence of palpable pulses, but they should nonetheless be converted to a normal rhythm. In this setting, synchronized cardioversion is the indicated treatment, beginning with 0.5 J/kg and increasing to progressively higher doses (up to 4 J/kg) if needed. Lidocaine, 1 mg/kg intravenously, can be given before or after cardioversion. If VT recurs, an infusion should be begun after a loading bolus dose of lidocaine. An infusion can be prepared by adding 120 mg lidocaine (40 mg/mL) to 97 mL 5 percent dextrose in water and infusing it at a rate of 20 to 50 mug/kg/min (1.0-2.5 mL/kg/h). [246] However, if the tachycardia is very rapid, as with rates of 300/min or more, and if it is associated with frank cardiovascular collapse (i.e., no palpable pulses), then this situation should be treated like VF.

Management of Cardiac Arrest

Once pulselessness ensues, therapy must be directed not only at correcting the underlying rhythm disorder, but also at maintaining organ viability during the period of cardiorespiratory arrest. Meticulous attention must be paid to ensuring proper CPR technique and the administration of drugs

that appear to help support perfusion pressures during cardiac arrest and resuscitation.

In the great majority of pediatric cardiac arrests, bradyasystole is the terminal cardiac electrical activity (see Fig. 75-18 (Figure Not Available)). Early dominance of the parasympathetic nervous system and alpha-adrenergic activity may, in part, explain this dominance of bradyasystolic mechanisms as the terminal events in infants. [249] In addition, ventricular tachyarrhythmias (VT/VF) are most commonly seen in infants and children with congenital heart disease. [249] Such children may have cardiac hypertrophy and increased ventricular muscle mass sufficient to provide an anatomic substrate for reentrant wavefronts that initiate and sustain VT or VF.

PEA and Asystole

PEA, as in adults, includes disorders in which some form of cardiac electrical activity is present, but without palpable pulses. In infants and children, this most commonly is an idioventricular rhythm at a very slow and irregular rate (bradyasystole) and is the usual predecessor to ventricular asystole. When PEA is present in the form of organized electrical activity (EMD), or even when any electrical activity is still present, an immediate and aggressive effort should

be made to identify correctable causes. As in adults, diagnoses to be considered immediately include hypovolemia, tension pneumothorax, cardiac tamponade, hypoxemia and/or acidosis, or hypothermia. Immediate consideration of these possibilities and corresponding direction of therapeutic efforts may avoid pursuing with drugs what will inevitably become a terminal situation if an underlying potentially reversible catastrophe is present.

For both PEA and asystole, epinephrine is the drug of choice, given initially in a dose of 0.01 mg/kg (0.1 mL/kg of 1:10,000 solution) intravenously. Subsequent doses of 0.1 mg/kg (0.1 mL/kg of 1:1,000 solution) repeated every 3 to 5 minutes are recommended because there is some evidence that high doses of epinephrine may be beneficial. Second and subsequent doses as high as 0.2 mg/kg (0.2 mL/kg of 1:1,000 solution) can be tried. [266] [267] It is also recommended that defibrillation at 4 J/kg be administered 30 to 60 seconds following each second and subsequent dose of epinephrine. [246]

If vascular access has not been achieved, initial treatment with epinephrine can be given via an endotracheal tube. For this purpose, the recommended dose is 0.1 mg/kg using a 1:1,000 solution. The dose should be repeated at 3- to 5-minute intervals, as long as arrest persists. Epinephrine is presumed to have the same beneficial actions in elevating perfusion pressure as discussed earlier in management of adult arrest. In an infant animal model (infant piglets), epinephrine increases cerebral and myocardial blood flow, a finding suggesting that it may have a similar beneficial action in infants and children. [268]

If venous cannulation cannot be achieved quickly, the intraosseous route, preferred over the endotracheal tube route, can be used. This access route is preferred for children 6 years old or younger, although it has been successfully used for older children. Figure 75-19 (Figure Not Available) outlines the current algorithm recommended for priorities for vascular access during resuscitation. Alternatives to peripheral venous access should be considered in this setting if reliable access cannot be achieved in three attempts or 90 seconds, whichever comes first. [6] [246]

There are two main types of devices currently available for intraosseous cannulation: the intraosseous infusion needle and the Jamshidi-type bone marrow aspiration needle. If either of these is not available in the emergency setting, then an 18-gauge spinal needle with a stylet may be considered for this use. Several publications describe the history, technique, and application of intraosseous infusion in the resuscitation of infants and children. [269] [270] [271] [272] Whichever needle is used, it is

inserted perpendicularly to the skin into the tibia approximately one finger-breadth below the tubercle on the anteromedial surface. The needle is advanced with a boring-type motion until the marrow cavity is entered, as evidenced by a distinct loss of resistance as the needle passes through the bony cortex. [272] The stylet is removed, and bone marrow is aspirated into a saline-filled syringe. The needle is then flushed with saline and is connected to an intravenous administration set. Any fluid or drug needed for resuscitation can be administered by this route. Whereas fluid should flow freely through the needle, administration of fluid with an intravenous pump can be considered if care is taken to ensure absence of subcutaneous infiltration.

In cardiorespiratory resuscitation of infants and children, it is recommended that a rapid glucose test be obtained and glucose injected if hypoglycemia is present. [6] [246] For those

Figure 75-19 (Figure Not Available) Priorities for vascular access. *(Modified from Chameides. [246] Reproduced with permission. Copyright American Heart Association.)*

infants and children who do not respond to resuscitative therapy, glucose administration should also be considered. However, as expressed earlier in the discussion of adult cardiac arrest, routine use of glucose-containing solutions should be avoided because of a potentially adverse impact on the neurologic outcome and because glucose administration may result in hyperglycemia and secondary osmotic diuresis. If glucose is necessary, the dose is 0.5 to 1.0 g/kg intravenously in a solution of 25 percent dextrose in water (2-4 mL/kg) for infants and children, preferably given as a continuous infusion rather than as a bolus to avoid a sudden increase in serum osmolality. [6] [246] The commercially available 50 percent dextrose in water solution can be diluted 1:1 with sterile water for this purpose. For the neonate, in general, the concentration of glucose administered should not exceed 12.5 percent, thus necessitating a further dilution of the 50 percent dextrose solution.

The same concerns discussed earlier regarding sodium bicarbonate therapy in adults also apply in pediatric patients. If it is used, 1 mEq/kg can be given initially, and 0.5 mEq/kg at 10-minute intervals thereafter, unless arterial blood measurements of pH, Pa CO_2 , and base deficit are available and indicate a different dosage scheme. [246] Likewise, there is no available evidence to support the continued use of calcium salts in cardiac arrest in infants and children. The use of calcium chloride should be reserved for the acute treatment of hyperkalemia, hypermagnesemia, hypocalcemia, or calcium channel-blocking drug toxicity. In these clinical situations, 0.2 to 0.25 mL/kg of 10 percent calcium chloride (5-7 mg/kg elemental calcium) can be given and repeated once in 10 minutes. [246]

Pulseless Ventricular Tachycardia or Ventricular Fibrillation

As indicated earlier, this is a relatively uncommon form of cardiac arrest in infants and children and is most likely to be seen when congenital heart disease and increased cardiac muscle mass are present to provide the anatomic and electrophysiologic milieu for maintaining reentrant wavefronts. Defibrillation should be done as soon as possible, and all defibrillators should be equipped with electrode paddles suitable for pediatric age groups. Pediatric defibrillator paddles, approximately 4.5 cm diameter, are recommended for infants weighing less than 10 kg. For those who weigh more, at approximately 1 year of age, adult paddles of 8 to 13 cm diameter should be used. [160] [273] The initial energy dose is 2 J/kg;

TABLE 75-4 -- Drugs Used in Pediatric Advanced Life Support

(Not Available)

From the American Heart Association, [6] copyright, American Medical Association.

if VT or VF is not terminated, 4 J/kg should be used and rapidly repeated twice if needed. For pulseless VT or VF persistent beyond these shocks, antiarrhythmic therapy is necessary, along with assessment of ventilation, oxygenation, and acid-base balance if feasible.

As long as pulseless VT or VF persists, epinephrine should be given in doses described for pulseless electrical activity-related cardiac arrest in an attempt to increase cerebral and myocardial perfusion pressure during CPR. A decision tree for intervention in cardiorespiratory arrest in infants and children is presented in Figure 75-20 (Figure Not Available) .

Lidocaine is the antiarrhythmic drug of choice, given in an initial intravenous dose of 1 mg/kg. In this situation, a continuous infusion, as outlined earlier for VT, can be begun after bolus injection. Alternatively, bretylium, in a dose of 5 mg/kg, can be injected, followed by a 4 J/kg shock. If VF persists, 10 mg/kg can be given followed by another defibrillatory shock.

One of the most difficult aspects of pediatric resuscitation is determination of correct drug dosages in the midst of the crisis, especially if one deals with cardiac arrests in infants and children infrequently. Various schemes have been proposed for simplifying this need. Table 75-4 (Table Not Available) incorporates a convenient scheme for selecting the proper dose of drug to be injected, based on body weight. It includes the major resuscitative drugs (i.e., epinephrine, atropine, lidocaine), along with additional drugs that could be used in some cardiac arrests or other pediatric emergencies.

ACKNOWLEDGMENTS

I wish to acknowledge the assistance of Scott E. LeBard, M.D., for reviewing and updating the section on pediatric resuscitation and Kimberly D. Sankey for her secretarial work in preparation of the manuscript.

Chapter 76 - Brain Death

Kenjiro Mori
Koh Shingu
Shin-ichi Nakao

INTRODUCTION

Because advancements in medicine have changed the definition and concept of death, legislation must also change accordingly. This issue results from progress in organ transplantation and the increasing number of patients who have a living body but a nonfunctioning brain. The latter circumstance results from new discoveries in resuscitative and life-support techniques. Such refinements in critical care medicine mean that not only neurologists and neurosurgeons but also anesthesiologists must now more than ever be able to make an appropriate diagnosis of "death."

HISTORY

In 1902, Cushing [1] first reported cessation of cerebral circulation when intracranial pressure exceeded arterial blood pressure in monkeys. He also described the use of artificial ventilation to prolong cardiac function for 23 hours after cessation of spontaneous respiration in a patient with a brain tumor. [1] In 1959, Bertrand et al [2] reported the maintenance of respiration by mechanical means for 3 days after death of a patient with otitis media who underwent circulatory collapse. Repeated convulsions in this patient had preceded a deep coma. Autopsy revealed extensive brain necrosis of the cerebral and cerebellar cortices, basal ganglia, and brain-stem nuclei, attributed to cessation of cerebral circulation during artificial ventilation. Also in 1959 appeared the first description of cessation of brain functions using a concept similar to today's definition of brain death, "le coma deasse" by Mollaret and Goulon. [3]

These historical reports support the argument that the concept of brain death is independent of, and was established before, the start of organ transplantation from brain-dead patients. However, there is still dispute whether brain death is or is not directly related to organ transplantation. Actually, the heated discussion on brain death started after the first heart implantation by Barnard in 1967. One year later, Harvard Medical School [4] published its criteria for brain death, followed by numerous other publications and criteria. [5] [6] [7] [8] [9]

TRADITIONAL CONCEPT OF DEATH OF AN ORGANISM

All living organisms take in oxygen by respiration, distribute the oxygen to peripheral tissues through circulation, and then excrete metabolites by means of both circulation and

respiration. Therefore, both respiration and circulation are vital to the living organism. Respiration is the functional expression of the brain stem, and cessation of brain-stem functions leads to the cessation of respiration. Furthermore, because the brain stem maintains its function through its supply of oxygen and nutrients, cessation of circulation ultimately leads to cessation of respiration. The functions of the brain, heart, and lungs are thus mutually dependent and share the basic role of maintaining life. An organism dies when one of these life-sustaining organ systems ceases to function.

The traditional concept of death of an organism emphasized the cessation of either respiration or circulation, without consideration for the role of the brain. This was so simply because assessment of brain function was not easy to accomplish. Furthermore, when mechanical ventilation was not widely used, cessation of brain functions related directly to cessation of respiration, and assessment of brain-stem functions was unnecessary.

CONCEPT OF BRAIN DEATH

"Brain death" represents death of the organism and not merely death or necrosis of the brain in a living body. The organism is an aggregation of living cells. However, a simple aggregation of living cells does not necessarily constitute an organism. An organism exists only when the cell aggregation is put under the control of modulating systems such as the central nervous system (CNS), the endocrine system, and the immune system. [10] [11] [12] Once any one of these systems ceases to function, death is inevitable unless artificial measures can be taken. The physiologic significance of brain death and of cardiac death is essentially equal; both types of death represent an irreversible loss of communication between the control center and peripheral cells and tissues and/or loss of modulation of an aggregation of cells. Without these systems, harmonious functioning of the individual cells as constituents of the whole organism ceases. Because total and irreversible elimination of immune or endocrine function is not a phenomenon of reality, in contrast to the CNS, the concept of endocrine or immune death does not exist.

Previously, cessation of respiration was equivalent to immediate death of the organism. Artificial ventilation is able to prolong the life of a body for a certain period of time. Until several years ago, cessation of brain functions inevitably led to cessation of cardiac function within 10 to 14 days. [13] [14] [15] [16] [17] Various functions are believed to reside in the hypothalamus and brain stem--endocrine, autonomic, and immune functions, as well as others that are currently unknown. The brain stem also contains the main tracts for neural communication between the control center and peripheral tissues. All the motor outputs from the hemispheres have to travel through the brain stem, as do all the sensory inputs to the brain (except sight and smell). Each of these functions of hypothalamus and brain stem can be monitored precisely and provided artificially. At present, autonomous respiratory function of the lower brain stem constitutes the border between life and death, and the need for mechanical devices to supply respiratory functions is defined as representing death of the individual. Possibly, most of the brain functions vital to life could be replaced with computers and drugs, and the circulatory functions could be maintained for months and years. However, the only function advance technology cannot provide is that constituting "humanity" or "personality," both of which are possibly products of the telencephalon.

The traditional concept of death has used the cessation of cardiac and respiratory functions as its basis, owing to acceptance of simple and nonmedical concepts: that life begins with the first inspiration after birth, that death comes with the last expiration, and that cardiac activity ceases within a few minutes of the last expiration. By contrast, today's concept of brain death adopts the conclusions of modern biologic science: (1) the CNS, including the brain stem, is the control center for the living organism; (2) cessation of CNS functions represents cessation of the harmony of life; and (3) without CNS control, the living organism is nothing more than a simple aggregation of living cells.

MECHANISM OF BRAIN DEATH

Brain injury has a number of sources, such as traumatic or cerebrovascular injury and generalized hypoxia, all of which produce brain edema. Based on the pathologic mechanisms involved, brain edema is classified as either vasogenic or cytotoxic. [18] [19] [20] Because it is rare that only one mechanism operates exclusively, the label "vasogenic" or "cytotoxic" is only relative.

Vasogenic edema is induced by an increase in cerebrovascular permeability after leaking of serum proteins into the brain parenchyma (i.e., after destruction of the blood-brain barrier). Chemical mediators such as histamine, serotonin, angiotensin, bradykinin, and prostaglandins are believed to induce destruction of the blood-brain barrier. [21]

Cytotoxic brain edema occurs in hypoxia and ischemic conditions and results from disturbance of cellular osmoregulation, a process that depends primarily on energydependent functioning of ionic pumps. The disturbance of osmoregulation increases entry of water into brain parenchyma. Although in a pure form of cytotoxic edema the blood-brain barrier would remain basically intact, cytotoxic edema would nevertheless disturb blood flow and thus would induce hypoxia and vasogenic edema.

Brain edema may be focal at first, but then it spreads throughout the whole brain in the following sequence. Because the brain is covered by a rigid bony skull, its edema is accompanied by an increase in intracranial pressure, which, if sufficiently high, exceeds arterial blood pressure. When cerebral circulation ceases, aseptic necrosis of the brain ensues. Within 3 to 5 days, the brain becomes a liquefied mass, a condition known as "respirator brain." [22] Such increased intracranial pressure compresses the entire brain, including the brain stem, and "total brain infarction" follows. [23]

NEUROPHYSIOLOGIC BASIS OF BRAIN DEATH

Areas of the Brain Involved

By definition, brain death is a total irreversible cessation of functioning of the brain. "Brain" includes all the CNS

structures except the spinal cord. However, the definition used by the International Federation of Societies for Electroencephalography and Clinical Neurophysiology includes the first cervical spine segment. [6] It is generally agreed that brain death does not include lower portions of the spinal cord (caudal from C2), because their location outside the skull spares them from compression during brain edema. Histologic studies of human spinal cord in brain death revealed divergent pathologic findings ranging from histologically intact tissues to complete destruction. [22]

The United Kingdom [9] and Belgium [24] adopted, and the Eurasian Neurosurgical Academy [24] supported, a rather exceptional criterion for brain death, one that excludes involvement of the bilateral cerebral cortices. [25] This state, known as "brain-stem death," does not require recording of an electroencephalogram (EEG) for its diagnosis. The rationale for excluding the cerebral cortices is that the brain stem, and not the cerebral cortices, plays the major role in controlling whole-body vital activities such as respiration, circulation, and other homeostatic functions. Furthermore, we believe that if the cerebral cortices were excluded, assessment of brain-stem functions would be more careful, and the danger of mistaking the vegetative state for brain death could be avoided.

Consciousness and the Electroencephalogram

Bremer [26] and Moruzzi and Magoun [27] demonstrated the essential role of the brain-stem reticular core in activating the cortical EEG. Segundo et al [28] showed that destruction of the brain-stem reticular core leads to loss of consciousness in laboratory animals. In brain death, the patient is believed to have no consciousness, no intellectual activity, and thus no true "humanity." This state is defined as "deep coma" and is the basis for the concept of brain-stem death.

Since the 1960s, laboratory studies have shown that the control mechanisms for the sleep-wake cycle are located in the lower brain stem (i.e., the pontine and medullary reticular formation). [29] Animals subjected to resection of the cerebral cortices and diencephalon still underwent a sleep-wake cycle, took a sphinx position, and responded to auditory stimuli. [29] This animal model represents the complete Apallic syndrome in humans. However, the psychophysiology of the Apallic syndrome has not been studied sufficiently in humans, and no information is available on the state of consciousness, personality, and intellectual activities of such patients.

Hockaday et al [30] and Schwab et al [31] studied the EEG of 550 comatose patients, analyzed EEG for 26 cases of sudden cardiac arrest and 13 cases of respiratory arrest, and classified abnormalities on EEG into five grades according to final outcome (Table 76-1) (Table Not Available) . The prognosis for patients belonging to grade I was favorable. The determination of the prognosis for grade II and III patients required repeated recording of the EEG. When the EEG showed improvement on the day 2 or 3 recording session, the prognosis was favorable. When the EEG tended to deteriorate, the prognosis was poor. In this system, grade Vb represented the EEG for brain death.

TABLE 76-1 -- Arbitrary Classification of Abnormalities on Encephalogram, With Two Subdivisions, Based on Final Outcome for 550 Comatose Patients

(Not Available)

Significant EEG changes occur when blood flow is less than 18 mL/100 g/min [32] and becomes isoelectric when blood flow is in the range of 12 to 15 mL/100 g/min. [33] Paolin et al [34] reported that 7 of 15 patients with a clinical diagnosis of brain death showed persistent electrical activity, although both cerebral blood flow measurements with xenon-133 (^{133} Xe) and selective cerebral angiography showed intracranial circulatory arrest.

Respiration

The primary respiratory center, consisting of the inspiratory and expiratory neurons, is located in the reticular core of the medulla oblongata. Although the other respiratory neurons distributed in the pons are believed to affect the activities of these neurons, [35] [36] this theory is undergoing modification. [37] [38] Various abnormal patterns of respiration (e.g., gasping, apneusis, and irregular shallow respirations) are observed in laboratory animals and humans having brain-stem lesions. In brain death, spontaneous respiration does not occur in patients even when arterial carbon dioxide partial pressure (Pa $_{CO_2}$) reaches 55 to 60 mm Hg. The presence or absence of respiration is assessed by visual observation of movement of the thorax or the respiratory bag connected to the endotracheal tube. Mechanical stimulation of the carina to induce the cough reflex may be helpful in detecting residual functioning of the medullary respiratory neurons.

Cardiovascular Functions

The central neurons that control the circulatory system distribute diffusely in the pontine and medullary reticular core. [39] Of these neurons, the vasomotor and cardioaccelerating

neurons undergo negative feedback control through the carotid and aortic sinus nerves, which relay at the nucleus solitarius. Activation of these cells induces sympathetic nervous outflow, thereby increasing heart rate and arterial blood pressure. Hypertension then suppresses these cells through the feedback mechanism, and circulation returns to preactivation levels.

During the process of brain death after head injury or intracranial bleeding, intracranial pressure increases, and compression of the brain stem leads to marked hypertension (Cushing syndrome). When intracranial pressure is elevated, arterial blood pressure suddenly decreases (Fig. 76-1) . This sudden decrease is the sign of "tonsillar herniation" (herniation of the cerebellar tonsils) through the foramen magnum on the cervical spinal cord, in which outflow of the cardioaccelerating and vasomotor neurons to the spinal cord suddenly ceases. This is one typical onset for brain death. Such dramatic changes in arterial blood pressure are not observed in

other types of brain death such as that induced by hypoxia or those involving other intricate factors. The vasomotor and cardioaccelerating neurons of the spinal cord (located in the lateral horn) obtain automaticity within several days of disconnection from the supraspinal structures, and arterial blood pressure returns to normal without supplementation with vasopressors. [40] This situation is familiar to anesthesiologists, because background arterial blood pressure is usually normal in tetraplegic patients.

After the establishment of brain death, different types of autonomic spinal cord reflexes develop, such as elevation of arterial blood pressure because of bladder distention. Extreme elevation by noxious stimulation is well known in patients with chronic tetraplegia, but it has not been reported for brain death. Although the cardioaccelerating and vasomotor neurons are located in the brain stem, changes in arterial blood pressure are not used as an index of brain-stem function. That is, the condition of the circulatory system changes greatly in brain death, making precise interpretation of the meaning of changes in arterial blood pressure therefore very difficult, if not impossible.

Regulation of Body Temperature

Rodbard [41] suggested that the neural mechanisms governing homeostatic temperature control developed in the hypothalamus from circulatory control neurons in the course of evolution from reptile to mammal. The heat-sensitive center consists of both the heat-loss center in the anterior hypothalamus and the heat-producing center in the posterior hypothalamus. [42] [43] [44] Body temperature is regulated when changes in blood temperature stimulate heat-sensitive receptors in the hypothalamus. Nerve impulses from cold receptors in the skin can also activate heat-producing neurons. The most important heat producers are the skeletal muscles, brain, liver, and heart. The greatest heat radiator is the skin, especially that on the hands. Local electrical stimulation of the heat-producing center induces shivering and constriction of blood vessels in the skin, thus activating vasomotor nerves and decreasing blood flow. Warming of the heat-loss center suppresses vasomotor nerve activity and in this way increases blood flow through the skin.

In brain death, the neural connection between the temperature-regulating center and peripheral body tissues is lost, and the patient becomes poikilothermic. When criteria from the National Institute of Neurological Diseases and Stroke were applied to establish brain death, such patients showed only a "tendency for the temperatures to be subnormal." [22] By contrast, when brain death was established using the criterion of cessation of all brain stem functions, "poikilothermia was found in all patients later than 24 hours after brain death." [45] Even if infection occurs, fever should not develop in brain death, because the temperature-regulating centers no longer function. After brain death, body temperature tends to be hypothermic, even with vigorous application of external heat.

Figure 76-1 The representative time course of arterial blood pressure and heart rate before and after brain death. The patient was an 18-year-old man involved in a traffic accident. Sustained hypertension was followed by a sudden and marked decrease in blood pressure. Dopamine was administered to increase blood pressure, which gradually became stable. Doses of dopamine were tapered and finally became unnecessary.

Hypothalamic-Pituitary Endocrine Functions

Not all the criteria used to establish brain death attempt to determine whether functions of the hypothalamus are preserved. Clinical studies have indicated that hypothalamic and anterior pituitary functions are preserved to a certain degree for a certain period of time after the onset of brain death. Hall et al [46] and Schrader et al [47] reported normal levels of anterior pituitary hormones, half-lives of which are less than 1 hour, such as thyroid-stimulating hormone, prolactin, growth hormone, and luteinizing hormone, as well as positive tests for the hypothalamic hormones luteinizing-hormone releasing hormone and thyrotropin-releasing hormone for 2 to 24 hours after determination of brain death. Sugimoto et al [48] confirmed that concentrations of these hormones were normal for more than 1 week. By contrast, vasopressin, a hormone produced in the hypothalamus and stored in the posterior pituitary, decreased sharply after brain death. [48] The occurrence of diabetes insipidus is variable. In one study, many patients did not have diabetes insipidus after brain death. [49] Another study said that diabetes insipidus did not develop in 23 percent of 31 patients with brain death. [50] Both results indicate sustained secretion of vasopressin. It has become evident that when arginine vasopressin is added to the infusion in cases of brain death with diabetes insipidus, the heartbeat can be maintained for several months. [51]

The diaphragma sellae protects the pituitary gland from compression caused by swelling of the brain. Blood supply to the pituitary gland comes mostly from the superior, middle, and inferior hypophyseal arteries and the capsular arteries. The portal venous system is another source of blood supply to the anterior lobe. In brain death, blood supply through the superior hypophyseal artery and the portal vein would be easily blocked. However, blood supply through the cavernous portion of the internal carotid artery and its branches, such as the inferior hypophyseal artery and the capsular artery, may possibly be spared. [48] [52] [53] Morphologic studies of brain death indicate that damage to the anterior lobe is incomplete but severe, whereas the posterior lobe is relatively preserved. [48] However, because antidiuretic hormone (ADH) is synthesized in the hypothalamus and is transferred to the posterior lobe of the pituitary through axoplasmic flow along the long axon, depletion of this hormone may be greater than one would expect from the only slight morphologic damage seen in the posterior lobe.

In studies on brain death, the hypothalamic hormones, such as growth hormone-releasing hormone, corticotropin-releasing hormone, thyroxine-releasing hormone, and luteinizing hormone-releasing hormone were at trace to subnormal levels. [48] [54] Schrader et al [47] reported a normal growth hormone response to hypoglycemic stimulation. Arita et al [55] also demonstrated that insulin and arginine increased growth hormone in brain-dead patients. Hypoglycemia affects glucoreceptors in ventromedial nucleus to stimulate release of growth hormone- and corticotropinreleasing hormones and finally stimulates growth hormone or corticotropin release, indicating that some hypothalamic function is preserved.

The origin of the hypothalamic hormones released in brain death cannot be identified. Results from morphologic studies of the hypothalamus are controversial. Walker et al [22] reported that the neurons with lytic changes were intermingled with relatively normal cells, a result that may account for the sustained secretion of hypothalamic hormones. Sugimoto et al [48] observed extensive necrosis of the hypothalamus after day 6 of brain death and postulated a nonbrain supply of these hormones, such as the pancreas, intestine, or adrenal gland. The hypothalamus receives its blood supply through the branches of the superior hypophyseal and posterior communicating arteries (Fig. 76-2) (Figure Not Available) . Blood flow to the hypothalamus, at least its basal part, may be preserved in relatively mild instances of intracranial hypertension. The survival of the hypothalamus after brain death is an issue for future study.

Immune System

The immune system is also under the control of the CNS. Even if the immune system is intact, its response to stimulation is modified considerably after total irreversible loss of CNS functions. No information is available as to whether brain death entails vulnerability to infection. Amado et al [56] investigated interleukin-1 beta, tumor necrosis factor-alpha, and interleukin-6 in brain-dead patients and reported that although interleukin-1 and tumor necrosis factor levels were within the normal range, interleukin-6 levels were clearly higher than the normal range in all patients.

Brain-Stem Reflexes

Various brain-stem reflexes are used to diagnose brain death, such as pupillary, oculocephalic, oculovestibular, and cough reflexes. Preservation of the cough reflex indicates preservation of the brain-stem respiratory center. All the brain-stem reflexes (except those of the respiratory centers) need not be present for the organism to be said to be alive, but they are tested simply to confirm the preservation of brain-stem functions.

/das/book/view/29494766/875/838.html

CRITERIA AND TESTS FOR DETERMINING BRAIN DEATH

Determination of brain death confirms the irreversible cessation of all functions of the entire brain, including the brain stem (Table 76-2) (Table Not Available) . [8] Irreversibility means that no treatment may reasonably be expected to change the condition. The responsible disorder may be thought of as structural, and it is not due to such functional, potentially reversible, causes as drug intoxication, hypothermia, and metabolic or endocrine disturbance. The passage of time is also an essential component in determining that a lesion is irremediable. Although testing all functions of the brain is conceptually impossible, the cessation of all functions of the brain is practically determined by (1) loss of consciousness, (2) loss of brain-stem responses, (3) lack of EEG activity, and (4) apnea. The absence of EEG activity is not a required criterion in the United Kingdom [9] and Belgium, [24] because loss of functions in the brain stem but not the entire brain is defined as the criterion for death of individuals in these nations.

Figure 76-2 (Figure Not Available) This illustration of the arterial blood supply to the human pituitary gland shows that small branches from the posterior communicating artery and the superior hypophyseal artery supply the hypothalamus. *(Modified from McConnell. [53] Reprinted by permission of Wiley-Liss, Inc., a subsidiary of John Wiley & Sons, Inc.)*

TABLE 76-2 -- Criteria for Determination of Death

(Not Available)

From Medical Consultants on the Diagnosis of Death, [8] copyright 1981, American Medical Association

Loss of Consciousness and Unresponsiveness

The patients should be in coma and should score 3 on the Glasgow Coma Scale. Motor responses of the limbs or facial muscles to painful supraorbital pressure should be absent. Motor responses (Lazarus sign) may occur spontaneously during apnea testing [57] and are considered of spinal origin. This sign is often observed during hypoxic or hypotensive episodes. Other spontaneous movements of spinal origin are observed.

Pupils

The shape of the pupils can be round, oval, or irregular. The size of the pupils may vary from 4 to 9 mm, but most are 4 to 6 mm. [58] Sympathetic cervical pathways can be intact in the state of brain death, connect with the radially arranged fibers of the dilator muscle, and dilate the pupils.

Brain-Stem Responses

The tests for brain-stem responses vary in different countries. The 1995 criteria of the American Academy of Neurology [59] include light reflex, oculocephalic reflex, caloric (vestibular) test, corneal reflex, jaw reflex, pharyngeal reflex, and cough reflex.

Apnea Test

Ever since equipment for measuring blood gas analysis became generally available, the importance of the value of Pa co_2 rather than the time for observation of apnea has been confirmed. During the apnea test, dramatic changes in vital signs, marked hypotension, and severe cardiac arrhythmias may be shown, and the intracranial pressure can increase markedly. Therefore, the apnea test should be performed as the last test after other tests fulfill the criteria of brain death. Further, the following prerequisites are suggested: [59] (1) core temperature higher than or equal to 36.5°C, (2) systolic blood pressure higher than or equal to 90 mm Hg, (3) euvolemia, (4) eucapnia (option: Pa co_2
40 mm Hg), and (5) normoxemia (option: Pa o_2
200 mm Hg). During the testing, blood pressure, electrocardiogram, and Sp o_2 should be monitored. Testing proceeds as follows: (1) the patient is mechanically ventilated with pure oxygen for 10 minutes; (2) the ventilator is disconnected; (3) 100 percent oxygen is delivered at 6 L/min through a catheter in the tracheal tube; (4) the clinician looks closely for respiratory movements; and (5) arterial blood gas analysis is performed occasionally (e.g., at 3, 5, 8, and 10 min) and confirms the increase in Pa co_2 to be greater than 60 mm Hg.

Controversy in the Apnea Test

The level of Pa co_2 to be achieved in the apnea test is controversial. Increase in Pa co_2 decreases pH in the cerebrospinal fluid, which stimulates the medullary respiratory chemical center. The ventilatory response to the increase in Pa co_2 rises lineally to 80 mm Hg, and then the slope become less steep and peaks at about 150 mm Hg in dogs. [60] The proposed levels of Pa co_2 to be achieved are 44 mm Hg, [61] 50 to 55 mm Hg, [62] 60 mm Hg, [63] and 80 to 90 mm Hg. [64] Ropper et al [61] investigated the levels of Pa co_2 at which spontaneous respiration resumed in 36 patients who fulfilled the other criteria for brain death. Results were between 41 and 51 mm Hg. Damage in the medullary respiratory center may affect the level of Pa co_2 for development of spontaneous respiration. Further, the level of Pa co_2 at which spontaneous respiration resumes is modified by Pa o_2 . The exact level of Pa co_2 to be achieved in the apnea test is unknown, but the generally accepted level is 60 mm Hg. [59]

Electroencephalographic Recording

Electrocerebral inactivity or electrocerebral silence is defined as no EEG activity of more than 2 muV when recording from scalp electrode pairs 10 cm or more apart with interelectrode impedances less than 10,000 ohm, but more than 100 ohm. Ten guidelines for EEG recordings are recommended: [65]

1. A minimum of eight scalp electrodes should be utilized.
2. Interelectrode impedances should be less than 10,000 ohm but more than 100 ohm.
3. The integrity of the entire recording system should be tested.

4. Interelectrode distances should be at least 10 cm.
5. Sensitivity must be increased from 7 muV/mm to at least 2 muV/mm for at least 30 minutes of the recording, with inclusion of appropriate calibrations.
6. Filter settings should be appropriate for the assessment of electrocerebral silence.
7. Additional monitoring techniques should be employed when necessary.
8. There should be no EEG reactivity to intense somatosensory, auditory, or visual stimuli.
9. Recordings should be made only by a qualified technologist.
10. A repeat EEG should be performed if there is doubt about electrocerebral silence.

PREREQUISITES TO DIAGNOSING BRAIN DEATH

Several disorders mimic brain death and can lead to an erroneous diagnosis. The absence of these conditions must be confirmed and the following factors considered before the criteria for brain death are applied.

Deep Coma and Its Cause

The patient must be in a deep coma, and the cause of the coma must be identified; that is, irremediable organic brain damage must be confirmed. Certainly, drug intoxication, intracranial hematomas, and other common treatable disorders should be ruled out, especially if the diagnosis is uncertain. However, it may be obvious within hours of a primary intracranial event such as head injury or spontaneous intracranial hematoma, or after neurosurgery, that brain damage is irremediable. [9]

Body Temperature

After cessation of brain-stem and hypothalamic functions, and after complete disconnection of the spinal cord from supraspinal brain structures, the patient becomes poikilothermic, and body temperature tends to be hypothermic, even with vigorous warming. [45] Because hypothermia suppresses CNS function and leads to misdiagnosis of brain death, body temperature must be within normal range (i.e., hypothermia must be corrected) before the criteria for brain death are applied.

Absence of Cardiovascular Collapse

When intracranial pressure increases, systemic hypertension occurs as a result of Cushing syndrome. This is followed by a sudden decrease in blood pressure because of sudden interruption of vasomotor output from the brain stem and hypothalamus to the spinal cord. Hypotension usually resolves spontaneously within several days because of restoration of spontaneous activity of the spinal cord vasomotor neurons. Because hypotension not only suppresses cerebral

---

blood flow but perhaps EEG activity and can thus promote a spurious diagnosis, administration of vasopressor is required. Vasopressor occasionally restores EEG activity for the determination of brain death.

SPECIAL CONSIDERATIONS

Cerebral Death ("Persistent Vegetative State")

Cerebral death, the so-called persistent vegetative state, refers to cessation of the functions of the cerebral cortices. Brain-stem functions governing the respiratory centers, autonomic nervous system, endocrine system, and immune system, which are vital for maintaining life, are preserved. Although the cortical EEG is flat, it is usually contaminated by electromyographic activity of the forehead, a sign of preservation of function of the facial nerve in the brain stem.

The persistent vegetative state represents irreversible loss of consciousness, but not irreversible loss of life or the mechanism of life; patients in this state can survive for months and years. The term cerebral death is occasionally used erroneously to indicate brain death, which includes the brain stem.

Cerebral death has not been accepted traditionally as equivalent to death. [66] However, some investigators have advocated that cerebral death should be accepted as the death of individuals because the critical elements of life are the organized cognition and "personhood" as the unique feature of human life, which originate from the cerebrum. [67] [68] The problems of this notion are that the permanence of cerebral dysfunction cannot be easily predicted in most clinical circumstances and would threaten the extremely senile and profoundly retarded, who could have severely damaged high-brain functions. [68] [69] The shortage of infant organs available for transplantation worldwide has promoted a growing recognition of the potential use of anencephalic infants, who are born without a forebrain and a cerebrum but with a rudimentary functional brain stem, as a donor. [70] [71] Their natural course is that half of the fetuses die *in utero* and about 95 percent of those born live usually die within 7 days. [71] The American Medical Association Council on Ethical and Judicial Affairs has changed its previous position and supports the use of live anencephalic infants as organ donors. [70] It claimed that anencephalic neonates are definitely different from individuals who are in a persistent vegetative state, infants with profound neurologic injury, and elderly adults with severe dementia, because they have no history of consciousness and no possibility of ever being conscious. In 1961, a kidney transplantation was first performed with an anencephalic newborn as a donor, [72] followed by other such attempts. [73] [74] However, Western countries, except Germany, consider anencephalic infants to be legally alive as long as the brain stem is functioning. [75] [76] This issue is still controversial. [70] [71] [77] [78] [79]

Spinal Cord Reflexes and Surgery

The CNS structures essential to the definition of brain death do not include the spinal cord. Histologic studies have shown that the spinal cord is the best preserved part of the CNS, and results have ranged from grossly normal histologic features to edema, neuronal loss, neurolysis, and, on rare occasion, infarction. [22] However, in brain death, the first cervical segment of the spinal cord (C1) or the junction of C1 and the caudal medulla oblongata is the most severely damaged. Because this is the site of herniation of the cerebellar tonsils, the blood supply is easily cut off by compression of the anterior and posterior spinal cord and vertebral arteries. [80]

Jorgensen [45] reported retention of spinal reflexes for 50 of 63 cases of brain death, and Ivan [80] observed spinal reflexes for 52 of more than 80 cases. The so-called flexor reflex, induced by stimulation of the skin and expressed by flexion of the extremities, was always confirmed when spinal cord reflexes were preserved. Ropper [57] reported bizarre, seemingly purposeful movements of the upper extremities in 5 of 25 cases of brain death. The movements were observed several minutes or more after cessation of ventilatory support, when the ventilator was removed permanently, or during apnea testing. It is important to remember that the patient moves in response to noxious stimulation, and that full curarization is thus required for surgical procedures involving brain death.

Considerations Regarding Children

The brain of infants and young children has greater resistance to damage. On neurologic examination, infants and young children may recover substantial brain functioning after periods of unresponsiveness that are longer than those from which adults could recover. [8] It is generally assumed that the brain of infants and children is more resistant to injury leading to death, although this issue is controversial and lacks convincing clinical documentation. [81] [82] However, the presence of open fontanelles and open sutures in young children makes the skull an expandable chamber. Therefore, intracranial pressure does not exceed mean arterial blood pressure, and cerebral blood flow continues.

There had been an increased need for facilitation of end-of-life decision and organ procurement in infants and children. In 1987, the Task Force for the Determination of Brain Death in Children endorsed the Determination of Death Act and offered the "Guidelines for the Determination of Brain Death in Children" [83] (Table 76-3) (Table Not Available) . The distinctions from the criteria for adults are three separate longer observation periods depending on the child's age and the necessity for two corroborating EEG or one EEG with corroborating radionuclide angiography. Farrell and Levin [84] claimed, in their review of brain death in pediatric patients, that the issues of the determination of brain death in children are as follows: (1) Do the adult criteria apply to infants and children? (2) Are ancillary tests necessary or even capable of establishing the criteria? (3) Are there appropriate time intervals between triggering events, the physical examination of death, the ancillary tests, and the pronouncement of death? (4) Is the whole-brain death definition of death the only acceptable one? It is generally agreed that except in very immature, preterm newborns, the same criteria of brain death can apply to full-term newborns, infants older than 7 days of age, children, and adults, [85] [86] [87] [88] [89] [90] [91] [92] [93] although there have been some reports criticizing this notion. [94] [95] [96] The Special

TABLE 76-3 -- Brain Death Guidelines in Children

(Not Available)

From Task Force for the Determination of Brain Death in Children [83]

Task Force excluded infants younger than 7 days old from its guideline. [83] Volpe [96] addressed the issues of diagnosis of brain death in newborns: (1) if the injury occurred *in utero,* the duration of the insult and severity may be difficult to establish; (2) normal systemic arterial pressure of newborn is not determined; (3) EEG and transcranial Doppler sonography (TCD) may not be 100 percent reliable; and (4) the clinical examinations cannot be reliable because of immaturity. Ashwal and Schneider, [93] [97] however, suggested that in infants younger than 1 week of age, the diagnosis of brain death can be made after observation over a 2-day period and in the preterm infant over a 3-day period, and that the developmental reflexes necessary to ascertain cranial nerve functions are present in the preterm infant by 34 weeks. Farrell and Levin [84] emphasized that no ancillary test is absolutely confirmatory of brain death except a four-vessel cerebral angiography test showing the lack of cerebral blood flow. Scher et al [98] reported that 15 of 20 neonates who showed isoelectric EEG preserved partial clinical brain function. The issues of brain death in pediatric patients concern not only how to diagnose but how to practice. Mejia and Pollack [99] investigated the variability in practices for determining brain death and organ procurement in pediatric intensive care units. Contrary to their expectation, there was great variability. Although apnea testing has been considered the most important criterion for brain death, [100] apnea testing was not carried out in 23 of 93 brain-dead patients (25%), and the methods of apnea testing were not

consistent with the Task Force guidelines for determination of brain death in children in 20 patients (22%). Four of 30 patients younger than 1 year of age did not have a confirmatory test. The investigators concluded that the variability in brain-death determination practices may reflect differences in documentation, lack of knowledge of the guidelines, or disagreement with them.

/das/book/view/29494766/875/841.html

ANCILLARY TESTS FOR BRAIN DEATH

Some ancillary tests are recommended and are adopted when applying the criteria for brain death (Table 76-4) . However, any ancillary test should be used in conjunction with appropriate clinical judgment.

Evoked Responses

Somatosensory evoked potentials (SSEP) are usually recorded as indicators of cerebral activity, whereas brain-stem auditory evoked potentials (BAEP) are considered indicators of the functional integrity of the brain stem.Although several studies describe the importance of recording sensory evoked potentials in the diagnosis of brain death, [101] [102] the need for special equipment and experts limits this practice.

BAEP are signals generated in the auditory nerves and brain stem following an acoustic stimulus. BAEP consist of five identifiable waves generated from specific brain-stem structures along the auditory pathways. Wave I represents the eighth nerve compound action potential; wave II, the eight nerve and cochlear nerves; wave III, the lower pons including the superior olive; waves IV and V, the upper pons and the midbrain, as high as the inferior colliculus. [103]

TABLE 76-4 -- Ancillary Tests for Brain Death

A. Electrophysiology
   1. Electroencephalography (EEG)
   2. Steady (DC) potentials
   3. Sensory evoked potentials
      a. Somatosensory evoked potentials (SEP)
      b. Auditory evoked potentials (AEP)
      c. Visual evoked potentials (VEP)
   4. Others (electroretinogram, electrocochleogram, blink reflex)

B. Cerebral blood flow
   1. Angiography
      a. Conventional (aortocranial, four-vessel)
      b. Digital subtraction
      c. Radioisotope
         (1) Intravenous (bolus technique)
         (2) Intracarotid
      d. Enhanced (dynamic) computed tomography (CT)
   2. Quantitative measurement
      a. N_2O inhalation
      b. Intracarotid injection
      c. Intracerebral injection
      d. Xenon computed tomography (Xe CT)
      e. Single photon emission computed tomography (SPECT)
      f. Positron emission computed tomography (PET)
   3. Echoencephalography
   4. Doppler ultrasonography (cervical, transcranial)
   5. Cerebral perfusion pressure and intracranial pressure

C. Cerebral metabolism
   1. Cerebral metabolic rate of oxygen (CMR_{O_2})
   2. Arteriovenous oxygen difference (AVD_{O_2})
   3. Jugular venous oxygen tension (Pjv_{O_2})
   4. Jugular venous oxygen saturation (Sjv_{O_2})
   5. Lactic acid content of the cerebrospinal fluid
   6. Single photon emission tomography (SPECT)
   7. Positron emission tomography (PET)
   8. Magnetic resonance spectroscopy (MRS)

D. Pathomorphology
   1. Computed tomography (CT)
   2. Magnetic resonance imaging (MRI)
   3. Cytology of the cerebrospinal fluid

Therefore, brain-stem abnormalities can be detected with BAEP. The loss of waves III to V, II to V, or no reproducible BAEP on both sides are usually regarded as brain death, [104] [105] although wave I sometimes remains. [106] [107] Previous deafness or severe peripheral auditory system damage must be checked, because it may lead to a false-positive diagnosis. Some cases with a loss of waves II to V or III to V in spite of maintained spontaneous breathing have been reported. [106] [108]

Following electrical stimulation of peripheral nerve, waves of SSPE are generated from the neural structures along the afferent somatosensory pathways: the brachial plexus, the upper cervical cord, the dorsal column nuclei, the ventroposterior thalamus, and the sensory cortex. [103] "Practice Parameters for Determining Brain Death in Adults," published in *Neurology,* recommended bilateral absence of N20-P22 responses with median nerve stimulation as a confirmatory laboratory test. [59] Facco et al [107] reported that the absence of components later than N13, which represents postsynaptic activity in the central gray matter of the cervical cord, or N13/P13 dissociation was reliable to confirm brain death. These investigators also recommended the combined use of BAER and SSEP for determining brain death. [109] Wagner et al [110] reported a comatose patient who showed apnea and brain-stem areflexia with preserved cortical SSEP.

Measurement of Cerebral Blood Flow

Possible mechanisms for brain death include an obstruction of circulation by cerebral swelling. Therefore, the demonstration of absent intracranial circulation would indicate irreversible cerebral damage. Adopting this concept, Scandinavian nations have taken the stance that total brain infarction constitutes brain death. [23] [111] [112] The following methods are used to measure cerebral blood flow.

Angiography

Contrast Angiography

Absence of blood flow to the brain leads to destruction of brain tissue. Cessation of cerebral blood flow confirmed by angiography is required for the diagnosis of brain death in Sweden and Norway. [111] [112] The greatest advantage of angiography for the determination of brain death is that it is influenced neither by CNS-depressant drugs nor by hypothermia. Therefore, this method has been recommended to confirm brain death. [34] [105] [116] [114] [115] [116] An article published in *Neurology* recommended the following criteria as a confirmatory test: [59] no intracerebral filling at the level of the carotid bifurcation or circle of Willis; patent external carotid circulation; and possibly delayed filling of the superior longitudinal sinus. Drawbacks of this method are that the patients need to be transported to the radiology suite, and the cost is relatively high. Furthermore, in conventional angiography, the contrast medium can be artifactually injected into the brain-supplying artery by pressure. [112] [116] Aortic arch or intravenous digital subtraction angiography has been shown to be as effective as conventional four-vessel angiography, less invasive, and easier to perform. [105] [112] [114] [115] These tests can be performed even at the patient's bedside.

Radionuclide Angiography

Confirmation of brain death using conventional dynamic radionuclide angiography with blood pool agents has been used for a long time. [117] [118] [119] [120] [121] Such investigations are carried out at the patient's bedside using a mobile scintillation camera. Technetium-99m (^{99m}Tc)-pertechnetate, ^{99m}Tc-diethylenetriaminepenta-acetic acid (DTPA), or ^{99m}Tc-glucoheptonate, which do not penetrate the blood-brain barrier, are administered as an intravenous bolus. The absence of intracranial arterial flow is considered a criterion for brain death. These agents, however, are not reliable indicators of posterior fossa and brain-stem blood flow, [122] and persistent filling of venous sinuses has been reported. [121] [123] [124] [125] [126] Lee et al [126] reported that the mere presence of a sagittal venous sinus in the absence of demonstrable cerebral arterial flow activity is not clinically significant and does not contradict the diagnosis of brain death. In recent years, the use of newer radioligands such as ^{99m}Tc-hexamethyl-propyleneamine-oxime (HMPAO) and *N*-isopropyl- *p*- [123] I-iodoamphetamine, which cross the blood-brain-barrier and are picked up and held by viable cells for several hours, have been recommended to confirm brain death. [127] [128] [129] [130] [131] [132] [133] [134] The lack of uptake of isotope in brain parenchyma ("hollow skull phenomenon") is characteristic of brain death. [59] These tests can be of value for patients who have no viable neurons in spite of preserved brain perfusion resulting from artifactual cerebral perfusion pressure or whose perfusion scans are inconclusive. ^{99m}Tc-HMPAO is also used for tomographic functional imaging (single photon emission computed tomography [SPECT]) to confirm the diagnosis of brain death, [135] [136] [137] [138] which allows much more precise regional information.

Computed Tomography

Dynamic CT has been thought to be useful as noninvasive tests to confirm brain death. [139] [140] [141] [142] [143] After intravenous bolus injection of iodinated contrast medium, time-density analysis in specific area can be obtained with a CT scanner equipped with a special software program, which can evaluate blood flow. This technique also has the advantage of demonstrating underlying intracranial disorders that may cause coma. Xe CT cerebral blood flow techniques have also been developed and applied to a wide variety of clinical problems including the confirmation of brain death. [34] [144] [145] [146] [147] This technique is accurate in quantifying low cerebral blood flow, the information of which can be directly coupled to CT anatomy. Pistoria et al [145] suggested that an average global flow of less than 5/mL/100 mL/min is confirmatory of brain death.

Magnetic Resonance

Magnetic resonance (MR) imaging (MRI) and MR angiography have been used for the confirmation of brain

death with the advent of MRI-compatible ventilators. [148] [149] [150] [151] [152] MRI allows an assessment of intracranial contents and is particularly helpful in defining abnormalities in the posterior fossa, which may be obscured by bone artifact inherent in CT. Orrison et al [151] reported that "carotid artery enhancement (intravascular enhancement sign)" and "prominent nasal and scalp enhancement (MR hot nose sign)" as well as "transtentorial and foramen magnum herniation," "absent in intracranial vascular flow void," "poor gray matter/white matter differentiation," and "no intracranial contrast enhancement" in MR findings provided additional imaging support in the clinical diagnosis of brain death.

Phosphorus and proton MR spectroscopy (MRS) has also been used for the determination of brain death. [153] [154] [155] [156] Total absence of high-energy phosphorus compound (including adenosine triphosphate) leaving only one single peak of inorganic phosphate in phosphorus-31 (^{31}P)-MRS and massive lactate concentration in hydrogen-1 (^{1}H)-MRS was demonstrated. However, this technique unfortunately lacks the information of regional brain condition.

Transcranial Doppler Sonography

This technique uses a 2-MHz ultrasonic probe affixed to the temporal area above the zygomatic arch, and usually the flow velocity of middle cerebral artery is monitored. However, it can also insonate the anterior cerebral artery and the posterior cerebral artery from the temporal window, the basilar and vertebral arteries from the occipital window, and the intracranial internal carotid artery and the ophthalmic arteries through the orbital window. Its merit is that it is noninvasive and inexpensive, and it can be performed at the patient's bedside without known risk to the patient. With an intracranial pressure increase, the mean flow velocity decreases, and the pulsatility index ([peak velocity - enddiastolic velocity]/mean velocity) increases. [157] When intracranial pressure reaches levels approaching the mean arterial pressure (brain death), TCD demonstrates systolic spikes, undetectable flow (no signal), or reversal of blood flow in diastole ("to-and-fro" or oscillating waveform). [158] [159] [160] [161] Feri et al [160] reported that these patterns were highly specific (100%) for brain death. Petty et al [161] also reported that these patterns were highly specific (100%) and sensitive (91.3%) for brain death. However, Paolin et al [34] addressed that "no signal" cannot be considered an expression of circulatory arrest unless it is confirmed by cerebral angiography or is the end point of deteriorating intracranial hemodynamics in patients submitted to serial TCD investigations. These TCD signals should be recorded from multiple intracranial arteries (both middle cerebral arteries or at least one middle cerebral artery and basilar artery) to be considered confirmatory of brain death without any other test [161] to rule out the possibility of the occlusion of a single artery.

Positron Emission Tomography

Positron emission tomography (PET) imaging involves intravenous injection of radiotracers labeled with positron-emitting nuclides (e.g., oxygen-15 [^{15} O], carbon-11 [^{11} C], nitrogen-13 [^{13} N]). These radionuclides are incorporated into organic compounds that are chemically similar to those present in the body, and several physiologic parameters can be measured. There have been some reports of the use of PET in the setting of brain death, a few of which indicated the utility of PET in the confirmation of brain death. No detectable glucose metabolism was reported using fluorine-18 fluorodeoxyglucose (^{18} F-FDG) in brain-dead patients. [162] [163] However, cerebral blood flow and cerebral glucose metabolism were reported in brain-dead children. Altman et al [164] reported two clinically brain-dead neonates with electrocerebral silence who demonstrated intact cerebral blood flow on a PET scan using ^{15} O-labeled water, although preservation of cerebral blood flow detected by other means in clinically brain-dead children is common. Medlock et al [165] reported a clinically brain-dead 2-month-old infant with no cerebral electrical activity who demonstrated the persistence of glucose metabolism. These investigators speculated that the preservation of glucose metabolism seems partly due to glial cells, which are more resilient than neurons. The use of PET in the investigation of comatose and/or brain-dead patients is still in an early stage of development, and it is limited by its high cost and need for special facilities. However, the capability of PET to measure diverse physiologic parameters accurately will make it a potentially powerful method of brain death.

Section 6 - Ancillary Responsibilities and Problems

Chapter 77 - Scope of Modern Anesthetic Practice

Fredrick K. Orkin
Stephen J. Thomas

INTRODUCTION

Turbulent, mercurial, exciting, challenging, and uncertain describe the specialty of anesthesiology during the 5 years since the last edition of this text. This undoubtedly reflects the volatile nature of our times--economic boom at home while the President fights impeachment, the Pacific Rim recovers from recession, and Russia fights economic and political meltdown. Scientifically, it has been the time of nitric oxide--meriting the Nobel Prize in Medicine, availability in our operating rooms (ORs) and intensive care units (ICUs) for the treatment of pulmonary hypertension, and the development and marketing of sildenafil citrate (Viagra).

However, it is the financing of health care, experiencing its most tumultuous changes since the inception of Medicare, that has affected medicine and anesthesiology so critically. The defeat of the Clinton Health Plan ushered in the "market solution" to health care--managed care--a cost-containment method of funding and delivering the "commodity" known as health care. [1] Major legislative, rather than market-based, reform of health care financing in the United States, where we currently spend 13 percent of the gross domestic product (GDP) yet still manage to leave 16 percent of the population uninsured, must await the millennium and the election of a new president.

The term "scope of practice" has multiple meanings. Medically, anesthesiology now encompasses the entire perioperative experience from preoperative evaluation to intraoperative regional or general anesthesia (given almost anywhere--hospital, ambulatory care center, procedure room, doctor's office) to the postanesthesia care unit (PACU) or ICU. It also now includes many types of management, both clinical--pain, PACU, ICU--and now administrative--the operating room (Ch. 82) . Scientifically, our scope of practice still includes the development of new, faster-acting drugs of short duration but expands now to molecular biologic techniques investigating issues from the adrenergic system to mechanisms of anesthesia and to outcome studies looking at the medical and economic effects of our actions. In fact, both the journals *Anesthesia and Analgesia* and *Anesthesiology* now have separate sections devoted to economics. This is important because of both physicians' concerns about their futures and the fact that the economics of our specialty--or at least the perceived economics--resulted in a precipitous decline in interest by American medical students, which only now is rebounding as the original perceptions and assumptions prove incorrect (and, perhaps, because the initial zeal for primary care on the part of managed care organizations and deans of medical schools proves misguided).

To better define the scope of the specialty, it is useful to review the definition of anesthesiology as defined by the American Board of Anesthesiology [2] :

> Anesthesiology and perioperative management is defined as a continuity of patient care involving preoperative evaluation, intraoperative and postoperative care and the management of systems and personnel that support these activities. It is the practice of medicine dealing with but not limited to: the assessment of, consultation for and preparation of patients for anesthesia; the provision of insensibility to pain during surgical, obstetric, therapeutic and diagnostic procedures, and the management of patients so affected; the monitoring and restoration of homeostasis during the perioperative period, as well as homeostasis in the critically ill injured, or otherwise seriously ill patient; the diagnosis and treatment of pain; the clinical management and teaching of cardiac and pulmonary resuscitation; the evaluation of respiratory function and application of respiratory therapy in all its forms; the conduct of research at the clinical and basic science levels to explain and improve the care of patients; the management of patient care delivery systems and the supervision, teaching and evaluation of performance of personnel, both medical and paramedical, involved in perioperative care; the administrative involvement in hospitals, medical schools, and outpatient facilities necessary to implement these responsibilities.

Scope of practice also has a distinct political interpretation, encompassing the questions of who can practice anesthesiology and under whose direction. The traditional approaches to delivery of anesthesia, either by the

anesthesiologist alone or as part of a care team [3] --including residents and/or Certified Registered Nurse Anesthetists (CRNA) and/or anesthesia assistants--is under increasing political pressure as CRNAs join other advance-practice nurses in seeking independent privileges to practice. [4] The Health Care Financing Administration and the Congress, as well as state legislators and judiciaries, are being asked to adjudicate this question. There is hope, however, that scientific inquiry into anesthetic outcomes will more appropriately decide these vexing and persistent issues. [5]

PREOPERATIVE EVALUATION

It is ironic that as our interest, expertise, and knowledge concerning preoperative evaluation increase, our abilities to meet and talk with patients directly appears to be decreasing (Ch. 23) . The emphasis on ambulatory surgery (see later) (also see Ch. 65) and same-day admissions, regardless of type of surgery, often makes personal contact with patients, whether in urban or rural settings, difficult. Despite such difficulties (as well as those relating to staffing, patient scheduling, and reimbursement), preoperative clinics appear to be increasing. Patients are seen, histories and physical examinations are reviewed, appropriate (and only appropriate) laboratory tests are ordered, and additional consultations, if indicated, are requested. [6] [7] Explanations of the anesthetic and surgical plans and options for postoperative pain relief decrease patient anxiety and give him or her a modicum of control over his or her own destiny. [8] Evaluation of comorbid conditions is not only directed to "getting the patient ready for surgery" but also focuses on the long-term prognosis of specific diseases. Diagnostic and therapeutic interventions are then ordered from that perspective. This is especially true in the area of cardiac disease. [9] [10]

Undoubtedly, new options for familiarizing patients about anesthesia and surgery will emerge in the ensuing years. These might, and in some cases already do, include supplemental videotapes, in-hospital on-demand television, and departmental or hospital-based Web sites accessible from any patient's home. [8] These sites will likely become interactive and a source for data input directly by the patient.

OPERATING ROOM

The OR continues to be the focus of the anesthetic practice. Whereas the anesthesiologist is comfortable in the operating room setting, it can be seen as a hostile environment both to patients and to other medical personnel. The use of various volatile anesthetics and the contamination of the environment by those gases are concerns that must be recognized by the anesthesiologist and appropriately monitored. Because anesthesiologists use needles and are constantly exposing themselves and others to blood and other body fluids, appropriate consideration and thought must be given to how to prevent injury, both to the anesthesia personnel and to others who work in the OR. [11] Unfortunately, not only are physician and nursing personnel subjected to needlestick injuries, but also housekeeping personnel are at risk because of potential inattention by anesthesia personnel. Certainly, it is in the best interest of the anesthesiologist to look at creative new ways to administer drugs and monitor patients that will decrease the incidence of contamination of personnel in the OR by body fluids from patients.

It is well recognized that the OR is a major consumer of hospital, physician, and patient resources. It is equally apparent that efficient management of ORs can minimize costs and at the same time maximize patient through-put, though not without extraordinary effort and continuing education. [12] Whereas few doubt the wisdom of these observations, fewer still have developed the ideal administrative and operational structure to effect the efficiencies needed in today's cost-constrained environment. [13] Nevertheless, the effort continues, and anesthesiologists, by their temperament, availability, and interest, will be some of the principal players in the game (Ch. 79) .

Triage is another important aspect of the anesthesiologist's role in the OR. Urgent or emergent cases need to be inserted into operative schedules during normal working hours, and often emergency cases vie for available resources during the off-hours. The anesthesiologist must have the broad medical and surgical knowledge to allocate resources and maximize treatment of patients in an orderly progression. If this triage responsibility is abdicated, patient care suffers. The anesthesiologist usually has the best overview of the surgical, nursing, and anesthesia personnel necessary to care for the patient.

AMBULATORY CARE

Arguably among the most significant trends affecting health care in the last quarter of the 20th century has been the development of ambulatory surgery. Indeed, two-thirds of U.S. surgery has already moved out of the hospital, with that fraction expected to reach almost three-quarters by the millennium (Fig. 77-1) . [14] Many factors contribute to this trend, including consumerism, especially because the public is increasingly eager to have an ever-larger decision-making role in its medical care; new technologies in anesthesia (rapidly acting, short-lasting anesthetic drugs and adjuvants) and surgery (tools for minimally invasive surgery, such as endoscopic devices and lasers); and changes in health-care economics. However, judging from the temporal aspects of the transition depicted in Figure 77-1 , economic factors are by far the pivotal factor.

The phase-in of Medicare's prospective payment system, beginning in 1983, limited payments for hospital inpatient care to predetermined amounts associated with the surgical procedure's diagnosis-related group. Suddenly, there was a potent financial incentive to move as much surgery (and other care) away from the hospital to escape the limitations imposed by these fixed rates. Thus, an increasing amount of surgery was shifted to the hospital's outpatient surgery facilities, where payment was based on the former, uncapped, cost-based system, thus allowing the hospital flexibility in setting charges. Shortly thereafter, noting both the safety and cost savings associated with outpatient surgery, Medicare (and then other insurers) covered an increasing array of procedures in hospital-independent, freestanding surgery centers, providing substantial incentive for a further shift of hospital cases into the ambulatory setting. More recently, increasing cost-consciousness has encouraged the movement

Figure 77-1 The growth of U.S. surgical procedures by site, 1981 to 2000. *(Hospital data through 1993 from the American Hospital Association; freestanding and office data through 1993 and all estimates after 1993 provided by SMG Marketing Group, Inc., Chicago.)*

of surgery to the setting with the lowest costs, the surgeon's office. What was once the only site for biopsies and dental extractions has matured into what might be termed freestanding single-specialty (e.g., hand and cosmetic surgery, cataract extractions, hernia repair) surgery centers. Indeed, the surgeon's office is now the most rapidly growing surgical site, expected to capture about 14 percent of the U.S. surgical caseload in the year 2000. Anecdotes describe a similar movement of pain management to freestanding offices.

Although economics, enhanced technology, and a ready and willing public account for the development and flourishing of this ambulatory care, what fosters this transition in care is its apparent safety. That is, the shift in the locus of care could not have occurred unless patient outcomes were at least comparable to those associated with inpatient care. The corollary is that it behooves anesthesiologists practicing in these various ambulatory sites to maintain the same procedural and institutional safeguards required for highquality care--including policies and procedures regarding patient and procedure selection, as well as practice standards--as pertain to inpatient care.

OTHER SITES

The need to provide anesthetics in non-operating room locations continues to increase at a furious pace (Ch. 66) . As procedures become "less invasive" and do not need the facilities of an operating room, it is now easier to bring the anesthesia to the patient than the converse. Areas qualifying for the label "off the floor" or "in the outfield" encompass almost every specialty and include in vitro fertilization laboratories, lithotripsy suites, electroshock therapy, and cardioversions. These environments require special knowledge, equipment, and preparation. Strict adherence to quality standards is important. The American Society of Anesthesiologists has developed a number of standards of care. In this instance, "Guidelines for Nonoperating Room Anesthetizing Locations" (approved in 1994) is the appropriate guide.

Interventional neuroradiology, the cardiac catheterization and electrophysiologic laboratories are areas where new procedures seem to appear on a monthly basis. The radiology equipment, the need for shielding, and the fact that many of these laboratories were designed neither for the anesthesiologist nor the necessary anesthesia equipment often make these procedures an event. An exception to this is the fact that when new cardiac catheterization laboratories are constructed, many are designed with the ability to become a complete operating room. However, the magnetic resonance imaging suite continues to be a less-thanhospitable place, whether we are called to care for a child, a trauma victim, or an inconsolable claustrophobic.

The electrophysiologic (EP) laboratory is a continual source of requests for care. Increasing knowledge of conducting systems of the heart permits electrical ablation of specific areas to control arrhythmias. Such procedures are extremely lengthy, and patients often become restless. Providing sedation and/or general anesthesia to these patients may be required. Additionally, the placement of implantable cardioverter-defibrillators, previously performed via a thoracotomy in the OR, is now carried out via the percutaneous route in the EP laboratory. Patients undergoing these procedures often have limited myocardial reserve and are being treated with a variety of antiarrhythmic drugs. Extensive knowledge of drug interactions for these patients is necessary, and the ability to support the circulation may be required.

POSTANESTHESIA CARE UNIT

PACUs have flourished. Requirements for medical direction, nursing education, and the quality of services provided in these units are discussed in Chapter 68 . It is now recognized that the same degree of vigilance that occurs in the OR must occur in the PACU. The evolution of new surgical procedures means that special consideration for patients is crucial. For example, the widespread use of laparoscopic procedures requires increased vigilance for unrecognized hemorrhage or bowel perforation (Ch. 56) .

In the past, management of postoperative patients and the resources of the PACU was ill-defined. Now, a medical director must be designated, and it is his or her responsibility to ensure the delivery of appropriate standards of care. This responsibility is gaining importance because of the increasing regulations and severity of illness seen in these areas. The anesthesiologist can effectively manage the PACU so as to maximize the efficiency of that unit while providing the best possible care.

The use of shorter-acting drugs and the prompt institution of effective pain relief, combined with acknowledged standards for PACU admission *and* discharge, have altered the approach to anesthetic recovery. [15] If a patient meets both anesthetic and surgical PACU discharge criteria to a second-stage unit, there is no reason not to go directly to the secondary recovery area immediately from the operating room. Dexter and Tinker [16] have shown that this type of flexibility, much more than anesthetic drug costs, can influence labor costs crucial to cost containment in the PACU.

CRITICAL CARE MEDICINE

Bendixen and colleagues, [17] in 1965, reviewed the pathophysiology of respiratory failure and detailed methods of mechanical respiratory support in their seminal book, *Respiratory Care.* (Also see Chs. 71 and 72 .) This documented the beginning of anesthesiology's involvement with critically ill patients outside the operating room. Initially, our role was to provide adequate ventilation for a patient and to determine when weaning from mechanical ventilation was feasible. It became obvious that respiratory function was only one aspect of care of the critically ill; therefore, the anesthesiologist became knowledgeable in cardiovascular support, nutrition, infection, and various diagnostic procedures needed for these patients.

In 1986, the Residency Review Committee (RRC) for Anesthesiology began to accredit programs training in critical care medicine (CCM) in departments that already had core residency training programs. At the same time, the American Board of Anesthesiology began examinations in CCM leading to subspecialty certification. It is worth noting that this followed fruitless negotiations with the specialties of surgery and pulmonary medicine in an attempt to define CCM jointly and to issue only one type of certification. Figure 77-2 demonstrates the fact that there is interest in CCM by anesthesiology residents, but it also confirms that CCM is not their overwhelming favorite. The number of CCM programs remains stable at around 50, with the number of trainees approximating 90. This is in marked contrast to the response following development of programs in pain management. This is unfortunate, because hospitals, given the transition to ambulatory care described previously, are devoting more and more of their bed space to intensive care. Pronovost and colleagues demonstrated improved outcomes in patients undergoing abdominal aneurysm resection where postoperative care was directed by an ICU physician who made daily rounds. [17A]

Some hospitals are taking a global approach and forming ICU administration groups that include all relevant physician specialties and jointly decide medical and administrative policies.

Critical care, however, is practiced not only in critical care units. More and more frequently, PACUs are substituting for the inadequate number of critical care beds. Appropriate resources and personnel must therefore be available in the PACU to serve these patients in a manner that is similar to what would be available in the ICU.

PAIN MANAGEMENT

John Bonica, the former chair of the anesthesiology department at the University of Washington, deserves credit for devoting time, effort, and interest in the understanding,

Figure 77-2 The number of critical care medicine programs in departments of anesthesiology and the number of residents in these programs for the years 1989-1997. As of December 1998, the American Board of Anesthesiology had awarded 855 certificates in critical care medicine. This number is greater than the number of trainees, because initially many candidates took the examination using temporary or practice criteria. *(Data provided by the American Board of Anesthesiology.)*

diagnosis, and treatment of pain (Chs. 69 and 70). Despite his entreaties, most departments devoted few resources--human, financial, or otherwise--to this area. Obviously, the turnabout has been remarkable; today almost every department--private, academic, or governmental--has the ability to treat acute, chronic, and cancer pain.

The recent development of acute pain services is yet another example of the expanding role of anesthesiologists in the medical center. We can now offer patients the prospect of a surgical experience that is totally (or almost totally) pain-free. The availability of intravenous patient-controlled analgesia, followed by other modalities--intrathecal, epidural, and intrapleural infusions, continuous nerve blocks--mandated that acute pain services be developed.

As society changes, the demands for health care change as well. The anesthesiologist's role in limiting postoperative pain by the appropriate use of drugs and devices is a very positive aspect of our specialty.

Interest in training in pain management continues to increase (Fig. 77-3) . There are now 250 to 300 residents taking an additional year of training in about 100 pain programs. As of December 1998, the American Board of Anesthesiology had awarded 2,238 certificates in pain management.

ANESTHESIA WORKFORCE

The workforce for anesthesia services continues to undergo dramatic change relating to its supply, diversity, and function. Historically an undersupplied specialty, unable to meet clinical demands in even the surgical operating room, anesthesiology has grown increasingly rapidly during the past 20 years. [18] Diverse trends account for this growth, including the increasing of sophistication of anesthesia care, itself related to maturation of subspecialty surgery (e.g., transplantation, cardiothoracic surgery); increasing incomes of physician specialists; and a doubling of the number of U.S. medical students graduated each year. As a result (and as described previously), anesthesiologists now work in sites well beyond the surgical operating room as well as sites outside the hospital, including the freestanding ambulatory surgery center, pain management office, and surgeon's office. Indeed, by 1990, anesthesiologists devoted the majority of their professional time to recognized subspecialties (e.g., ambulatory, cardiothoracic, obstetric, and pediatric anesthesia, critical care medicine, and pain management). Clearly, anesthesiology has entered a period of maturation if not sophistication in its professional development.

The growth in the supply of anesthesiologists--109 percent during the period between 1980 and 1996, compared with 58 percent for the total physician supply [19] --has markedly altered the mix of U.S. anesthesia care providers. Whereas there were two nurse anesthetists for every anesthesiologist 30 years ago, [20] by the latter 1980s, the two provider groups had equal numbers. In 1991, there were about 21,000 nurse anesthetists and 25,000 anesthesiologists [20] ; at the end of 1996, there were 33,318 anesthesiologists. [19] Approximately 500 anesthesiologists' assistants have also been trained since the two training sites opened in the early 1970s. These personnel are deployed in a highly variable array of configurations across the United States, even in the same community. Most anesthesia care is delivered by an anesthesia care team comprising an anesthesiologist medically directing nurse anesthetists and anesthesiology residents, with differing ratios among the provider types reflecting the composition of the care delivered. However, in much of the West, anesthesiologists tend to provide direct care, without nurse anesthetists, and in rural areas, nurse anesthetists often work in the absence of anesthesiologists. [18] [20] [21] Overall, there is an almost 6-fold variation in the per capita presence of the anesthesiologist across the United States (Fig. 77-4) (Figure Not Available) .

As dramatic as these workforce changes have been, they constitute merely a preface to future changes. The marked growth in the supply of anesthesiologists peaked by the mid-1990s, when the rate of production of new practitioners was about three times that of attrition. As a result, coupled with marketplace changes related to accelerating growth of managed care, graduates experienced difficulty finding jobs, medical students shunned the specialty, and new trainee cohorts more closely approximated attrition (currently, about 600 per year); now professional opportunities again seem adequate. However, looming on the horizon are diverse factors that are likely to alter the equilibrium if not the practice of anesthesiology. Among factors that may encourage more

Figure 77-3 The number of pain management programs in departments of anesthesiology and the number of residents in these programs for the years 1993-1997. *(Data provided by the American Board of Anesthesiology.)*

Figure 77-4 (Figure Not Available) The geographic distribution of anesthesiologists per 100,000 population, by hospital referral region in 1996, ranged from 4.3 (Harlingen, Texas) to 25.5 (Hinsdale, Illinois). *(From Wennberg and Cooper. [24] Copyright, the Trustees of Dartmouth College, 1997.)*

students to opt for anesthesiology are the emerging recognition that the shortage of primary care physicians proclaimed early in the decade was either quickly treated or a forecasting error; further expansion of the anesthesiologist's role and practice sites; and increasing sophistication of surgery. Certain factors may dissuade students, though the extent to which these factors will occur is still conjectural. They include the continued political fight to alter Medicare regulations (that would be adopted by other insurers) fostering independent practice by nurse anesthetists; further decreases in federal support of graduate medical education, especially specialist training; continued increases in students' already high loan indebtedness coupled with potential reductions in anesthesiologists' income relative to those of other specialties; and continued managed-care-related contraction of professional opportunities. Clearly, the anesthesia workforce continues to change subject to a most dynamic marketplace.

VALUE-BASED ANESTHESIA CARE

A feast-and-famine U.S. health-care marketplace had developed by the early 1990s. Several decades of runaway health-care cost escalation at two to three times the general economy's inflation rate, coupled with a large uninsured segment of the population and health indices (e.g., life-span, infant mortality) below those of countries with lower per capita health-care spending, increasingly suggested misallocation of resources in the U.S. health-care system. When federal reform failed in 1994, the marketplace accelerated the fundamental restructuring of health-care financing and delivery that had begun. What has resulted is a payer-dominated, constrained, increasingly competitive health-care marketplace that seeks greater *value,* which may be represented as

Value-based anesthesia care is a neologism advanced to encourage anesthesiologists to look beyond widely misunderstood concepts, such as cost-effectiveness, to focus on meeting the challenge of enhancing the value of care by providing the best patient outcome achievable at reasonable cost. [22] Given a large literature documenting that perhaps 25 percent of care is inappropriate [23] and large variations in resource use for similar care exist across small geographic areas, [24] it has become clear that quality and cost are not tightly linked: Better quality is not necessarily associated with higher cost, nor does spending less (by doing less) necessarily lead to lower quality.

Insights into the relationship between patient outcome (or benefit) and cost may be gleaned by noting the relationship between overall health benefit and incremental inputs to health care (Fig. 77-5 (Figure Not Available) A). As in other productive endeavors, the anesthesiologist should continue to add resources (e.g., newer and more costly drugs; special patient monitoring; adjunctive pain management protocols) to care as long as positive benefit results. Beyond "the top of the curve," the point of maximal benefit and thus optimal investment, further investment merely results in *negative* benefit (e.g., complications, higher cost without patient benefit). Whereas it is commonly believed that the U.S. health-care system has passed the top of the curve, we may "rationalize" our decision-making by reducing investment and moving back to the point of maximal benefit (Fig. 77-5 (Figure Not Available) B).

Seemingly arcane, this economic construct applies well to most decisions anesthesiologists face, including drug choice, equipment acquisition, and administrative policies. Common to each decision is choosing the appropriate technology or using technology appropriately. (We must acknowledge that *medical technology* is not limited to devices such as patient

Figure 77-5 (Figure Not Available) (A) The hypothetical relationship between inputs to a productive process and the benefits derived describes a *production function.* As investment continues, the net benefit, segment $DeltaB_n$, progressively decreases, then becomes negative, illustrating the law of diminishing return. (B) Rationalizing rather than rationing health-care technology achieves maximal benefit at "the top of the curve," a level of investment associated with the optimal investment. *(Panel A is reproduced from Orkin. [25] Panel B is modified from Orkin [25] and Reinhardt. [26])*

monitors, but, according to the congressional Office of Technology Assessment, also includes drugs, medical and surgical procedures, protocols, support systems, and organizational systems through which health-care professionals deliver care. [27]) The challenge of knowing when we are doing what is "appropriate" (and no more or less) is especially difficult, because our knowledge of the effectiveness of our clinical practices, among other complex issues, is incomplete. [23] The quandary is further complicated because of our rudimentary understanding of outcomes and economics, which extend well beyond the purely clinical and financial, to include quality of life, patient preferences, and patient-based assessment of care, among other seemingly subjective topics. [28] Although general [29] [30] and anesthesia-specific [28] [31] [32] guidance is available, few anesthesiologists will have sufficient time or expertise to undertake this outcomes-related research. Yet, anesthesiologists must develop an appreciation of the considerations when evaluating or planning value-based comparisons of care (Table 77-1) (Table Not Available) .

Once a potential, value-enhancing practice change is

TABLE 77-1 -- Considerations in Value-Based Comparisons of Care

(Not Available)

Modified from Orkin [22]

identified from the work of others (e.g., article in a professional journal) or through research in one's own institution, the next challenge is implementation. In truth, there is no shortage of good ideas, but putting them into action is often difficult. A major problem is inertia within the institution (e.g., "We always do it this way"). Moreover, even when an improved practice is implemented, the improvement is usually short-lived, due to regression to former practice patterns. For example, a new departmental policy dictates use of specified lower-cost drugs with similar patient outcomes in each drug class, but if the full array of drugs remain readily available, backsliding often occurs. Maintenance of the desired improvement requires fundamental change in the system of processes comprising practice patterns. Indeed, an authority on achieving improvement in institutions notes, "Every system is perfectly designed to get the results it gets." [33] Thus, lasting improvement requires modifying systems and related care processes to sustain desired practice patterns that enhance the value of care.

A recent report documented substantial cost savings without apparent adverse outcomes consequent to adoption of department-defined pharmaceutical practice guidelines for limiting the use of several high-cost drugs. [34] Acceptance ("buy in") of the guidelines was achieved in part through soliciting comments from all anesthesia care providers and including among the guideline committees ardent proponents of particular drugs. Compliance was maintained by several mechanisms, including widely publicizing the *department*' *s* successes, periodic feedback to each provider on his or her practice patterns, making compliance with the guidelines more convenient than noncompliance, and permitting departures from the guidelines for appropriate circumstances.

Ideally, we want to concentrate our improvement efforts where they would have greatest effect; however, in many situations we have only vague impressions, in part because the processes of care are themselves so complicated and outcomes are not tracked. A variety of sources can guide the focus of improvement efforts: patient complaints, staff suggestions, critical incident reports, accreditation survey results, benchmarking (i.e., comparison with similar institutions), statewide databases, peer review organization results, and articles in professional journals. Once a focus is chosen, Figure 77-6

Figure 77-6 General schema for improving the value of health care by applying the clinical value compass model. *(Modified from Nelson et al. [35])* Underlying this framework are several assumptions: Health is composed of biologic, physical, mental, and social aspects; the aim of health care is to reduce or limit the burden of illness by restoring or improving health functioning; quality health care provides care processes most likely to achieve the health outcomes desired by the patient at a price representing value for that patient; and the value of health care is a function of quality, costs, and volume.

provides a framework for conceptualizing the improvement effort. Improving the care requires that we understand the underlying processes, particularly where there may be wasted time and resources. Flowcharting the core processes by a team comprising representatives of the personnel involved intimately in the care aids in identifying likely opportunities for improvement. An initiative is adopted and pilot-tested in the care setting, and appropriate outcomes are tracked. Besides the purely clinical, other outcomes include patient satisfaction (e.g., wait times, delays, adequacy of instructions) and cost (including institutional performance). If improvement is documented, the relevant processes are modified to "hold the gain"; regardless of whether improvement occurs, the team moves on to other improvement opportunities. Although superficially resembling what institutions have been doing to satisfy external requirements (e.g., accreditation) for clinical tracking on a limited number of indicators, this measurement approach is more flexible and serves the need to enhance the value of care.

EDUCATION

Resident training is governed by the Resident Review Committee for Anesthesiology. It is charged by the Accreditation Council on Graduate Medical Education with developing standards for residency education, which are reviewed and revised every 5 years, and with inspecting and evaluating all residency programs, both core and subspecialty. The parent organizations for the anesthesia RRC are the American Board of Anesthesiology, the American Society of Anesthesiologists, and the American Medical Association. In 1998, for the first time a resident member was added to the RRC bringing the unique and welcome view of the trainee to the discussions.

As mentioned previously and depicted in Figure 77-7 , American medical student interest declined dramatically secondary to the perception that there were few practice opportunities. Anesthesia programs followed this trend. In 1988, there were 161 anesthesia residency programs; the number fell to 136 in 1998

The American Board of Anesthesiology, similar to most other specialty boards, will issue time-limited primary certificates beginning January 1, 2000. The time limit is 10 years.

RESEARCH

The Congress ending in 1998 did one spectacular thing for medicine; it increased the budget for the National Institutes of Health (NIH) by 15 percent. The exact proportion of the money that will go to anesthesiology is unknown, but hopefully it will stimulate more effort to secure a treasured R-01 grant from NIH. It would be presumptuous to attempt to detail the myriad domains in which anesthesiologists are asking questions, seeking answers. The 84 chapters in this text can be a starting point for the interested scientific traveler.

FUTURE

Predicting the future is hazardous business. One is safe in saying that the period until the next edition of this book will be just as tumultuous and challenging for the specialty as the 5 years since the last edition.

Because economic influences were so predominant in explaining our current situation, it might be useful to review some predictions that have been made. Smith and colleagues from the HCFA [36] have ventured a few guesses concerning medical expenses for the next 10 years. In 1998, total

Figure 77-7 Number of first-year residents in anesthesiology registered with the American Board of Anesthesiology over the years 1989-1998. *(Data provided by the American Board of Anesthesiology.)*

health-care dollars amounted to $1.1 trillion (~14% of GDP). They predict this will double to $2.1 trillion (16.6% of GDP) by the year 2007. This increase will be concentrated in the private sector, will be triggered by technology and longevity (the baby boomers will definitely have arrived), and will be fostered by the fact that managed care as we currently know it already enrolls 85 percent of the workforce and cannot be expected to effect substantial new savings.

The aging of the population combined with technological advance should make many positions available for anesthesiologists. Our expansion into new areas should do the same. The renaissance of interest among medical students is exhilarating to all involved in medical education. Our techniques in pain management will make the operative experience less frightening and less of a physiologic trespass.

Chapter 78 - Finding Professional Information on the Internet

Ira J. Rampil

INTRODUCTION

An interconnection of computers known as the Internet is changing the nature of information dissemination. Information on every conceivable topic has become instantaneously accessible by telephone or even satellite anywhere in the world. Publishing information on the Internet has spurred a revolution that may come to be seen as significant as the development of the printing press because the impediment to instant, global publication has essentially disappeared. Public and private professional agencies, commercial interests, universities, and private citizens have all taken advathe Internet to publish medical information. Subsequently, as the corpus of medical literature moves to electronic form, it is also being transformed from its classical, controlled, peer-reviewed, article-based format to a more free form with variable provenance. This review focuses on sites that serve as key depots of information and on strategies for efficiently locating anesthesia-related information of the highest quality. Although every effort has been made to use current Internet addresses, the dynamic nature of the Internet ensures that some of these addresses will change over time.

The information content within the Internet is packaged by its provider or publisher in one of several ways. Each type of package provides a different "look and feel" or interface to the end user, and each is transmitted by a different software protocol. At present, the most widely used protocols are electronic mail (E-mail), World Wide Web pages (WWW, or Web), bulletin boards (USENET), and simple file transfer protocol (FTP).

The development of hypertext technology is probably the dominant alluring feature of the Web. The basic concept of hypertext was originated by Vannevar Bush [1] and was developed by Theodore Nelson. [2] [3] Simply put, text can be annotated or cross-referenced by marking key words. If activated by the reader with a mouse click, these "hot word links," or simply, "links" in text bring the reader to a new text that expands on the original linked words. Reading is thus converted from a sequential or linear process to a readercontrolled nonlinear experience, with the reader skipping around ("surfing") as interest or mood strikes. The concept of hypertext has been expanded for two-way communication between the reader and the publisher by way of data entry forms. Forms are presented to the reader as an area of a Web page with blank boxes that await reader-entered text as well as buttons, check boxes, and other elements of the common graphical user interfaces.

In the 1960s, when computers filled special air-conditioned rooms and communicated by exchanging magnetic tapes, the Internet began as an experiment in direct, wired, communication. With funding from the U.S. Department of Defense Advanced Research Projects Agency (ARPA), the Internet developed into a matrix of computers that could pass data around the country, even if part of the matrix was disabled. Through the early 1990s, the Department of Defense funded the expansion of the network for military and scientific research purposes. During this time, computer scientists developed a variety of uses for the network in addition to the original transfer of data files. These ancillary Internet services grew in popularity, eclipsing the original research intent, and eventually convinced the government to commercialize the Internet. The Internet continues to expand, as it has from its inception, with more than 18 million computers assigned network addresses and more than 100 million daily users worldwide as of the summer of 1997.

The rapid expansion of public and commercial use of the Internet has to some extent "clogged its arteries," slowing data transfer rates for the research community. Therefore, the National Science Foundation has helped fund the creation of Internet II, which has much higher capacity than the original; at present, it is only open to certain research universities and industrial users.

When the government of the United States relinquished control over access to the Internet, the demographics of Internet

publishers shifted dramatically from university-based academics to a population composed predominantly of commercial interests and average citizens. The nearly absolute freedom to publish material on the Internet has led to the present situation, in which valuable medical and scientific information must compete for attention with advertising, hucksterism, quackery, and fringe opinion. Nevertheless, the Internet remains a valuable resource that can be efficiently mined for medical information, if the user knows where to look.

SOURCES OF TRUSTWORTHY MEDICAL INFORMATION

Peer-Reviewed Literature

The National Library of Medicine (NLM), a branch of the National Institutes of Health (NIH) in the United States, has been collecting a bibliographic database of the world's serial literature of biomedical science since 1966. This database, known as MEDLINE, has citation information and author abstracts from roughly 3,800 journals and more than 9 million papers and is widely considered the premier source of peer-reviewed medical information. [4] Once the domain of librarian-specialists and expensive subscription services, the NLM now provides free MEDLINE access to all on the World Wide Web. MEDLINE is available through two different styles of user interface.

Internet Grateful Med (http://igm.nlm.nih.gov) is the free continuation of an old fee-based subscription service. Grateful Med is a Web page that has a data entry form containing many fields with which the user may control the search process. Grateful Med allows searches by subject word, author name, or title word. At the top of the search form, a button labeled "Find MeSH/Meta Terms" is the link to the NLM metathesaurus that allows the user to convert arbitrary or common English language phrases or concepts into precise MeSH (medical subject heading) search terms. For example, the metathesaurus suggests converting "mad cow" into "encephalopathy, bovine spongiform." Use of the metathesaurus is highly recommended to ensure that all relevant citations are retrieved. A set of pop-up menus limit parameters for the search, including publication type (e.g., clinical trials, editorials, reviews), gender of study subjects, age groups, dates of publication, and language of publication. An asterisk appended to the start of a subject word informs the search engine that the subject must be a major component of the citation. Once a search has been performed, the resulting citations are listed, eight at a time, in an abbreviated format. The short format has the full title and author list, the affiliated institution, the journal citation, and a note as to whether an abstract is available. Each citation in this list also has a checkbox that selects the citation for more detailed secondary display that includes abstract and MeSH headings. Grateful Med has an option to save the detailed search results to the user's local disk. This feature is particularly useful for filling a bibliographic database used in conjunction with a word processor. Users who choose to use non-Web-based access software to Grateful Med must still pay a subscription fee, but they are entitled to order (for an additional fee) reprints of articles they find in a search.

PubMed (http://nlm.nih/gov) is a simpler, but still powerful, alternative interface to the MEDLINE database. The entry screen to PubMed uses only a single field in which one may enter subject words and authors. The grammar for basic searching is relaxed compared with that of Grateful Med: list the words of interest, separated by spaces. For example pulmonary vasodilation nitric oxide locates all articles with these terms as MeSH subjects, title words, or abstract words. When more than one search term is entered in the simple entry field, the terms are presumed to be ANDed together. If a multiword phrase is sought, it can be enclosed in quotation marks. Author names may be entered as only surnames or with initials. When initials are added, they should be delimited with a comma. The entries Hamilton WK, anesth* find all the publications of W.K. Hamilton that contain a root or MeSH term that starts with "anesth." The asterisk is a wild card that allows a match to all subjects and MeSH terms starting with "anesth," including anesthesia, anesthetic, anesthesiologist, and anesthesiology. Advanced users may employ a more sophisticated search grammar that includes Boolean expressions (AND, OR, NOT) and specific search fields (Table 78-1) . For example: clonidine[majr] AND anesthesiology[ta] AND 1996[pdat] locates the eight papers that appeared in *Anesthesiology* in 1996 with a major subject of clonidine. Note that the Boolean operator words must be capitalized, whereas the search field descriptors (abbreviations) are lower case. PubMed has an advanced search page that prompts the user with pop-up menus for the search field descriptors and Boolean operators. In advanced mode, a search may be incrementally refined by adjusting terms and limits after each search. A powerful feature of PubMed is the "see Related Articles" link, which appears next to each citation in the short display list. This feature uses a complex algorithm to compare both the text and the MeSH terms of articles when they are entered into the system to define "neighbors" on the basis of similarity of content. The list of related articles is sorted by degree of similarity. As with the Grateful Med interface, PubMed can save the results of a search in a variety of formats for later use. PubMed provides direct links in citations to that small number of journals (currently <100) whose publisher provided the full text of articles on-line. Although detailed discussion of search strategies within MEDLINE is beyond the scope of this review, it is important to note that the quality of the search results is very sensitive to the approach the user takes to searching. One example was provided by two different searches for randomized controlled trials in epilepsy. [5] In this case, one search strategy located 103 papers, and the other strategy, 275 of 308 known relevant papers. The long-term solution for users of these databases is the evolution of database search software to automatically translate vocabularies of disciplines and to efficiently extract core semantic concepts from the archived manuscripts. [6] A database user may then rely on the search engine to find the right citations, even if they do not include the exact wording sought.

Computer database search results are frequently plagued by the inclusion of irrelevant citations. Nonspecific citations are a particular problem for clinicians who seek efficiency. The NLM has taken some steps to solve this problem with the Clinical Queries system. In Clinical Queries, the user enters

TABLE 78-1 -- PubMed Database Search Fields[a]

FIELD	ABBREVIATION	DESCRIPTION
Affiliation	AD	Contains the institutional affiliation and address of the primary author and sometimes of other authors.
All fields	ALL	Covers all searchable PubMed fields.
Author name	AU	Contains the list of authors for a paper in the literature. The format for author names is the last name, followed by a space and the first initial(s), without periods, e.g., David J. Lipman would be Lipman DJ; James Ostell would be Ostell J. Initials may be omitted when searching.
E.C. number	RN	Is a number assigned by the Enzyme Commission to designate a particular enzyme. This field also includes Chemical Abstract Service registry numbers.
Journal title	TA	Is the name of the journal where the record was published. Journal names are stored in the database in abbreviated form, e.g., the *Journal of Biological Chemistry* is stored as J Biol Chem. If one is not sure how a journal name is abbreviated, one uses "List Terms" mode to browse the journal titles. One may also enter the complete journal name or the ISSN number in this field. A "Journal Browser" is also available to look up the full name, abbreviation, and ISSN number of a journal.
Language	LA	Is the language in which the article was published. Note that many non- English articles, however, do have English abstracts.
MeSH major topic	MAJR	Includes all MeSH terms that are marked as being of major importance to this record by the National Library of Medicine indexers for MEDLINE.

MeSH terms	MH	Includes all of the terms in the MeSH terms, a controlled vocabulary of terms used to index MEDLINE. Each MEDLINE citation is given a group of MeSH terms that relate to the subject of the paper from which it is drawn. Frequently, MeSH terms have an additional term, called a "subheading," that further defines how the MeSH term relates to the article it is associated with. This subheading is appended to the MeSH term, e.g., "pneumonia/diagnosis." Searching on the MeSH term (here, "pneumonia") retrieves all of the articles that use that MeSH term, whether they have subheadings or not. One uses the subheading terms if one requires more specificity than the MeSH term alone allows. *Note:* MeSH terms searched for using the MeSH or MeSH major topic fields are automatically "exploded" by PubMed, i.e., all terms that are logical subsets of the term entered are included. For instance, "vision disorders" includes "blindness." MeSH terms found using the "All Fields" search, however, are *not* exploded.
Modification date	MDAT	Contains the date that the record was placed into PubMed, in the format year/month/day, As for publication date, see below.
Page number	PG	Is the number of the first journal page that the article appears on.
Publication date	DP	Contains the date that the article was published in the format year/month/ day, e.g., 1984/10/06. Entry of a year alone (e.g., "1984") retrieves all articles for that year; entry of a year and month (e.g., "1984/03") retrieves all articles for that month. Journals vary in the way the date appears, some including only year, some year plus month, some year plus month plus day. PubMed takes the date as it appears in the journal.
Publication type	PT	Refers to the form of presentation of an article or other work. Examples include review articles, clinical trials, randomized controlled trials, and retracted publications. (See Table 78-2.)
Substance	NM	Contains the names of any chemicals associated with this record from the Chemical Abstract Service (CAS) registry and the MEDLINE "Name of Substance" field.
Text words	TW	Includes all words in the title and abstract, plus individual words from MeSH terms and chemical substance names.
Title words	TI	Includes only those words found in the title of a record.
Volume	VI	Is the number of the journal volume in which this article is published.
MEDLINE ID	UI	Is the MEDLINE unique identifier of a given citation.
PubMed ID	PMID	Is the PubMed unique identifier of a given citation.

[a] *Derived from http://www.ncbi.nlm.nih.gov/PubMed/pubmedhelp.html#SearchFields. Partial listing only.*

the usual search terms plus a category: therapy, diagnosis, etiology, or prognosis. The system will then report only the most relevant papers. See Table 78-2 .

The NLM has coordinated a program with local medical libraries to deliver copies of full articles on request. Fees and form of delivery depend on the local library.

Besides MEDLINE, the NLM has other databases that contain a wealth of information for the researcher, the practitioner, and the public. These databases are listed in Table 78-3 . The NLM provides a Web page (www.nlm.nih.gov/ databases/alerts/clinical alerts.html) that lists NIH "Clinical Alerts." These alerts are a public service tAlerts." These alerts are a public service that reviews the outcomes

of major NIH-funded clinical trials and provides notice of results that are believed by the NIH to have the potential for major impact on medical practice.

Other useful sources of information include the drug nomograph database at cponline.gsm.com and the government's consumer guide to health care at www.healthfinder.gov.

Journals

Many traditional peer-reviewed journals have developed electronic outposts on the World Wide Web. These Web sites are in varying states of evolution, and thus, each provides a different set of features. Most provide a set of contact addresses for the respective editorial offices and manuscript preparation instructions for authors. Many provide timely search access to published article abstracts, and a few provide access to published full papers with illustrations. Although successful economic models of paperless publishing have yet to be developed, the trend away from paper publishing and third-class mailing seems clear. Table 78-4 provides a small sample of the medical journals now on the Web. A more complete, updated list is available at www. yahoo.com/Health/Medicine/journals.

Textbooks and Patient Care Protocols

Many of the major textbooks of anesthesiology and medicine in general now have electronic counterparts. To date, these works have been commercial and proprietary and are available for sale only on a CD-ROM rather than on the Internet. At least two groups of volunteer authors have therefore started to produce Web-based texts. The first, *Global Textbook of Anesthesiology* (http://gasnet.med.yale.edu/gta), has a structure similar to that of traditional texts with major sections and chapters. At present, the 26 available chapters tend to be narrowly focused and together cover perhaps 5 to 10 percent of the field of anesthesiology. The chapters have been neither reviewed nor edited. The second effort is called the *Virtual Anaesthesia Textbook* (http://www.usyd.edu.au/ su/anaes/VAT/VAT.html). This site is actually an organized compendium of preexisting anesthesia-related Web pages. Volunteer chapter organizers seek out Web pages with appropriate key words and list them within the framework of a "chapter." Although this is certainly an interesting experiment in electronic collaboration, the results are predictably

uneven. Some of the linked pages are of high quality, others of marginal quality or relevance, and the thematic coverage is spotty and subject to the organizers' ability to track down what other people have written.

Some of the pages linked by the *Virtual Anaesthesia Textbook* were written as teaching handouts. A small number of academic departments, professional societies, and individuals have placed resident-oriented teaching materials on the Internet. These include electronic versions of lecture notes and local protocols for the anesthetic conduct of certain types of cases. These pages often provide useful insight into case management and are a reminder to the variability in approach across institutions. However, this type of Web page is not reviewed by the Food and Drug Administration or even peer reviewed in general. Therefore, suggestions regarding pharmacology, especially off-label use of drugs, must be considered only advisory. A few examples of patient care protocols that have been published on the Internet are listed in Table 78-5 .

Grants and Funding Information

In the present competitive funding environment, access to the current NIH Requests for Proposals (RFP) and other Institute news and offerings can be quite useful. The NIH provides several means by which investigators may stay abreast of funding opportunities. The NIH Guide is available on the World Wide Web (http://www.nih.gov/grants/ guide/index.html). Versions of the NIH application forms that can be downloaded are also available at http:// www.nih.gov/grants/forms.htm. Each institute maintains its own Web site as well. The RAMS-FIE company offers a free E-mail notification system (FEDIX Opportunity Alert). This system allows subscribers to note their fields of interest, and the system then notifies them periodically to relevant funding opportunities across all federal funding agencies. FEDIX Opportunity Alert may be subscribed to at www.rams-fie.com/opportunity.html.

The NIH maintains a database (CRISP) of funded research projects that may be searched via the Web. CRISP contains project abstracts and investigator and institutional information. The CRISP search engine may be accessed at http://www-commons.cit.nih.gov/crisp.

Politics and News

The impact of political and social forces on the practice of medicine has never been greater. Changing social policy regarding access to health care and the ascendancy of competitive he is therefore as important in this area as it is in the scientific arena.

Professional organizations, including the American Society of Anesthesiologists (http://www.asahq.org) and the American Medical Association (http://www.ama-assn.org), have Web sites that offer practice news and commentary in addition to membership-oriented services. The American Society of Anesthesiologists Web site also maintains a library of downloadable practice guidelines that have been reviewed and approved by the organization. Several anesthesia-related subspecialty organizations have developed a presence on the Internet (Table 78-6) . These organizations provide newsletters, information regarding scientific and professional meetings, and some access to subspecialty journals. For those with an interest in the latest alterations in regulations, reimbursement, and enforcement issues, the Department of Health and Human Services Health Care Financing Administration maintains a Web site at www.hcfa.gov.

General news is available from many Internet sources. Daily newspapers and weekly magazines are available at Web sites or via subscription E-mail. Reputable

news organ-izations like the *New York Times* (www.nyt.com) and CNN (www.cnn.com) often have timely coverage of major medical stories. A current listing of general news sources may be obtained from a Web directory, such as Yahoo (www. yahoo.com/news).

Departments of Anesthesia

Many academic and private departments of anesthesia have Web sites. These sites provide information on the faculty; the residency program, if present; and in some cases, descriptions of special clinical services for prospective patients. Up-to-date lists of links to anesthesia departments can be found at http://www.yahoo.com/Health/Medicine/

Discussion Groups

A popular means of professional communication on the Internet is known as the discussion group. In essence, a group of interested people sends their E-mail addresses to a central party known as a host or list server, creating a list of recipients. A member of that list may then send an E-mail message to the host, which in turn rebroadcasts the message to all members of the list. The message traffic on these lists may be rare or dozens of messages per day. The content of the messages ranges from the seeking and rendering of clinical advice, discussion of cases, or even frank commercial Spam (unsolicited junk E-mail). Many busy discussion groups provide a digest service as an alternative to receiving dozens of individual messages. The largest anesthesiarelated discussion group is GASNet (http://gasnet.med. yale.edu/maillist/). A current list of more than 50 anesthesia-related groups with their electronic contact addresses can be obtained at www.eur.nl/cgi-bin/wrt4.pl.

A service known as USENET provides another variant of the discussion group. Instead of using E-mail to communicate with a fixed list of subscribers, USENET uses a public bulletin board format. In USENET, there are topical boards, also known as newsgroups, where anyone may read or post messages. At present, USENET has almost 33,000 separate newsgroups, although none relate directly to the practice of anesthesia or critical care at present. Newsgroups are named to place themselves within a subject hierarchy. For example, comp.sys.mac.digest is a newsgroup within the computers group (comp) related to Macintosh computers (.sys.mac) that contains summaries of news, commentary, and new file postings (.digest). Another example is rec.auto.bmw, a newsgroup in which hobbyists and enthusiasts (rec = recreation) discuss the minutiae of BMW automobiles. Topics of general medical interest may be found within the sci.med hierarchy, such as sci.med, sci.med.cardiology, sci.med.pharmacy, and sci.med.informantics.

On-Line Journals

Early in the genesis of the Internet, the ability to instantly and inexpensively disseminate information proved tempting to investigators eager to get their message out. The physicists were first, creating in the 1980s an on-line archive of preprint manuscripts, followed by an on-line peer review system for both traditional and purely electronic publications. There has been an effort to create a similar venue for the field of anesthesiology. A purely electronic, peerreviewed journal, the *Internet Journal of Anesthesiology,* now appears at http://www.ispub.com/journals/ija.htm. This journal provides a venue for publications that include multimedia (video, sound, and color pictures) and interactive features. Eventually, mainstream paper-based journals can be expected to move to a predominantly Web-based existence.

General Information

With more than 70 million Web pages and millions more FTP and gopher sites, as well as many hundred thousand USENET messages per week, some information is available on almost any conceivable topic. A hallmark of this collection of information is that there is absolutely no central control or official index. Finding relevant information is almost always an uncertain venture. Because of the great popularity of the Web, several commercial ventures have arisen that index the Internet and provide free searches to the public in exchange for providing advertising banners. Each of these services has different characteristics; some are presented as primarily search engines, such as Alta-Vista and Open Text, whereas others, like Excite, Infoseek, Lycos, and Yahoo, are designed for use as directories, although they have some search capability. Search engines usually locate more Web pages than directories, but the directory results are usually more relevant. Most of these services search the newsgroups of USENET as well as the Web. The Alta-Vista search engine is the most complete Web database. It catalogs more than 50 million Web pages and 8 billion words. Other services range from nearly that large to lists of only several hundred thousand Web sites that have been selected for content or, in some cases, commercial consideration. These indexes of the Web are dynamic, with new entries constantly being fed into the databases by so-called Web spiders. Spiders are software programs that aggressively map the World Wide Web by reading all the text and links on a page, then following up on the found links in an iterative process that tries to find all available Web pages. Because the Web is so large, a complete traversal by a spider program can take months. Therefore, some fraction of the Web sites found in a search or a directory are no longer available at the listed universal resource locator (URL). Most searches find pages that do not really relate to the search subject. Many of the search services allow the user to refine with Boolean terms, a search that may produce a massive number of listings. The Alta-Vista site also has a unique graphical approach to refining

a search. Efficiently finding the Web pages that are truly interesting requires knowing the "grammar" of each search engine because they are all different. Most of these services provide a tutorial page for their system's search request grammar.

Often, a URL is rendered obsolete by a rearrangement of files in the disk of the server, rather than an actual deletion. In such cases, there is no harm in removing the file directory information in the URL, leaving just the domain name. Reading the top Web page of the server often provides a path or at least a clue to the missing pages. When using a search or directory services for medical information, one must remember that random Web pages resulting from a search may well have a random probability of containing accurate information. The power and failing of the Internet is that it provides a medium for true freedom of the press, but when one is seeking professional medical information, it is prudent to exercise judgement and to rely on sources of known provenance.

Appendix 1-Glossary [a]

Address
: Every computer on the Internet is assigned a unique numerical (IP) address that must be used to direct communications. Most computers also have an alphabetic (domain) name that is easier to remember.

Applet
: A small JAVA program embedded within a Web page.

ASCII
: American standard code for information interchange. The numeric code by which computers represent alphabetic letters, numbers, and symbols.

Bandwidth
: The speed rating of a communications link. Usually measured in bits per second, in which an ASCII character is eight bits and a full page of text is about 16,000 bits. Standard modems provided a band width of 28,800 bits per second.

Domain name
: An alphabetic name that is assigned to the IP number address.

FAQ
: Frequently asked questions. A list of common questions and answers. Usually an unreviewed volunteer effort.

FTP
: File transfer protocol.

HTTP
: Hypertext transfer protocol. The communications protocol that drives the World Wide Web.

HTML
: Hypertext markup language. A system of markup or formatting tags used to create Web pages.

IP
: Internet protocol number. A numeric address unique to each computer on the Internet. An IP address consists of four 8-bit numbers separated by periods, e.g., 128.218.173.143. Each IP can have a domain name.

JAVA
: A computer programming language designed to create programs downloaded as part of a Web page and executed on the user's computer.

MeSH
: Medical subject heading. A controlled hierarchical vocabulary used to index MEDLINE.

Modem
: Modulator-demodulator. A device that converts binary computer data into sound signals for transmis- sion across a telephone network.

MIME
: Multipurpose Internet mail extensions. A protocol to convert binary data to ASCII so that it may be E- mailed through the Internet.

NNTP
: Network news transfer protocol.

PKI
: Public key infrastructure. A means of providing secure, private communications between two parties. PKI creates two coding keys for each party, one key is held secret, the other made public.

RFC
: A request for comment document. The documents are the actual technical description and specifica- tions for Internet protocols. They are published by a group known as the Internet Engineering Task Force (IETF). RFCs may be read via the Internet at http://ds.internic.net/ds/dspg1intdoc.html.

Spam
: Unsolicited electronic junk mail.

TCP
: Transmission control protocol. The underlying data transmission schemes that move data across the Internet.

URL
: Uniform resource locator. An expanded address to define the location of information on the World Wide Web. Each URL contains a protocol, an IP address (or its equivalent domain name), and a file ad- dress within the remote computer. The protocol is separated from the actual IP address by a colon and two forward slashes, e.g., http://www.anesthesiology.org.

UUEncode
: Unix-to-Unix encoding. A protocol to convert binary files into a format by which they may be trans- ferred via E-mail or USENET.

[a] For a larger glossary, see www.matisse.net/files/glossary.html.

Appendix 2-Computer Network Protocols

Each type of computer network service makes use of a different computer protocol. These protocols set certain limits on how information is available by use of that service.

E-MAIL

E-mail is a service designed to transmit a message privately from one party to another. The transmission process moves the message from one computer host to another until the message arrives at the computer from which the recipient can retrieve the message. The transmission process is not secure, and messages may be intercepted and read with little effort at any point along the transmission route unless the message is encrypted. (PKI encryption is most widely used.) E-mail may include binary data as well as text. The binary data are translated into a form of ASCII by use of UUEncode or MIME for transmission across the network, but the translation process is usually invisible to both the sender and the receiver.

FTP

FTP is a file transfer protocol that requires its own server software on a server computer. When a document is transmitted via FTP, it is moved directly from the host's hard disk to the client's hard disk without being displayed on the screen. Long documents or raw data files are usually transferred by FTP. Web spiders do not access the contents of FTP documents, and so Web directories can index files at an FTP server site only by file name, if they are indexed at all. FTP services require that the client or user log into the host computer. Those FTP sites that allow public access commonly grant that access to users who enter the name "anonymous" or "guest" as the log-in name with a password of "guest" or the user's actual E-mail address.

GOPHER

Gopher is a protocol similar to FTP except that it does not require the user to log in to read the files being served. Gopher sites are not indexed by spiders; instead, there is a separate system that uses search software known as JUGHEAD or VERONICA (www.yahoo.com/computers and internet/ internet/gopher/searching/). Gopher, like FTP, requires only a text-based user interface, which was the common mode of Internet access before inexpensive personal computers and graphical Web browser software replaced them.

USENET

USENET is a distributed message passing system. The actual messaging protocol is known as network news transfer protocol (NNTP). NNTP uses the "pouring water" technique to pass messages, which implies that a message "poured" into a host spreads horizontally. Specifically, a user may "post" a message on a particular newsgroup through a local host; the message is then broadcast to neighboring NNTP servers in the network. The neighbors in turn pass the message to their neighbors until all NNTP servers get the message. Individual USENET users may then retrieve the message from their local server.

HTTP

Hypertext transfer protocol (HTTP) is the basic communication service used by the World Wide Web. Its purpose is to provide a means by which remote clients (Web browsers) may request downloads of files. Web page files are written in a document description language known as Hypertext markup language (HTML). HTML pages are ASCII text that declares the actual readable text, the formatting for the text, and URLs for whatever embedded objects may be in the page, e.g., pictures, applets, hypertext links. There are now many software products that allow creation of HTML Web pages in a process akin to word processing. An individual may then "publish" these pages on the World Wide Web by transferring the files to their Internet service provider.

Appendix 3-Access to the Internet

An individual user may access the Internet easily from most of the developed world. To use the Internet, one must first have a personal computer with Web browsing software installed. Most personal computers sold today have this software and a modem preinstalled. Several browsers are available; all are roughly comparable in features required for professional information gathering. The other necessary component is a connection to the network. From the hospital work environment, this often is as simple as plugging into the medical center information network. Some hospitals that have an information infrastructure do not allow access to the Internet because of security concerns for patient and financial data. From home, there are several possible ways to attach to the Internet. At present, the most common is via a telephone line with a computer-attached modem. A connection is then made to a remote computer, which mediates the Internet conversation. The remote computer may belong to a national information carrier like American Telephone & Telegraph (ATT), a private computer network like America On-Line (AOL), or a local Internet Service Provider (ISP). All of these services offer Internet connections for a monthly fee in the range of $20.00 with unlimited connect time. Alternative connections that are more popular in the areas served by them include cable television modems, DSL (telephone-based Digital Subscriber Line) wireless modems in urban areas, and direct satellite links. These technologies offer much higher bandwidth (communication speed), but they have limited availability and higher cost.

Chapter 79 - Quality Assurance/Quality Improvement

Barbara A. Dodson

INTRODUCTION

The practice of medicine in the United States is undergoing profound changes. Advances in medical technology have raised to new heights the public's expectations of and demands for health care. However, the costs for these advance also continue to increase. Indeed, the Health Care Financing Administration (HCFA) has predicted that more than 16 percent of every dollar spent in the year 2007 will be spent on health care. Cost containment and reduction have become major issues in the current era of health care. Clinicians are faced with the difficult task of significantly reducing costs and resource utilization while maintaining quality of care and patient satisfaction with an aging and increasingly sicker patient population. In this economic environment, the need to monitor and ensure quality health care has become increasingly important. This has been recognized by the Joint Commission on the Accreditation of Healthcare Organizations (JCAHO), professional organizations, government agencies, and the health-care industry. Changing terminology reflects changing in the field of quality of health care. Following the 1995 shift from quality assurance to quality improvement activities in the JCAHO accreditation process, the term *quality assurance* was replaced by *quality improvement.*[1] Recently, with the increasing emphasis on performance/outcome measurements in quantifying quality in health care, the terminology has begun to shift from *quality improvement* to *performance improvement* or *value improvement.* Although types of programs (and their terminology) change, the goal for any quality improvement process in anesthesia continues to be improving health care. This chapter discusses the basic concepts in quality improvement as well as some of the methods used to monitor quality as they relate to health care in general and the practice of anesthesiology in particular.

DEFINITION OF QUALITY

Quality is a concept embodied with positive connotations whose definition subjectively depends on the definer. [2] The Institute of Medicine defines quality of patient care as "the degree to which health services for individuals and populations increase the likelihood of desired health outcomes and are consistent with current knowledge." [3] Others have developed similar and complementary definitions, including "that kind of care which is expected to maximize an inclusive measure of patient welfare, after one has taken account of the balance of expected gains and losses that attend the process of care in all its parts." [4] To the health-care consumer, quality in health care is that which produces the best health with the fewest complications for the least amount of money in the most timely fashion. The confusion caused by this lack of a single definition has led to defining quality in terms of its attributes or components. Quality in health care has been defined in terms of seven attributes requiring assessment: safety, provider competence, acceptability, accessibility, efficiency, appropriateness, and effectiveness. In a similar fashion, the JCAHO has identified nine components in defining quality in patient care (Table 79-1) (Table Not Available) . [5] A model by Donabedian [6] widely used in the health-care industry defines quality of care in terms of three elements or indicators: structure, process, and outcome. *Structure* is the setting in which care is provided and includes the personnel, equipment, and physical plant used to provide health care. Included in structure are the qualification and licensing of personnel, ratio of health-care personnel to patients, standards for medical equipment and facilities, and the organizational structure in which health care is delivered. *Process* refers to a goal-directed interrelated series of actions, events, mechanisms, or steps, including the sequence, coordination, and

TABLE 79-1 -- Components of Quality Performance

(Not Available)

From the Joint Commission on Accreditation of Healthcare Organizations [5]

delivery of patient care activities. [5] A *function* is a goaldirected group of interrelated processes. [7] *Outcome* is the effect of care or the result of the performance or nonperformance of a function or process [5] ; that is, what is accomplished for patients with regard to their health status following the delivery of care. [4] For an organization to function properly, the structure must be adequate to perform its mission, the processes must be workable and efficient, and both must be effective in improving outcomes. As such, much of the focus of quality improvement programs has been on evaluating and quantifying these three elements in an attempt to measure and improve the quality of health care.

WHY MONITOR QUALITY OF HEALTH CARE

Quality in today's health care is not driven solely by the professional integrity of health-care providers. It has also developed a strong economic component. Quality is being defined and demanded by health-care consumers. Indeed, in a 1998 *Wall Street Journal*/NBC News poll, 23% of those surveyed placed quality as the most important issue in health care, as compared with 8 percent in 1993. [8] Employers, providers, and third-party payers also are demanding accountability in health-care outcomes. Therefore, to survive within the competitive health-care market, quality and its quantification must become a priority for health-care organizations.

QUALITY ASSURANCE PROGRAMS

The goal of traditional quality assurance programs has been to identify deviations from the norm. To this end, quality assurance programs have focused on defining the norm (i.e., standards of care), determining whether adverse events were caused by deviations from the norm, and preventing their occurrences.

Peer Review

Peer review is the oldest method for evaluating quality in medical care. With peer review, diagnostic and therapeutic decisions and professional behavior are reviewed by other physicians; that is, one's peers. The basic premise of peer review is that the medical profession is best equipped to govern and police itself. Peer review may take many forms, including informed consultation with colleagues and chart reviews. The most well-known form of the peer review process is the morbidity and mortality review conference.

An example of a departmental peer review program, based on a clinical competence model, was published by the American Society of Anesthesiologists (ASA) Committee on Peer Review. [9] [10] The program contains three major concepts:

1. Peer review should be used to determine a practitioner's competence.
2. The best indication of competence is outcome.
3. Although people are inherently fallible, one error does not necessarily imply incompetence.

Both peer review and quality improvement techniques are used in the evaluation. At the core of the program is an ongoing collective outcomes analysis. Error analysis is used to judge competence. The database consist of anesthesiarelated adverse events, either self-reported or reported by others. The departmental quality improvement committee evaluates blinded reports with respect to (1) relationship to anesthesia care, (2) grading with a negative outcome score, (3) identification and classification of the type of error, (4) conclusions with explanations and references, and (5) recommendations for future prevention. The report is then presented to the entire department. If there is departmental concurrence, the report become part of the practitioner's "error profile." This profile is compared to minimal performance levels and to the departmental aggregate profile. The program is based on the principle that incompetent practitioners will have error patterns markedly different from those of competent practitioners (approximately one to two important errors per year [10]). This approach to peer review is not without its limitations. Two major criticisms are its reliance on self-reported (see subsequent discussion) and its individual-based rather than process-based focus.

Medical staff credentialing, clinical privileging, performance reviews, and reappointments are also part of the peer review process. Anesthesia privileges must be officially granted, delineated in writing, and renewed annually or biannually. Medical staff committees have traditionally performed peer review for a hospital. In cases of quality issues

or professional behavior, the appropriate medical staff committee reviews, investigates, and recommends action to the service chief, medical board, chief medical officer, and/or hospital governing body. Medical staff credentialing has expanded in recent years from a hospital-based function to a process required by many other health care sectors, including insurers, health maintenance organizations, preferred provider organizations, medical groups, and independent practice associations. Recognized accreditation bodies such as the JCAHO, National Committee for Quality Assurance (NCQA), and American Accreditation Health Care Commission/Utilization Review Accreditation Committee have all set standards for the credentialing of health-care providers. Indeed, a credentials verification industry has developed in an attempt to make the process of medical staff credentialing more consistent, efficient, faster, and less expensive. [11]

The HCFA of the federal government has used the peer review process in its Professional Review Organizations (PROs) to monitor quality of care rendered to patients under the Medicare program. Physician surveyors reviewed hospital charts to assess quality of care as well as Medicare utilization review. Anesthesia-related categories in the Generic Quality Screens of PROs include deaths during or following elective surgery, deaths following return to an intensive care unit within 24 hours of transfer, life-threatening complications of surgery, and a life-threatening transfusion error or reaction. A major criticism of this peer review process is its lack of universally accepted definitions and standards for quality health care. This has frequently led to individual reviewers using their personal knowledge and experience to judge whether the process of care and its outcome was appropriate. [6] There is considerable debate as to the reliability and validity of unstructured judgments by a single reviewer. [12] Goldman [13] found that the degree of physician agreement regarding the quality of care was only slightly better than chance in an analysis of 12 studies of the peer review. In contrast, Caplan et al [14] found significant agreement ($P < .0001$) with respect to judgments on appropriateness of clinical care, presence or absence of human error, and role of better monitoring in the prevention of mishap in a study of peer reviewer agreement in evaluating major anesthetic mishaps. Furthermore, differences in practice type, time in practice, and previous experience with adverse event review did not appear to influence agreement.

In its 1992 Health Care Quality Improvement Initiative, HCFA changed the methodology of its PROs from using local criteria for evaluating individual clinical events to using more specific and explicit nationally uniform criteria called Uniform Clinical Data Sets to examine outcome trends. [15] [16] With this initiative, HCFA hopes that by focusing on differences between observed and achievable outcomes rather than on specific deficiency occurrences and by helping providers identify problem areas, PROs will both monitor and improve quality of care.

The use of multiple reviewer procedures and structured assessment instruments, particularly for reviews that have major consequences for patients and health care providers, has been proposed because of questions as to the reliability and validity of unstructured, single-reviewer judgments. [17] [18] Bias must also be addressed in peer review processes. For example, in a study of anesthesiologists assessing identical case scenarios but with different outcomes, Caplan et al [19] found a significant inverse relationship between severity of outcome and judgments of appropriateness of care. That is, care was judged appropriate if the injury was temporary and inappropriate if the injury was permanent. Because of outcomes biases, attention must also be given to critical events resulting in both negative outcomes and/or no injury. All adverse events should be analyzed for areas of improvement.

Another limitation in the peer review process is the reluctance of physicians to testify against a colleague. Reasons for this reluctance include the desire to protect colleagues and to not publicize intraprofessional problems. Another reason is fear of reprisal by the reviewers, with respect to both their own potential adverse outcomes and possible legal actions by the health-care provider against whom they testified. This potential for liability in the peer review process was addressed by the federal government with the Health Care Quality Improvement Act of 1986, which shields medical staff from suits brought about by peer review actions. Part A of the Act provides peer review board members with qualified state and federal immunity from private suits. [20]

Despite its limitations, the peer review process remains an important method for reviewing the appropriateness, adequacy, and effectiveness of medical care. Department-wide peer review incorporates an educational component into a quality improvement program. It also provides a basis for analysis of critical incidents,

trends in measured outcomes, possible causes for such occurrences, and potential directions for improvement. In addition, it is the main mechanism for disciplinary action toward individual physicians by departments, hospital boards, and state licensing authorities.

Risk Management

Risk management is a term developed by the insurance industry in the 1960s in relation to funding and control of predictable business losses. In health care, risk management is the process for preventing accidents and their consequences--specifically, the risk and cost of litigation to the health-care system. [21] All large health-care organizations have risk managers who are responsible for identifying potential litigation, investigating the sequence of events, assessing potential liability, and, if necessary, aiding in the defense of the institution in case of malpractice proceedings. Another, more proactive aspect of a risk-management program is to reduce risks by preventing similar injury to other patients, thus reducing the number and costs of legal suits. This latter function is a quality-management tool, because identifying ways of reducing the risks of suits often provides opportunities to improve care and outcome. [22] [23]

National Practitioner Data Bank

The National Practitioner Data Bank (NPDB) was formed as part of the Health Care Quality Improvement Act of 1986. It is an aggregate (since September 1990) database of physicians' malpractice payments by insurers and adverse actions by state medical boards and hospitals regarding medical privileges as well as membership actions by medical

societies that have formal peer review processes. [24] NPDB reports are now required information in the process for acquiring staff privileges, professional credentials, and licenses. Despite attempts to define a minimum dollar amount necessary to report, at present any payment made on behalf of a health-care professional in response to a written complaint or claim must be reported. This has made clinicians increasingly reluctant to settle nuisance suits because of the resultant inclusion of their names in the NPDB files.

A physician is notified when a report is submitting to the NPDB and has 60 days from the date of NPDB report processing to dispute it. The reporting body may also correct or void the form during this time. The physi-cian also has the option of filing a brief statement with the report or appealing to the Secretary of Health and Human Services, who may also correct or void the form, or both. Once a form is entered into the data bank, it cannot be removed.

American Society of Anesthesiologists Closed Claims Project

The most clinically relevant aspects of risk management are prevention of patient injury, adherence to standards of care, documentation, and attention to patient relations. To this end, the ASA has developed the ASA Committee on Professional Liability's Closed Claims Project (CCP) (Ch. 22) . The ASA CCP is an ongoing, in-depth investigation of closed anesthesia malpractice claims designed to identify major areas of loss, patterns of injury, and strategies for prevention. Closed claims are examined by trained anesthesiologist reviewers using standardized, objective, dataabstracting procedures. [14] This standardized collection of case summaries of anesthesia-related adverse outcomes was started in 1985 and now contains about 4,000 claims from 35 insurance companies that insure approximately 14,500 anesthesiologists.

A recent data analysis by the ASA CCP suggests that severe anesthesia-related adverse events (e.g., death and brain damage) have become less frequent in the past 20 years (56% versus 31%, 1975-1979 versus 1990+). [25] The most common source of these claims is ventilation-related adverse events, with the most frequent events being inadequate ventilation, esophageal intubation, and difficult intubation (Ch. 39) . However, claims for death or brain damage for this subset have also decreased significantly in this same 20-year period, with the greatest reduction in claims for inadequate ventilation (22% versus 7%). In contrast, claims for severe cardiovascular-related adverse events have increased from 12% to 24% over the same period. There was also a slight decrease in equipmentrelated claims for death and brain damage. [26] One possible explanation for the decreases in ventilation-related claims for death or brain damage is the increased use of pulse oximetry (Sp O_2) and end-tidal CO_2 (ET CO_2) capnography (Chs. 28 to 35). [27] These two monitors came into use in the latter part of the 1980s and became ASA standards of practice in the early 1990s. Interestingly, claims for severe ventilation/respiration-related events began to decrease even before the widespread use of pulse oximetry. Furthermore, a large study of 20,000 surgical patients found that the use of pulse oximetry had no effect on decreasing postoperative complications. [28] However, claims for injury due to inadequate ventilation and esophageal intubation have decreased in the 1990s, whereas those for difficult intubation have not, supporting the benefit of increased monitoring on outcomes. In an attempt to decrease injuries due to difficult intubation, the ASA has developed evidence-based practice guidelines for the management of difficult airways (i.e., the difficult airway algorithm). [29] The ASA CCP Subcommittee is currently evaluating all new closed claims to determine whether the guidelines are being followed clinically, and, if so, what their effects have been on the incidence of claims for difficult intubation mishaps.

Other major areas of loss have been identified using from ASA CCP database. For example, closed claims analysis suggests that, despite opinion to the contrary, monitored anesthesia care poses significant risk, especially for elderly and chronically ill patients (Ch. 61) . [30] A high percentage of claims involving MAC were associated with death and brain damage (34% and 19%, respectively). Eye injuries, especially those caused by patient movement, also were common (12%). Indeed, eye injuries alone, including corneal abrasion and those secondary to patient movement, account for 3% of all closed claims. [31] With respect to obstetric claims, the most frequent causes for claims were death (22%), newborn brain damage (20%), and headache (12%), as compared with death (39%), nerve damage (16%), and brain damage (13%) in the nonobstetric group (Ch. 57) . [32] Obstetric claims involving general anesthesia were more frequently associated with severe injuries and higher payments than those involving regional anesthesia. [32] Anesthesia-related nerve injuries represent approximately 17% of all claims, with the ulnar nerve injury accounting for 25% of total nerve injuries (Ch. 22) . [33] The mechanism of the injury was unknown in many cases, leading to the observation that "in certain susceptible patients, nerve injury may occur in spite of conventionally accepted methods of positioning and padding." [34] The ASA CCP also found that ventilationrelated adverse events were more common (43% versus 30%), the mortality rate was higher (50% versus 35%), and anesthetic care more frequently was determined less than appropriate (54% versus 44%) in pediatric than in adult claims. [35] With regard to regional anesthetics, the ASA CCP identified inadequate recognition of level of sedation and inadequate treatment with alpha-agonists to counteract sympathetic blockade as the two major factors associated the poor outcome (Chs. 42 and 43). [36]

The ASA CCP reports have been helpful in delineating areas requiring further attention to reduce anesthesiarelated adverse events and, consequently, liability claim. However, the ASA CCP database reflects only closed claims and not all patient injuries. The decrease in claims in the last 20 years may reflect changes in litigation practices rather than increase in quality of anesthetic care. Nevertheless, the database suggests that fewer claims for death or brain damage are being successfully pursued. ASA CCP Subcommittee findings are published on a regular basis both in *Anesthesiology* and in the ASA newsletter and are also available on the Web at http://depts.washington.edu/~asaccp/.

Practice Guidelines and Standards of Care

Practice parameters were originally designed to both define standard of care and provide clinical guidelines in an effort to decrease adverse events. In recent years, these practice parameters have become increasingly important in providing a basis for quality/performance assessments. [37] Although practice parameters can be used for many purposes, they roughly fall into four major categories: (1) medicolegal standards of care, (2) voluntary guidelines to clinical management, (3) guidelines for reimbursement decisions by third-party payers, and (4) measurement tools in the quality improvement process. Standards are defined as absolute minimum requirements for patient care. They specify what is always expected without exception. An example would be the ASA Standard for Basic Anesthesia Monitoring. [38] In contrast, practice guidelines are defined as "systematically developed statements to assist practitioner and patient decisions about appropriate health care for specific clinical circumstances." [39] Generally, guidelines are recommendations that identify specific patient management strategies. Guidelines differ from standards in that they specify what is usually recommended or expected while allowing for exceptions or modifications to fit specific clinical circumstances. Guidelines can be precepts, boundaries, or clinical algorithms. [9] *Precepts* are general principles with few specifics; *boundaries* define limits of appropriate care; and *algorithms* are very detailed decision trees. A similar concept, care plans, has become part of nursing practice. These plans consist of a group of procedures designed to optimize the process of care. More recently, practice guidelines and care plans have been combined to form critical pathways. These are series of guidelines and care plans that guide patient care throughout an illness or hospitalization. An example of a critical pathway with considerable anesthesia input and involvement is the perioperative

management of cardiac patients (Ch. 49) . [40]

The federal government, health-care organizations, and third-party payers view practice parameters as mechanisms for reducing care variability, improving quality, measuring outcomes, and reducing costs and malpractice litigation. [41] In 1989, The Agency for Health Care Policy and Research (AHCPR), a Department of Health and Human Services agency, was established, in part, to develop and periodically review and update clinically relevant guidelines, standards of care, performance measures, and medical review criteria. [42] Examples of federal practice guidelines are the HCFA Uniform Clinical Data Sets used in Medicare reimbursement. [15] [16] Private organizations, including accreditation agencies, are also issuing practice parameters with significant implications for clinical anesthesia. Although accreditation by the JCAHO is theoretically voluntary, reimbursement for hospital services is contingent on its accreditation, thus making it, in reality, mandatory. [43] Therefore, JCAHO standards are extremely important and frequently define health-care delivery. Table 79-2 (Table Not Available) contains examples of specific JCAHO standards regarding anesthesia care. [44] [45]

Some clinicians see practice parameters as regulatory tools imposed by nonphysicians resulting in a further erosion of clinical autonomy. Indeed, the application of nonmedical

TABLE 79-2 -- Joint Commission on the Accreditation of Healthcare Organizations Standards Regarding Anesthesia Care

(Not Available)

From the Joint Commission on Accreditation of Healthcare Organizations. [44]

values combined with intense economic pressures can create an environment for guideline misuse. [46] Others believe that practice parameters can provide health-care providers with valuable medical information, improve objectivity in medical decision-making, and provide a way of maintaining if not improving quality of health care in an era of cost containment. Many medical organizations, including the American Medical Association, and specialty associations have been actively developing practice policies. An example of a nonanesthesia guideline with significant anesthetic implications is the American College of Cardiology/ American Heart Association guidelines for perioperative cardiovascular evaluation for noncardiac surgery. [47]

The ASA has been a leader among medical specialty groups in developing practice parameters. [38] (Because of their importance, all ASA practice parameters are published in this text; see appropriate chapters.) The ASA developed its first practice guidelines in 1968 and published its first set of stricter practice standards in 1986. An impetus for ASA practice parameter development is the belief that physicians should develop their own standards rather than have them imposed by nonphysician third parties. [48] These practice parameters have had a significant impact on clinical anesthesia, especially with regard to perioperative physiologic monitoring (Chs. 28 to 38). [48] These standards originated in part from the Harvard Medical School's Anaesthesia Practice Standards [49] and include criteria for minimal monitoring, requirements for anesthetizing locations outside the operating room, apparatus checkout, and postanesthesia care. [38] ASA guidelines regarding specific areas of practice have been published for acute pain management in the perioperative setting, [50] blood component therapy, [51] cancer pain management, [52] chronic pain management, [53] management of the difficult airway, [54] perioperative transesophageal echocardi-ography, [55] pulmonary artery catheterization, [56] and sedation and analgesia by nonanesthesiologists. [57] Guidelines for preoperative fasting and obstetric anesthesia are under development and should be published shortly. These guidelines were developed by the ASA to assist in the practice of anesthesiology with the proviso that they may be adopted, modified, or rejected according to clinical needs and constraints. ASA practice policies (Table 79-3) (Table Not Available) undergo frequent modifications and amendments and should be reviewed on a regular basis. The ASA Standards of Practice, Guidelines and Statements are published yearly in the ASA Directory of Members and are available from the ASA on the Web at http://www.asahq.org/.

Development of Practice Guidelines

According to the Institute of Medicine, good guidelines have eight attributes: validity, reliability, clinical applicability, clinical flexibility, clarity, multidisciplinary process of development, scheduled review for warranted revision, and documentation. [58] Guidelines must be based on the best available information and be developed through a rigorous, standardized process that ensures that all of the available evidence is examined and considered, including cost/benefit information, if they are to be accepted by physicians. [59] They

TABLE 79-3 -- American Society of Anesthesiologists Standards, Guidelines, and Statements

(Not Available)

Adapted from the American Society of Anesthesiologists. [36]

must be specific enough to be useful in delineating what particular course of action is indicated in a specific circumstance, but not be so complex as to be difficult to use. They should be comprehensive enough to encompass all of the nuances of a particular clinical situation, but be limited so as to prevent unsubstantiated inferences to topics not expressly covered. Furthermore, the development of practice guidelines must be open, honest (both ethically and intellectually), and unbiased. [37]

Several methods have been described for developing practice guidelines. [60] [61] [62] The AHCPR has outlined a five-step process: process definition, clinical benefits and harm assessment, assessment of health policy issues, preparation of practice guideline, and evaluation of its effect. [63] An example of the process is the AHCPR guidelines for acute postoperative pain management. [64] Initially, a multidisciplinary panel of pain experts reviewed current and emerging practices, principles, technologies, and costs as well as the need for guidelines in this area. This review included examination of existing guidelines and standards and expert opinion from consultants, panel discussions, and open forums. The panel then reviewed the published scientific literature. Topics included pain assessment, pharmacologic and nonpharmacologic treatments, complications, patient satisfaction, and cost information. The information obtained was also analyzed using meta-analysis or best evidence synthesis. [65] [66] A draft document was then developed and subjected to both external peer review and beta testing by the intended users. Comments elicited from both groups relative to the clarity, clinical applicability, flexibility, resources and training needed for implementation, and cost implications of the guidelines were incorporated into the document. Finally, the guidelines were issued.

The process of developing practice guidelines must be considered a dynamic process. Once released, the validity of the guidelines should be verified by examining the relationship of the guidelines to outcomes. [9] [67] Mechanisms must be provided for review of the clinical experience with the guidelines and for revision, if warranted, based either on clinical experience or on new evidence produced by ongoing research. [39]

Implementation of Guidelines

Although methods for producing guidelines are relatively well understood and continue to improve, implementation has proven difficult for a variety of reasons. [68] [69] Most attempts at implementation rely on provider education. This has often failed because physicians frequently viewed guidelines as a form of "cookbook" medicine. [70] Critics have emphasized that often, little attention is paid to guideline quality (i.e., scientific validity), goals, impact, implementation, and evaluation. [39] [71] Recommendations are often worded in highly specific language that achieves clarity at the expense of scientific validity, resulting in guidelines that do not represent accepted medical practice. As discussed earlier, physicians also worry that guidelines will decrease their clinical autonomy and income and increase medicolegal liability. A particular concern relates to the expansion of enforcement programs that require clinicians to follow guidelines or face financial or other penalties. Rigid enforcement of such guidelines could harm patients, interfere with the individualization of care, increase costs, and promote unfair judgments against clinicians who deviate from them for good reasons. [70]

There are relatively few studies examining the clinical impact of practice parameter implementation. [72] [73] [74] For example, Worrall et al [72] found in a review of 13 trials of clinical practice guidelines that only 5 of the 13 trials improved patient outcomes. In contrast, Wachtel and O'Sullivan [75] found significantly less frequent use of laboratory tests, radiographs, and electroencephalograms by physicians participating in a guideline initiative than in those not participating (Ch. 23) . [75] The use of

clinical practice guidelines in outcome studies is discussed in more detail later.

In general, practice guidelines will not be rapidly implemented into clinical practice unless they are (1) directed toward problems that would have substantial impact if improved, (2) perceived to be of high scientific quality by clinicians, (3) well publicized and readily available, (4) integrated into clinical decision-making and practice patterns of the clinicians, and (5) linked with incentives for use that are powerful enough to motivate compliance (e.g., financial, medicolegal, or quality improvement incentives). [76] [77] [78] Implementation will occur only if the guidelines are perceived by the front-line health-care providers to improve patient care and outcomes while not adding time-consuming tasks of no immediate help to either the providers or their patients. [79] [80] Ultimately, acceptance is fostered by peer pressure, which requires institutional or medical professional and administrative leadership to support the concept of practice guidelines. [79]

Standards, Guidelines, and Litigation

Lack of adherence to standards of care is a frequent basis for litigation following adverse events and has significant implications with respect to the likelihood and amount of financial recovery by the plaintiff. However, expert medical witnesses often rely on implicit (unstated, personal) criteria rather than explicit (published) criteria in determining standard of care. This frequently results in divergent opinions as to whether appropriate care was given. [81] Furthermore, there is still a greater than 40 percent chance that payment will be made for a malpractice claim even if an anesthesiologist can support the assertion of appropriate care. [82]

Guidelines have developed medicolegal implications. Even though practice guidelines are meant as clinical recommendations rather than standards or absolute requirements, they can be interpreted as establishing the relevant standard of care in medical malpractice. [74] [83] This is unfortunate, because interpreting guidelines as constituting express legal standards of care would limit creative initiatives to discover methods of patient care that result in good outcomes but do not conform to traditional medical practice. Physicians would likely feel both limited in their clinical choices and reluctant to deviate from the guidelines except under the auspices of carefully controlled research protocols. [83] The legal implications of clinical practice guidelines are not well defined and promise to be a topic of considerable debate in the future.

For better or worse, practice parameters will have an increasing role in clinical anesthesia. Practice parameters can

provide a powerful tool in resolving the complexity of medical decisions by freeing health-care providers from weighing the pros and cons of each decision. They can also provide a method for dissemination of research information and professional consensus as to appropriate and current clinical practices. [37] Continuous quality improvement programs can provide a mechanism for implementing and monitoring practice guidelines, analyzing their effects on outcomes, and involving health-care providers in the assessment and revision of guidelines. [84]

QUALITY IMPROVEMENT PROGRAMS

Continuous Quality Improvement

Traditional quality assurance programs focused on identifying the outliers, or "bad apples." Adverse events were interpreted to be a function of individual or "operator" error, and, as such, problems were addressed on the individual level. Unfortunately, this method did little besides document the incident, assign blame, and repeat the refrain that such an event would not happen again. Although numerous studies suggested that most adverse events (up to 80% in anesthesia) are secondary to human error, it has become increasingly recognized that the individual involved in an event is a single element in the complex system that constitutes health-care delivery. [85] [86] [87] This has led to a conceptual change in the philosophy underlying quality of care programs from defining and ascertaining deviations from the norm to constant testing and improving--that is, continuous quality improvement (CQI). [88] CQI programs focus on the health-care system itself, where the system is defined to be all the components involved in health-care delivery including health-care professionals, patients and their families, material management, administration, and so on. In the CQI process, adverse events are considered a function of system errors and, therefore, represent opportunities for identifying underlying causes for such incidents and developing methods for improving the structure and process for patient care. [89]

The CQI process involves identification of processes for improvement by continuous monitoring of important aspects of patient care. Identification can be by peer review processes or by the use of specific standards and indicator measurement systems. Once a problem area is identified and documented and its current performance measured, the structures and processes leading to the problem areas are analyzed. If changes that may result in improved care are identified, they are implemented into the system. After a specified length of time, the problem area is remeasured to determined effectiveness of the changes. The CQI process is then directed either to continued improvement in the problem area or to identify other areas and different processes for improvement. [90] As with practice parameters, it is important for anesthesiologists to actively participate in the development and application of these projects to ensure the delivery of quality anesthetic care. [91] [92]

The CQI method has been extended into the concept of total quality management (TQM), where TQM encompasses all aspects of health-care delivery including operating room scheduling, clinical care, medical records, material management, billing, and so on. [89] [93] CQI/TQM processes are being examined as programs to reconcile cost/quality conflicts, increase patient satisfaction, and improve hospitals' competitiveness and operational and financial performance. [94] [95] They are also required as part of the JCAHO accreditation process. [96] However, although CQI/TQM is excellent in theory, there is still debate as to its overall effectiveness in improving patient care. [97] [98] [99] As with practice guidelines and for similar reasons, CQI/TQM implementation into health-care organizations has been difficult. [100] CQI/TQM administrators are rarely clinicians, which leads to conflicts over loss of clinical autonomy. Physicians consider many of the CQI/TQM issues to be clinically irrelevant. Data collection, review, and analysis in CQI/TQM can be costly and time-consuming. Finally, CQI/TQM administrators often become process-oriented rather than outcome-oriented, resulting in organizational changes with little clinical or economic advantage. Modifications suggested to improve compliance in the CQI/TQM process include involving physicians in the change process, building an infrastructure that promotes clinical leadership, ensuring that the clinical information and data analyses used to generate the changes are scientifically sound, and reliably measuring the clinical and economic impact of the changes on patient care. [69] [94] [95]

To be successful, continuous quality improvement activities must become integral parts of the routine activities of medical departments. [101] The observations, recommendations, and plans of the department quality improvement program should be reported and discussed at departmental meetings. Medical staff should receive training as to how to participate in quality improvement activities and should be asked to suggest topics for improvement. Cooperation is also predicated on a constructive aim to the process. Physician cooperation is most likely if positive clinical results are achieved and the medical and hospital leadership is to actually committed to changes.

JCAHO Requirements for Quality Improvement Programs

Anesthesiology departments are required to have comprehensive quality/performance assessment and improvement programs that comply with institutional bylaws and JCAHO, federal (e.g., HCFA, Food and Drug Administration, Occupational Safety and Health Administration), state, and local health department regulations and guidelines. JCAHO requirements for quality improvement programs are updated on an annual basis. All areas of departmental involvement (e.g., postanesthesia care unit, pain management program, critical care units) need to be included in the departmental CQI program. Departmental involvement is also needed in other hospital medical staff committees, including medical records review, blood and blood component usage review, drug usage evaluation, and infection control. The department head is ultimately responsible for both providing quality anesthetic care and assessing and improving this care as outlined by JCAHO and government directives.

A department's CQI program, formally documented and approved by both the department's and the institution's

medical staff leadership, must outline the evaluation process, identify the individuals responsible, and detail the communication pathway to the departmental and hospital medical staffs and hospital leadership. Policies and procedures for credentialing and continuing staff education should also be included. A manual containing information on anesthesia CQI programs, including a checklist of steps in the CQI process and sample charts, is available from the ASA. [102]

The JCAHO has specifically identified anesthesia care as a function critical to patient care, where anesthetic care is defined as "the administration (in any setting, by any route, for any purpose) of general, spinal, or other major regional anesthesia or sedation with or without analgesia for which there is a reasonable expectation that, in the manner used, the sedation or analgesia will result in the loss of protective reflexes for a significant percentage of a group of patients." [44] Policies and procedures for the administration of anesthesia are required to be consistent (i.e., standard of care) for all anesthetizing locations within a health-care facility. During its accreditation and review process, the JCAHO will focus on an organization's performance, using, in part, its standards for anesthesia (see Table 79-2 (Table Not Available)). [44] [45]

QUANTIFYING QUALITY IMPROVEMENT

One of the chief characteristics of the CQI process is quantification of CQI activities, both baseline and ongoing, that can be used to benchmark performance, track and validate performance measures or indicators, and identify problems in the health delivery system. The CQI database can provide information on type, frequency, and length of procedures performed, patient acuity, complication rates, blood utilization, and so on. Information in such CQI databases is necessary for any cost/benefit analysis. The question is what variables are important, how to collect and store them, and how to analyze the data to obtain useful information. Examples of volume statistics important to anesthesia CQI programs include total number of anesthetics, the number of patients who received general or regional anesthesia or monitored anesthesia care, the number of intraoperative deaths, the number of unplanned hospital admissions, the number of emergency versus elective cases, the number of patients seen for acute and chronic pain treatment, and the number of intensive care unit admissions, length of stay, and daily census. Volume statistics (i.e., number of cases or patients) allow department and hospital administrators to both assess departmental activity and track trends and changes in practice. These statistics may also be used as the denominators for evaluating clinical indicators. Volume statistics are usually tallied on a monthly basis, with an annual summary.

Another method of collecting CQI data is the retrospective medical record review. Important considerations in data collecting include triggers or thresholds for reporting, standards definitions, and appropriate sampling techniques. Chart review is especially advantageous in quantifying adequacy of documentation. Quality assessment should be restricted to information normally included on an anesthetic record (e.g., blood loss, blood pressure, temperature). Quality issues need to be explicitly defined and the definitions standardized. For example, hypotension maybe defined as an absolute (systolic blood pressure <75 mm Hg) or relative (<80% of baseline for >5 minutes) measurement. If possible, definitions should be contextualized. For example, excessive blood loss should be defined with respect to both total blood loss and type of surgical procedure.

Reduction in adverse outcomes is a commonly used variable in documenting and quantifying improvements in patient care. However, adverse outcomes (resulting in mortality or serious mortality) are relatively rare for patients undergoing surgical procedures. Recent studies conservatively estimated the rates of deaths due to anesthesia to be 1:20,000 to 1:65,000. [103] [104] [105] [106] Such low occurrences make improvement measurements statistically extremely difficult. Therefore, other CQI measures, such as incident reporting and indicator systems, have been developed to monitor patient care.

Incident Reporting

The monitoring of patient care and departmental operations involves the evaluation of adverse events, including deaths, life-threatening or unusual complications, equipment problems, and adverse drug reactions (these must also be reported to the pharmacy). Some state health codes require that certain types of clinical incidents be reported to the state health department. All adverse events should be evaluated. Equipment involved in an incident should be sequestered, medical records reviewed, and involved personnel debriefed as soon as possible. A confidential investigation should attempt to determine the cause of the event. Corrective CQI actions may include counseling and educating an individual or group of practitioners, changing policy, or revising procedures. The actual policies and procedures by which an anesthesia department systematically investigates adverse events should be a documented part of the department's quality improvement program. An example of such procedures are the Harvard Medical School's Anaesthesia guidelines for response to an adverse event. [107]

Self-reporting of anesthesia-related adverse events is frequently used for for CQI data collection and analysis. [10] [108] Many self-reporting systems use a checklist of adverse events and outcomes that is completed by the clinician for each anesthetic. Other systems have general guidelines for adverse event reporting without specific check-off items. Posner et al [108] described one such CQI program that uses a dichotomous (yes/no) response on the anesthesia record with immediate case investigations providing data for systematic peer review. In a study of 10,740 cases, they found a doubling (537 cases) in reporting of problems related to anesthesia management as compared with the previously used checklist system (5% versus 2.7% of all anesthetics).

Self-reporting of adverse events can be extremely useful in monitoring patient care. Australia has used such as system for the last 30 years and has shown a substantial decrease in anesthetic mortality. [105] [109] Unfortunately, self-reporting of adverse events appears to be, at best, an incomplete method of data acquisition. For example, in a comparison of an automated anesthesia system to a voluntary, manual-entry, electronic reporting system, Sanborn et al [110] found that only 4.1 percent of deviations from predefined limits of vital signs

identified by the automated system were also voluntarily reported. Similarly, Cullen et al [111] reported that only 6 percent of hospital adverse drug events were voluntarily reported through health-care organizations incident report system. Part of the problem lies within the culture of medicine in the United States. Both the medical community and the public expect medical care to be error-free and assume that any adverse event must be secondary to negligence on the part of the health-care provider. [112] Therefore, to report an adverse event would be to admit an error in management, which could lead to both professional censure and litigation. Improvement in self-reporting depends on continuing to change the focus of analysis of adverse events from assignment of individual blame to fixing system problems. Better incentives, such as demonstration of the usefulness of reporting on patient care and protection from unwarranted public scrutiny, are needed to improve self-reporting. [113]

Sentinel Events

The JCAHO requires that all adverse events or patterns of adverse events be intensively assessed. Of particular significance are those adverse events that the JCAHO defines as "sentinel events"; that is, "an unexpected occurrence or variation involving serious physical or psychological injury, or risk thereof." [114] This includes adverse events that lead to an "unanticipated death or permanent loss of function, ... is associated with a significant deviation from the usual process(es) ....; or has undermined, or has the potential to undermine, the public's confidence in the hospital." [114] The event is called *sentinel* because it sends an alarm or signal that requires immediate attention. The health-care organization must take immediate corrective action whenever such an event occurs. However, what specific adverse events a health-care organization defines as sentinel events remains somewhat vague. Furthermore, as of October 1998, the mandatory reporting of sentinel events to the JCAHO (the accreditation watch process) has been suspended because of confidentiality and liability concerns. [115]

Indicator Monitoring and Evaluation

An important component of a health-care organization's CQI program is the monitoring and evaluation process mandated by the JCAHO. [5] This involves (1) identifying the most important aspect of care and service provided by an organization, department, or service, (2) using quantitative measures called indicators to systematically monitor specific aspects of care and service in an ongoing way, (3) evaluating the care or service when predetermined thresholds or trigger points are reached to identify opportunities to improve services or care, and (4) taking actions to improve care or service, to solve problems, and to evaluate the effectiveness of those actions. The monitoring and evaluation process has two major elements: measuring what is happening (quality/performance measurement and assessment), and using these data to improve care (quality/performance improvement). It can be performed in a variety of ways analogous to the development and implementation

of practice guidelines. One of the most popular methods is the JCAHO's ten-step process. [116] In CQI programs, these standards and indicators focus on patient processes and outcomes, with standards furnishing the basis for measuring and guaranteeing quality.

The main component of this process is the tracking of indicators, where indicators are defined as quantitative measures of an aspect of patient care. They are not direct measures of quality but rather screens or flags indicating areas for more detailed review. [117] That is, the occurrence of an indicator, like an adverse event, should trigger a quality improvement review of the circumstances under which it occurred. Indicators should monitor important, preferably high-risk, high-volume aspects of care (e.g., the incidence of pneumonia in postoperative patients). [118] Indicators may monitor single or multiple components of care as well as desirable or undesirable events. For example, the indicator "unplanned postoperative admissions to ICU" may monitor patient selection, scheduling procedures, and intraoperative anesthetic management. [119] Indicators can be single or combined event measures. Combined data indicators involve collection and aggregation of data about many events. Indicators can also be continuous or rate-based measures. [120] Continuous variable indicators measure variables that can fall anywhere along a continuous scale (e.g., weight change during nutritional support). Rate-based (or discrete variable) indicators monitor an event for which a certain proportion of the events that occur are expected. An example would be mortality rate.

It is extremely important in indicator tracking that both the number of indicators or events recorded (numerator) and population at risk (denominator) be defined and measured. [121] This is necessary to establish the rate of a specific event as well as determine whether an occurrence is common or random. Exclusions from the denominator population must also be defined. Most importantly, it is necessary to collect reliable data and to use appropriate statistical analysis so that valid conclusions can be reached.

It is also important in indicator tracking to define an evaluation trigger or threshold. [21] For rate-based indicators, triggers can be set by review of clinical literature, internal or external expert opinion, evaluation of trends, or by using statistical analysis. This has been referred to as *benchmarking,* where a benchmark is defined as a point of reference or standard by which something can be measured or judged. [7] Internal benchmarking occurs within an organization, whereas external benchmarking occurs between institutions. [7] [122] However, it is extremely important when using external benchmarks to ascertain that conditions, such as patient populations and surgical techniques, are comparable. Often it is necessary to perform a preliminary retrospective or prospective study to determine the institutional rate. Another way to evaluate indicator data and establish thresholds is to analyze trends (e.g., to compare current performance to that of a previous period of time). Statistical analysis can also be used to identify triggers.

The exact data and method of collection must be considered in great detail prior to initiation of collection. The sources of the data must be reliable and valid. [123] Prospective data collection may be more appropriate because medical records frequently do not contain the required data. [124]

Concurrent data collection is the preferred method, because it permits rapid review and hasty retrieval of missing data. [125] If a sample, rather than entire population, is being examined, the sample size and sample selection must be defined. Preferably, data should be entered directly into a computer to facilitate rapid analysis. Data may also be obtained from computerized patient information systems, such as anesthesia record-keeping systems or hospital information systems. [110] [126] [127]

PERFORMANCE MEASUREMENTS

Performance measurements are rapidly becoming a way of life for health-care providers. With the incorporation of CQI processes including performance measurement into its review and accreditation process, the JCAHO has shifted from defining specific expectations for each discipline and department to describing functions that it defines as critical to patient care. The JCAHO expects health-care organizations to use indicators in their interdisciplinary quality/ performance improvement activities to systematically measure and assess the level at which the organization carries out these functions. The specific 1995 JCAHO requirement is that "the organization designs processes well and systematically measures, assesses, and improves its performance to improve patient health outcomes." [128] Proof of such activities is a prerequisite for JCAHO accreditation. [44] The general format for this recurrent CQI performance evaluation is the design of a process or function, measurement of its performance, assessment of performance measurements through statistical analysis or comparison to other data sources, and improvement of the process or function. The focus is on the systems and processes of the health-care organization rather than on individuals.

Examples of indicators that can be tracked by an anesthesia department include (1) causes of canceled surgery; (2) incidence of postoperative nausea, vomiting, and hypothermia; (3) causes of delays in beginning anesthesia; and (4) incidence of reintubation in the postanesthesia care unit (PACU). In addition, under its Indicator Measurement System (IMS), the JCAHO is developing its own quality improvement indicators for all medical specialties, with a gradual phase-in of these specific clinical and organizational performance indicators into its reaccreditation and review processes. [5] [44] [117] Under the IMS, health-care organizations will submit indicator data (without patient or health-care provider identifiers) to the JCAHO for analysis. JCAHO will provide organizations with information, including comparative data from other health-care organizations, that they can then use to monitor and improve their performance, while helping meet external needs for performance measurement. [117] In addition, after risk stratification, information relative to complications will be made available to health-care consumers to allow them to make health-care purchasing decisions. Each institution will track the same indicators and the data will be collated and analyzed by the JCAHO. It is hypothesized that this will permit continuous collection of objective data to provide comparative data among institutions, identify patterns within institutions, and develop a national database for health services research. One of its first sets of indicators developed by the JCAHO involved anesthesia (Table 79-4) (Table Not Available) . [5] All cases will be screened and the occurrence of any one of these events will trigger a quality improvement review of the particular circumstances of the case. Other indicators have been identified or are under development for obstetric care, oncology, cardiovascular disease, trauma, infection control (including an indicator that focuses on postoperative pneumonia that occurs within 10 postoperative days), medication use (including timing of intravenous prophylactic antibiotics within 2 hours before first surgical incision), and home infusion therapy. JCAHO standards will likely play an even greater role in clinical anesthesia in the future.

Outcome Measures

An increasingly important way by which performance/ quality improvement is quantified is by measuring changes in outcomes. Outcomes have been called "the paramount criterion of good quality either by themselves or as related to costs if efficiency and optimality are to be determined." [4] Measuring outcomes has become an essential part of any quality improvement effort. This trend toward outcome measurement is driven in part by economics. [129] For example, health maintenance organizations are interested in outcomes such as hospital mortality, complication rates, complications after discharge, patient satisfaction, and level of daily function in negotiating contracts with health-care organizations.

In general, outcome measures fall into four main categories: [130]

1. *Financial outcomes.* These include utilization of health-care services for specific patient cohorts and cost for providing these services. Outcomes are measured as costs per service rendered, overall cost, and utilization rates. Total cost is usually quantified on a per patient rather than a per usage basis.
2. *Performance outcomes.* These include internal measures of institutional performance and external evaluations based on patient, third-party provider, and payer satisfaction. Patient satisfaction surveys are used extensively in performance outcome studies.
3. *Clinical outcomes.* These include the quantification of appropriateness and effectiveness of different types of treatment and care. Specific surgical procedures are also being examined in both large-scale, multicenter clinical trials and smaller, perioperative re-engineering projects in attempts to ascertain predictive factors for outcomes. Examples of surgical procedures that have undergone large-scale clinical outcome trials include coronary artery bypass surgery and carotid endarterectomy.
4. *Perceived health outcomes.* These include outcome measurements that attempt to quantify patients' perceptions of their health status and quality of life. Two widely used measures of health-related quality of life are the Short Form-36 Health Survey (SF-36) and the Quality of Wellbeing Scale (QWB). Both have been used extensively in characterizing health outcomes over time in patients having serious illnesses, including cancer and acquired immunodeficiency syndrome. [131]

A major strength of outcome measures is that they are integrative (i.e., they measure the effects of all causes within and outside the system). Other reasons that outcomes measures are important include (1) being of immediate interest to practitioners, patients, and payers of health-care services; (2) directing organizational attention to the processes that contribute or lead to the outcome; (3) setting priorities for improvement of processes; and (4) measuring effects of implementing one or more process changes. [7] Outcomes allow for both intrainstitutional and interinstitutional performance comparisons.

As discussed earlier, it is quite difficult to monitor changes in clinical outcomes where outcome is defined in terms of mortality or serious mortality. These adverse events are relatively rare for patients undergoing surgical procedures, and large sample sizes are required to demonstrate tangible differences. Edsall estimated that a denominator of 230,000 cases would be needed to detect a 50 percent difference in mortality rates between groups of patients treated by two anesthesiologists. [132] This requirement for large sample sizes for statistical significance necessitates the use of large, multicenter, prospective studies to determine both risk factors and effect of therapies on outcomes. [133] When mortality and morbidity are used as outcome measures, they must be stratified for such factors as age, sex, physical status score, case mix, disease severity and comorbidity, length of operation (as an index of surgical severity), and emergency status. [134] Because differences in adjusted rates are often assumed to reflect differences in "quality," [135] severity adjustment must be rigorously performed and results must be interpreted with caution. [136] [137] Temporal change factors that may alter outcomes (e.g., change in patient population, surgical and/or anesthetic technique, type of anesthetic practitioner) must also be continuous re-evaluated.

Much of the focus of anesthesia outcome research has been on the differences between specific techniques (e.g., epidural versus general anesthesia [138]), anesthetics (e.g., intravenous versus inhalational agents [139]), adjunct drugs (e.g., antiemetics [140] [141] [142]), and types of surgical patients (e.g., obstetric [143] [144] or

cardiac versus noncardiac [145] [146] [147] [148]). Of increasing importance for future anesthesia outcomes studies will be the inclusion of patient satisfaction issues (e.g., nausea, vomiting, headache, hypothermia, ease of admis-sion and discharge from outpatient facilities) into their analysis. [149] [150]

Proponents of practice parameters contend that practice guidelines improve patient outcomes by reducing practice variations, controlling unnecessary care, reducing health-care cost, and improving the quality of patient care. [151] [152] These assertions have been supported in the development and implementation of "fast-track" protocols for cardiac surgery. [40] [153] Nevertheless, caution must be taken in interpreting outcome data. It is particularly important to monitor the effect of cost containment on other aspects of patient outcomes. For example, Weingarten et al [154] found that implementation of guidelines for reducing hospital stay after hip or knee surgery did resulted in reduction in total length of stay (Ch. 60) . However, very short lengths of stay for patients undergoing hip surgery were associated with increased intensity of care following discharge, suggesting both cost shifting and total cost increases. That is, the cost incurred by transferring patients to rehabilitation facilities may have been greater than the cost of the patients' remaining in the acute care hospital for an additional 1 or 2 days and then sent directly home.

Outcome studies examining ways to reduce anesthetic drug costs have become increasingly popular. Two major reasons for this popularity are that drug costs are visible and easy to quantify. [155] [156] However, anesthesia drugs constitute only small percentage (5-6%) of total perioperative costs, with staff salaries making up the largest allotment of costs. [157] This can also lead to potential cost shifting. For example, Lubarsky et al [158] found that implementation of pharmaceutical guidelines on anesthetic drug usage reduced drug cost from $56 per case to $32 per case. However, they also found an increase in both time from end of surgery to arrival in the PACU and admission of inpatients receiving

MAC to the PACU as compared with directly admitted to the floors (11 ± 7 minutes versus 14 ± 8 minutes, $P < .0001$ and 6.5 versus 12.9%, $P < .02$, respectively). [158] Changes in patient outcomes such as these could potentially increase rather than decrease total perioperative costs. Overall, considerably more savings could be actualized by improving perioperative efficiency (better scheduling of cases, more efficient processing of patients into and out of the PACU, and so on) than on reducing anesthetic-related drug costs. [91] Nevertheless, as with all new technologies, careful evaluations of all new anesthesia drugs should be performed to assess all associated costs and benefits, including patient personal preferences and patient satisfaction, for subsets of patients undergoing different types of surgical procedures. [159]

There are still relatively few studies that have evaluated the effect of different practice parameters on outcomes. [72] To address this lack of relevant outcome data, the AHCPR has increased financial support for outcomes research. [42] In 1993, AHCPR budgeted $48.2 million for the establishment of Patient Outcome Research Teams. The 14 comprehensive 5-year studies currently underway are composed of four elements: a review and synthesis of available research data; data collection and analysis to identify practice variations and outcome differences; the development of recommendations regarding the effectiveness and appropriateness of the various management techniques; and the dissemination of the information to health-care providers. The AHCPR will continue to play a leading role in funding the development of practice guidelines and outcomes research. [42] However, additional funds will be necessary to expand the field of outcomes research, especially with respect to large-scale outcome studies. [133]

Health-Care Report Cards

Recently, performance data have been used to generate health-care report cards, which are defined as any effort that quantifies or qualifies specific health-care indicators or criteria to established comparative estimations of quality of health care. [160] The indicators used in report cards include items such as length of hospital stay, cost of services, morbidity and mortality rates, and patient satisfaction. NCQA and JCAHO both use report card systems in their accreditation processes in an effort to measure the quality of care provided by health-care organizations. NCQA reviews and accredits health maintenance organizations as well as point-of-service health plans and certain physician-hospital organizations. NCQA's Health Plan Employer Data and Information Set (HEDIS) was created to standardize the way in which health plans calculate and report information about their performance, thereby enabling comparisons among plans. In the future, health plans will be required to submit HEDIS data as part of the NCQA survey process. In 1997, JCAHO began phasing in requirements for performance/ outcome data as part of its accreditation process. [161] As part of JCAHO's ORYX initiative, by the end of 1998, health-care organizations were required to select a sufficient number of clinical indicators to evaluate 25 percent of its patient population or eight performance measures, with data to be submitted by July 1999. [162] [163] These required measurements are scheduled to increase in number and will in the future contain patient satisfaction measures. ORYX was designed as a report card system to provide health-care organizations objective feedback to be used internally for performance improvement projects and externally to demonstrate accountability to the public, third-party payers, and other stakeholders in the organization. [163] In terms of health report cards, JCAHO accreditation decisions are available to the public. In addition, HCFA publishes individual hospital mortality rates, while the New York State Department of Health annually releases the adjusted adult cardiac surgery mortality rate of surgeons performing more than 200 such operations per year.

Health-care report cards are purported to provide accountability to the health-care consumer interested in finding the best medical care, both clinically and economically. However, there has been considerable debate as to the usefulness of such performance data. [164] [165] The four main issues of debate are the quality of the data sources, [166] [167] methods of risk adjustment and stratification, [168] development of outcome "standards" or benchmarks, and data and report standardization. [93] [169] [170] Despite these problems, health-care report cards will most likely play an increasingly important role in defining comparative performances in an increasingly competitive health-care market. For example, hospitals and surgeons with better outcomes reported in the New York State Cardiac Surgery Reports experience a relative increase in their market share and prices. [171] Therefore, increasing effort must be made in defining performance indicators, verifying and standardizing the collection and reporting of data, and demonstrating the improvement of health care from the release of such data. [170]

SUMMARY

Health-care reforms have resulted in profound changes in the practice of medicine. Governmental directives and corporate imperatives continue to have significant consequences on health-care delivery. JCAHO now requires a multidisciplinary rather than individual or department focus in quality improvement programs. Individual departments constitute a single element in CQI/TQM focus on the system-wide processes involved in patient care. Measurement and assessment of performance and outcome will become increasingly important in evaluating the consequences of CQI/TQM programs. Anesthesiologists will have to be able to justify their practices, as well as be capable of quantifying the effects of reforms on their patients' outcomes. By necessity, CQI has become an integral part of clinical anesthesia. [37] Professional societies will need to maintain their leadership in developing guidelines and standards while continuing to educate their members in the safe and effective practice of anesthesia.

Chapter 80 - Human Work Environment and Simulators

David M. Gaba

/das/book/view/29494766/875/876.html

INTRODUCTION

The safe conduct of anesthesia depends on the appropriate application by the skilled anesthetist of knowledge concerning the physiology of patients during and after anesthesia, the characteristics of anesthetic and adjuvant drugs, and the means of monitoring the patient and the life-support equipment throughout the perioperative period. In this chapter, the term *anesthetist* refers to any anesthesia practitioner, whether a physician or a certified nurse anesthetist.

Traditionally, it has been assumed that an adequately trained anesthetist automatically performs appropriately. Deviations from optimal outcomes were understood to be due to imperfections in the art and science of anesthesia, leading to a heavy emphasis on the scientific and technical part of anesthesia training and care. More rarely, adverse outcomes were ascribed to negligence or incompetence on the part of the anesthetist.

Today, there is a more complete understanding that anesthetists themselves, both as a profession and as individuals, have strengths and vulnerabilities pertaining to their work environment. The performance of human beings is incredibly flexible and powerful (no computer can match human beings in this regard), but at the same time it is vulnerable to distractions, biases, and errors. This chapter surveys some of the human characteristics that define the performance parameter of the anesthetist. The domain of the anesthetist is very challenging, being every bit the equal of domains, such as aviation, that more readily capture the public's imagination. The last 10 years have seen new research concerning the nature and limitations of professional judgment and decision making in this dynamic and complex world. The second section of this chapter explores developments in simulation technology that have contributed to this research and that may open new opportunities to prepare anesthetists to handle the challenges that they will face in their work.

The literature related to human performance is vast (standard reference works are available [1] [2]), and this chapter only samples a portion of it as it most closely relates to the work of anesthetists. Moreover, this chapter does not deal to any great extent with human-machine interactions and the physical design of the work environment. These aspects of human factors or ergonomics in anesthesia have considerable importance in their own right. The reader is referred to several publications that review these issues in detail. [3] [4] [5] [6]

Study of Human Performance

The study of human performance involves research paradigms that are different from those usually considered in the science of anesthesia. There are many obstacles to obtaining hard, statistically valid data on human performance. There are no animal models for expert human performance, no "Sprague Dawley anesthesiologists" to be studied in detail, nor can studies of professional performance be conducted using the psychologist's typical experimental subject, the university undergraduate student. Recruiting expert anesthetists to be the subjects of study is difficult, raising issues of selection bias concerning those who do volunteer. Especially if conducted during actual patient care, investigations of human performance are strongly influenced by concerns about litigation, credentialing, and confidentiality, thus making it difficult to execute optimal studies. Furthermore, the variability among individual anesthetists is quite striking, because different anesthetists respond to the same situation in different ways, and each individual may act differently on different days or at different times of the same day. The magnitude of this *intra*individual variability is often nearly the same as the *inter*individual variability.

"Performance" itself is an intuitively meaningful concept that is difficult to define precisely. There are no gold standards for the clinical decisions and actions of anesthetists. They depend heavily on the context of specific situations. In addition, determining how anesthetists perform their job, whether successfully or unsuccessfully, means delving into their mental processes. These cannot be measured easily. On the one hand, one can use experimental designs that involve artificial laboratory tasks, for which performance can be objectively measured. These tasks will then be far removed from the real world of administering anesthesia. On the other hand, investigating the actual performance of trained practitioners in the real world yields primarily subjective and indirect data. Understanding the anesthetist's performance must be seen as analogous to solving a jigsaw puzzle. Pieces of the puzzle likely come from a variety of sources, none of which by itself captures the entire picture. These pieces include objective data from artificial laboratory tasks, prospective observation of routine patient care, analysis of retrospective reports of near misses or anesthetic mishaps, and prospective observation of the response to simulated events. To achieve the best possible understanding of the situation, it is necessary to accept many data that seem uncomfortably subjective to the physical or biologic scientist. Because the research methodologies may be unfamiliar to anesthetists, the key studies of anesthetist performance are described in detail in this chapter.

Why Study Human Performance in Anesthesia?

How can an improved understanding of the human performance of anesthetists help them to provide patient care more safely, in a wider variety of clinical situations, with greater efficiency, and with increased satisfaction to both patients and practitioners? The possibilities include the following:

1. *Improved operational protocols and enhanced training of anesthetists.* The way in which individuals conduct anesthesia is based, in part, on knowing the limits of their performance envelope. Anesthetic techniques and operating room (OR) practices should draw on anesthetists' abilities and should mitigate their weaknesses. Anesthetists' abilities are strongly affected by training. Understanding the required performance characteristics and inherent human limitations will lead to improved training, which will develop most fully the strengths and counter the existing vulnerabilities of the anesthetist. This process should make patient care safer, less stressful, and more efficient to provide.
2. *A more rational view of professional work and legal responsibility (Ch. 85) .* Modern medicine, especially in the United States, is strongly influenced by medicolegal concerns. The litigation system has a major selection bias in that every case that comes before it involves an adverse outcome for a patient. The duty of the practitioner is to render care as a "reasonable and prudent" specialist in the area of anesthesia. What is reasonable and prudent? What type of performance is to be expected from appropriately trained human beings in a complex and dynamic environment? By understanding human performance, it may be possible to generate a more rational view of what is, and is not, within the standard of care.

3. *A more effective work environment (Ch. 81).* Anesthetists now perform their tasks using an array of technology, most of which has not been designed to support the anesthetist's work most optimally. By understanding the anesthetist's tasks and performance requirements, the workspace and tools could be improved to support the most difficult tasks better. This, too, can lead to greater safety and to greater efficiency and work satisfaction.
4. *A more efficient organizational system (Ch. 82).* Anesthesia is embedded within a larger system of organizedmedical care that involves interactions among numerous institutions, organizations, and professional domains. Understanding how the anesthetist's work relates to the larger system may enable the development of more rational and efficient flows of information and organizational control.

/das/book/view/29494766/875/877.html

ANALYZING THE ANESTHETIST'S DOMAIN: THE OPERATIONAL WORLD VERSUS THE ORGANIZATIONAL WORLD

Psychologists and cognitive engineers who study people at work refer to each field of work as a domain. Each domain has specific characteristics that set it apart from others, including the nature of the tasks to be performed, the relationships among the tasks, the time scale over which they must be executed, and the criteria for their successful performance. This chapter deals primarily with the operational domains in which anesthesia care is delivered, primarily the OR, the postanesthesia care unit (PACU), and the intensive care unit (ICU). However, as pointed out by Reason, [7] [8] as well as by Woods and Cook and colleagues, [9] [10] [11] [12] what goes on in the operational domain is extensively shaped by the organizational and managerial environment in which it is located, even to the point that operational personnel believe themselves to be the "victims" of problematic decisions further back in the system.

In everyday practice, these distinctions are hidden or blurred. The positive and negative contributions of the organizational and management elements are often so embedded in the normal routine that they are difficult to isolate. The most interesting information about the system often comes from considering abnormal situations, accidents, or near misses, instead of normal events. Traditionally, one speaks of errors arising in decisions and actions that led to a mishap. The term *error* is increasingly considered an inappropriate way to categorize behaviors (being a judgment of attribution and blame) and should be thought of merely as a way to identify behaviors at the locus of a critical situation. Some errors are actively produced in the operational domain (active errors), and others are introduced by the organizational environment. James Reason, a psychologist at the University of Manchester, England, introduced the concept of "latent errors" [7] [8] :

> errors whose adverse consequences may lie dormant within the system
> for a long time, only becoming evident when they combine with other factors to
> breach the system's defenses. [They are] most likely to be spawned by
> those whose activities are removed in both time and space from the direct
> control interface: designers, high-level decision makers, construction workers,
> managers and maintenance personnel.

Latent errors probably exist in all complex systems, and Reason has adopted a medical metaphor to describe them as "resident pathogens." Like microorganisms in the body, the resident pathogens remain under control until sets of local circumstances "combine with these resident pathogens in subtle and often unlikely ways to thwart the system's defenses and bring about its catastrophic breakdown" [8] (Fig. 80-1) (Figure Not Available) .

A complementary analysis of complex systems by the organizational theorist Charles Perrow [13] called attention to two features that make a system particularly vulnerable to the occurrence of accidents: (1) the complexity of interactions among the system's elements; and (2) the presence of tight coupling among the system's elements. When these characteristics coexist, abnormal sequences of events can sometimes be hidden, and they can have complex and unpredictable consequences. Typically, active errors in the system do not result in an accident because they are trapped at some point by the system's multiple layers of checks and defenses (see Fig. 80-1 (Figure Not Available)). In the presence of latent errors, even a minor active error can cause normal system behaviors to become out of control because of complex interactions and tight coupling. Perrow called this a "normal accident" because it arises out of apparently normal system operations. He suggested that attention should be directed at strengthening the recovery pathways by which small events can be properly handled before they evolve to a serious accident. Perrow also emphasized the effects of the "larger system" on operational mishaps and the ways in which the incentives offered by the system could influence safety-related decisions.

Complexity and Tight Coupling: Latent Errors in Anesthesia

Clearly, the anesthesia domain involves complex interactions with tight coupling. [14] The complexity stems to some degree from the variety of devices in use and their interconnections, but these are, in truth, vastly simpler than those

Figure 80-1 (Figure Not Available) James Reason's model of accident causation. Latent failures at the organization level may combine with psychologic precursors and event triggers at the operational level to initiate the accident sequence. Most accident sequences are trapped at one or more layers of the system's defenses. The defenses can fail either because of organizational failure or because of performance failures of the operators. *(From Reason [6])*

found in an oil refinery, a 747 aircraft, or the space shuttle. A more important source of complexity is the "uncertainty complexity" of the patient. [14] The human body is an incredibly complex system containing numerous components the interactions of which are only vaguely understood. Because many body systems affect each other, the patient is a major site of tight couplings. Furthermore, the anesthetic state tends to ablate the buffers among some of these interconnected systems, thus strengthening the coupling among them and between the patient and external mechanical supports. Galletly and Mushet [15] studied anesthesia "system errors" and observed tight coupling associated with "the use of neuromuscular blocking drugs, the presence of cardiorespiratory disease, certain types of surgical procedure, and from the effect of the general anesthetic agents. Looser coupling was observed with the use of high concentrations of oxygen and air mixtures, preoxygenation, and spontaneous breathing techniques."

A variety of latent failures can exist in the anesthesia environment. They may include such issues as how surgical cases are booked, how cases are assigned to specific anesthetists, what provisions are made for preoperative evaluation of outpatients, and what relative priority is given to rapid turnover between cases or avoiding the cancellation of cases as opposed to the avoidance of risk. Latent errors can also result from the design of anesthesia equipment and its user interfaces. Manufacturing defects and failures of routine maintenance are also sources of latent failures.

Eagle and Davies [16] described a number of active failures and latent failures in a case report concerning a severely ill patient who died 6 days after suffering aspiration of gastric contents during general anesthesia for cystoscopy. The initial urologist in this case made an active error by booking the case inappropriately to be performed under local anesthesia. This active error interacted with other latent features of the system. For example, the OR scheduling system improperly allowed the urologist to be assigned to two different cases simultaneously, which led to the surgical procedure's being transferred to another urologist who was unfamiliar with the patient. The second urologist requested a general anesthetic, at which point an anesthetist, who was equally unfamiliar with the patient, was brought into the situation. Through this combination of events, the seriously ill patient did not receive a thorough evaluation in advance of his surgery. Specifically, the anesthetist was not aware that the patient had suffered an episode of projectile vomiting at 4 AM on the day of surgery. This information was available in the hospital's computerized record-keeping system, but there was no computer terminal in the OR. The information was not contained on the patient's chart. The nursing notes in the chart indicated that the patient had been fasting for 24 hours. The second urologist and the anesthetist believed that the case was an urgent addition to the OR list. They decided to go ahead with the case despite their cursory evaluation of the patient.

The analysis of Eagle and Davies reinforced the concept that investigation of untoward events must address both latent and active failures and both the organizational and managerial environment and the operational domain. One risk of focusing solely on active failures is that the operational personnel believe

themselves to be victims of the system, making them defensive and uncooperative. Rasmussen, [17] as well as Cook and Woods et al, [9] [11] [12] [18] pointed out that if one looks at the chain of events in an accident sequence, one can always find a failure on the part of an operator. If the analysis stops at this point, the operator (i.e., the anesthetist) may be wrongly blamed for a failure the real roots of which go back to latent failures in the organization.

One trend in the study of several high-hazard industries attempts to define the important organizational elements that promote or inhibit safety. One school of thought, which is sometimes contrasted with the approach of Perrow, focuses on successful high-risk activities (such as aircraft carrier flight operations) involving "high-reliability orga-nization." [19] [20] [21] [22] [23] The key elements of a high-reliability organization are as follows:

1. Priority of safety and reliability as a goal by political elites and organizational leadership.
2. High levels of redundancy in personnel and technical safety measures.
3. Development of "high-reliability culture" in decentralized and continually practiced operations (with high proceduralization).
4. Sophisticated forms of trial and error organizational learning.

Anesthesiology in most institutions contains some elements of a high-reliability organization, particularly technical safety measures. However, many elements are not as fully realized as they are in classic high-reliability organizations in the military and in commercial aviation. Another analysis of the impact of the organization on safety comes from sociologist Diane Vaughan's book *The Challenger Launch Decision.*[24] Vaughan's main thesis is that the Challenger exploded *not* because "risk-taking" managers "broke the rules," but because the system evolved to make excessive risk a part of "following the rules." This occurred because of four key organizational elements she identified:

1. A culture of production (ingrained production pressure).
2. Risk as a social construction.
3. Normalization of deviance (explaining away abnormal findings).
4. Structural secrecy.

These same features can also be identified in many medical environments including anesthesiology. I am currently conducting a 2-year comprehensive comparison, funded by the Robert Wood Johnson Foundation, of the organizational, system, and safety-cultural aspects of tertiary care medicine versus other high-risk industries.

Nature of the Operational Domain of Anesthesiology

Accepting the important caveat that the performance of anesthetists is strongly affected by organizational factors and by latent failures present in the work environment, it is still in the operational domain of actual patient care in which anesthetists put their skills on the line. Thus, this chapter examines the operational environment and the anesthetist's performance in more detail.

The operational domain of anesthesia is a complex, dynamic world [25] that presents a cognitive profile common to

many real-world task domains. The analysis of complex dynamic worlds in the last decade has departed sharply from previous conceptions of decision making. [26] Classic decision-making approaches, such as decision theory and multiattribute utility theory, were mathematic techniques that were traditionally used as the dominant framework for understanding human performance. They worked well in simplified laboratory experiments on decision making and action, yet a number of investigators had significant difficulty in applying them to real-world decision and action settings. [26] Orasanu and Connolly [26] identified eight factors that characterize such naturally occurring complex dynamic worlds. They apply to anesthesia as follows:

1. *Ill-structured problems.* Unlike in traditional decision experiments, there is not a single decision to be made. There are a variety of interrelated decisions to be made by the anesthetist and the surgeon. The patient's physiologic behavior is not an independent random variable but is causally linked to previous decisions and actions.
2. *Uncertain dynamic environment.* Dynamism stems from the frequency of routine and anomalous changes or events, the rapidity with which they evolve, and the unpredictability of the patient's physiology and response to interventions. The anesthetized patient during surgery is in a constant state of change, with many events outside the anesthetist's control. Although preventive measures can reduce the likelihood of some events, others cannot be avoided because they are inevitable side effects of medically necessary procedures (e.g., surgical blood loss). Unpredictable and dynamic occurrences compete with the preplanned aspects of the case driving the anesthetist's actions. The true state of the patient cannot usually be measured directly. It must be inferred from ambiguous patterns of clinical observations and data from electronic monitors. These data are imperfect because, unlike industrial systems that are designed and built with sensors in key areas to measure the most important variables, patients are typically instrumented to measure the variables that are easiest to monitor, predominantly using noninvasive methods. Most physiologic functions are observed indirectly through weak signals available at the body surface and thus are prone to various types of electrical and mechanical interference. Invasive measurements are also vulnerable to artifacts and uncertainties of interpretation. Even if the anesthetist knew the exact state of the patient, the patient's response to interventions would be unpredictable.
3. *Time stress.* Because the OR is a scarce resource, there is an incessant overall time pressure to use it efficiently. There is an even more intense immediate time stress within each case, generated by dynamic situations that evolve rapidly and that must be dealt with in a timely fashion.
4. *Shifting, ill-defined, or competing goals.* Multiple goals of case management (e.g., hemodynamic stability, good operating conditions for the surgeon, rapid emergence from anesthesia) may compete with each other. The surgeon's goals may sometimes compete with those of the anesthetist. All these goals shift as the patient's situation shifts dynamically throughout the case.
5. *Action/feedback loops.* The time constants of actions and their effects are very short, on the order of seconds to minutes. There is a complete intermixing of decision-making and action; these functions are not performed in separate cycles. Most decisions and actions are implemented and evaluated incrementally with the effect of one cycle assessed before deciding on further possible actions.
6. *High stakes.* The stakes are high because, even for elective surgery in healthy patients, there is an ever-present and very real risk of injury, brain damage, or even death. A catastrophe is often the end result of many pathways that begin with seemingly innocuous triggering events. Each intervention, even if appropriate, is associated with side effects, some of which are themselves serious. Some risks cannot be avoided. Unlike a commercial flight, which can be delayed or aborted if a problem occurs, immediate surgery may be necessary to treat a medical problem that is itself life-threatening. Balancing the risks of the anesthesia and surgery against that of the underlying surgical disease is often extremely difficult.
7. *Multiple players.* The anesthesia domains involve multiple players from different professional backgrounds. Each individual has a set of goals, abilities, and limitations. In some situations, interpersonal interactions dominate the work environment.
8. *Organizational goals and norms.* The anesthetist works within the stated and unstated norms of the OR suite, the anesthesia department, the institution, and the profession as a whole. Decisions are sometimes made to conform to these norms that are not wholly subscribed to by the anesthetist.

Although many of these features apply to other domains of medicine, anesthesiology is unique in that all eight factors are prominent. In particular, what sets anesthesia apart from clinic-based or ward-based medicine is the intensity of dynamism, time pressure, and uncertainty. Each of these factors exacerbates the difficulties posed by the others.

ANESTHETIST'S TASKS

The investigation of a complex work environment typically starts with a task analysis. One type is an abstract analysis of the work procedures and the tasks required to perform them. A second technique is to observe what skilled practitioners actually do in their work and to classify these actions into task elements. In this section, the anesthetist's task is examined in the abstract. In the following section, the empirical task analysis approach is reviewed.

There are two distinct phases of anesthetic care: (1) preoperative evaluation, planning, and preparation; and (2) conduct of the anesthetic regimen and immediate postoperative care.

Preoperative Evaluation and Planning

There are few data on how well anesthetists identify important patient conditions through history-taking and physical examination (Ch. 23) . A frequent organizational obstacle to the anesthetist's evaluation task is the inability to obtain the patient's previous medical records. The performance of

anesthetists in selecting appropriate laboratory tests has been found to be relatively poor. Roizen [27] (Ch. 25) states that:

> Even when physicians agree to reduce testing by using specific, agreed upon criteria for selectively ordering tests based on history and physical examination, they still make a surprising number of mistakes when ordering tests. Approximately 30 to 40 percent of patients who should have certain tests ... do not get them, and 20 to 40 percent of patients who should not have tests are subjected to them.

Roizen has argued for the automation of routine patient questioning and selection of laboratory tests and has participated in the development of commercial devices to do so. Whether these devices, in combination with human follow-up for patients with medical problems, will improve the efficiency and accuracy of preoperative evaluation remains to be determined. The performance of anesthetists at interpreting electrocardiograms (ECG) [28] and chest radiographs [29] also appears to be poor relative to specialists in these fields. The extent to which this factor influences the design of anesthetic plans or patient outcomes is unknown.

Anesthetic Plan

In constructing the plan, the anesthetist uses the preoperative evaluation of the patient to match the technical requirements of the surgical procedure and the physiologic characteristics of the patient to the mental, physical, and technologic resources available. A typical anesthetic plan contains several elements. For example, the plan for general anesthesia includes choices for the means of inducing anesthesia, securing the airway and ensuring proper ventilation, maintaining anesthesia, conducting emergence from anesthesia, and postoperative pain control. Skilled planning is as critical to safe patient care as is skilled execution. If a significant feature of the situation is missed in formulating the plan, it can leave the patient vulnerable, regardless of how adeptly the plan is implemented.

The technical requirements of most surgical procedures are well known. Most patients do not have medical problems that could significantly alter the anesthetic plan, although Gibby et al [30] found that 20 percent of outpatients, most of them with American Society of Anesthesiologists (ASA) physical status 1 or 2, had conditions identifiable through an anesthetist's history and examination that required changes from a "standard" anesthetic plan. When a procedure is new or challenging, when the patient has significant underlying disease, or when needed resources are not available, creative planning may be needed to identify a set of physiologic goals for the anesthetic regimen. Routine anesthetic plans can be modified or combined to produce a compromise plan that best fits the goals and constraints of the situation.

Although faculty anesthetists routinely critique the anesthetic plans of residents, and planning is explicitly probed during the oral examination of the American Board of Anesthesiologists, the process of constructing anesthetic plans has been studied very little. Most of the existing literature on preoperative planning concentrates only on the medical and physiologic aspects of underlying diseases and their anesthetic ramifications.

Pre-Use Preparation and Checkout of Equipment

After the plan is established, the anesthetist must prepare the work environment (Chs. 7 and 11). This involves obtaining necessary equipment and supplies, assembling infusions, preparing syringes of needed drugs, and conducting pre-use checkouts of life support equipment. The performance of anesthetists at these tasks is not optimal. Buffington et al [31] demonstrated that only 3 percent of anesthetists examining an anesthesia machine could identify all five faults with which it had been rigged; most practitioners found only two of the five. Nearly 30 percent missed such major faults as the complete absence of both unidirectional valve disks in a circle anesthesia breathing system or a swap of the nitrous oxide and oxygen cylinders (made possible by a fault in the pin-indexing system).

The U.S. Food and Drug Administration (FDA), in cooperation with the ASA, the Anesthesia Patient Safety Foundation (APSF), and experts from academics and industry, developed a set of recommendations for the checkout of anesthesia apparatus. [32] This checklist was widely disseminated by the ASA and the APSF. However, it was found that use of the checkout procedure was minimal and that the extent of pre-use checkout by practitioners was extremely variable. A newer study [33] was conducted to compare the checkout of anesthesia machines by practitioners with and without the use of the FDA checkout procedure. Most of the faults were detected by 50 percent or fewer of participants, regardless of the checkout procedure used. Only for one fault, the failure of the oxygen/nitrous oxide ratio protection system, did the FDA checklist offer significant advantages; when using it, the detection rate went up to 65 percent. Interestingly, 34 percent of faults that were not detected occurred for practitioners who correctly answered three out of three written test questions concerning that fault. This suggests that although some of the performance deficit may be related to a lack of knowledge, a substantial proportion is due to the inability to apply abstract knowledge to the practical performance of equipment checkout. There were many criticisms of the original checklist, particularly of its complexity. [34] A streamlined version of the original checklist was published by the FDA in 1993. [35] There are no data at this time as to whether the new checklist will assist clinicians to detect machine faults better than the original checklist.

Execution and Adaptation of Plans

Anesthetic plans are dynamic. The anesthetist must monitor the plan as it is executed and must adapt it in response to dynamically changing events. The key features of this task are (1) checking for the achievement of milestones and (2) reactive plan adaptation. These are shown schematically in Figure 80-2 (Figure Not Available) . At various points of a case, there are critical milestones that must be achieved in order to keep the original plan unaltered. If a milestone is not achieved, the anesthetist must decide whether to delay the next action in the sequence, to modify the plan, or to suspend or abort the case. On some occasions, the milestones are

explicitly identified in advance, whereas in other cases, the milestones are implicit.

Figure 80-2 (Figure Not Available) Schematic diagram of the dynamic adaptation of preoperative plans. The anesthetist begins the anesthetic with an intravenous induction as planned (top left). On achieving the milestone of successful induction of anesthesia, the blood pressure is checked before proceeding with laryngoscopy and intubation (lower left). If it is not satisfactory, the next step may be delayed and the plan amended to optimize the blood pressure. If necessary, the case could even be aborted at this stage. Throughout the case, the anesthetist is vigilant for the occurrence of new problems (the "police cars"). If a problem is detected, a process of reactive problem solving takes place, which may result in new adaptations to the plan (in this case, treatment of bronchospasm). *(From Gaba [10])*

The anesthetist must also react to a large number of other contingencies, some of which can be predicted in advance, based on the patient's history and the type of surgery, whereas others cannot be anticipated. Incoming data streams must be constantly scrutinized (see the "police cars" in Fig. 80-2 (Figure Not Available)), to determine whether an expected or unexpected contingency is occurring. If so, the existing plan may have to be modified. As plans are changed, actions may be taken that invalidate other aspects of the previous plan, requiring further adaptation of the plan. In some cases, even the original goals of the anesthetic plan may need to be adapted.

Frequency of Events Requiring Active Intervention by the Anesthetist

This abstract analysis suggests that anesthetists must be prepared to react dynamically to changing events. How frequent is this requirement? In the Multicenter Study of General Anesthesia, [36] 17,201 patients received general anesthesia under specific protocols with random stratification to receive one of four anesthetic techniques (each of the three common volatile anesthetic drugs or narcotics plus nitrous oxide). The anesthetists observed the patients for the occurrence of any of a large variety of carefully defined perioperative outcomes, which were adverse events ranging from minor events such as sore throat or hypotension (i.e., systolic blood pressure reduced more than 20% from baseline), to serious events such as myocardial infarction or death. There were 34,926 observed outcomes in the 17,201 patients. Clearly, some patients had more than one outcome, whereas others had none, but 86 percent of patients had at least one undesirable outcome. Although most events were minor and caused no injury to the patient, more than 5 percent of patients had one or more severe events requiring "significant therapy, with or without full recovery." This incidence is probably a lower limit for severe events because the entry criteria of the study precluded the enrollment of critically ill patients or emergency surgeries for which the likelihood of severe problems requiring intervention would be expected to be high.

In another study by Cooper et al, [37] impact events, defined as "undesirable, unexpected, and which could cause at least moderate morbidity," occurred in 18 percent of patients either

---

in the OR or in the PACU. Three percent of all cases involved a "serious" event. These figures are also probably lower limits because, for technical reasons, the study excluded patients going directly from surgery to an ICU.

Moller et al [38] reported on a Danish randomized evaluation of the effect of pulse oximetry on patient outcome. In the oximetry group (which most closely resembled current U.S. practices), 10,312 patients underwent anesthesia and surgery with pulse oximetry in use in addition to all other case-appropriate monitoring modalities. Patients were carefully observed for cardiovascular, pulmonary, and neurologic occurrences that met the criteria of "impact event" as in the study cited earlier. There were 4,439 events detected in these patients either in the OR (2,441) or in the PACU (1,998). Here again, some patients had several events, whereas others had none. The investigators did not compute the frequency of severe events, but overall, these data appear to be consistent with the earlier studies.

Model of Event Evolution

These findings, as well as the larger system issues raised by Reason and Perrow, can be summarized in a model of event evolution [14] [39] [40] [41] (Fig. 80-3) (Figure Not Available) . Similar models incorporating some of the same features have also been described. [15] [42] [43] Underlying aspects of the system can generate latent failures. Either by random chance or because of interactions between the latent failures, an event may be triggered in one of four components of the operational system in the OR--the anesthetist, the surgeon, the patient, or the equipment. Anesthetists have traditionally been most interested in events they triggered themselves (such as esophageal intubation), but, in fact, most events are initiated by a combination of underlying patient disease and another of the triggering factors. Most problems are not directly harmful to the patient unless they evolve further. The possibilities for problem evolution include the following:

1. A single problem worsens and by itself evolves into an adverse outcome.
2. The problem begins to evolve but remains self-limited without any intervention.
3. Multiple small problems combine to trigger a problem that can evolve into an adverse outcome; the original problems by themselves would not have evolved further.
4. A single problem triggers another problem that evolves into an adverse outcome.
5. An evolving problem should be able to be stopped, but the recovery pathway is faulty.

The system has a variety of interruption points at which the occurrence of problems can be prevented (preoperative evaluation of patients and pre-use checkout of equipment) or at which the process of accident evolution can be thwarted before an adverse patient outcome actually occurs. The interruption of accident evolution corresponds to the "defense-in-depth" in Reason's model (see Fig. 80-1 (Figure Not Available)) and to recovery from a normal accident in Perrow's paradigm.

In the prospective studies of intraoperative events cited earlier, there was a surprisingly high incidence of undesirable situations, whereas the rate of actual patient harm was quite low. The patient's safety was frequently protected only

Figure 80-3 (Figure Not Available) Chain of accident evolution in anesthesia. As in Reason's model, underlying latent failures predispose to the triggering of an accident sequence by equipment, the patient, the surgeon, or the anesthesiologist. This sequence can be prevented by prophylactic measures such as preoperative evaluation and treatment of patient diseases or pre-use checkout of life support equipment. Once a problem occurs, it may remain self-limited, or it may evolve further down the accident chain. Using dynamic decision making, the anesthetist must detect and correct problems that do occur at the earliest possible point in the chain of evolution. The interruption of the accident chain is made more difficult when there is tight coupling within the system, when there are multiple interacting problems, or when problems disrupt recovery processes. *(From Gaba et al [41])*

---

by the skilled intervention of a trained anesthetist. Note that this is a markedly different picture from that in commercial aviation. Although the accident rate in aviation is very low (for both commuter and major airlines, the 1995 accident rate was approximately 0.4 per 100,000 departures, according to the National Transportation Safety Board World Wide Web page), adverse events in aviation matching the "impact event" criteria given earlier are relatively unusual and come nowhere near to approaching 1 event every 5 flights. The actual number of aviation "impact events" is not known, but it is probably at least 100 times greater than the number of accidents, but even so, this would still make aviation impact events far less frequent than the 3 to 5 percent rate of significant impact events in anesthesia. Based on these data, it is clear that the intraoperative management of dynamically changing events remains the critical locus of anesthesia skill.

Empirical Studies of the Anesthetist's Tasks

Over the past 20 years, there have been a number of studies [44] [45] [46] [47] [48] [49] [50] [51] [52] [53] [54] of the anesthetist's intraoperative activities. The earliest studies used time-lapse photography of a handful of anesthetic cases with a frame-by-frame analysis of tasks. One major finding of the first task analysis, by Drui et al in 1973 [44] was that "the anesthesiologist's attention was often directed away from the patient-surgical field." In subsequent studies, [45] [46] [47] [48] it was found that about 40 to 50 percent of the time, the anesthetist's gaze was directed away from the patient or surgical field. McDonald and Dzwonczyk, [47] studying cases from 1981, classified a direct patient activity as "one during which the anesthetist had contact with the patient and a view of the surgical field." These investigators explicitly noted "observation of skin color," "palpation of pulse," and "auscultation of heart and breath sounds" as direct patient activities. Observing the arterial pressure or ECG and

observing or adjusting the anesthesia machine or intravenous infusions were classified as indirect patient activities. In this study, 83 percent of the anesthetist's time was spent on activities that were not direct patient activities. The same group [48] repeated its study in 1985 and demonstrated a much higher rate of direct patient monitoring than obtained in 1981 (44.8 versus 16.8%). This group attributed this difference to the change from manual ventilation in 1981, which took up much of the anesthetist's visual attention, to the use of mechanical ventilators in 1985, which freed the anesthetist to watch the patient.

It has become a truism that looking at the patient and at the surgical field is a hallmark of an excellent clinician. Opponents of technology decry the degree to which monitors and therapeutic devices distract the anesthetist's gaze from the patient. However, an important distinction has to be made between the anesthetist's attention, which surely must be directed to the patient's needs, and the anesthetist's gaze, which, in fact, may best serve the patient by being directed elsewhere. Many of the tasks cited in the McDonald and Dzwonczyk study [47] were highly related to the management of the patient, even though they did not involve direct visualization of or contact with the patient. The critical question, which task analysis by itself cannot answer, is this: When anesthetists gaze at the surgical field, how often are they gathering information, and how often are they just "watching the scenery"? Put more generally, what is the information content of the various observations being made and what is their relation to action tasks and to the goals of conducting a safe anesthetic regimen?

Intriguingly, Drui et al [44] had asked physicians who were helping to code their films to consider "what information, if any, do you gain from the direct performance of this activity?" However, these investigators never described what information was available from each activity, although they seem to have assumed that turning the anesthesiologist's gaze away from the patient and surgical field was bad. Boquet et al [45] not only studied the gaze of anesthetists (using a sophisticated eye tracking system), but they also asked consultant anesthetists to grade the importance of different visual targets and manual tasks. "The patient" was assigned the maximal importance on the scale. However, "the surgical field," which occupied 25 percent of the anesthetist's time (
10 s/gaze), was apparently not listed by the consultants. Perhaps, in their minds, the surgical field was lumped together with the patient.

Another key finding of the study by Drui et al [44] was that 40 percent of the anesthetist's time was coded as "idle," meaning that no obvious task was seen on that frame of film. In 1988, McDonald and Dzwonczyk [47] stated that this and other "studies showed that the anaesthetist spends most time performing tasks that are either secondary or unrelated to patient care." However, in their original article, Drui et al [44] correctly recognized that the absence of visually apparent activity did not mean that the anesthetist was truly idle; in fact, they hypothesized that this time was used by anesthetists to make the decisions on which the observable tasks were based.

The most detailed task analyses have taken place in a series of studies [49] [50] [51] [52] [53] [54] carried out by a collaboration of investigators from the University of California San Diego (UCSD, primarily involving Weinger and Herndon) and from the Department of Veterans Affairs (VA) and Stanford University (Gaba). These analyses have used progressively more task categories (11 to 28 to 32) to analyze the activities of novice and experienced anesthetists in day surgery cases and of senior residents during cardiac surgery. These studies have shown that a small number of tasks, repeated frequently, occupy the majority of case time. In one study, four tasks (observing monitors, recording, conversing with attending staff for novice residents, and adjusting monitors) accounted for 50.1 percent of total case time. Specific activities such as airway management (e.g., bag ventilation, laryngoscopy) occurred in brief, but intense clusters (Fig. 80-4) . Given the larger number of task categories, the anesthetist was rarely seen to be idle.

These studies have attempted to determine whether there is a difference between the task patterns of novice versus experienced anesthetists. Confirming a priori expectations, these investigators found that novices perform many of the same tasks as do experienced personnel at specific phases of an anesthetic regimen, but the novices had a longer dwell time, on average, for each task. These investigators also found that experienced providers had a lower heterogeneity of tasks and greater efficiency of tasks per unit time. [53]

Of note (but also not unexpected), novice residents spent more time speaking to their attending staff (
11% of preintubation

Figure 80-4 Distribution of the anesthetist's tasks during an actual ambulatory surgery procedure. The anesthetist was directly observed by an investigator who recorded a code number for each task as it was performed (there were 28 task codes). Certain tasks, such as bag ventilation, were clustered in specific phases of the case, whereas others, such as observing monitors, were repeated frequently throughout the case.

time) than did experienced residents or certified registered nurse anesthetists (CRNA). Interestingly, experienced personnel observed the surgical field more than did the novices by roughly the same proportion of time. Again, the implications of this finding are not clear. Novices did take longer to complete patient preparation and anesthesia induction, but it appeared that some of the extra time taken by novices working under supervision was offset by the efficiency of off-loading concurrent other tasks to the attending anesthesiologist, such that preintubation time was increased by only 6 minutes for novices. [53] This group also reported that as the density of tasks per unit time increased, the dwell time on each task decreased, and vice versa. This finding has important implications for how anesthetists allocate their attention (see *Management and Coordination of the Core Process*).

Automation

The early task analyses identified repetitive tasks that did not appear to offer substantial information content or therapeutic benefit as candidates for automation. Drui et al [44] identified filling out anesthesia records, measuring the blood pressure, and adjusting intravenous infusions. Kennedy et al [46] identified data display and trend plotting. Many of these tasks have, in fact, been automated in the last 20 years. Loeb, [55] from the University of California, Davis (UCD), showed that anesthesiologists typically observed monitors for about 1 to 2 seconds every 10 to 20 seconds, and they usually took several observing cycles before detecting a subtle cue on the monitor. Gurushanthaiah et al [56] studied the effect of more sophisticated display modalities on the signal detection of anesthesiologists and found that histogram and polygon formats improved response latency in the laboratory setting compared with formats using raw numbers only. However, the applicability of this laboratory finding to the more complex signal detection that must occur in the midst of patient care is uncertain. Incidentally, the experience in aviation suggests that automation of both monitoring and therapeutic devices produces its own problems in human-machine interactions and may well be a causative or contributing factor in some adverse anesthetic events. Some of the same types of automation-related adverse events seen in aviation [57] [58] are now being observed in anesthesiology. [59] [60]

The impact of automation on task distribution is uncertain. The change to mechanical ventilation did affect the analyses of McDonald and Dzwonczyk, [47] as detailed earlier. A study by Dzwonczyk et al [61] showed no reduction in time spent recording when automated record-keeping devices were used. However, the UCSD/VA-Stanford collaboration published data demonstrating a 20 percent reduction in the time spent record-keeping when automated record-keeping was in use during cardiac anesthesia. [52] [54] There was a slight, but not significant, increase in time spent on direct patient care activities when electronic record-keeping was in use. Thus, there is no clear evidence that electronic record-keeping will yield a marked enhancement of the anesthetist's ability to perform other patient care tasks, although automated record-keeping may yield other benefits. Both the UCD and UCSD/VA-Stanford groups demonstrated that electronic automated record-keeping does not significantly reduce the vigilance of anesthetists. [54] [62]

Mental Workload of Administering Anesthesia

The observable tasks do not tell the whole story of what the anesthetist is doing. As Drui et al [44] suggested, there is mental activity going on even when the anesthetist appears idle. What, then, is the mental workload of administering anesthesia? Mental workload is another concept that is readily understood but difficult to define precisely. There are various ways to measure workload, none of which is ideal. The primary task performance measure assesses the subject's performance on the standard work tasks as they are

made progressively more difficult by increasing the number of tasks, the task density, or the task complexity. At first, the subject is able to keep up with the increasing task load, but at some point, the workload exceeds the ability to manage it, and performance on the standard tasks decreases. The disadvantage of the primary task performance measure is that, in many complex task domains, there is no accepted way to measure objectively the subject's performance on the primary work tasks except by loading to the point of catastrophic performance failure, which is easily detected. In actual high-risk domains, one cannot allow primary task performance to

degrade, and certainly not to fail catastrophically. Although experiments of this type are in principle feasible using anesthesia simulators, they have not yet been attempted.

Secondary Task Probing

A more useful technique, secondary task probing, tests the subject with a minimally intrusive secondary task that is added to the primary work tasks. The secondary task is a simple one for which performance can be objectively measured, and the subject is instructed that the primary tasks of patient care take absolute precedence over the secondary task. [63] Therefore, assuming that the secondary task requires some of the same mental resources as the primary task, the performance of the subject on the secondary task is an indirect reflection of the spare capacity available to deal with it, and thus it is an inverse measure of primary task workload (the greater the spare capacity, the lower the primary workload). Secondary tasks such as reaction time (with or without choice), finger tapping, and mental arithmetic have been used for this technique in the psychology laboratory, in high-fidelity simulators, and in some field studies of actual work situations. [63]

Gaba and Lee [64] presented two-digit addition problems on a computer screen placed in the anesthesia workspace at random approximately every 45 seconds. The delay in responding to problems and the number of problems skipped were logged over time and were correlated with a concurrent six-category task analysis. The dynamic ebb and flow of mental workload during cases of varying complexity was documented. For example, cardiopulmonary bypass was confirmed as a time of very low workload for the anesthetist, whereas the induction of anesthesia was confirmed as a period of high workload. Manual tasks and conversing with the attending were correlated with a delayed or absent response to the secondary task.

Subsequent studies by the UCSD/VA-Stanford group [53] [54] and the UCD group [55] [62] [65] used the reaction time to a changing display in or around the clinical monitors as a secondary task to assess mental workload and/or vigilance. For the UCSD/VA-Stanford group, the display was a red light placed next to the main physiologic monitor. This secondary task was analogous to, but totally separate from, the standard tasks of clinical work. When the secondary task was embedded in the regular work tasks, it was called an *embedded task.* The UCD group used a secondary task involving recognition of changes in the alphanumeric display of an unused channel of an actual clinical monitor (a parameter labeled "Vig" on the monitor changed values from "5" to

Figure 80-5 Test of the anesthetist's vigilance. The figure shows the mean reaction time of novice residents and experienced anesthetists to the illumination of a red light placed next to the electrocardiogram monitor display during actual ambulatory surgery procedures. For both groups, reaction was faster in the maintenance phase than during induction of anesthesia. Novices reacted significantly more slowly than did experienced anesthetists. Because the distribution of reaction times was asymmetric and nongaussian, error bars are not shown, and nonparametric statistics were used for hypothesis testing.

"10"). This task was only partially "embedded" because although it did involve an actual clinical monitor, it displayed on an otherwise unused channel and was not of clinical significance. The VA-Stanford group has been experimenting with fully embedded secondary tasks during simulator anesthetic cases, in which the values of actual clinical variables can be manipulated at will to evaluate the subject's response time to the excursion of data values beyond predefined reporting thresholds.

The mean response time to the red light used by UCSD/VA-Stanford was markedly less than 60 seconds for experienced subjects in both the induction and postinduction (maintenance) phases, but it was much higher for novice residents during the induction phase (Fig. 80-5) . The probe was not given frequently enough to track the ebb and flow of workload. The response to the UCD task typically (56%) occurred within 60 seconds, but 16 percent of stimuli overall (27% during the induction period) were not responded to within 5 minutes. The conclusion was that spare capacity may be limited by the workload of the case during certain periods of anesthesia care.

There are several problems with these workload studies. One is interference with the "response channel." If responding to the probe requires manual activity with a mouse or keyboard (as for the studies of Gaba and Lee and UCD), it cannot be performed whenever the subject is occupied with a manual task. This is especially true during a sterile procedure. Thus, it may be impossible to distinguish between a high primary task load (i.e., no spare capacity to address the secondary task) and a low primary task load that happens to usurp the manual response channel. However, in the Gaba and Lee study, [64] 37 percent of the problems that were skipped for lack of spare capacity did not occur during a manual task. The UCSD/VA-Stanford studies have all allowed

multiple response channels (manual, voice, and gesture), so there was no response channel interference, but the potential for interference remains in the UCD studies. An additional problem with all these studies is that even these simple secondary tasks were intrusive when repeated frequently. Thus, there was a tradeoff between the temporal resolution of the measurement and its intrusiveness. There is also controversy about whether these probes measure "vigilance" or "workload," although the same techniques probably measure both aspects of performance. When probes occur infrequently, are subtle, have multiple response channels, and are performed with a low level of existing workload, they are more likely to measure "vigilance," whereas when they are frequent, readily detectable, require manual response, and are performed during a high workload period, they probably are more indicative of spare capacity and workload.

Subjective Measures

A third modality of workload assessment consists of subjective measures in which individuals are asked, either in retrospect or in real time, how much load they were or are under during actual work situations. Subjective measures complement objective measurements because the subjective perceptions of the anesthetist may be an important source of stress and anxiety; conversely, an anesthetist may subjectively underestimate the workload in settings in which objective measurements demonstrate a marked reduction in spare capacity.

Various scales have been proposed to measure dimensions of mental workload that are, in theory, different. [63] However, Gaba and Lee [64] adapted a set of workload scales from those used at the National Aeronautics and Space Administration (NASA) [66] and showed that workload ratings on each of the scales were highly correlated. In subsequent studies by the UCSD/VA-Stanford group [53] a single dimension of overall load was assessed using an asymmetric numeric scale that minimized biases caused by a tendency to group responses at the middle and extremes of symmetric scales. This group demonstrated that a neutral observer can estimate the subjective workload of the anesthetist in real time with a high correlation to the self-rated workload of the subject. Again, as could be expected, subjective workload was highest during induction and emergence from anesthesia, especially for novices.

Physiologic Measures

The final set of techniques for assessing workload consists of physiologic measures. Visual or auditory evoked potentials have been used successfully to assess mental workload, but this technique can only be used in a static laboratory environment. Heart rate is a relatively easily measured variable that may be altered by mental workload. Toung et al [67] [68] showed that the anesthetist's heart rate increases at the time of intubation, and the amount of increase is inversely related to the amount of overall medical training. Azar et al [69] found that anesthesia faculty members' heart rate and blood pressure increased during induction of anesthesia, and one individual developed significant ST-segment depression. Bitetti et al [70] confirmed that heart rate changes occurred during anesthesia, but these did not always correlate with contemporaneous self-recordings of "stress."

Because of the many factors that affect heart rate, the beat-to-beat variability of heart rate is thought to be a better indicator of mental workload. [63] The frequency components of heart variability can be separated by spectral analysis; a component at 0.1 Hz has been linked to mental workload. Although several groups have acquired heart rate data on anesthesiologists, none has reported an analysis of the workload-related frequency components.

Applications of Task Analysis and Workload Methodologies

The results of the task analyses and workload measurements have primarily provided objective confirmation for a number of intuitive beliefs about anesthesia practice. The real importance of these studies is that a coherent methodology has been developed that may be useful for studying a variety of interesting questions. The question of the impact of electronic automated record-keeping systems is addressed earlier. Another question concerns transesophageal echocardiography (TEE). This new monitoring modality has become commonplace during cardiac anesthesia and anesthesia for other patients with cardiovascular disease who undergo

complex operations. It is widely recognized that evaluating TEE images and manipulating the TEE probe require substantial visual and mental attention.

The UCSD/VA-Stanford group published data suggesting that vigilance (as measured by response latency to illumination of a red light) was substantially lower when the anesthesiologist was involved with manipulating, adjusting, or examining the TEE compared with other patient care tasks [54] (Fig. 80-6) (Figure Not Available) . This may be due, in part, to the layout of the workspace. The TEE machine is large and is often placed near the left side of the head of the OR table, whereas the anesthesia machine and attendant monitors, by convention, are typically placed near the right side of the head of the table. Remote displays slaved to the primary monitor are also more likely to be on the patient's right side. This arrangement makes it difficult physically to glance from one modality to another. The degree to which the mental concentration required to use TEE itself detracts from vigilance for other signals remains to be determined explicitly. Furthermore, it is important to differentiate the different uses of TEE. When it is used to answer specific clinical questions triggered by events or milestones during the procedure, the value of the information may be worth an investment of effort, even with a reduction in overall vigilance. When it is used as a continuous monitor for myocardial ischemia, or when conducting a detailed routine examination, the reduction of vigilance must be considered when evaluating the potential benefits of the technology. Some practitioners describe special ways to handle the attention requirements of TEE, including tightening alarm thresholds (to provide audio warnings of changed values) or assigning specific patient monitoring functions to another individual while conducting the initial TEE placement and examination.

Figure 80-6 (Figure Not Available) Vigilance test data during anesthetic tasks with and without automated record-keeping. The figure depicts the range of data for each of four task categories for electronic automated record-keeping (EARK) and for manual record-keeping (MAN). Each box contains 50 percent of the data for that subgroup (upper limit of box is 75th percentile; lower limit is 25th percentile), whereas the maximum and minimum are shown by the upper and lower bars. The response latency during record-keeping was not significantly different between EARK and MAN. In both record-keeping groups, subjects had significantly slower responses when observing or adjusting the transesophageal echocardiogram (TEE) when compared with record-keeping, observing monitors, or adjusting intravenous lines* ($P < .05$). Subjects in both groups had faster response latency when observing the monitoring array, which contained the red light; $P < .05$ compared with all three other tasks. *(From Weinger et al [54])*

There remain many other interesting questions concerning the performance of anesthetists that can be addressed with the techniques of task analysis and workload and vigilance assessment, including the following:

1. How do the task load and task density differ between private practice settings and academic settings?
2. How do the work patterns of novices change to become those of "experts"? How can the training of novices be focused to support these changes best? Is suboptimal performance of novices detectable through analysis of task distributions and mental workload?
3. How much task load can the average, single anesthetist handle? How are tasks distributed among personnel (i.e., between resident and faculty, between CRNA and supervisor, or among staff anesthetists) during the high-workload periods of patient care? This question is just beginning to be addressed (by the UCSD/VA-Stanford study) by applying the task-analysis techniques described earlier to videotapes of actual anesthetic cases. Using the tape, the task sequences of multiple anesthesia personnel can be elicited separately, as can the communications used to coordinate their activities.

OTHER STUDIES OF "VIGILANCE" AND DECISION-MAKING BY ANESTHETISTS

Studies of "Vigilance"

The dominant metaphor for the mental activity of the anesthetist has been that of a vigilance task. "Vigilance" is the motto on the seal of the ASA. What is vigilance, and to what degree does it capture the complex nature of the anesthetist's work? "Vigilance, or sustained attention refers to the ability of observers to maintain their focus of attention and to remain alert to stimuli for prolonged periods of time" (J. Warm, presentation at the Panel on Vigilance, ASA annual meeting, 1992). There is an enormous literature concerning vigilance. Many laboratory studies have demonstrated vigilance decrements during prolonged vigilance tasks, which are exacerbated or ameliorated by a variety of factors. These studies have generated considerable controversy. Some psychologists believe that the results of laboratory studies of vigilance have little application to complex real-world task domains. [71] [72] Certainly, the anesthetist's work involves vigilance as a necessary component, because if new stimuli are not perceived, no meaningful work can be accomplished. However, the anesthetist's task is much more complex than just vigilant alertness to stimuli. Therefore, vigilance is a necessary but not sufficient condition for appropriate performance. [14]

Several studies have attempted to quantitate the vigilance of anesthetists to changes in clinically important variables using low-fidelity simulation. Beatty et al [73] had anesthetists watch for changes in displays of six vital signs on a video monitor. Denisco et al [74] used videotapes containing abnormal changes of anesthesia flowmeter settings and physiologic monitor displays. The raw reaction times were not reported, only the "vigilance scores." These studies purported to demonstrate a degradation of performance for sleep-deprived and fatigued residents, but there were methodologic flaws. For example, in the study of Denisco et al, [74] the subjects were never told the threshold of change for them to report. In addition, the work environment of the anesthetist is much more complex than that presented in these low-fidelity simulations. Although it could be argued that complexity would worsen vigilance performance, this is not necessarily the case. Complexity can combat boredom, which is a distinct possibility in vigilance experiments. In addition, the real work environment often provides redundant data cues of changes, offering multiple possibilities for their detection.

A study of rested anesthetists [75] using a realistic anesthesia simulator (see the section on simulators later) measured detection

times (first awareness of a problem) for a variety of intraoperative events embedded within a realistic case situation. Interestingly, an event that caused alarms to sound immediately, such as ventricular tachycardia/fibrillation, was detected in 10 seconds or less (confirming its veracity and acting on it took longer in many instances, however). Another event, occlusion of the intravenous line, was detectable only by visual observation in the direction opposite from the anesthesia machine and monitors. This event took several minutes (on average) to detect, but it was corrected quickly after detection. The redundancy of cues in the task domain was confirmed in that 6 different observational modalities were used by at least 1 of the 19 residents studied to detect an endobronchial intubation initially.

Other vigilance studies have focused on detecting the loss of an existing monitoring modality during actual patient care. In one study, [76] the esophageal stethoscope was occluded with a clamp following a staged distraction (conversation or a loud noise). Subjects most commonly detected the occlusion by observing the clamp, rather than by noting a loss of sound. Although this study purported to show a difference in vigilance related to the use of automatic blood pressure measurement devices, the artificial distraction could have biased the results, the subjects typically failed to hear the loss of sounds, and there was a significant result only for one group of residents, arbitrarily stratified by length of training. Another study [77] that evaluated reaction time to loss of esophageal stethoscopy more carefully showed that 13 percent of occlusions were detected after 1 minute. However, this study required a manual response, and the investigators noted that in some instances of delay, the subject was involved in a manual clinical activity such as administering blood or drugs.

Apparent reductions in vigilance could be due either to a reduction of "spare capacity" to attend to the stimuli immediately or to a reduction in the overall alertness of the anesthetist. Enhancements in the display and annunciation of relevant information would be a useful ameliorative strategy in the first case, whereas this strategy would not be useful if the anesthetist's overall alertness is impaired, as by sleep deprivation or illness.

Empirical Studies of Complex Decision-Making and Action by Anesthetists

Traditional concepts of decision-making in medicine have concentrated on relatively static, well-structured decisions. For example, should patient A with an elevated blood pressure be treated for hypertension with drug X, or should no treatment be started? [78] Other investigators have looked only at "diagnosis" as an isolated task (specifically "diagnostic explanation") both in internal medicine [79] [80] [81] and in radiology. [82] These approaches to decision-making have not captured the unique aspects of dynamism, time pressure, and uncertainty seen in anesthesiology. Over the past decade, a paradigm has emerged concerning decision-making and action in complex real-world situations. [8] [17] [25] [26] [83] [84] [85] [86] [87] [88] Several teams both from inside the anesthesiology profession and from the human performance community have been striving to develop a more comprehensive understanding of the complex performance of anesthetists. Their work has been based on a small number of new experiments (often involving medium- or high-fidelity anesthesia simulators), the reinterpretation of previous experiments, direct and indirect observation of the conduct of anesthesia, and extrapolations from other industries to anesthesiology. Because each experiment has probed several aspects of decision-making and action, these results are described first, before describing cognitive models that synthesize the results.

Responding to Simulated Critical Incidents

Using a realistic hands-on anesthesia simulator, Gaba and DeAnda [75] [89] [90] studied the response of anesthesia trainees and experienced anesthesia faculty and private practitioners to six preplanned critical incidents of differing type and severity: (1) breathing hoses too short to turn the table 180 degrees, as requested by the surgeon; (2) endobronchial intubation (EI) resulting from surgical manipulation of the tube; (3) intravenous tubing occlusion; (4) atrial fibrillation (AF) with rapid ventricular response and hypotension; (5) disconnection between the endotracheal tube and the breathing circuit; and (6) ventricular tachycardia/fibrillation. These investigators measured both the detection time (as described in the section on vigilance) and the correction time (the time from the event's onset until any one of a predefined set of corrective actions was first taken). They assessed the information sources by which subjects detected the incidents and then confirmed and diagnosed the problem. They asked subjects to "think aloud," to allow subjective analysis of their decision-making strategies. A summary of the data is shown in Figure 80-7 (Figure Not Available) . Major findings from this set of studies included the following:

1. *Events differed from each other in their inherent ease of solution.* Some events (airway disconnection) were rapidly detected and corrected. Some problems (intravenous occlusion) were difficult to detect, but once they were detected, the diagnosis and therapy were rapidly achieved. Other problems (EI, AF) were easy to detect, using one of several redundant information sources as the first clue (six for EI, four for AF), but they required additional time (7-8 minutes for EI; 1.5-4.5 minutes for AF) to confirm the abnormality, to establish a diagnosis, and to initiate appropriate therapy. Diagnosis and the planning and monitoring of therapy used a large number of information sources (11 for EI; 9 for AF).
2. *For each incident, there was considerable interindividual variability in detection and correction times, in information sources used, and in the actions taken.* In

each experience group, there were some who required excessive time to solve the problem or who never solved it. In each experience group, at least one individual made major errors that could have had a substantial negative impact on a patient's clinical outcome. For example, one faculty member never used electrical countershock to treat ventricular fibrillation. One private practitioner treated the EI as if it were "bronchospasm" and never assessed the symmetry of ventilation. One resident never found the airway disconnection.

3. *The average performance of the anesthetists tended to*

improve with experience, although this varied by incident. The performance of the experienced groups was not definitively better than that of the second-year residents (who were in their final year of training at that time). Many (but not all) novice residents performed indistinguishably from more experienced subjects.

4. *The elements of suboptimal performance were both technical and cognitive.* Technical problems included choosing defibrillation energies appropriate for internal paddles when using external paddles, ampule swap, and failure to inflate the endotracheal tube cuff, resulting in a leak. Cognitive problems included failure to allocate attention to the most critical problems and fixation errors.

Figure 80-7 (Figure Not Available) Response times of anesthesiologists with different levels of experience to four simulated critical incidents: (A) Endobronchial intubation, (B) intravenous occlusion, (C) atrial fibrillation, and (D) airway disconnection. Detection time is shown with open circles, and correction time is shown with filled circles (see text for definitions of these times). Unless there is overlap between response times, each circle represents a single individual. The scale of response times is different for each event. There is substantial variability among incidents and among individuals. Although there was a trend to better performance with increased experience, major errors were made by individuals in all groups. *(From DeAnda and Gaba [90])*

Schwid and O'Donnell, [91] from the University of Washington, used the Anesthesia Simulator Consultant (ASC) screen-only simulator to perform an experiment similar to those of Gaba and DeAnda using a realistic simulator. This method enabled them to evaluate some elements of anesthetist behavior more carefully, albeit with the limitations imposed by presenting the OR "on the screen." After working on several practice cases without critical incidents, each subject was asked to manage three or four cases involving a total of four serious critical events (esophageal intubation, myocardial ischemia, anaphylaxis, and cardiac arrest). The progression of each event was mediated by the interaction of physiologic and pharmacologic models with the actions taken by the subject. The anesthesiologists studied had varying experience levels. One group was made up of ten anesthesia residents with at least 1 year of anesthesia training, whereas the other two groups contained ten anesthesia faculty members and ten private practitioners, respectively.

Major findings of the study included the following:

1. Significant errors in diagnosis or treatment were made in every experience group (Table 80-1) (Table Not Available) . The errors occurred

for both diagnosis of problems and for deciding on and implementing appropriate treatment. For example, 60 percent of subjects did not make the diagnosis of anaphylaxis despite available information on heart rate, blood pressure, wheezing, increased peak inspiratory pressure, and the presence of a skin rash. In managing myocardial ischemia, there were multiple failures (Table 80-2) (Table Not Available) .

2. Thirty percent of subjects did not compensate for severe abnormalities while considering diagnostic maneuvers.
3. Fixation errors were frequent in which initial diagnoses and plans were never revised, even when they were clearly wrong.

TABLE 80-1 -- Incidence of Totally Correct Diagnosis or Treatment of Simulated Critical Incidents Using the Anesthesia Simulator Consultant

(Not Available)

From Schwid and O'Donnell [91]

Westenskow et al [92] used a test lung and remotely activated faults in the breathing circuit to test the anesthetist's ability to identify faults related to ventilation and the anesthesia breathing circuit after hearing an alarm. One group of subjects used standard alarms, set to factory defaults, of an Ohmeda Modulus II anesthesia machine, which included a capnograph. The other group used the same anesthesia machine with the alarms disabled along with a neural network-based intelligent alarm and fault identification system. The mean "human response time," which was the time between the sounding of the first alarm and the time of event identification, ranged from approximately 15 seconds for airway disconnection to approximately 90 seconds for an endotracheal tube cuff leak. The 10 anesthesiologists tested with the standard alarm setup were unable to identify the fault within 2 minutes on 11 occasions--5 cuff leaks, 3 airway obstructions, and 3 stuck-open expiratory valves. However, in such circumstances, they did take appropriate compensatory actions while continuing to search for the cause (e.g., increasing the fresh gas flow to compensate for a cuff leak).

The intelligent alarm apparatus used data from three sensors (in-line capnograph, spirometer, and airway pressure). A neural network determined whether any of seven faults was present, and if so, displayed a text message specifying the fault as well as an animated diagram of the lung, airway, and anesthesia breathing circuit with the faulty component highlighted in red. Interestingly, the smart alarm system took slightly longer on average to detect a fault than did the conventional alarm system (25 versus 21 seconds), but the human response time was markedly reduced for three of the seven faults. There were no statistically significant differences between anesthesia residents and faculty members using either alarm system.

The investigators suggested that the more specific alarm messages in their intelligent alarm system could direct the attention of the anesthetist to the occurrence of specific problems and in so doing would decrease workload and reduce the likelihood of fixating on inappropriate information. They stated that such a system's advantages would be even greater in a more realistic clinical environment in which the anesthetist has multiple complex tasks, not just the detection and identification of ventilation-related events.

Complex, Multiple Personnel Simulations of Anesthetic Crises

In the process of evaluating a new type of training for anesthetists concerning crisis management, Howard et al [93] collected anecdotal data on the responses of teams of anesthetists, surgeons, and nurses to planned (and unplanned) critical events. These experiments largely confirmed the results of the studies described earlier and extended them to

TABLE 80-2 -- Failure Rate in the Management of Simulated Myocardial Ischemia Using the Anesthesia Simulator Consultant

(Not Available)

From Schwid and O'Donnell [91]

include more complex management issues and team interactions. Howard and coworkers found a substantial incidence of difficulties in managing multiple problems simultaneously, applying attention to the most critical needs, acting as team leader, and communicating with personnel and using all available OR resources to best advantage.

Botney et al [94] [95] analyzed similar videotapes from 18 different simulator training sessions on crisis management. In one event, a volatile anesthetic vaporizer had been left on at 4 percent and was hidden beneath a printout from the noninvasive blood pressure monitor. Simultaneously, there was a mechanical failure of the capnograph, making it impossible to confirm endotracheal intubation using CO_2 measurements. This event purposefully presented an invitation to become fixated on the endotracheal tube while ignoring other relevant information. Five of 18 subjects never discovered the volatile anesthetic overdose despite catastrophic effects on blood pressure and heart rate and clear evidence that the endotracheal tube was correctly placed. Of those who did detect the vaporizer setting, the average time to

detection was nearly 4 minutes, with some subjects taking more than 12 minutes.

In the second event studied, there was a loss of pipeline O_2 supply while an anesthetist was assuming the care of a critically ill patient who required an inspired O_2 fraction (F_{IO_2}) of 100 percent to achieve satisfactory blood oxygenation. The O_2 cylinder on the machine was empty (i.e., it had not been checked by the initial anesthetist, who left the case after becoming ill). The pipeline failure was quickly detected (19 seconds), but the responses to it were extremely variable and showed a variety of problems. Five of 18 anesthetists closed the anesthesia circuit (which preserves the existing oxygen in the circuit), but all 5 subsequently switched to ventilation with a self-inflating bag using room air or to mouth-to-tube ventilation. Five of 18 could not open the reserve oxygen cylinder because they could not locate the tank wrench attached to the machine (it tended to rest between two gas cylinders). Several teams had trouble in mounting a new oxygen tank on the anesthesia machine; problems with the gasket disk were frequent. The individuals did not appear to have a well-formulated plan for managing this event, and they did not optimally coordinate their actions with their assistants or with the other OR personnel.

Indirect Observation of Anesthetists Involved in Difficult Cases

An unusual approach involving indirect observation of actual cases was used by Cook et al [9] at the Ohio State University. Rather than collecting data on the case itself, these investigators transcribed the discussions of interesting cases occurring at a weekly quality assurance conference. They argued that this approach allowed them to apply a "neutral observer criterion" to the behavior of the anesthetist. The investigators acknowledged the risks of hindsight bias and selection bias of this methodology, but they suggested that their technique provided a unique window on human performance issues.

Fifty-seven cases were analyzed, of which 21 had a full cognitive analysis for the final report. From the presentation and discussion of a case, the investigators classified the evolution of the events into one of five categories: acute incident, going-sour incident, inevitable outcome incident, difficult airway incident, and no-incident incident. For each case, the cognitive analysis was "based on using knowledge about the cognitive demands of the task domain and data about practitioner activities to analyze practitioner's information processing strategies and goals, given the resources and constraints of the situation." The investigators postulated a cognitive cycle described by Neisser [96] as a component of data-driven activation of knowledge and knowledge-driven observation and action.

Cook et al [9] called attention to several issues that surfaced in their cognitive analysis of these cases. These include the following:

1. *Multiple themes.* Many cases involved several lines of concern simultaneously, each of which could have interacted with another (e.g., tight coupling). Each theme had multiple means available to deal with it. Maintaining "situation awareness" was important. The multiple themes sometimes generated competing or conflicting goals. Adaptive planning (as described in the section on the abstract task analysis) was sometimes required.
2. *Unusual situations.* The greatest expertise was seen with infrequent or unusual situations, rather than with typical situations.
3. *Allocation of attention.* The allocation of attention to relevant stimuli or to the most important "theme" was an important issue. The attentional shifts were not always well supported by existing alarm and display technologies.
4. *Cognitive workload.* Anesthetists attempted to reduce their cognitive workload whenever possible.
5. *Team interaction.* Cooperative work, team interaction, and communications issues were problems in several cases. These stemmed from both individual and organizational failures to coordinate information and efforts from different organizational components (e.g., ICU and OR, or surgeons and anesthesiologists).

Direct Observation of Anesthetists

A team of cognitive scientists and anesthesiologists at the University of Toronto [97] [98] conducted direct observations of anesthesiologists and obtained verbal "think aloud" protocols during actual case management. Their work centered on the active management of workload and is discussed later in this chapter.

Video Analysis of Actual Trauma Resuscitations and Anesthetics

Mackenzie et al [99] [100] [101] pioneered the analysis of actual clinical care of anesthetists captured on videotape, focusing on trauma resuscitations and anesthesia of trauma patients at the Maryland Shock Trauma Unit. The sophisticated recording system captures audio, video, and vital signs data and only requires the clinicians to insert a videotape to start the whole system. Analyses of these cases have revealed inadequacies in the availability and arrangement of monitoring

equipment, nonexistent or ambiguous communication, and weak interactions between the anesthesia care team and the surgical team. [101]

Problems faced by all investigators are the lack of an accepted standard for objective or subjective evaluation of anesthetist performance and the absence of an agreed-on methodology for analyzing and describing anesthetist performance. Several of the previously mentioned groups are working on methodologies for evaluating both technical and behavioral aspects of performance. [102] [103] [104] [105] [106] [107] The measurement of complex performance is a difficult problem, and it is likely to be some time until there is a well-established metric for performance assessment (see the later section on performance evaluation using patient simulators).

COGNITIVE PROCESS MODEL OF THE ANESTHETIST

The empirical data can best be interpreted in accordance with an explicit model of the cognition involved in the anesthetist's performance. Several investors [9] [10] [14] [39] [40] [41] [60] [97] [98] [108] [109] [110] [111] [112] [113] [114] have written about the cognitive elements in anesthesiology. The model I have developed is explicit, comprehensive, and specific to anesthesia. It is described in detail as a framework for understanding the empirical data and provides a vocabulary for discussing the elements of both successful and unsuccessful performance by anesthetists. However, this model draws heavily from the work of Woods and Cook and from a number of other investigators [8] [9] [18] [83] [84] [85] [86] [87] [115] [116] [117] [118] [119] [120] [121] [122] [123] studying human performance in a variety of complex, dynamic worlds.

Decision-Making Involves Multiple Levels of Mental Activity

The model (Fig. 80-8) (Figure Not Available) depicts the anesthetist as working at five different interacting cognitive levels to implement and control a core process of observation, decision, action, and reevaluation. The core process must then be integrated with the behavior of other team members and with the constraints of the work environment.

The division of mental activities into levels follows the work of Rasmussen [17] [86] [124] and Reason. [8] [125] [126] Having multiple levels supports parallel processing (performing more than one task at a time) and multitasking (performing only one task at a time, but switching very rapidly from one task to another). The anesthesia task analyses [44] [45] [46] [47] [48] [49] [50] [51] [52] [53] [54] and the direct observations of anesthetists in Toronto [97] [98] have provided clear evidence for the occurrence of parallel processing and multitasking.

At the sensorimotor level, activities involving sensory perception or motor actions take place with minimal conscious control; they are smooth, practiced, and highly integrated

Figure 80-8 (Figure Not Available) Cognitive process model of the anesthetist's real-time problem-solving behavior (see text for detailed description). Five levels of cognition operate in parallel. The core process involves a main loop (heavy black arrows) of observation, decision, action, and reevaluation. The core process is managed by two levels of metacognition, involving supervisory control, allocation of attention, and resource management (above the core process). Each component of the model requires different cognitive skills, and each component is vulnerable to a different set of performance failures or "errors." BP, blood pressure; CO, cardiac output; MAP, mean arterial pressure; SVR, systemic vascular resistance. *(From Gaba et al [41])*

patterns of behavior. At the procedural level, the anesthetist performs regular routines in a familiar work situation. These routines have been derived and internalized from training and from previous work episodes. A level of abstract reasoning is used during preoperative planning, and intraoperatively it is used in unfamiliar situations for which no well-practiced expertise or routine is available from previous encounters.

Dynamic Adaptation of the Anesthetist's Thought Processes

Rasmussen's model [17] [86] [124] was extended by the explicit addition of two additional levels of mental activity that provide for dynamic adaptation of the anesthetist's own thought processes. This ability to "think about thinking" in order to control one's own mental activities strategically is called *metacognition* by psychologists, [83] [121] and it is thought to be an important component of working in complex, dynamic domains. Supervisory control is concerned with dynamically allocating finite attention between routine and nonroutine actions, among multiple problems or themes, and among the five cognitive levels. Resource management deals with the command and control of available resources, including teamwork and communication. [127] [128]

Core Process

Observation

Management of rapidly changing situations requires the anesthetist to assess a wide variety of information sources. These include visual observation of the patient and the surgical field, visual inspection of a multitude of displays from electronic monitors, visual observation of the activities of nurses and the contents of suction cannisters and sponges, listening for normal and abnormal sounds from the patient and equipment; interpreting radiographs, and the reading of reports of laboratory test results. Because the human mind can only attend closely to one or two items at a time, the anesthetist's supervisory control level must decide what information to attend to and how frequently to observe it.

The multitasking involved in observing multiple data streams was probed by the experiments measuring secondary task performance and vigilance. The realistic simulation studies demonstrated the large number of information sources actually used during the response to a critical event. Routine parts of the core process operate primarily at the sensory motor and procedural levels and are executed repetitively throughout the course of an anesthetic. The results from the UCSD/VA-Stanford group concerning the vigilance of experienced anesthetists compared with novices suggest that the novices had not fully developed their core process as a highly automated function, requiring them to devote more mental resources to routine activities.

Verification

In the OR environment, the available information is not always reliable. Most monitoring is noninvasive and indirect and is therefore susceptible to artifacts (false data). Even direct clinical observations such as vision or auscultation can be ambiguous. Brief transients (true data of short duration) can occur that quickly correct themselves. To prevent them from triggering precipitous actions that may have significant side effects, critical observations must be verified before the clinician acts on them. Verification uses a variety of methods:

1. Repeating the observation or observing the short-term trend.
2. Observing an existing redundant channel (e.g., invasive arterial pressure and cuff pressure are redundant).
3. Correlating multiple related (but not redundant) variables (e.g., heart rate, heart rhythm, and blood pressure).
4. Activating a new monitoring modality (e.g., placing a pulmonary artery catheter).
5. Recalibrating an instrument or testing its function.
6. Replacing an entire instrument with a back-up device.
7. Asking for a second opinion from other trained personnel.

Knowing when and how to verify data is a good illustration of strategic knowledge (metacognition). For example, the anesthetist must decide under what conditions it

is useful to invest time, attention, and energy in establishing a new information source (e.g., a pulmonary artery catheter) in the middle of a case, rather than relying on more indirect information sources that are already in place.

Problem Recognition

Whereas anesthetists are taught the importance of scanning their instruments and environment, they must use these observations to decide whether the patient's course is "on track" or whether a problem is occurring. If a problem is found, a decision must be made as to its identity and its importance. This process of problem recognition (also known as situation assessment) is a central feature of several theories of cognition in complex, dyna-mic worlds. [88] [110] [123] [129] [130] [131] Problem recognition involves matching sets of environmental cues to patterns that are known to represent specific types of problems. Given the high uncertainty seen in anesthesia, the available information sources cannot always disclose the existence of a problem, and even if they do, they may not specify its identity or origin. Westenskow's [92] experiment with the intelligent alarm system mainly probed these parts of problem recognition. In this experiment, subjects were already alerted to the existence of a problem by an alarm, so they could immediately focus their attention specifically on information sources concerning ventilation. In 11 cases, the fault could not be identified, but there was successful compensation for the fault, as described in the next paragraphs.

The supervisory control level mediates the decision when a clear-cut match or "diagnosis" cannot be made. Anesthetists and other dynamic decision-makers use approximation strategies to handle these ambiguous situations; psychologists term such strategies *heuristics.*[132] One heuristic is to categorize what is happening as one of several "generic" problems, each of which encompasses many different underlying conditions. Another is to gamble on a single diagnosis

(frequency gambling [125]), initially choosing the single most frequent candidate event. During preoperative planning, the anesthetist may adjust a mental "index of suspicion" for recognizing certain specific problems anticipated for that particular patient or surgical procedure. The anesthetist must also decide whether a single underlying diagnosis explains all the data, or whether these data could be due to multiple causes. [9] [11] [115] This decision is important because excessive attempts to refine the diagnosis can be very costly in terms of allocation of attention. By contrast, a premature diagnosis can lead to inadequate or erroneous treatment. [133]

The use of heuristics is typical of expert anesthetists and often results in considerable time savings in dealing with problems. However, it is a two-edged sword. Both frequency gambling and inappropriate allocation of attention solely to expected problems can seriously derail problem solving when these gambles do not pay off if the reevaluation component of the core process does not correct the situation.

Prediction of Future States

Problems must be assessed in terms of their significance for the future states of the patient. [88] [110] Those problems that are already critical or that can be predicted to evolve into critical incidents receive the highest priority. Prediction of future states also influences action planning by defining the time frame available for required actions. Cook and Woods [9] described "going sour" incidents in which the future state of the patient was not adequately taken into account when early manifestations of problems were apparent.

Precompiled Responses and Abstract Reasoning

Having recognized a problem, how does the expert anesthetist respond? The classic paradigm of decision-making posits a careful comparison of the evidence with various causal hypotheses that can explain them. [26] This is then followed by a careful analysis of all possible actions and solutions to the problem. This approach, although powerful, is relatively slow and does not work well with ambiguous or scanty evidence. In complex, dynamic domains such as anesthesia, many problems require quick action to prevent a rapid cascade to a catastrophic adverse outcome. For these problems, deriving a solution through formal deductive reasoning from "first principles" is too slow.

In complex, dynamic domains, the initial responses of experts to the majority of events stem from precompiled rules or response plans for dealing with a recognized event. [8] [17] [125] This method is referred to as *recognition-primed decision-making,*[85] [134] because once the event is identified, the response is well known. In the anesthesia domain, these responses usually are acquired through personal experience alone, although there is a growing realization that critical response protocols need to be codified explicitly and taught systematically. [41] Experienced anesthetists have been observed to rearrange, recompile, and rehearse these responses mentally based on the patient's condition, the surgical procedure, and the problems to be expected. [9] [97] Ideally, precompiled responses to common problems are retrieved appropriately and are executed rapidly. When the exact nature of the problem is not apparent, a set of generic responses appropriate for the overall situation may be invoked. For example, if a problem with ventilation is detected, the anesthetist may switch to manual ventilation using a higher F_{IO_2} while considering further diagnostic actions.

However, the experiments involving screen-only [91] and realistic [90] [93] [94] [95] [104] simulators have demonstrated that even experienced anesthetists show great variability in their use of response procedures to critical situations. This finding has led these investigators to target simulator-based training on the systematic training in responses to critical events.

Even the ideal use of precompiled responses is destined to fail when the problem does not have the suspected cause or when it does not respond to the usual actions. Anesthesia cannot be administered purely by precompiled "cookbook" procedures. Abstract reasoning about the problem utilizing fundamental medical knowledge still takes place in parallel with precompiled responses even when quick action must be taken. This seems to involve a search for high-level analogies [8] [125] or true deductive reasoning using deep medical and technical knowledge and a thorough analysis of all possible solutions. Anesthetists managing simulated crises have linked their precompiled actions to abstract medical concepts. [91] It is unclear whether this represented merely self-justification, as opposed to true abstract reasoning, in part because the particular simulated crises they faced did not require novel abstract solutions. At this time, the degree to which abstract reasoning is necessary for optimal intraoperative crisis management is unknown.

Action Implementation

A hallmark of anesthesia practice is that anesthetists do not just write orders in a patient's chart; they are directly involved in implementing the desired actions. Action implementation can usurp a large amount of the anesthetist's attention. In addition, anesthetists engaged in a manual procedure are strongly constrained from performing other manual tasks, as demonstrated in several of the mental workload and vigilance studies described earlier.

Errors in executing a task are termed *slips,* as distinguished from errors in deciding what to do, which are termed *mistakes.*[117] [135] Slips are actions that do not occur as planned, such as turning the wrong switch or making a syringe swap. Thus, when critical incident [136] [137] and quality assurance studies described "technical errors" in using equipment, they were referring to slips, whereas "judgment errors" referred to mistakes. One particular type of execution error, termed a *mode error,*[117] is becoming more frequent in all domains with the increased use of microprocessor-based instrumentation and devices. [58] [59] [60] [138] In a mode error, actions appropriate for one mode of a device's operation are incorrect for another mode. An example in anesthesiology is the "bag/ventilator" selector valve in the anesthesia breathing circuit, which selects between two modes of ventilation. Failing to activate the ventilator when in the "ventilator mode" can be catastrophic. Mode errors can also occur

for monitoring or drug delivery devices if they assign different functions to the same displays or switches depending on the mode of operation selected.

Particularly dangerous slips of execution can be addressed through the use of *engineered safety devices*[13] that physically prevent incorrect actions. For example, newer anesthesia machines have interlocks that physically prevent the simultaneous administration of more than one volatile anesthetic drug. Other interlocks physically prevent the selection of a gas mixture containing less than 21 percent O_2 .

Certain very complex issues concerning human-machine interactions and the ways in which technology affects behavior in complex patient care environments are

beyond the scope of this chapter. Other publications address these issues. [3] [4] [5] [6] [59] [60] [135]

Reevaluation

In order to cope with the rapid changes and the profound diagnostic and therapeutic uncertainties seen during anesthesia, the core process must include repetitive reevaluation of the situation. Thus, the reevaluation step returns the anesthetist to the observation phase of the core process, but with the following specific assessments in mind:

1. Was the initial situation assessment or diagnosis correct?
2. Did the actions have any effect? (e.g., did the drug reach the patient?)
3. Is the problem getting better, or is it getting worse?
4. Are there any side effects resulting from previous actions?
5. Are there any new problems or other problems that were missed before?

The process of continually updating the situation assessment and of monitoring the efficacy of chosen actions is termed *situation awareness.*[88] [123] [129] [130] [131] There has been a review of situation awareness issues in anesthesiology. [110]

Fixation Errors

Faulty reevaluation, inadequate plan adaptation, or loss of situation awareness can result in a type of human error termed a *fixation error.*[116] [140] A fixation error is the persistent failure to revise a diagnosis or plan in the face of readily available evidence that suggests that a revision is necessary. This type of error is extremely common in dynamic situations. There are three main types of fixation errors [116] [140] .

1. This and only this:

   Persistent failure to revise a diagnosis or plan despite plentiful evidence to the contrary.

   Available evidence interpreted to fit the initial diagnosis.

   Attention allocated to a minor aspect of a major problem.

2. Everything but this:

   Persistent failure to commit to the definitive treatment of a major problem.

   Extended search for information made without ever addressing potentially catastrophic conditions.

3. Everything is OK:

   Persistent belief that no problem is occurring in spite of plentiful evidence that it is.

   Abnormalities attributed to artifacts or transients.

   Failure to declare an emergency or accept help when facing a major crisis.

Fixation errors have been described by all the investigators conducting experimental studies of anesthetist responses to abnormal situations. [90] [91] [94] [111]

Management and Coordination of the Core Process

The empirical studies have clearly demonstrated that attention sharing is needed among cognitive levels, among tasks, and often among problems. The intensive demands on the anesthetist's attention could easily swamp the available mental resources. Therefore, the anesthetist must strike a balance between acting quickly on every small perturbation (which requires a lot of attention) and adopting a more conservative "wait-and-see" attitude. This balance must be constantly shifted between these extremes as the situation changes. However, during simulated crisis situations, some practitioners showed a great reluctance to switch from "business as usual" to "emergency mode" even when serious problems were detected. Erring too far in the direction of "wait and see" is an error that can be particularly catastrophic.

In addition to the attentional demands of the anesthetist's core tasks, the OR environment is full of distractions. Routine events, such as turning the OR table or repositioning the patient, distract attention from the main process of conducting the anesthetic. Noise is prevalent, with peak levels exceeding that of a freeway. [141] [142] Practitioners find false auditory alarms from monitors or other equipment to be extremely distracting. [143] [144] [145] [146] [147] Other distractions include teaching in progress, [148] incoming telephone calls, background music, and conversation with OR personnel. Expert anesthetists modulate the distractions, eliminating them when the workload is high while allowing them to occur when workload is low (in order to improve morale and team building).

One major aspect of strategic control of attention is the active management of workload. Rather than passively dealing with rising or falling workload, the anesthetist actively manages it. Schneider and Detweiler [149] and Gopher (position paper, Conference on Human Error in Anesthesia, Asilomar, Calif, 1991) described the theoretical basis for a variety of strategies of workload management. These strategies have been addressed specifically for anesthesiology by several investigators. [9] [40] [41] [97] The anesthetist actively manages workload by the following techniques.

1. *Avoiding high workload situations:* Experts may choose techniques and plans that reduce the workload (especially when their individual and team resources are limited), even when those plans are marginally inferior from a technical standpoint. For example, a single anesthetist may choose not to use a high-technology, high-workload monitor such as TEE, because of the high workload required to use it properly.
2.

   Distributing workload over time: The anesthetist can prepare for future tasks when the current load is low (preloading) and can delay or shed low-priority tasks when the workload is high (offloading). Resources that require a significant amount of workload to prepare, such as intravenous infusions, are often made ready before the case starts. Multitasking is also a way to distribute work over time. Each task is made up of several subtasks, each of which has a finite duration. Because close attention may not be required during each of these subtasks, they can be interleaved with a fixed amount of attention (multiplexing). Multiplexed tasks must be scheduled and coordinated in real time by the supervisory control level.
3. *Distributing workload over personnel:* When workload cannot be distributed over time, and when additional resources are available, tasks can be distributed to them. Some resources are internal to the individual anesthetist, whereas others require additional personnel. For example, a single anesthetist can simultaneously ventilate the patient by hand, assess the cardiac rhythm, and discuss patient care with the surgeon. The single anesthetist cannot simultaneously insert a pulmonary artery catheter and ventilate the patient's lungs by hand. If these tasks are to be performed at the same time, they must be assigned to different individuals.
4. *Changing the nature of the task:* The nature of a task is not fixed. Surgery and anesthesia can be postponed or aborted. Tasks can be executed to different standards of performance; as the standards are loosened, the workload required to perform them is reduced. For example, during periods of massive blood loss, the anesthetist focuses primarily on administering blood and fluids and on monitoring the blood pressure. In such cases, less critical tasks such as writing on the

anesthesia record are offloaded to lessen the workload. The acceptable limits of blood pressure will also be widened.

Special rules may be adopted to help manage tasks. Xiao et al [96] cited the example of an anesthetist who always left his hand on the ventilator power switch when turning it off transiently as a reminder to turn it back on again. Such a technique helps to prevent this critical subtask from becoming forgotten during high workload periods or when unanticipated events usurp attention from planned tasks.

Action Selection and Scheduling

At any time during an anesthetic regimen, there may be multiple things to do, each of which is intrinsically appropriate, yet they cannot all be done at once. The simulator experiments have shown that anesthetists sometimes have difficulty in selecting, planning, and scheduling actions optimally. The anesthetist must consider the following factors:

1. Preconditions are necessary for carrying out the actions (e.g., it is impossible to measure a thermodilution cardiac output if there is no pulmonary artery catheter in place).
2. Constraints are placed on the proposed actions (some actions are incompatible with other aspects of the situation; e.g., it is impossible to check the diameter of the pupils when the head is fully draped in the surgical field).
3. Side effects of the proposed actions often play a controlling role in choosing among possible drug therapies.
4. Rapidity and ease of implementation of proposed actions are factors; those that are easily and rapidly performed are preferred over those that require more time, attention, and skill.
5. Certainty of success of the actions is often traded off against rapidity and ease of implementation (under some circumstances, the higher certainty of success of a set of actions justifies the investment of time, attention, and resources needed to implement them).
6. Reversibility of the action and the cost of being wrong are considered, with rapidly reversible actions preferred over those that cannot be reversed, especially when potential side effects are significant.
7. Cost of the action in terms of attention, resources, and money is taken into account.

Experts in other complex, dynamic domains (specifically tank commanders and fire chiefs) have been observed [85] to conduct a mental simulation of the actions they are contemplating to determine whether there are hidden flaws in their plans. Anesthetists have been observed [9] [97] [98] to rehearse a plan mentally in advance of a case, but the degree to which this is done in real time is not known. Because most actions can be executed incrementally, as in titrating a drug in small aliquots, adverse consequences can often be discovered through repetitive reevaluation.

Resource Management

The ability of the anesthetist to command and control all the resources at hand to execute the anesthetic regimen as planned and to respond to problems that arise is termed *resource management* (another concept first described in aviation that applies equally well to anesthesiology). This involves translating the knowledge of what needs to be done into effective team activity, taking into account the limitations of the complex and ill-structured OR, PACU, or ICU domain. Resource management explicitly requires teamwork and crew coordination. It is not enough for the anesthetist to know what to do or even to be able to do each task alone. The anesthetist can only accomplish so much in a given time, and there are some tasks that can only be performed by other skilled personnel (e.g., laboratory tests, taking radiographs). When the task load exceeds the resources available, the anesthetist must mobilize help and must distribute the tasks among those present. Many issues concerning optimum resource management and crew coordination are not yet well understood and are the focus of active research by cognitive scientists and experts in many complex and dynamic domains. [150] [151] Research in aviation has already demonstrated that a large proportion of aircraft accidents was linked to failures on the part of crews with appropriate technical skills to manage the flight deck effectively. [83] [127] [152] [153] [154] The hallmarks of resource management derived from these studies include the following:

1. Prioritization of tasks.
2. Distribution of workload.
3. Leadership and crew coordination.
4. Communication.

5. Mobilization and use of all available resources.
6. Monitoring, cross-checking, and utilization of all available data.

Complex multiple personnel simulations of anesthetic crises addressed these issues. Although the data from these sessions are still preliminary, it appears that poor supervisory control and resource management were substantial components of suboptimal management of the simulated crises. [94] [95] In other words, like the pilots, anesthetists had the knowledge and technical skill to manage the patient, but they failed to manage their environment properly to achieve success.

Resource management is now taught systematically to crew members of all major U.S. airlines through training programs in Crew (originally "cockpit") Resource Management (CRM). [151] A similar program in anesthesiology is described in the section of this chapter dealing with anesthesia simulators.

SOCIAL PSYCHOLOGY AND ANTHROPOLOGY OF THE OPERATING ROOM ENVIRONMENT

Unlike teams in aviation, the military, or police and fire services, the OR team is unusual in that there is an ambiguous command structure. The physicians (surgeon and anesthesiologist) are nominally superior to nursing and technical staff, but the physicians are coequally responsible for the patient during the immediate perioperative period. Each physician, as well as the nurses and technicians, has a primary territory of knowledge, skill, and responsibility, but there is considerable overlap among them.

Strictly speaking, a team is defined as "a distinguishable set of two or more people who interact, dynamically, interdependently, and adaptively toward a common and valued goal/objective/mission, who have each been assigned specific roles or functions to perform, and who have a limited life-span of membership." [122] A team is distinct from a group in that a group is an ad hoc collection of individuals without a specific mission and without specific roles. [122] In the OR, all team members have the common goal of a good outcome for the patient. However, there can be considerable disagreement on how to achieve this goal and which elements of patient care have the highest priority. These differences are probably traceable to the fact that the OR team is itself made up of several crews (i.e., surgery, anesthesiology, nursing, perfusionist, radiology), each of which has its own command hierarchy, its own global properties (professional standing, culture, traditions, and history), and its own set of local goals and objectives for management of the patient. The differences among the crews can be so striking that some investigators refer to them as separate tribes (transcript of Conference on Human Error in Anesthesia, Asilomar, Calif, 1991).

Crew members work together to form a crew, and crews work together to form a team. A critical component of the success of this process is the establishment and maintenance of a shared mental model of the situation. [121] To the degree that this can be accomplished, the different individuals will be able to tailor their efforts toward a common goal. Experience working together as a crew or team will improve the likelihood of generating a shared mental model.

As yet, there are few data about these issues in the OR, concerning both the interactions within the anesthesia crew and the interaction between the anesthesia and surgical crews. Gild and Posner led a team at the University of Washington investigating the relationships between cardiac anesthetists and cardiac surgeons in and out of the OR using ethnographic (anthropologic) techniques. These investigators tentatively identified several areas for more intensive study, including coordination between perfusionists and anesthesiologists during cardiopulmonary bypass (CPB), sharing of control during weaning from CPB, and methods used by anesthetists and surgeons to resolve conflicts (presented at the annual meeting of the Society for Technology in Anesthesia, 1993).

A more recent study of crew and team behaviors in operating rooms was carried out in Basel, Switzerland. [103] [155] The authors found that "communication at the interface between anesthesia and surgical teams was classified as unacceptable/absent in approximately 20 percent of the observations." These communications were rated "within the lower half of the scale" in 70 percent of observations.

Status and Hierarchy Effects

Status and hierarchy effects are important in team performance. Especially in crisis situations, the lower-status crew member tends to defer to the higher-status individual, even if that individual is performing poorly. In aviation, some airplane crashes have occurred in which overbearing captains were combined with unassertive subordinates (first officer copilot and flight engineers). The team was not able to respond effectively, even when the subordinates knew that something was wrong. [156]

In aviation, as in academic anesthesia, training is an ongoing activity in the domain. Although the captain is in charge of the flight, the captain and the first officer (who is essentially in training to become a captain) traditionally alternate the roles of "pilot flying" and "pilot not flying" on each leg of a flight. Each of these roles is carefully defined and involves separate but interrelated tasks (the pilot flying handles the flight controls, whereas the pilot not flying handles radio communications and other tasks). In anesthesiology, the roles of the trainee and the faculty member during patient care are rarely made explicit. The trainee is often expected to do all tasks with only occasional assistance from the supervisor (part of a training method known as *cognitive scaffolding*). The exact responsibility for different tasks in a crisis is not predefined. Interestingly, two factors frequently found to be associated with critical incidents in anesthesia have been "teaching in progress" and "inadequate supervision." [148]

Production Pressure

The social and organizational environment may also act as a source of production pressure on anesthetists. Production pressure encompasses the economic and social pressures on workers to place production, not safety, as their primary priority. [13]

In anesthesiology, this typically means keeping the OR schedule moving speedily, with few cancellations and minimum time between cases. When anesthetists succumb to these pressures, they may skip appropriate preoperative evaluation and planning, or they may fail to perform adequate pre-use checkout of equipment. Even when preoperative evaluation does take place, overt or covert pressure from surgeons (or others) can cause anesthetists to proceed with elective cases despite the existence of serious or uncontrolled medical problems. Production pressures can cause anesthetists to choose techniques that they otherwise believe to be inadvisable.

Gaba et al [157] reported on a randomized survey of California anesthesiologists concerning their experience with production pressures. They found that 49 percent of respondents had witnessed a situation in which patient safety was compromised by pressure on the anesthesiologist. Thirty percent reported strong to intense pressure from surgeons to proceed with a case they wished to cancel. Notably, 20 percent agreed with the statement that "If I cancel a case, I might jeopardize working with that surgeon at a later date." The economic pressures are obvious. Production pressure also leads to haste by the anesthetist, a psychologic precursor to the commission of unsafe acts. In the survey, 20 percent of respondents answered "sometimes" to the statement "I have altered my normal practices in order to speed the start of surgery," whereas 5 percent answered "often" to this statement. Twenty percent of respondents rated pressure by surgeons to hasten anesthetic preparation or induction as strong or intense. Repeated exposure to these conflicts can cause the anesthetist to internalize pressures; 38 percent of survey respondents felt strong to intense internal pressure to "get along" with surgeons, and 48 percent reported strong internal pressures to avoid delaying cases. They may then feel impelled to go ahead with cases against their better judgment, even in the absence of overt pressure. Investigating these aspects of the work environment is difficult because these relationships are driven by economic considerations as well as by the complex organizational and interpersonal networks linking the different medical cultures. Changing the environment will be equally challenging.

/das/book/view/29494766/875/882.html

PERFORMANCE-SHAPING FACTORS

With a few exceptions, the foregoing discussion of the performance of skilled anesthetists has assumed that they are normally fit, rested, and acting in a standard working environment. Experience in human performance in the laboratory and other domains suggests that there are profound effects on the abilities of even highly trained personnel from internal and external performance-shaping factors. The degree to which performance-shaping factors affect the overall performance of anesthetists and the outcomes for patients is highly uncertain. In extreme cases, such as profound fatigue, there is no question that these factors can result in severe degradation of the anesthetist's performance or even complete incapacitation. However, these extreme conditions are quite unusual, and it is unclear whether the levels of performance decrement likely to be induced in typical work situations have any significant effect. Although the practice of anesthesia does require an attentive and skilled individual, it does not require peak human performance. It would be unrealistic to expect peak performance for every anesthetic regimen because there are on the order of 60,000 anesthetic regimens administered each day in the United States by a total of approximately 40,000 to 60,000 anesthetists.

With these caveats in mind, however, there are several performance-shaping factors that are potentially of sufficient magnitude to be of concern. Ambient noise, music, fatigue and sleep deprivation, aging, illness, drug use, and attitudes are discussed later. Several other factors that are not discussed include the level of illumination and environmental temperature. These can be shown to have a performance-shaping effect in the laboratory, [2] [158] but it is uncertain how much they affect performance in the OR.

Ambient Noise and Music in the Operating Room

The OR is a relatively noisy work environment. [141] [142] [159] [160] Mean sound levels are considerably higher than in most offices or control rooms (continuous air movement through an open surgical suction tip is a common source of continuous noise), whereas peak sound levels can be quite high. Some sources of noise are uncontrollable, such as surgical drills, monitor alarms, or inadvertently dropped instrument pans; other sources are controllable, such as conversation and music (see later). There is evidence in the general literature that noise can adversely affect human performance. [161] [162] Furthermore, studies by Murthy et al [163] demonstrated that volume-accurate replay of recordings of OR noise significantly interfered with the speech-discrimination ability of anesthesia residents during laboratory testing. The OR noise also caused a significant reduction in residents' performance on psychometric tests of mental efficiency and short-term memory. [164] The potential interference of noise with communication among personnel in the OR is particularly worrisome to those concerned with optimizing teamwork in this complex work environment.

The use of music in the OR is now widespread. Many health-care professionals believe that music enlivens the work day and can build team cohesiveness when all team members enjoy the music. A controversial study by two social psychologists, Allen and Blascovich, [165] suggested that surgeon-selected music improved surgeons' performance on a serial subtraction task and reduced their autonomic reactivity (i.e. "relaxed" them) when compared with control conditions with experimenter-selected music or no music at all. The methodology of the study has been criticized. [166] Anesthesiologists Swamidoss et al [167] presented preliminary data from a study of anesthesiologists' autonomic reactivity and problem-solving performance using a screen-based anesthesia simulator. They did not find any significant effect of "least enjoyed" music compared with either "most enjoyed" music or no music at all for autonomic reactivity or recognition and correction of simulated critical incidents.

In response to Allen and Blascovich, several anesthesiologists challenged the notion that the surgeon's preference for type or volume of music can or should override the needs of the other members of the team. [166] [168] This issue generates considerable controversy among surgeons and anesthesiologists. In a reply to some of the letters to the editor generated by their study, Allen and Blascovich [169] stated: "The letters here suggest that not everyone on the surgical team always

appreciates the type of music chosen by the surgeon, and anesthesiologists in particular appear to prefer silence in surgery. When we asked the surgeons in our study about this issue, we were told that the environment of surgery does not lend itself to the democratic process, and music was part of the environment in which they felt most comfortable."

There is no simple answer to the question of the proper role of music in the OR. Clearly, optimal patient care is the primary goal. Some surgical or anesthesia personnel explicitly forbid any type of music in the OR. A more common approach of many OR teams is to allow any team member to veto the choice or volume of music if they believe that it interferes with their work.

Reading in the Operating Room

The observation that some anesthetists were observed to read journals or books casually during patient care [170] led to a vigorous debate of the appropriateness of such an activity. [171] Although it is indisputable that reading *can* distract attention from patient care, there are no data at present to determine the degree to which reading *does* distract attention, especially if the practice is confined to low-workload portions of a case. Furthermore, many anesthetists pointed out that reading as a distraction is not necessarily any different from many other kinds of activities not related to patient care that are routinely accepted, such as idle conversation among personnel. [171] Many comments about the issue related not to the actual vigilance decrement induced by reading, but rather the impact of the negative perception of the practice (and of those who do it) by surgeons, and by patients (were they to be aware of it).

A noted researcher on human performance in anesthesia, Matt Weinger, was asked to comment on the practice of reading in the OR. [172] He pointed out that reading can combat boredom, which can be a significant distractor in its own right. He concluded that, in the absence of data specifically on the topic, it would be unscientific to condemn the practice outright, but that reading--like all other distractions--should not be allowed to impair vigilance and patient care. My colleagues and I teach, in our training course on anesthesia CRM, that the anesthetist is responsible for modulating *all* controllable distractions, for example, allowing music during routine work (if all agree) but eliminating it when the situation becomes complex or urgent. Similarly, although our own institution does not have a policy against reading in the OR (or against casual conversation for that matter), we *do* expect the anesthetist to terminate all incidental activities when necessary and to have a very low threshold for abandoning any potential distractions.

Sleep Deprivation and Fatigue *

General Principles

Scientists are discovering the importance of adequate sleep to allow normal human performance. A consensus report by the leaders in the field of sleep medicine stated that:

> [we] evaluated scientific and technical reports on the distribution throughout the 24-h day of medical incidents (such as heart attack and stroke) and performance failures (such as vehicular accidents and human errors in industrial and technical operations that can affect public safety). We found that these events occur most often at times of day coincident with the temporal pattern of brain processes associated with sleep. It thus appears that the occurrence of a wide range of catastrophic phenomena are influenced by sleep-related processes in ways heretofore not fully appreciated. <refref refref="r080010173" refnum="173">

This report goes on to give many examples of catastrophes that have occurred at least in part because of the effects of sleep deprivation and fatigue. Investigations in other complex industries (aviation, nuclear power, maritime, long-haul trucking) have identified fatigue as the probable cause, or a contributing factor, in many accidents. The National Transportation Safety Board (NTSB) determined that fatigue was a probable cause of the Exxon *Valdez* accident, one of the most visible and costly transportation accidents in history. Other disasters in which fatigue has been identified as causal or contributory include the nuclear disasters at Three Mile Island and Chernobyl and the space shuttle Challenger explosion.

Based on these findings, it is likely that chronic sleep dep-rivation, circadian rhythm abnormalities, and fatigue can be blamed for some iatrogenic adverse patient outcomes. However, it is difficult to determine the degree to which this is true. These factors have long been minimized or ignored by health-care professionals, and we believe that an understanding of them is critical to maximize patient safety.

Normal Sleep

Carskadon and Dement [174] referred to sleep as a reversible behavioral state of perceptual disengagement from and unresponsiveness to the environment that is usually accompanied by postural recumbancy, quiescence, closed eyes, and other indicators commonly associated with sleeping. Sleep can be thought of as a physiologic drive state similar to hunger or thirst and is necessary for the maintenance of alertness, performance, and overall well-being. The intensity of this drive can be inferred from noting how quickly an individual falls asleep. Just as eating and drinking satiate hunger and thirst states, sleeping reverses the desire to sleep.

The amount of sleep *required* by any individual is that which allows him or her to be awake and alert throughout the day. The average sleep time for young adults is 7 to 8 hours in a 24-hour period, with an approximately 15 percent interindividual variation. These sleep requirements are not constant and can vary over time.

Sleep is studied with a polysomnograph. Electrodes are placed on the scalp to monitor the electroencephalogram (EEG), near the eyes to monitor eye movements (extraoculogram [EOG]), and on the chin to monitor muscle tone (electromyogram [EMG]). Sleep is scored in 30-second epochs using standardized criteria to determine the particular sleep state and stage. [175] There are two states of sleep that can be distinguished from analysis of the EEG. The states are referred to as *non-rapid eye movement* (NREM) sleep

* This section was cowritten by Steven K. Howard, M.D., staff anesthesiologist, VA Palo Alto Health Care System, and assistant professor, Stanford University School of Medicine, Stanford, Calif.

and *rapid eye movement* (REM) sleep. NREM is further broken down into four stages (1, 2, 3, 4) based on the form of the EEG signal, in which stages 3 and 4 are sometimes combined together and referred to as delta sleep or slow-wave sleep (SWS). REM sleep is the state in which dreams occur most frequently, and it is characterized by EEG activation similar to the awake EEG, reversible muscle atonia, and rapid eye movements.

Sleep in normal individuals begins through an initial period of NREM sleep followed by the first REM period 80 to 110 minutes after sleep onset. NREM and REM sleep then cyclically alternate throughout the night approximately every 90 to 110 minutes. In young, healthy adults, SWS predominantly occurs during the first third of the night, whereas longer REM periods occur during the latter third. In healthy young adults without sleep complaints, NREM sleep accounts for 75 to 80 percent of sleep, whereas REM comprises 20 to 25 percent of sleep. SWS decreases dramatically as we age, whereas the percentage of time spent in REM sleep stays approximately the same. Brief awakenings (both reportable and nonreportable by the individual), which can fragment sleep and greatly diminish its quality, also increase in frequency with age. Elderly sleepers exhibit the greatest interindividual variability, making it particularly difficult to make broad generalizations regarding sleep-related issues for this population.

Sleep Debt

Individuals have their own particular sleep requirement in a 24-hour period. If adequate sleep is not obtained for whatever reason, daytime sleepiness and impaired performance ensue. Sleep loss is cumulative, resulting in what is referred to as a *sleep debt.* The individual who has obtained an optimal amount of sleep is better prepared to perform long periods of sustained work compared with one who is operating from a sleep debt.

Even minor sleep loss on a nightly basis can insidiously accumulate into a substantial sleep debt. [176] Importantly, the *only* way to pay back a sleep debt is with sleep. After accruing a sleep debt, the recovery sleep shows a particular pattern. SWS predominates over REM sleep. REM sleep rebound or recuperation follows after the body has recovered SWS. The reason for this prioritization of SWS over REM sleep is not known, but it may be due to a "restoring" effect of SWS.

Chronic sleep debts are commonplace in our culture. Shift work, long and irregular work hours, and the demands of family and recreation lead to irregular sleep patterns and prevent restful sleep. This may be particularly true for physicians, who often work in shifts, have long duty periods, and must frequently care for patients beyond normal working hours.

Fatigue

Fatigue is defined technically as a diminished ability to perform work, and it is caused by excessive physical or cognitive work. [177] Physical fatigue is usually produced by excessive muscular work. It is accompanied by a diminished ability of the muscles to respond, feeling of muscle tiredness, and a decrease in physical performance. Physicians are exposed to periods of physical fatigue during duty periods where they are asked to care for patients for long periods of time. For example, surgeons who participate in prolonged operations stand in the same position for many hours, leading to muscle fatigue.

There are also cognitive components to physical fatigue such as when the mind succumbs before the muscles. Mental fatigue is accompanied by subjective feelings of tiredness after periods of sustained performance on predominantly cognitive tasks. Nonstimulating environments also bring about feelings of boredom that can compound feelings of mental fatigue. Sleep deprivation accentuates the feelings of mental fatigue and probably also decreases an individual's motivation to perform during these periods. Mood, initiative, and enthusiasm all decline as fatigue progresses. Fatigue can also result from disturbed circadian rhythms.

Circadian Rhythms

Rhythms that fluctuate on a 24-hour time scale are known as *circadian rhythms,* from the Latin *circa,* meaning "about," and *dies,* meaning "day." The biologic clock that is responsible for these rhythms is located in the suprachiasmatic nucleus in the human brain. The best-known circadian rhythms are those of body temperature, hormone secretion, metabolism, and the sleep/wake cycle. The circadian system is synchronized to the 24-hour day by external stimuli referred to as *zeitgebers,* the most influential of which is the light/dark cycle of day and night.

The circadian system is biphasic, producing a state of increased sleep tendency and decreased performance capacity during two periods throughout the 24-hour day--from 2 AM to 6 AM and from 2 PM to 6 PM. These periods are sometimes referred to as *circadian lulls.* The circadian clock is very resistant to alterations, and it does not adjust rapidly to changes such as that produced by jet lag or shift work. Disruption of the normal circadian rhythm or incomplete circadian adaptation leads to acute and chronic sleep deprivation, decreased alertness, increased subjective fatigue, and decreased physical and mental performance. [178]

Sleepiness and Alertness

Sleepiness and alertness are at opposite ends of a continuum. The most obvious effect of failing to obtain adequate sleep is sleepiness at times when the body should be awake, most commonly referred to as *daytime sleepiness.* Healthy adults are maximally alert by midmorning. This is sequentially followed by a circadian lull in the early afternoon (causing some cultures to incorporate an afternoon "siesta"), increased alertness in the early evening, and finally increased sleepiness that normally results in falling asleep at night.

Patients often present to sleep disorder clinics with complaints of excessive sleepiness. Such patients have an increased incidence of automobile accidents and of accidents on the job or of being fired from employment because of sleepiness. The most extreme periods of sleepiness become

---

manifest when one is required to remain awake when one would normally be asleep (2 AM to 6 AM). Data from the NTSB reveal that the greatest numbers of single-vehicle accidents take place during the early morning hours when people are at a circadian lull of alertness. These accidents are thought to be due to inadvertent lapses in driver attention brought about by extremes of sleepiness.

Determinants of Sleepiness

Knowing what determines the level of daytime sleepiness may allow the development of measures to minimize its effects. [179] The major factors causing sleepiness are decreased quantity of sleep, poor quality of sleep (sleep fragmentation resulting from multiple awakenings or abnormal progression of sleep states and stages), disrupted circadian rhythms, and the use of certain medications. The amount of sleep obtained is directly related to daytime sleepiness. If sleep is restricted in healthy adults, daytime sleepiness can be demonstrated the following day. [176] [180] If one is allowed to extend sleep beyond the usual sleep time, increased alertness can be demonstrated in the laboratory. [181] Sleep quality is affected by many things. Sleep fragmentation affects the elderly and patients with sleep disorders such as sleep apnea and periodic limb movements. Sleep fragmentation commonly occurs in young physicians who are awakened from sleep to care for children at home or to care for patients while in the hospital.

Different drugs can either delay or hasten sleep onset, but in either case, they may disrupt normal sleep structure, which can be detrimental even if total sleep time is increased. For example, depressant drugs such as barbiturates, benzodiazepines, ethanol, clonidine, and certain antihistamines do hasten sleep onset, but they have been shown to cause hangover effects the morning after ingestion that can alter the individual's sleepiness and performance the following day. [182] These effects may not be readily apparent to the individual or to others. Depressant drugs also act in conjunction with the level of preexisting sleepiness so that the central nervous system (CNS) depressant effect is likely to be even more profound if it is superimposed on a chronic sleep debt.

Caffeine is used frequently to increase alertness temporarily, but there are caveats to its use. [183] [184] Caffeine and other stronger stimulants are known to reduce nocturnal sleep if ingested close to bedtime, hence decreasing sleep quantity and quality. Potent stimulants such as amphetamines do produce increased alertness, but they have significant side effects, and the individual must undergo a substantial amount of recovery sleep ("crash") after their effect is gone.

Mood

Long work hours, fatigue, and sleep deprivation have also been shown to bring about dramatic changes in mood and emotions. [185] [186] Depression, anxiety, irritability, anger, and depersonalization have all been shown to increase during testing of chronically fatigued house staff. These emotions are an obvious source of stress between anesthetists and their coworkers, patients, and families.

Vigilance

Vigilance, the centerpiece of the ASA logo, is defined as "the ability to remain alertly watchful especially to avoid danger." [187] Vigilance is critical, although studies of the performance of anesthesiologists make it clear that vigilance is not the only key characteristic of the careful anesthesiologist. [40] Vigilance is a necessary but not sufficient condition to permit the safe passage of a patient through the perioperative period. If vigilance and other aspects of decisionmaking are impaired by performance-shaping factors such as sleep deprivation and fatigue, there will be a greater likelihood of an adverse patient outcome.

Monitoring slowly changing stimuli is a classic vigilance task, which makes up a significant proportion of the anesthetist's work. This type of task is the most sensitive to the degrading effects of sleepiness and fatigue. During the performance of lengthy vigilance tasks, the most common types of decrements include increased reaction time, lapses (a transient period of unawareness), and a reduction in the probability of detecting an alarm. [188] This type of performance impairment has been documented after as little as 30 minutes of time on task, and the decrement is even more pronounced if the individual is physiologically sleepy at the beginning of the vigilance task.

Microsleep Events

The most extreme cause of impaired vigilance is the occurrence of actual sleep episodes *(microsleeps)* encroaching into periods of wakefulness. Microsleep events, as measured by the EEG, typically last a few seconds to a few minutes. They are intermittent in onset, and their impending occurrence is difficult for the individual to predict. Most individuals underestimate their level of sleepiness when they can be objectively shown to be extremely sleepy, thus making this problem even more insidious. In other words, one can fall asleep and not be perceptually aware of it.

Microsleeps are a sign of extreme sleepiness and are harbingers of the onset of true sleep. Microsleeps typically occur during periods of low workload or stimulation and when the individual is maximally sleepy. In addition, the individual's performance between microsleep episodes is also impaired. Frequent and longer microsleeps increase the number of errors of omission.

If a truck driver is driving down the interstate at 70 mph and has a brief microsleep, there is a high likelihood that the driver will have an accident, possibly killing himself or others. Although the anesthetist's work environment does not (usually) evolve as fast as that of the truck driver, the safety implications of falling asleep while providing anesthesia care are obvious.

Studies reveal that a significant proportion of shift workers actually do fall asleep on the job. Akerstedt et al [189] [190] conducted ambulatory EEG studies of train engineers demonstrating microsleep episodes during periods of train operation. Are similar events occurring nightly in ORs around the world?

Scientists at the NASA Ames Research Center studied the occurrence of microsleep episodes on pilots during transmeridian flights. [191] These flights involve multiple time

---

zone changes with long, irregular work schedules and a resultant disruption of circadian rhythms. This situation causes fatigue, sleepiness, and decreased performance, which are believed to have an impact on flight safety. The protocol compared two pilot groups flying equivalent flights: a control group and a nap group. This experimental study had to be cleared by the Federal Aviation Administration (FAA), whose rules do not normally allow sleep on the flight deck. EEG monitoring of the pilots was performed to determine the extent of microsleep episodes and also to document whether pilots were actually able to nap if given the opportunity. In brief, the study revealed that (1) crew members were able to nap if given the opportunity, (2) the non-nap crew had significantly more microsleep episodes during critical phases of flight when compared with the crew that had napped, and (3) performance on a standardized test of visual reaction time was impaired in the non-nap group when compared with the group that had napped. This study demonstrated that microsleeps do occur even in a work environment in which sleep is strictly forbidden and (as detailed in a later section) in which work hours are tightly regulated. Napping appears to be a reasonable countermeasure to decrease the likelihood of microsleeps, and that improves performance. Results from this study and others may be used to make major changes to regulations governing scheduled

rest on the flight deck.

Do anesthetists suffer microsleep events? The answer almost certainly is yes. Anecdotal evidence as well as unpublished reports from our own surveys suggest that these events do occur from time to time. No formal study of anesthesia care providers has been completed, although I am in the process of collecting these data. Anesthetists should realize that they are vulnerable to these dangerous episodes, which can strike without warning.

Shift Work

Because very long duty periods are problematic, shift work is a common method for providing 24-hour coverage in various work environments. It is estimated that 20 to 30 percent of the U.S. work force engages in some type of shift work. Comparisons of male shift workers versus nonshift workers reveal that men working irregular shifts report higher rates of alcohol use, job stress, and emotional problems. The many difficulties caused by shift work suggest that it is not a perfect solution for 24-hour duty requirements.

The ability to cope well with shift work depends on the interaction of three factors on the individual: circadian rhythms, sleep-related issues, and social factors. The circadian system often takes days to change to an altered work shift. Once circadian realignment to an evening or night shift is achieved, it is very difficult to maintain this schedule because our society is structured strongly on a day-night basis. It is socially "abnormal" to sleep during the day, and shift workers often adopt a nocturnal orientation during the week but revert back to the more normal diurnal orientation during the weekend and on days off from work. In this situation, a worker never fully adjusts to working on the night shift, and the circadian system is constantly disordered. [178]

The normal human circadian system runs on a cycle of approximately 25 hours. This fact and data from studies of jet lag provide an explanation for the finding that some work schedule changes are easier to adjust to than others. Because the circadian cycle is slightly longer than the 24-hour day, it is usually easier for workers to adjust to shifts in a forward direction (day shift to evening shift to night shift), thereby stretching the work schedule to conform to the body's natural rhythm. This is the same reason that jet lag is typically less severe flying westward when compared with flying eastward.

Sleep-related factors play an important role in shift work adjustment. For a variety of reasons, night shift workers average less sleep than those who work during the day. It is very difficult to screen out all environmental stimulation and noise that take place during the daytime. Even when screened from sunlight and noise, people do not sleep as well during the day because their circadian system is not reset sufficiently to command sleep at this time. This situation leads to chronic sleep deprivation, which becomes increasingly prevalent as night work is maintained. Sleep lost during the week can be partially recovered on days off and during the weekend, but sleep is often not given sufficient priority when compared with the demands of family and recreation.

Social factors also play a major role in the quantity and quality of sleep that shift workers are able to obtain during the day. Many household duties can only be performed during daytime "working hours," a factor that obviously decreases the likelihood of obtaining adequate sleep. In our society, the female shift worker is often expected by her significant other to continue to manage the household and to be the primary caregiver to the children. This situation diminishes daytime sleep for the woman, and it also can be a source of stress in the relationship because mood can be dramatically altered as sleep deprivation ensues.

From a practical standpoint, shift work will remain a common method to provide 24-hour care in the hospital setting. Workers and managers should learn how circadian factors, sleep-related factors, and social factors affect the lives of workers and their families. Organizations should make it a priority to establish that workers are appropriately rested, just as they try to ensure that workers are not impaired by drugs or alcohol on the job. However, given current knowledge concerning shift work and the many factors that affect an individual's ability to cope, there is no single "best" schedule for shift work. Some workers tolerate systems that others find excessively onerous. If given a choice, many workers choose suboptimal shiftwork rotations when doing so gives them increased pay or more time off from work.

An example of physiologically based shift work scheduling was studied by Czeisler et al [192] in a potash mining and processing facility. [192] These investigators intervened by changing the workers' rotating shifts in ways that allow for better circadian adjustment (phase delay to later shifts, every 3 weeks). These shift changes were associated with an improvement in health indexes, a reduction in personnel turnover, and a marked increase in the productivity of the workers.

Methodologies for Assessing Sleepiness
