There are several potential variables that can interact to cause or aggravate intracranial hypertension (Fig. 52-3) . For the clinician faced with the problem of managing increased ICP, the objective is, in general, to reduce the volume of the intracranial contents. For mnemonic purposes, in developing a clinical approach, the clinician can divide the intracranial space into four subcompartments: cells (including neurons, glia, tumors, and extravasated collections of blood), fluid (intracellular and extracellular), CSF, and blood. Again for mnemonic purposes, the blood compartment can be subdivided into venous and arterial components. It is this last compartment, the blood compartment, that is most amenable to rapid manipulation by the clinician, and accordingly, it is the compartment to which the greatest level of attention is directed.

1. The cellular compartment. This is largely the province of the surgeon. However, it may be the anesthesiologist's responsibility to pose a well-placed diagnostic question. When the brain is bulging into the surgical field at the conclusion of the evacuation of an extradural hematoma, the clinician should ask whether there is a subdural or extradural hematoma on the contralateral side that warrants either immediate bur holes or immediate postprocedure radiologic evaluation.
2. The CSF compartment. There is no pharmacologic manipulation of the size of the CSF space whose time

course and magnitude are relevant to the neurosurgical setting. The only relevant means for manipulating the size of this compartment is by drainage (Table 52-2) . A tight surgical field can sometimes be improved by the passage of a brain needle, by the surgeon, into a lateral ventricle to drain CSF. This maneuver may be relevant in both supratentorial procedures and in infratentorial operations when poor conditions in the posterior fossa are thought to be the result of downward pressure by the contents of the supratentorial space. Lumbar CSF drainage can be used to improve surgical exposure when there is no substantial hazard of uncal or trans-foramen magnum herniation.

3. The fluid compartment. This compartment can be addressed with steroids and diuretics. The use of these drugs is discussed in later sections.
4. The blood compartment. This is the compartment that receives the anesthesiologist's greatest attention because it is the most amenable to rapid alteration. The blood compartment should be considered as two separate components: venous and arterial.

Figure 52-3 The pathophysiology of intracranial hypertension. Those elements that are potentially under the control of the anesthesiologist are indicated by asterisks (*). BP, blood pressure.

TABLE 52-2 -- Intracranial Compartments and Techniques for Manipulation of Their Volume

COMPARTMENT	VOLUME CONTROL METHODS
Cells (including neurons, glia, tumors, and extravasated blood)	Surgical removal
Fluid (intracellular and extracellular)	Diuretics
	Steroids (principally tumors)
Cerebrospinal fluid	Drainage
Blood	
Arterial Side	Decrease cerebral blood flow
Venous side	Improve cerebral venous drainage

We suggest giving first consideration to the venous side of the circulation. It is largely a passive compartment that is frequently overlooked. Passive though it is, engorgement of this compartment is a common cause of increased ICP or poor conditions in the surgical field (Fig. 52-4) . A head-up posture, to ensure good venous drainage, is routine in neurosurgical

Figure 52-4 The effect of cerebral venous outflow obstruction on intracranial pressure in a patient with an intracerebral hematoma. Bilateral jugular compression was applied briefly to verify the function of a newly placed ventriculostomy. The intracranial pressure response illustrates the importance of maintaining free cerebral venous drainage.

anesthesia and critical care. Obstruction of cerebral venous drainage by extremes of head position or circumferential pressure (Philadelphia collars, endotracheal tube ties) should be avoided. Phenomena occurring downstream from the venous structures of the neck may also be relevant. Anything that causes increased intrathoracic pressure can result in obstruction of cerebral venous drainage. This possibility includes a variety of commonplace events such as kinked or partially obstructed endotracheal tubes, tension pneumothorax, coughing/straining against the endotracheal tube, or gas trapping from bronchospasm. These, too, should be sought and remedied. Most practitioners carefully maintain the patient's paralysis during a craniotomy procedure unless there is a contraindication because a sudden cough can result in dramatic herniation of cerebral structures through a craniotomy.

Thereafter, the anesthesiologist should address the arterial side of the circulation. Attention to the effect of anesthetic agents and techniques on cerebral blood flow (CBF) is an established part of neuroanesthesia (Ch. 19) . This attention is relevant because, in general, increases in CBF are associated with increases in cerebral blood volume (CBV). [1] [2] [3] The notable exception to this rule occurs in the context of cerebral ischemia caused by hypotension or vessel occlusion, when CBV may increase as the cerebral vasculature dilates in response to a sudden reduction in CBF. However, the relationship generally applies, and attention to the control of CBF is relevant when volume compensation mechanisms are exhausted or ICP is already increased. The general approach is to select anesthetic agents and to control physiologic parameters in a manner that avoids unnecessary increases in CBF. The parameters that influence CBF are listed in Table 52-3 and are discussed in Chapter 19 .

Anesthetic Selection

The question of which anesthetic agents are appropriate, especially in the context of unstable ICP, arises often. Chapter 19 provides relevant information in detail, and only broad generalizations are made here.

In general, intravenous anesthetic, analgesic, and sedative agents are associated with parallel reductions in CBF and

cerebral metabolic rate (CMR) and have no adverse effects on intracranial compliance. Ketamine, given in large doses to patients with a generally normal level of consciousness before anesthesia, may be the exception. It appears that, in general, autoregulation and CO_2 responsiveness are preserved during administration of intravenous agents (Ch. 19) .

All the volatile agents cause dose-dependent cerebral vasodilation. The order of vasodilating potency is approximately halothane >> enflurane > isoflurane
sevoflurane
desflurane. The net CBF effect of introducing a volatile agent depends on the interaction of several factors: the concentration; the extent of prior CMR depression; simultaneous blood pressure changes acting in conjunction with prior or anesthetic-induced autoregulation abnormalities; and simultaneous changes in the arterial CO_2 tension (Pa_{CO_2}) acting in conjunction with any disease-related impairment of CO_2 responsiveness. Nitrous oxide (N_2O) is also a cerebral vasodilator, the CBF effect of which is greatest when it is administered as a sole agent, least when it administered against a background of narcotics, propofol, or benzodiazepines, and intermediate when administered in conjunction with volatile agents (Ch. 19) . Nonetheless, experience dictates that both N_2O and volatile agents, the latter usually in sub-MAC concentrations, administered as components of a balanced anesthetic technique in combination with narcotics, can be used in most elective and many emergency neurosurgical procedures. Exceptions are rare. When they occur (the somnolent, vomiting patient with pap-illedema, a large mass, and compressed basal cisterns; the head-injury victim with an expanding mass lesion or obliterated cisterns and sulci on CT scan), the clinician may be well advised to use a predominantly intravenous technique until such time as the cranium and dura are open and the effect of the anesthetic technique can be directly assessed. Inhaled agents are entirely acceptable components of most anesthetic regimens for neurosurgery. However, when ICP is persistently elevated (in a closed cranium procedure) or the surgical field is persistently "tight," N_2O and volatile agents should be viewed as potential contributing factors and should be eliminated from the anesthetic regimen in favor of intravenous agents.

Muscle relaxants (Chs. 12 and 19) that have the potential to release histamine (curare, metocurine, mivacurium, atracurium) should be given in small, divided doses. Although succinylcholine has been associated with ICP increases, those increases are small and transient. Moreover, these increases can be blocked by a preceding dose of metocurine, 0.03 mg/kg, [4] and, in at least some instances, they do not even occur in patients with common emergency neurosurgical conditions such as head injury or subarachnoid hemorrhage (SAH). [5] Accordingly, in a clinical situation that calls for rapid relaxation for the purposes of controlling or protecting an airway, succinylcholine, in conjunction with proper management of the airway and MAP, is reasonable.

From the foregoing material and the discussion of cerebral physiology in Chapter 19 , a systematic clinical approach should follow readily. A schema for approaching the problem of acute elevation of ICP or of an acute deterioration in conditions in the surgical field is presented in Table 52-4 . If, after following the approach in Table 52-4 , the problem has not resolved satisfactorily, what then? Table 52-5 presents the options.

TABLE 52-4 -- High Intracranial Pressure/"Tight Brain" Checklist

1. Are the relevant pressures controlled?
Jugular venous pressure
Extreme head rotation or neck flexion?
Direct jugular compression?
Airway pressure
Airway obstruction?
Bronchospasm?
Straining, coughing, adequately relaxed?
Pneumothorax?
Partial pressure of CO_2 and O_2 (Pa_{CO_2}, Pa_{O_2})
Arterial pressure
2. Is metabolic rate controlled?
Pain/arousal?
Seizures?
3. Are any potential vasodilators in use? (nitrous oxide, volatile agents, nitroprusside, calcium channel blockers)
4. Are there any unrecognized mass lesions? (blood, air ± nitrous oxide)

TABLE 52-5 -- Methods for Rapid Reduction of Intracranial Pressure/Brain Volume

Cerebrospinal fluid drainage (ventriculostomy, brain needle)

Diuresis (usually mannitol)
Cerebral metabolic rate suppression (usually barbiturates)
Mean arterial pressure reduction (if dysautoregulation) (Lobectomy)

CSF drainage is discussed earlier. The use of an additional osmotic diuretic is theoretically limited by an upper acceptable osmolarity limit of 320 mOsm/L. However, in extreme circumstances, the use is frequently empirical, and repeated doses, such as 12.5 g, are administered until a clinical response is no longer observed. Barbiturates, sometimes supplemented by lidocaine, have been used most frequently to induce CMR reduction, with the objective of causing a coupled reduction in CBF and CBV. Propofol is gaining popularity for this application. Note, however, that whereas the use of barbiturates is supported by an intensive care unit (ICU) experience demonstrating efficacy in ICP control [6] (if not outcome), no such experience has been accumulated for propofol. MAP reduction occasionally reduces vascular engorgement and thereby reduces total brain bulk. This effect is most likely to be relevant in the event of dysautoregulation occurring in the context of resection of arteriovenous malformations (AVM) (see later).

Partial Pressure of Carbon Dioxide Management

At the outset, the anesthesiologist and the surgeon should agree on the objectives with respect to Pa $_{CO_2}$. The induction of hypocapnia is a time-honored part of the management of intracranial neurosurgical procedures. The rationale is principally that the concomitant reduction in CBF (see Fig. 19-4) and CBV will result in a reduction of ICP or "brain relaxation." The rationale is valid. However, there are two considerations that should influence the clinician's use of hyperventilation. First, the vasoconstrictive effect of hypercapnia has the potential to cause ischemia in certain situations. Second, the CBF-lowering effect is not sustained.

Hypocapnia-Induced Cerebral Ischemia

There was at first skepticism that hyperventilation could actually result in ischemia, and it does, in fact, appear that normal brain is unlikely to be damaged by typical clinical use of hyperventilation. However, that may not be the case in certain pathologic conditions.

Normal Brain.

The data [7] [8] [9] [10] [11] [12] [13] [14] indicate that, in healthy subjects, ischemia does not occur at a Pa $_{CO_2}$ greater than 20 mm Hg. This generalization appears also to apply during induced hypotension. [15] [16] [17] However, physiologic alterations, as evidenced by both metabolic and electroencephalographic (EEG) abnormalities, have been observed in human volunteers [10] [12] [18] and in healthy animals [7] [11] [14] at extreme hypocapnia (Pa $_{CO_2}$ < 15 mm Hg), as well as in dogs submitted to the combination of severe hypocapnia (Pa $_{CO_2}$, 10 mm Hg) and severe anemia (hemoglobin, 5 g/dL). [9] In one of these studies, [12] EEG abnormalities and paresthesias occurred in volunteers hyperventilating to Pa $_{CO_2}$ values less than 20 mm Hg, and these effects were reversed by hyperbaric oxygenation, a finding suggesting that these effects may truly have been caused by ischemia. In two separate investigations in cats at Pa $_{CO_2}$ levels of 10 to 12 mm Hg, [7] [14] modest reductions in brain phosphocreatine levels with increased brain lactate but normal levels of adenosine triphosphate (ATP) were observed. It has been suggested [14] that the observed changes may, in part, reflect pH-related alterations in enzyme function (specifically, an increase in the activity of phosphofructokinase causing increased lactate formation), [18] rather than ischemia. Accordingly, given that a Pa $_{CO_2}$ of less than 20 to 25 mm Hg offers very little additional benefit in terms of improvement of intracranial compliance, it seems prudent to limit acute Pa $_{CO_2}$ reduction to 25 mm Hg in previously normocarbic individuals. Normal brain is not injured by this degree of hypocapnia.

Injured Brain.

Although preventing herniation, maintaining ICP at less than 20 mm Hg, minimizing retractor pressure, and facilitating surgical access remain priorities that may justify hypocapnia, there is also accumulating evidence that hyperventilation is potentially deleterious, [19] [20] [21] [22] [23] [24] [25] [26] [27] [28] [29] [30] [31] [32] [33] and it should not be overused. In the setting of head injury, there is evidence that hyperventilation can result in ischemia, [21] [34] especially when baseline CBF is low, [34] as is commonly the case in the first 24 hours after injury. [24] [35] [36] [37] An increased frequency of brain regions with very low CBF in head-injured patients who were acutely hyperventilated has been demonstrated. [21] In addition, from centers that monitor jugular venous oxygen saturation (Sjv $_{O_2}$), there have been numerous observations that a low Sjv $_{O_2}$ can be increased and lactate levels in the jugular venous effluent can be decreased by reducing the degree of hyperventilation. [24] [34] [38] [39] However, at present there is little information to confirm a deleterious effect of hyperventilation. The closest thing to "proof" resides in a study by Muizelaar et al. [23] These authors studied patients with moderate head injuries.

They divided the patients into a near-normocapnic group in whom Pa $_{CO_2}$ was maintained at approximately 35 mm Hg, a hypocapnic group in whom Pa $_{CO_2}$ was maintained in the vicinity of 25 mm Hg, and a third group in whom the Pa $_{CO_2}$ was maintained at 25 mm Hg and the buffer tromethamine (Tham) was administered. Tromethamine is a buffer that can cross the blood-brain barrier (BBB), and it has been theorized that this buffer can attenuate the adverse effect of the reduction of bicarbonate levels in CSF and brain extracellular fluid that occurs with chronic hyperventilation. These investigators examined outcome at 3 and 6 months following injury and observed a poorer status in a post hoc subpopulation of the hyperventilation group. That subpopulation included those patients with the best initial motor scores, that is, a subgroup in whom the severity of injury was such that these patients merited intubation by conventional criteria, but whose clinical condition may have been such that hyperventilation was not necessarily required for ICP control and who therefore had little to gain from hyperventilation.

Accordingly, hyperventilation should not be an automatic component of every "neuroanesthetic" regimen. It should be treated like any other therapeutic intervention. There should be an indication for instituting it, usually elevated or uncertain ICP and/or the need to improve conditions in the surgical field. It should be used with the knowledge that there is the potential for an adverse effect, and, as is the case with any other therapeutic intervention, it should be withdrawn as the indication for it subsides. The concern regarding the hazards of hypocapnia, which evolved in the context of head injury, has influenced all of neurosurgery. In particular, hyperventilation is now widely avoided in the management of SAH because of the postictal low CBF state that is known to occur. [40] In addition, brain beneath retractors can have a similarly reduced CBF. [28]

Duration of Hypocapnia-Induced Cerebral Blood Flow Reduction

The effect of hypocapnia on CBF is not sustained. Figure 52-5 is a nonquantitative representation of changes in CBF and CSF pH occurring in association with a sustained period of hyperventilation. With the onset of hyperventilation, the pH of both CSF and the brain's extracellular fluid space increases, and CBF decreases abruptly. However, the cerebral alkalosis is not sustained. By alterations in the function of the carbonic anhydrase enzyme, the concentration of bicarbonate in the CSF and the brain's extracellular fluid space is reduced, and, with a time course of 6 to 18 hours, the pH of those compartments returns to normal. [41] At an equal pace, CBF returns toward normal levels. [41] [42] The implications are 2-fold. First, the clinician should ideally hyperventilate patients for only as long as brain volume reduction is required. Prolonged but unnecessary hyperventilation may lead to a circumstance wherein subsequent clinical events call for additional maneuvers to reduce the volume of the intracranial contents. However, if Pa $_{CO_2}$ is already in the range of 23 to 25 mm Hg, it would be difficult to impose sufficient additional hyperventilation once again to accomplish the original reduction of CBF without the hazard of pulmonary barotrauma. Second, in the patient who has been hyperventilated

Figure 52-5 Arterial CO_2 tension (Pa $_{CO_2}$), cerebral blood flow (CBF), and cerebrospinal fluid (CSF) pH changes with prolonged hyperventilation. Whereas the decreased arterial Pa $_{CO_2}$ and the systemic alkalosis persist for the duration of the period of hyperventilation, the pH of the brain and CBF return toward normal over 8 to 12 hours.

for a sustained period of time (e.g., 2 days in an ICU setting), rapid restoration of Pa $_{CO_2}$ from values in the vicinity of 25 mm Hg to typical normal values, such as 40 mm Hg, should ideally be accomplished slowly. A sudden increase in Pa $_{CO_2}$ from 25 to 40 mm Hg in an individual who has been hyperventilated on a long-term basis will have the same physiologic effect that a rapid change from 40 to 55 mm Hg would have in a previously normocapnic subject. If hypocapnia has been required as

an adjunct to brain relaxation during craniotomy, CO_2 levels should also be allowed to rise once retractors are removed (if dural closure requirements permit) in order to minimize the residual intracranial pneumatocele (see the later discussion of pneumocephalus).

Blood Pressure Management

Acceptable blood pressure limits should similarly be agreed on at the beginning of a neurosurgical procedure. One of the prominent themes of contemporary neurosurgery is that CPP should be maintained at normal or even high normal levels following acute insults to the central nervous system (CNS) and during most intracranial neurosurgical procedures. This concept evolves from the growing appreciation that CBF is frequently perilously low in some brain regions following acute neurologic insults, in particular, head injury (see the additional discussion later) and SAH. [24] [35] [40] There are two additional factors. The first is that the autoregulatory response to decreasing blood pressure may not be intact throughout the brain. Figure 52-6 depicts the ischemic hazard that attends the circumstance of a low resting CBF and absent autoregulation even at blood pressures considered safe when autoregulation is intact. In addition, there is the appreciation that maintenance of arterial pressure is also relevant to brain compressed under retractors, [28] because the effective perfusion pressures there are lowered by increased local tissue pressure. Although

Figure 52-6 Normal and absent autoregulation curves. The "absent" curve indicates a pressure-passive condition in which cerebral blood flow (CBF) varies in proportion to cerebral perfusion pressure (CPP). This curve is drawn to indicate subnormal CBF values during normotension, as have been shown to occur immediately after both head injury [24] and subarachnoid hemorrhage. [40] The potential for modest hypotension to cause ischemia is apparent. MAP, mean arterial pressure.

there are few data to support the notion, it seems reasonable that this attitude regarding blood pressure should be extrapolated to patients who have sustained a recent spinal-cord injury, patients whose spinal cord is under compression because of a disease process (most commonly cervical spinal stenosis), or patients undergoing surgery involving retraction of the spinal cord.

Steroids

The administration of steroids for the purpose of reducing or limiting the formation of edema is another time-honored practice in neurosurgery. The efficacy of steroids in reducing the edema associated with tumors is well confirmed. [43] [44] [45] The time course of this effect is relatively rapid, although not so rapid as to be relevant to the management of intraoperative events. However, administration of steroids beginning 48 hours prior to an elective surgical procedure has the potential to reduce edema formation and to improve clinical condition by the time of the craniotomy. [43] [44] [46] It has been noted that whereas clinical improvement, that is, a decreased frequency of ICP plateau waves and an improvement in the pressure-volume response (the ICP increment in response to a standardized intracranial volume challenge), occurs within 24 hours, [43] a reduction of ICP may not occur for 48 to 72 hours after initiation of therapy. [43] This finding has been interpreted to indicate that steroids in some way improve the "viscoelastic properties" of the intracranial space before edema reduction occurs, although the mechanism is undefined. [46] Steroids are usually given intraoperatively and postoperatively to maintain the effects achieved with preoperative treatment.

The practice of administering steroids to the adult patient with head injury has largely been abandoned as the result of controlled trials that demonstrated either no benefit or a deleterious effect in patients who received steroids. [47] [48] [49] No such studies have been performed in the pediatric trauma victim, and practices vary among pediatric neurosurgeons with respect to the administration of steroids following head injury in this population. One European trial reported a benefit in adult victims of head injury of the administration of large doses of triamcinolone. [50] The potent fluorinated steroids had not been studied previously in this population. It is possible that there will be reconsideration of the use of steroids in adult victims of head injury.

Diuretics

Diuretics are used widely in neurosurgery to reduce the volume of the brain's intracellular and extracellular fluid compartments. It is probably largely the extracellular compartment that is influenced because neurons and glia have quick and efficient cell volume-regulation mechanisms. Both osmotic and loop diuretics have been employed. Although there are data to suggest that loop diuretics can be effective, [51] osmotic diuretics, principally mannitol, are preferred clinically because of their speed and efficacy. The only osmotic diuretic available on most formularies is mannitol, although urea once had its proponents. However, urea is a smaller molecule that clearly has greater potential to enter brain parenchyma. That is not to say that mannitol does not enter brain parenchyma. There are data to indicate that it enters brain and, over a reasonably short time course, appears in the CSF space. [52] The possibility that the mannitol that gains access to the parenchyma aggravates swelling has resulted in varying degrees of reluctance among clinicians to administer this drug. [53] Most clinicians, nonetheless, find mannitol a mainstay of ICP management. There is the concern that it will be effective only when some degree of BBB integrity is preserved in a significant portion of the brain. Most clinicians respond to this concern by making empirical use of this agent, that is, if it is effective in reducing ICP or improving conditions in the surgical field, repeated doses can be administered or will be administered. If it is ineffective (or if serum osmolarity reaches the traditional limit of 320 mOsm/L), its administration is withheld.

The dosages of mannitol employed vary from 0.25 g/kg to 100 g "for all comers." One gram per kilogram appears to be the most common dose. However, a systematic study in

head-injured patients demonstrated that an equivalent initial ICP-reducing effect can be achieved with 0.25 g/kg, although that effect may not be as sustained as with larger doses. [54]

Some clinicians advocate the combined administration of a loop diuretic (usually furosemide) and an osmotic diuretic. The superficial rationale is that mannitol establishes an osmotic gradient that draws fluid out of brain parenchyma, and furosemide, by hastening excretion of water from the intravascular space, facilitates the maintenance of that gradient. A second mechanism may add additional justification for the practice of combining the two agents. Neurons and glia, as mentioned earlier, appear to have powerful homeostatic mechanisms to ensure regulation of cell volume. Neurons and glia that shrink in response to an increased osmolarity in the external environment recover their volume rapidly as a consequence of the accumulation of so-called "idiogenic" osmoles that serve to minimize the gradient between the internal and external environment. One of those idiogenic osmoles is chloride. It has been demonstrated in the laboratory that the loop diuretics inhibit the chloride channel through which this ion must pass and thereby retard the normal volume-restoring mechanism. [55]

The normal volume-regulatory mechanisms of neurons and glia may also be relevant to the phenomenon of rebound swelling. Rebound is commonly attributed to the prior use of mannitol and is assumed to be a function of the accumulation of mannitol in cerebral tissue. Although this may be part of the story, the rebound may, in fact, be "hypertonic rebound," rather than "mannitol rebound." It seems reasonable to be concerned that, after a sustained period of hyperosmolarity of any cause, rebound swelling of neurons and glia may occur in the event that systemic osmolarity decreases rapidly toward normal levels. It is certainly well known that rebound cerebral swelling can occur after an episode of extreme blood glucose elevation. Accordingly, it should not be assumed that the use of, for instance, hypertonic saline rather than mannitol will obviate this phenomenon.

Anticonvulsants

The general principle is that any acute irritation of the cortical surface has the potential to result in seizures. This includes acute neurologic events such as head injury and SAH. Cortical incisions and brain surface irritation by retractors may similarly be potential foci. Given the relatively benign nature of phenytoin, provided it is given judiciously (i.e., at rates of
50 mg/min), routine administration in patients undergoing most supratentorial craniotomies as well as in patients who have sustained a significant head injury or SAH seems appropriate in the absence of a contraindication.

Positioning

The intended surgical position and the necessary position aids should be agreed on at the outset (Ch. 26) . The commonly used positions and positioning aids/supports are

TABLE 52-6 -- Common Neurosurgical Positions and Positioning Aids

Positions
Supine
Lateral (park bench)
Semilateral (Jannetta)
Prone
Sitting
Positioning aids/supports
Pin head holder
Radiolucent pin head holder
Horseshoe headrest
Foam "block" head support
Vacuum mattress ("bean bag")
Wilson-type frame
Andrews ("hinder binder")-type frame
Relton-Hall (four-poster) frame

listed in Table 52-6 and are described in the following sections.

General Considerations

The prolonged duration of many neurosurgical procedures should be taken into account in all positions. Pressure points should be identified and padded carefully. Pressure and traction on nerves must be avoided. Thromboembolic precautions including support hose and sequential pneumatic compression devices are often appropriate. Almost invariably, some component of head-up posturing, such as 15 to 20 degrees, is appropriate to ensure optimal venous drainage. The conspicuous exception occurs with evacuation of a chronic subdural hemorrhage, after which patients are usually nursed flat, to discourage reaccumulation. Patients are often also maintained flat after CSF shunting to avoid overly rapid collapse of the ventricles.

Supine Position

The supine position is used with the patient's head neutral or rotated for frontal, temporal, or parietal access. Extremes of head rotation can obstruct the jugular venous drainage, and a shoulder roll can combat this problem. The head is usually in a neutral position for bifrontal craniotomies and for transphenoidal approaches to the pituitary. The head-up posture is best accomplished by adjusting the operating table to a chaise lounge (lawn chair) position (flexion, pillows under the knees, slight reverse Trendelenburg position). This orientation, in addition to promoting cerebral venous drainage, decreases the patient's back strain.

Semilateral Position

The semilateral position, also known as the Jannetta position after the neurosurgeon who popularized its use for microvascular decompression of the fifth cranial nerve, is used for retromastoid access. It is achieved by lateral tilting of the table 10 to 20 degrees, combined with a generous shoulder

roll. Again, extreme head rotation causing compression of the contralateral jugular vein by the chin should be avoided.

Lateral Position

The lateral position can be used for access to the posterior parietal and occipital lobes and the lateral posterior fossa including tumors at the cerebellopontine angle and aneurysms of the basilar artery and vertebrobasilar junction. A vacuum mattress that can be molded to the patient's anatomic features greatly facilitates maintenance of a stable lateral position. An axillary roll is important for preventing brachial plexus injury.

Prone Position

The prone position is used for spinal cord, occipital lobe, craniosynostosis, and posterior fossa procedures. The prone position has also been referred to, aptly, as the Concorde position because, for cervical spine and posterior fossa procedures, the final position usually entails neck flexion, reverse Trendelenburg positioning, and elevation of the legs, usually with pillows. This orientation serves to bring the surgical field to a horizontal position.

Before turning the patient to the prone position, the anesthesiologist should ensure that the intravenous catheter and endotracheal tube are secure and that appropriate personnel are available to prevent injury during the turn. The anesthesiologist should have a plan for detaching and reattaching monitors in an orderly manner to prevent an excessive monitoring "window." Awake tracheal intubation and prone positioning can be employed in patients with an unstable cervical spine in whom an unchanged neurologic status should be confirmed before induction of anesthesia in the final surgical position. It is also occasionally performed in very obese patients.

The head can be positioned in a pin head holder (applied before the turn), a horseshoe headrest, or a disposable foam headrest. Complications of the prone position to which there must be constant attention are retinal ischemia and blindness from orbital compression. This problem may be compounded by low arterial pressure, low hematocrit level, and poor cerebral venous drainage. [56] It must be intermittently ascertained, such as every 15 minutes and after any surgery-related head/neck movement, that pressure has not come to bear on the eye. Various degrees of pressure necrosis of the forehead and maxillae can also occur, especially during prolonged spinal procedures. Other pressure points to be checked include the axillae, breasts, iliac crests, femoral canals, genitalia, knees, and heels. An antisialogogue, such as glycopyrrolate, may help to reduce loosening of tape used to secure the endotracheal tube.

An objective during prone positioning, especially for lumbar spine surgery, is the avoidance of inferior vena caval compression. Impairment of vena caval return diverts blood to the epidural plexus and increases the potential for bleeding during laminectomy. This avoidance is an objective of all the spinal surgery frames and is accomplished very effectively by both the Relton-Hall and the Andrews variants. This does, however, introduce a risk of air embolism, [57] although clinical occurrences have been very infrequent.

There should be attention to preventing injury to the patient's tongue in the prone position. With both cervical and posterior fossa procedures, it is frequently necessary to flex the patient's neck substantially to facilitate surgical access. This reduces the anteroposterior dimension of the hypopharynx, and compression ischemia of the base of the tongue (as well as the soft palate and posterior wall of the pharynx) can occur in the presence of foreign bodies (endotracheal tube, esophageal stethoscope, oral airway). The consequence is "macroglossia" and unexpected postextubation airway obstruction. Accordingly, unnecessary

paraphernalia in the pharynx should be avoided. Omitting the oral airway entirely is unwise because the tongue may then protrude between and be trapped by the teeth as progressive swelling of facial structures occurs during a prolonged procedure with the patient in the prone position. A bite block akin to those used with laryngeal masks prevents this problem without adding bulk to the hypopharynx.

Sitting Position

There have been three reviews of large experiences with procedures performed with patients in the sitting position. [58] [59] [60] All concluded that the sitting position can be employed with acceptable rates of morbidity and mortality. However, these reports were prepared by groups performing 50 to 100 or more of these procedures per year, and the hazards of the sitting position may be greater for teams who have less frequent occasion to use it. With increasing frequency, the sitting position is being avoided through the use of one of its alternatives (prone, semilateral, lateral positions). However, we are likely to continue encountering it because even surgeons who are inclined to use alternative positions may opt for the sitting position when access to midline structures (the floor of the fourth ventricle, the pontomedullary junction, and the vermis) is required. Nonetheless, alternative positions for posterior fossa surgery exist and should be considered when a patient has contraindications to the sitting position.

Achieving the Sitting Position.

The properly positioned patient is more commonly in a modified recumbent position, as shown in Figure 52-7 (Figure Not Available) , rather than truly sitting. The patient's legs should be kept as high as possible (usually with pillows under the knees) to promote venous return, thereby enhancing circulatory stability. Ideally, the head holder should be attached to the back portion of the table (see Fig. 52-7 (Figure Not Available) A) rather than to the portions under the patient's thighs or legs (see Fig. 52-7 (Figure Not Available) B). This technique permits lowering of the head, and closed chest massage if necessary, without the necessity to take the patient out of the head holder.

When procedures are performed with the patient in the sitting position, the clinician should think in terms of measuring and maintaining perfusion pressure at the level of the surgical field. This is best accomplished by referencing transducers to the interaural plane or at the level of the cervical spine in the event of cervical laminectomy. If a manual

Figure 52-7 (Figure Not Available) The sitting position. The patient is typically semirecumbent rather than sitting. (A) The head holder support is correctly positioned such that the patient's head can be lowered without the necessity to first detach the head holder. (B) This configuration, with the support attached to the thigh portion of the table, should be avoided. *(From Martin [244])*

blood pressure cuff on the patient's arm is employed, a correction to allow for the hydrostatic difference between the arm and the operative field should be applied.

Hazards are associated with the sitting position. Circulatory instability, macroglossia, and quadriplegia are discussed in this section. Venous air embolism, paradoxic air embolism, and pneumocephalus are discussed later in this chapter. Several of these hazards are also relevant when cervical spine and posterior fossa procedures are performed with patients in nonsitting positions, but they occur with greater frequency in the sitting position.

Cardiovascular Effects.

Placing the anesthetized patient in the sitting position conveys some risk of impaired cardiovascular function, in particular hypotension (Ch. 26) . Pressor administration is required in some patients. Measures to avoid hypotension include prepositioning hydration, wrapping of the patient's legs with elastic bandages to counteract gravitational shifts of blood and slow, incremental adjustment of table position. Both aggressive volume loading and the G suit (also known as pneumatic antishock trousers or MAST suit) have been shown to attenuate the effects of assuming the sitting position. [61] [62] [63] [64] However, neither of these measures has been widely applied. In the majority of healthy persons, the hemodynamic changes are of a nonthreatening magnitude. In a study of healthy (American Society of Anesthesiologists [ASA] I and II) anesthetized adult subjects, ages 22 to 64 years, Marshall et al [65] observed relatively modest changes. MAP was relatively unaffected, whereas wedge pressure, stroke volume and cardiac index decreased, the latter by approximately 15 percent, although there was some variation with the anesthetic agents employed. The combination of an unchanged MAP (which in general requires the use of a "light" anesthetic with high sympathetic tone) and a reduced cardiac index implies that systematic vascular resistance (SVR) rose. These calculations and the observations of other investigators, [66] in fact, reveal significant elevation of SVR. Accordingly, for patients in whom an abrupt increase in SVR may be poorly tolerated, the sitting position may represent a physiologic threat, and alternative positions should be considered. A pulmonary artery catheter may be warranted when there is clinical or historical evidence of antecedent coronary artery or valvular heart disease, and it may be used arbitrarily in patients older than 60 to 65 years of age.

During procedures performed with the patient in the sitting position, MAP should be transduced at or corrected to head level in order to obtain a meaningful index of CPP. Specifically, CPP (MAP minus estimated ICP) should be maintained at a minimum value of 60 mm Hg in healthy patients in whom it is reasonable to assume a normal cerebral vasculature. The safe lower limit should be raised for elderly

---

patients, for those with hypertension and/or known cerebral vascular disease, for those with degenerative disease of the cervical spine or cervical spinal stenosis who may be at risk for decreased spinal-cord perfusion, and in the event that substantial or sustained retractor pressure must be applied to brain or spinal-cord tissue.

Macroglossia.

There have been sporadic reports of upper airway obstruction following posterior fossa procedures in which swelling of pharyngeal structures including soft palate, posterior wall, pharynx, and base of tongue have been observed. [67] These episodes have been attributed to trauma/ischemia occurring as the result of foreign bodies (usually oral airways) causing pressure on these structures in the circumstances of lengthy procedures with sustained neck flexion (which is usually required to improve access to posterior structures). It is ideal to maintain at least a fingerbreadth's distance between the chin and the sternum to prevent excessive reduction of the anteroposterior diameter of the oropharynx. In addition, it is our practice to position patients with the oral airway in place and then, once the final head position is achieved, to withdraw the airway until its tip functions as a bite block between the teeth. Consideration of the macroglossia phenomenon may also be relevant as clinicians contemplate moving their transesophageal echocardiogram (TEE) from the cardiology department and using them in the neurosurgery suite. The centers that routinely employ the TEE in neurosurgery, for the most part, use either pediatric or custom-made small-diameter probes to avoid trauma to pharyngeal and perilaryngeal structures.

Quadriplegia.

The sitting position per se has been implicated as a cause of rare instances of unexplained postoperative paraplegia. It has been hypothesized [68] that neck flexion, which is a common concomitant of the seated position, may result in stretching or compression of the cervical spinal cord. This possibility may represent a relative contraindication to the use of this position in patients with significant degenerative disease of the cervical spine, especially when there is evidence of associated cerebral vascular disease. The blood pressure management implications are mentioned in the preceding paragraph. It may also represent a justification for somatosensory evoked response monitoring during the positioning phase of a sitting procedure for patients perceived to be at high risk.

Pneumocephalus

The issue of pneumocephalus arises most often in connection with posterior fossa craniotomies performed with the patient in a head-up posture because these operations entail the probability that air will be retained within the cranium. [69] During the procedure, the intracranial air is almost invariably in free communication with the atmosphere. However, on other occasions, it is suspected that air may enter the supratentorial space, much as air enters an inverted pop bottle. Depending on the relationship of the brain stem and temporal lobes to the incisura, the pressure in the air collection may or may not be able to equilibrate with atmospheric pressures consistently. This phenomenon has relevance to the use of N_2O because any N_2O that enters a trapped gas space augments the volume of that space. In those

(probably uncommon) intraoperative circumstances in which there is, in fact, a completely closed intracranial gas space, the use of N_2O may result in an effect comparable to that of an expanding mass lesion. We do not view N_2O as absolutely contraindicated because, prior to dural closure, intracranial gas is probably only rarely trapped. Nonetheless, attention to this possibility is important when one is presented with the problem of an increasingly "tight" brain during a posterior fossa craniotomy. [70] [71]

When surgical closure has reached a stage such that the intracranial space has been completely sealed from the atmosphere, it is probably appropriate to omit N_2O when performing posterior fossa procedures with the patient in a head-up posture because of the possibility of contributing to a tension pneumocephalus. Note that the use of N_2O up to the point of dural closure may actually represent a clinical advantage, [72] in that the gas pocket can be expected to shrink more rapidly because of the presence of N_2O (because N_2O diffuses out much more quickly than nitrogen).

Tension pneumocephalus can occur as a complication of intracranial neurosurgery unrelated to the use of N_2O. It is one cause of delayed awakening or nonawakening following both posterior fossa [73] and supratentorial procedures (Fig. 52-8) . It occurs because air enters the cranium when the patient is in a head-up position at a time when the volume of the intracranial contents are at an absolute optimum because of some combination of hypocapnia, good venous drainage, osmotic diuresis, and CSF loss via the operative field. When the cranium is closed and the patient is returned to the near-supine position, CSF, venous blood volume, and extracellular fluid return or reaccumulate, and the

Figure 52-8 Postoperative computed tomography scan demonstrating a large pneumocephalus after a subfrontal approach to a suprasellar glioma. Immediately postoperatively, the patient was confused and agitated and complained of severe headache.

air pocket becomes an unyielding mass lesion (because of the very slow diffusion of nitrogen). It may cause delayed recovery of consciousness or severe headache. Among supratentorial craniotomies, the largest residual air spaces occur after frontal skull base procedures in which energetic brain relaxation measures are used to facilitate subfrontal access (see Fig. 52-8) . Once again, we doubt that the possible occurrence of this phenomenon represents a contraindication to N_2O. However, withdrawal of N_2O may be appropriate at the time of cranial closure. The diagnosis of pneumocephalus is confirmed by a brow-up lateral x-ray film or CT scan. The treatment is a twist-drill hole, followed by needle puncture of the dura. Residual intracranial air should be considered at the time of repeat anesthesia, neurosurgical or nonneurosurgical. Air frequently remains evident on CT scan for more than 7 days after a craniotomy. [74]

Venous Air Embolism

The rate of occurrence of venous air embolism (VAE) varies according to the procedure, the position, and the detection method used. During posterior fossa procedures done with the patient in the sitting position, VAE is detectable by precordial Doppler in approximately 40 percent of patients and in 76 percent using TEE. [75] [76] [77] The incidence of VAE during posterior fossa procedures performed with the patient in other positions is much less (12% using precordial Doppler in the report of Black et al [60]), and it is probable, but unproven, that the average volume of air entrained per event is smaller with the nonsitting positions. The rate of VAE is apparently lower with cervical laminectomy (25% using TEE in the sitting position versus 76% for posterior fossa procedures [77]). Although VAE is principally a hazard of posterior fossa and upper cervical spine procedures, especially when they are performed with the patient in the sitting position, it can occur with supratentorial procedures. The most common situations involve tumors, most often parasagittal or falcine meningiomas, which encroach on the posterior half of the sagittal sinus. Pin sites and trapped gas under pressure can also lead to VAE just as with posterior fossa procedures, although clinically relevant events have been very rare.

The common sources of major VAE are the major cerebral venous sinuses, in particular the transverse, the sigmoid, and the posterior half of the sagittal sinuses, all of which may be noncollapsible because of their dural attachments. Air entry may also occur via emissary veins, particularly to suboccipital musculature, the diploic space of the skull (which can be violated by both the craniotomy and pin fixation), and the cervical epidural veins. It is the authors' belief (not confirmed by systematic study) that VAE risk associated with cervical laminectomy is greatest when the exposure requires dissection of suboccipital muscle with the potential to open emissary veins to the atmosphere at their point of entry into occipital bone. There is also anecdotal evidence [78] that air under pressure in the ventricles or subdural space can occasionally enter the venous system, perhaps following the CSF's normal egress route.

Detection

The monitors employed for the detection of VAE should provide (1) a high level of sensitivity, (2) specificity, (3) a rapid response, (4) a quantitative measure of the VAE event, and (5) an indication of the course of recovery from the VAE event. The combination of precordial Doppler and expired CO_2 monitoring meet these criteria and are the current standard of care. Doppler placement in a left or right parasternal location in the second to fourth intercostal spaces has a very high detection rate for gas embolization, [79] and when good heart tones are obtained, maneuvers to confirm adequate placement appear unnecessary. TEE is slightly more sensitive than the precordial Doppler (Fig. 52-9) (Figure Not Available) to VAE, [80] and TEE offers the advantage of identifying right-to-left shunting of air. [80] [81] [82] However, its safety during prolonged use, especially in patients with pronounced neck flexion, is not well established. Expired nitrogen analysis is theoretically attractive. However, the expired nitrogen concentrations

BP, blood pressure.

involved in anything less than catastrophic VAE are very small and push the available instrumentation to the limits of its sensitivity. [83] Furthermore, effective application requires absolute freedom from air contamination of the ventilator and anesthetic circuit. Figure 52-10 (Figure Not Available) presents the physiologic and monitor response to an air embolic event. Table 52-7 offers an appropriate management response to such an event.

Which Patients Should Have a Right Heart Catheter?

Essentially all patients who undergo posterior fossa procedures in the sitting position should have one. Although catastrophic, life-threatening VAE is relatively uncommon, a catheter that permits immediate evacuation of an air-filled heart occasionally is essential for resuscitation. The latitudes

TABLE 52-7 -- Management of an Acute Air Embolic Event

Prevent further air entry

(Administer pressors/inotropes)
(Apply chest compression)

are much wider with the nonsitting positions, and it is frequently appropriate, after a documented discussion with the surgeon, to omit the right heart catheter. The perceived risks of VAE associated with the intended procedure and the patient's physiologic reserve are the variables that contribute to the decision. Microvascular decompression maneuvers of the fifth and seventh cranial nerves for tic douloureux and hemifacial spasm, respectively, are examples of procedures for which the right heart catheter is usually omitted. The essentially horizontal semilateral position and the very limited retromastoid craniectomy have resulted (at our institution) in a very low incidence of Doppler-detectable VAE. However, one should come to know the local surgical practices, particularly with respect to the degree of head-up posture, before becoming casual about right atrial catheterization. For instance, with regard to the Jannetta procedure, recall that the necessary retromastoid craniectomy is performed in the angle between the transverse and sigmoid sinuses, and that venous sinusoids and emissary veins in the suboccipital bone are common. If this procedure is performed with the patient in any degree of head-up posturing, the risk of VAE may still be substantial.

Which Vein Should Be Used for Right Heart Access?

Although some surgeons may ask that neck veins not be used, a skillfully placed jugular catheter is often acceptable. In a very limited number of patients, high ICP may make the head-down posture undesirable. In others, unfavorable anatomy with an increased likelihood of a difficult cannulation

and hematoma formation may also encourage the use of alternate access sites. Access to the brachial veins has been greatly facilitated by the commercial availability of multiorificed catheters that utilize a Seldinger cannulation technique and a lengthy J-tipped guide wire to negotiate the axilla or deltopectoral groove.

Positioning the Right Heart Catheter

The investigation of Bunegin et al [84] suggests that a multiorificed catheter should be located with the tip 2 cm *below* the junction of the superior vena cava and the atrium and a single orificed catheter with the tip 3 cm *above* this junction. Although these small distinctions in location may be relevant for optimal recovery of small volumes of air when cardiac output is well maintained, for the recovery of massive volumes of air in the face of cardiovascular collapse, anywhere in the right atrium should suffice. Confirmation of right heart placement can be accomplished by (1) radiography, (2) pull back from the right ventricle while monitoring intravascular pressure, or (3) intravascular electrocardiography (ECG). [85] While there is no literature to support the practice, with catheter access via the right internal jugular vein, a measured placement to the level of the second right intercostal space should suffice when the catheter passes readily. The intravascular ECG technique makes use of the fact that an ECG "electrode" placed in the middle of the right atrium initially "sees" an increasing positivity as the developing P-wave vector approaches it (Fig. 52-11) and then an increasing negativity as the wave of atrial depolarization passes and moves away from it. The resultant biphasic P wave is characteristic of a midatrial "electrode" position. The technique requires that the CVP catheter become an exploring ECG electrode. This is accomplished by filling the catheter with an electrolyte solution (bicarbonate is best) and attaching an ECG lead (the leg lead if lead II is selected) to the hub of the central venous pressure (CVP) catheter. Commercial CVP kits with an ECG adapter are available. The ECG configurations that are observed at various intravascular locations are shown in Figure 52-11 . To minimize the microshock hazard, a battery-operated ECG unit should be employed, and unnecessary electrical apparatus should be detached from the patient during catheter placement.

Paradoxic Air Embolism

There has been much concern expressed about the possibility of the passage of air across the interatrial septum via a patent foramen ovale (PFO), which is known to be present in approximately 25 percent of adults. [86] The concern is that this phenomenon carries the risk of major cerebral and/or coronary morbidity, although there has been no precise definition of the morbidity that can realistically be attributed to paradoxic air embolism (PAE). Although the precise pressure required to open a probe PFO is not known with certainty, it is thought that the necessary gradient may be as much as 5 mm Hg. It has reasonably been assumed that the risk of the occurrence of PAE is greatest at times when right atrial pressure exceeds left atrial pressure. Clinical investigations

Figure 52-11 Electrocardiographic (ECG) configurations observed at various locations when a central venous catheter is used as an intravascular ECG electrode. The configurations in the figure are observed when lead II is monitored and the positive electrode (the leg electrode) is connected to the catheter. P indicates the sinoatrial node. The heavy black arrow indicates the P-wave vector. Note the equi-biphasic P wave when the catheter tip is in the middle right atrial position. [85]

revealed that the use of positive end-expiratory pressure (PEEP) increased the incidence of a positive right atrial pressure-pulmonary capillary wedge pressure gradient [87] and that generous fluid administration (e.g., 2,800 mL/patient versus 1,220 mL/control patient [88]) reduced it. As a result, the use of PEEP, which had previously been advocated as a means of preventing air entrainment, diminished, and the practice of more generous fluid administration for patients undergoing posterior fossa procedures evolved. However, subsequent data indicated that even when *mean* left atrial pressure exceeds mean right atrial pressure, PAE can still occur because transient reversal of the interatrial pressure gradient can occur during each cardiac cycle. [89] Some centers have explored the possibility of using preoperative precordial echocardiographic examination to identify patients with a PFO with a view to using alternatives to the sitting position in this subpopulation. [82] [90] [91] The practice has not become widespread. Initially, the number of patients identified was sufficiently far less than the incidence of PFO at autopsy or using TEE that widespread enthusiasm for preoperative screening did not evolve. However, more recently, Schwarz et al [92] reported

a precordial method that resulted in a 25 percent preoperative identification rate. A second group reported a similarly high yield using transcranial Doppler (TCD) of the middle cerebral artery to detect galactose microbubbles after peripheral injection. [93] Accordingly, consideration of preoperative screening of candidates for the sitting position may be renewed.

It is substantially easier to identify a PFO using the TEE (with agitated saline as the contrast medium) than it is with the precordial technique. [94] [95] Selecting the surgical position to be used on the basis of TEE performed after induction seems feasible. However, this approach has not been employed on a widespread basis. The expense of the necessary equipment is inevitably part of the reason. However, it also seems likely that, because the morbid events attributable to PAE have been quite infrequent, surgeons who are convinced that the sitting position is the optimal for a given procedure are loathe to be dissuaded from using it on the basis of what may seem like the very remote possibility of an injury to the patient occurring by this mechanism. At this juncture, maneuvers to identify a PFO prior to the use of the sitting position are decidedly not a community-wide standard of care.

Transpulmonary Passage of Air

It appears likely that air can occasionally traverse the pulmonary vascular bed to reach the systemic circulation. [96] [97] Transpulmonary passage is more likely to occur when large volumes of air are presented to the pulmonary vascular "filter." [98] There is also evidence suggesting that pulmonary vasodilators, [98] including volatile anesthetic agents, may lower the threshold for transpulmonary passage. [99] The magnitude of differences among anesthetics does not appear to mandate any related "tailoring" of anesthetic techniques. However, it does reinforce the notion that even apparently minor VAE should be treated with respect and should prompt discontinuation of N_2O.

Techniques for Reducing the Incidence of Venous Air Embolism

As noted earlier, PEEP was advocated in the past as a means both of reducing the incidence of VAE and of responding to an acute VAE event to prevent further air entry. However, a study by Perkins and Bedford [87] presented data that suggest that PEEP increases the risk of PAE and that accordingly argues against the use of PEEP in patients in the sitting position during neurosurgical procedures. Furthermore, as the authors point out, even 10 cm of PEEP would be unlikely to result in positive venous pressures in cerebral venous structures that may be as much as 25 cm above the heart. The inefficacy of PEEP [100] and the relative superiority of

jugular venous compression [101] [102] in raising cerebral venous pressures have been confirmed by other investigations. An inflatable neck tourniquet available for rapid inflation in the event of VAE has been studied in animals and used in humans by Pfitzner and McLean. [103] The G suit has also been shown to be more effective in producing increases in right atrial pressure than 10 cm of PEEP and can do so without increasing the right atrial-wedge pressure gradient. [104] This latter report is available only in a non-peer-reviewed (abstract) form. There are additional arguments against the short-term use of PEEP in the event of VAE. The various investigations of the identification of PFO have confirmed the efficacy of a Valsalva maneuver, in particular its release, as a means of *promoting* paradoxic embolism. [90] [105] In addition, the impairment of systemic venous return caused by the sudden application of substantial PEEP may be undesirable in the face of the cardiovascular dysfunction already caused by the VAE event.

It has been recommended that the patient who has sustained a hemodynamically significant VAE be placed in a lateral position with the right side upward. The rationale is that air will remain in the right atrium, where it will not contribute to an air lock in the right ventricle and where it will remain amenable to recovery via a right atrial catheter. The first difficulty is that this repositioning is all but impossible with a patient in a pin head holder. In addition, the only systematic attempt to examine the efficacy of this maneuver, albeit performed in dogs, failed to identify any hemodynamic benefit. [106]

Nitrous Oxide

N_2O diffuses into air bubbles trapped in the vascular tree, and accordingly N_2O should be eliminated after a clinical VAE event to avoid aggravating the cardiovascular impact. Note that the PAE phenomenon adds an additional reason for eliminating N_2O *after* the occurrence of VAE. When major VAE occurs, no matter how the right atrial pressure-left atrial pressure gradient was manipulated before the event, right atrial pressure rises abruptly with respect to left atrial pressure, [107] and major VAE always results in an acutely increased risk of PAE in those patients with a PFO. Should N_2O be used at all in patients at risk for VAE? Some clinicians decide that it is easier simply to avoid it and thereby to avoid having to worry about the considerations it creates. However, N_2O can be used with the knowledge that it neither increases the incidence of VAE [108] nor aggravates the hemodynamic response to VAE, provided it is eliminated when VAE occurs. [109]

Monitoring

Neurologic monitoring techniques are discussed in Chapter 35 . Invasive monitoring is frequently appropriate in neurosurgery. Some of the numerous indications for an arterial catheter are listed in Table 52-8 . Patients with increased ICP may be intolerant of the vascular engorgement associated with sudden hypertension occurring as a consequence of light anesthesia. Surgical relief of increased ICP may be associated with sudden hypotension as brain-stem compression is relieved. Beat-by-beat arterial pressure monitoring also serves as an important monitor of the depth of anesthesia and as a neurologic injury early-warning system. Much of the brain is insensate. As a consequence, the intracranial portion of many neurosurgical procedures is not very stimulating, and, to achieve circulatory stability, relatively light anesthesia is often necessary. There should be constant attention

TABLE 52-8 -- Relative Indications for Intra-Arterial Pressure Monitoring

Elevated intracranial pressure
Ischemia or incipient ischemia of neurologic tissue
Recent subarachnoid hemorrhage
Recent head injury
Recent spinal-cord injury
Intended or potential temporary vessel occlusion
Circulatory instability
Trauma
Spinal-cord injury (spinal shock)
Sitting position
Possible barbiturate coma
Possibility of induced hypotension
Possibility of induced hypertension
Anticipated/potential major blood loss
Aneurysm clipping
Arteriovenous malformations
Vascular tumors
Tumors involving major venous sinuses
Craniofacial reconstruction
Extensive craniosynostosis procedures
Anticipated light anesthesia without paralysis
Brain-stem manipulation/compression/dissection
Anticipated cranial nerve manipulation (especially CN V)
Advantageous for postoperative intensive care
Hypervolemic therapy
Head injury
Diabetes insipidus
Incidental cardiac disease

to the possibility of sudden arousal, most often associated with cranial nerve traction or irritation. This is especially important when paralysis is precluded by the use of electromyographic (EMG) recording from facial muscles to monitor cranial nerve integrity. Blood pressure responses may reveal imminent arousal. These responses may also serve to warn a surgeon of excessive or unrecognized irritation, traction, or compression of neurologic tissue. These responses occur most often with posterior fossa procedures involving brain stem or cranial nerves, and abrupt changes should be reported to the surgeon immediately.

The use of right heart catheters for air retrieval is discussed earlier. Thereafter, anticipated blood loss and fluid flux (including aggressive mannitol use) and an evaluation of the patient's physiologic reserve should determine the necessity for CVP or pulmonary artery catheters. Doppler use is also described earlier.

Fluid Management

The general principles of fluid management for neurosurgical anesthesia are (1) to maintain normovolemia and (2) to avoid reduction of serum osmolarity. The first principle is a derivative of the concept presented earlier that it is in general ideal to maintain a normal MAP in patients undergoing most neurosurgical procedures. Maintaining normovolemia is simply one element of maintaining a normal MAP. The second principle is a derivative of the common observation that lowering serum osmolarity results in edema of both normal and abnormal brain. Administering fluids that provide free water (i.e., fluids that do not have sufficient nonglucose solutes

to render them iso-osmolar with respect to blood) will lower serum osmolarity if the amount of free water administered is in excess of that required to maintain ongoing free water loss. A fluid such as half-normal saline is probably reasonable for the traditional maintenance fluid allowance. However, fluids administered to replace blood and third-space loss (i.e., iso-osmolar losses) should be ideally essentially iso-osmolar. Normal saline (which is, in fact, very slightly hyperosmolar, 308 mOsm/L) seems an ideal fluid. In practice, many clinicians use lactated Ringer solution (272 mOsm/L), and although this solution is, in theory, not ideal for either maintenance fluids or replacement of losses, it serves as an entirely reasonable compromise and is very suitable in most instances. However, in a normal experimental animal, it is possible to reduce serum osmolarity and to produce cerebral edema with a large volume of lactated Ringer solution. [110] Therefore, in the setting of massive fluid administration, such as multiple trauma, granted that there is very little advantage to lactated Ringer solution over normal saline, it seems reasonable to use normal saline.

The crystalloid versus colloid discussion is a recurrent one. It usually arises in the context of the head-injured victim of multiple trauma. Although there are numerous fervent beliefs regarding this issue, there has, in fact, been only a single demonstration that the reduction of colloid oncotic pressure in the absence of a change of osmolarity can actually contribute to an augmentation of cerebral edema in the setting of head injury. [111] The transcapillary membrane pressure gradients that can be produced by reduction of colloid oncotic pressure are, in fact, very small by comparison with those created by changes in serum osmolarity. Nonetheless, it appears that those small gradients do, probably in the setting of a BBB injury of intermediate severity, have the potential to augment edema. It seems reasonable then to select a fluid administration pattern that, in addition to maintaining normal serum osmolarity, prevents substantial reductions in colloid oncotic pressure. For most elective craniotomies, this will not require the administration of colloid solutions. However, in those situations requiring substantial volume administration (multiple trauma, aneurysm rupture, cerebral venous sinus laceration, fluid administration to support filling pressure during barbiturate coma), a combination of isotonic crystalloid and colloid may be appropriate.

What colloidal solutions should be used? Albumin and plasma protein fraction are both reasonable choices. The dextran-containing solutions are generally avoided because of their effects on platelet function. The various starch-containing solutions have generated some controversy. [112] [113] It appears certain that the starches have a specific inhibitory effect on factor VIII, [112] in addition to a dilutional reduction of coagulation factors. There have been several reported instances of bleeding in neurosurgical patients that has been attributed to hetastarch administration. However, all those episodes involved circumstances in which the manufacturer's recommended limit of 20 mL/kg/d was exceeded. The decision to use or not use these products is frequently a local one. If they are used, the manufacturer's recommended limit (20 mL/kg/24 h) should be observed.

There is substantial current interest in the use of hypertonic fluids, in particular in the circumstance of resuscitation

---

of the multiple trauma victim. [114] It appears unlikely that the effect of these fluids on the brain is substantially different from that of an equi-osmolar exposure to mannitol. [115] Accordingly, when decisions about the appropriateness and relevance of these fluids in the resuscitation process are eventually made, it seems unlikely that those decisions are made on the basis of specific cerebral effects. It seems more likely that the final judgment regarding this class of fluids is made on their effects on the systemic circulation. [116] In general, an intervention that has the advantage of more effectively restoring systemic hemodynamics is likely to be advantageous to the brain. That assertion is made with the provision that sustained hyperosmolarity, such as that greater than 320 mOsm/L, caused by any fluid has the potential to result in rebound swelling of the brain.

Hypothermia

The effects of hypothermia on cerebral physiology and its potential cerebral protective mechanisms are presented in Chapter 19 (Table 19-8; Ch. 37) . There have been numerous laboratory demonstrations of the efficacy of mild hypothermia (32-34°C) in reducing the neurologic injury occurring after standardized cerebral and spinal cord ischemic insults. This has resulted, in spite of the absence of any demonstration of efficacy in humans, in the relatively widespread use of induced hypothermia in the management of cerebral vascular procedures, in particular aneurysms [117] [118] and occasionally AVM. Although mild hypothermia is perceived to convey certain hazards, including coagulation dysfunction and an increased postoperative wound infection rate, neither of these problems has been evident in the context of aneurysm surgery, although once again there has not been systematic study. Anecdotally, hypertension on emergence from anesthesia has been noted to occur in patients who are not adequately rewarmed, and a modest overshoot in temperature has been observed to occur among patients who were cooled intraoperatively. [119] The issue of where body temperature should be recorded in order to reflect brain temperature best during craniotomy has been addressed. [120] It appears that esophageal, tympanic membrane, pulmonary artery, and jugular bulb temperatures are all very similar and provide a reasonable reflection of deep brain temperature, whereas bladder temperature does not. Superficial layers of cortex may be substantially cooler than deep brain and central temperatures.

Because ischemia is recognized to make a postinsult contribution to neuronal injury after head injury, [24] [121] hypothermia was also studied in the laboratory in the context of traumatic brain injury. [122] It was effective, and this resulted in at least four single institution trials of 24 to 48 hours of mild hypothermia after head injury. These trials demonstrated either significant improvement in outcome or favorable trends. [123] [124] [125] [126] A multicenter, prospective trial of hypothermia after head injury is ongoing. A report is anticipated early in 2000. Those investigations have revealed some physiologic dysfunction associated with more prolonged mild hypothermia, all of which has been reversible with restoration of normal temperature. This included decreased creatinine clearance, elevation of pancreatic enzymes, and a suggestion of an increased infection rate. A decreased incidence of seizures was an apparent adjunctive benefit in one study.

On the basis of a lack of demonstrated efficacy in humans, routine use of hypothermia cannot be advocated in a standard text. The decision to employ it, usually in the context of aneurysm surgery, is local. If employed, hypothermia should be used with attention to the possibility of cardiac dysrhythmias and coagulation dysfunction if temperatures become too low and with attention to the necessity to rewarm the patient adequately prior to emergence to avoid shivering and hypertension.

Emergence From Anesthesia

Most practitioners of neuroanesthesia believe that there is a premium on a "smooth" emergence, that is, one free of coughing/straining and arterial hypertension. The avoidance of arterial hypertension is seen as desirable because of the belief that arterial hypertension can contribute to intracranial bleeding and increased edema formation. [127] [128] [129] [130] In the face of a poorly autoregulating cerebral vasculature, hypertension also has the potential, through vascular engorgement, to contribute to elevation of ICP. Much of the concern with coughing/straining has a similar basis. The sudden increases in intrathoracic pressure are transmitted to both arteries and veins, thus producing transient increases in both cerebral arterial and venous pressure with the same potential consequences: edema formation, bleeding, and elevation of ICP. Coughing is a specific concern with certain individual procedures. In transsphenoidal pituitary surgery in which a surgeon has opened, and subsequently taken pains to close, the arachnoid membrane to prevent CSF leakage, there is the belief that coughing has the potential to disrupt this closure because of the sudden and substantial increases in CSF pressure. Opening a pathway from the intracranial space to the nasal cavity conveys a substantial risk of postoperative meningitis. In other procedures, notably those that have violated the floor of the anterior fossa, there is also the potential for air to be driven into the cranium and, in the event of a flap-valve mechanism, to cause a tension pneumocephalus. This latter event can only occur when coughing occurs after the endotracheal tube has been removed.

It should be acknowledged that there is a paucity of systematically obtained clinical data to give perspective to the actual magnitude of the risks associated with emergences from anesthesia that are not "smooth." One clinical investigation confirmed the association of increased CBF velocity in association with hypertension during emergence. [131] A second retrospective study revealed that elevated postoperative blood pressure was a correlate of intracerebral bleeding following craniotomy. [132] However, there is not, in fact, any proof to show that it is specifically hypertension occurring during emergence that is correlated with postoperative intracerebral bleeding. The same acknowledgment must be made with the matter of edema formation. It has been demonstrated in animals that sudden substantial increases in arterial pressure in anesthetized animals can result in a breech of the BBB with extravasation of tracers such as Evans blue. However, there are no data to confirm that the

---

pressure transients associated with the typical coughing episode or typical emergence hypertensive transient are, in fact, associated with increased edema formation. Nonetheless, it seems reasonable to take measures, to the extent that these measures do not themselves add potential patient morbidity, to prevent these occurrences.

A common method for the management of systemic hypertension during the last stages of a craniotomy is the expectant and/or reactive administration of vasoactive agents, most commonly labetalol and esmolol. Several other drugs are acceptable. There are also many approaches to the prevention of coughing and straining. We have several biases and encourage trainees to include in their anesthetic technique as much narcotic as is consistent with spontaneous ventilation at the conclusion of the procedure. That practice is based on the same physiologic effect that justifies the administration of codeine and related compounds as antitussive medication, that is, the depression of airway reflexes by narcotics. We also have the bias that patients emerge more rapidly and smoothly when the last inhalation agent to be withdrawn is N_2O and that clinicians should seek to avoid the "neither here nor there" phase of anesthesia that occurs in patients who are stimulated in the face of residual exhaled concentrations of volatile agent on the order of 0.2 to 0.3 minimum alveolar concentration (MAC). A common practice among neuroanesthetists near the conclusion of a craniotomy is the relatively early discontinuation of the volatile agent with supplementation of residual N_2O with propofol by either bolus increments or infusion at rates in the range of 25 to 100 mug/kg/min.

An additional principle relevant to the emergence from neurosurgical procedures that practitioners will learn either from a book or from experience is that emergence should be timed to coincide not with the final suture (as may be appropriate for a cholecystectomy), but rather with the conclusion of the application of the head dressing. Many a good anesthetic regimen for neurosurgery has been spoiled by severe coughing and straining that occurs in association with endotracheal tube motion during the application of the head dressing. Another nuance of our practice has been to withhold administration of neuromuscular antagonists as long as possible as a hedge against misjudgment while lightening anesthesia in a patient in the later stages of the procedure. An additional popular and apparently effective technique for reducing airway responsiveness and the likelihood of coughing/straining while reducing the depth of anesthesia is the administration of lidocaine. Bolus doses on the order of 1.5 mg/kg are appropriate for this purpose.

The premium placed on minimizing coughing/straining and hypertension usually causes patients to be very expediently extubated once extubation is appropriate. There may, in some instances, be a temptation to extubate patients prior to complete recovery of consciousness. This method may be acceptable in some circumstances. However, it should be undertaken with caution when the circumstances of the surgical procedure make it possible that neurologic events have occurred that will delay recovery of consciousness or when there may be lower cranial nerve dysfunction. In these circumstances, it is generally best to wait until the likelihood of the patient's recovery of consciousness is confirmed and/or until patient cooperation and airway reflexes are likely to have recovered.

SPECIFIC PROCEDURES

Many of the considerations relevant to individual neurosurgical procedures are generic and are presented earlier in this chapter. The descriptions that follow highlight only procedure-specific issues.

Supratentorial Tumors

Craniotomies for excision and/or biopsy of supratentorial tumors are among the most common neurosurgical procedures performed. Gliomas and meningiomas are among the most frequent tumors. The relevant preoperative considerations include the patient's ICP status and the location and size of the tumor. Location and size give the anesthesiologist an indication of the surgical position and the potential for blood loss, and occasionally they reveal a risk of air embolism. The VAE risk is quite low for the majority of other supratentorial tumors. However, lesions (usually convexity meningiomas) that encroach on the sagittal sinus may convey a substantial risk of VAE. Accordingly, full VAE precautions, including an atrially placed CVP catheter, are usually reserved only for supratentorial tumors that lie near the posterior half of the sagittal sinus.

Patients with craniopharyngiomas and pituitary tumors with suprasellar extension may undergo procedures that involve dissection in and around the hypothalamus. Irritation of the hypothalamus can elicit sympathetic responses including hypertension. Damage to the hypothalamus can result in a spectrum of disturbances in consciousness varying from lethargy to obtundation. Disturbances of water balance may also occur. Diabetes insipidus is the most likely disorder, although the cerebral salt-wasting syndrome can potentially occur. The latter has been very infrequent. The various disturbances of water balance typically have a delayed onset, beginning 12 to 24 hours postoperatively, rather than in the operating room. Postoperative temperature homeostasis may also be disturbed.

Patients who undergo a craniotomy involving a subfrontal approach may, on occasion, manifest a disturbance of consciousness in the immediate postoperative period. Retraction/irritation of the inferior surfaces of the frontal lobes can result in a patient who is lethargic and does not awaken "cleanly." Patients exhibiting this phenomenon are sometimes referred to "frontal lobe-y." The phenomenon is more likely to be evident when there has been bilateral subfrontal retraction than when it occurs only unilaterally. The anesthetic implication is that the clinician should be more inclined to confirm the patient's return of consciousness before extubating the patient than to extubate while awaiting the patient's return to consciousness. A further implication taken by these authors (although not confirmed by any systematic study) is that a less liberal use of fixed agents (narcotics, benzodiazepines) may be appropriate. This is based on the rationale that low residual concentrations of these agents that would be compatible with reasonable recovery of consciousness in the majority of patients may be less well tolerated in this population. Subfrontal approaches are most commonly employed in patients with olfactory groove meningiomas and in patients with suprasellar tumors (craniopharyngiomas and pituitary tumors with suprasellar extension).

Preoperative Preparation

Patients with a significant tumor-related mass effect, especially if there is tumor-related edema, should receive preoperative steroids. If the patient is not receiving a steroid, it is the anesthesiologist's responsibility to ask why. A 48-hour course is ideal (see the discussion of steroids earlier), although 24 hours is sufficient for a clinical effect to be evident. Dexamethasone is the most commonly used agent. Regimens such as 10 mg intravenously or orally followed by 10 mg every 6 hours are typical. Because of the concern about producing CO_2 retention in a patient whose intracranial compliance is already abnormal, patients with any substantial mass effect are usually not premedicated with anything beyond full-dose reassurance.

Monitoring

Frequently, the nature of the procedure does not require anything more than routine monitoring. However, some situations do argue for invasive monitors (see earlier). Preinduction placement of an arterial line may be appropriate in patients with severe mass effect and little residual compensatory latitude. It is the period of induction during which hypertension with its attendant risks in a patient with impaired compliance and autoregulation is most likely to occur. Procedures with a substantial perceived blood loss potential (tumors encroaching on the sagittal sinus, large vascular tumors) may also justify arterial and/or CVP catheters. Is ICP monitoring ever warranted for intraoperative management? In our opinion, no. Clinicians have a sufficient understanding of the potential impact of anesthetic agents and techniques that they should be able to manage induction of anesthesia. Then, once the cranium is open, observation of conditions in the surgical field provides equivalent information.

Management of Anesthesia

The principles governing the choice of anesthetic agents are presented in the earlier section on anesthetic selection in the discussion of ICP control.

Aneurysms and Arteriovenous Malformations

Contemporary management of intracranial aneurysms calls for early surgical intervention following SAH. The definition of "early" varies up to and including the first 72 hours after bleeding. [133] This approach is usually applied only in patients in the better neurologic grades: grades I to III and perhaps IV of the World Federation of Neurosurgeons classification (Table 52-9) or grades I to III of the Hunt-Hess classification (Table 52-10) . If early intervention is not feasible, then surgery is usually delayed for at least 2 weeks in order to be safely beyond the period of maximal vasospasm risk, that is, days 4 to 12 after SAH.

TABLE 52-9 -- World Federation of Neurosurgeons Subarachnoid Hemorrhage Scale

WORLD FEDERATION OF NEUROSURGEONS GRADE	GLASGOW COMA SCALE SCORE	MOTOR DEFICIT
I	15	Absent
II	14-13	Absent
III	14-13	Present
IV	12-7	Present or absent
V	6-3	Present or absent

From Drake et al [235]

TABLE 52-10 -- Hunt-Hess Classification of Neurologic Status After Subarachnoid Hemorrhage

CATEGORY	CRITERIA[a]
Grade I	Asymptomatic or minimal headache and slight nuchal rigidity
Grade II	Moderate to severe headache, nuchal rigidity, no deficit other than cranial nerve palsy
Grade III	Drowsiness, confusion, or mild focal deficit
Grade IV	Stupor, moderate to severe hemiparesis, possibly early decerebrate rigidity, and vegetative disturbances
Grade V	Deep coma, decerebrate rigidity, moribund appearance

From Hunt and Hess [24]

[a] Serious systemic disease such as hypertension, diabetes, severe arteriosclerosis, chronic pulmonary disease, and severe vasospasm seen on arteriography result in placement of the patient in the next less favorable category.

The rationale for early clipping of the aneurysm is several-fold. The sooner the aneurysm is clipped, the less is the likelihood of rebleeding, and rebleeding is the principal cause of death for patients hospitalized after SAH [134] . The management of the ischemia caused by vasospasm involves volume loading and induced hypertension. Early clipping of the aneurysm eliminates the risk of rebleeding associated with this therapy. Vasospasm appears to be related to the presence of blood in the basal cisterns in the vicinity of the circle of Willis. Some of this blood can be removed at the time of the aneurysm clipping, and, accordingly, early clipping not only makes the therapy of vasospasm safer, but also it may reduce the incidence and severity of the problem. Early access to the circle of Willis also allows direct instillation of tissue plasminogen activator into the basal cisterns to aid further in the clearing of clot from the circle of Willis. [135] [136] The results of the initial evaluations of tissue plasminogen activator therapy are suggestive of a substantial benefit, although this therapy remains experimental. Prior surgical practices entailed maintaining the patient at bed rest until approximately day 14, when the period of spasm risk had passed. Early aneurysm clipping reduces the period of hospitalization and reduces the incidence of the medical complications (deep venous thrombosis, atelectasis, pneumonia) associated with a lengthy period of enforced bed rest.

Early intervention can make the intraoperative course more difficult. The brain in the early post-SAH period is likely to be more edematous than following a 2-week delay. A mild degree of hydrocephalus is common after blood contaminates the subarachnoid space. [137] In fact, up to 10 percent of victims of SAH may actually require CSF shunting at some point in their course. [138] Early intervention may also somewhat enhance the risk of intraoperative aneurysmal rupture because of the lesser period of time for clot to organize over the site of the initial bleeding. All this places a substantial premium on techniques designed to reduce the volume of the intracranial contents (see earlier) in order to facilitate exposure and to minimize retraction pressures.

Preoperative Evaluation.

Many patients scheduled for intracranial aneurysm clipping come directly from the ICU, and elements of their management there may influence their immediate preoperative status.

Fluid Management.

Some patients develop syndrome of inappropriate antidiuretic hormone (SIADH) after SAH and are appropriately managed with fluid restriction. However, hyponatremia after SAH is more likely to be the result of the cerebral salt-wasting syndrome, [139] [140] [141] [142] [143] which probably occurs as a result of the release of a natriuretic peptide (which is similar to but may not be the same as that occurring in the heart [144] [145]). The syndrome is characterized by the triad of hyponatremia, volume contraction, and high urine sodium concentrations (>50 mmol/L). The distinction between this syndrome and SIADH is important. SIADH, which is characterized by normovolemia or mild hypervolemia, is treated by volume restriction. Cerebral salt wasting is associated with *contracted* intravascular volume. [143] Fluid restriction and further volume contraction may be especially deleterious in the patient who has had an SAH, [140] and these measures should be avoided.

Vasospasm.

When neurologic deterioration occurs subsequent to the patient's initial period of stabilization, vasospasm is frequently the cause. Drowsiness is a common initial clinical sign. In patients in whom there is a clinical suspicion or an angiographic demonstration of vasospasm, surgery is commonly deferred. If it is to proceed, CPP should be maintained intraoperatively in a high-normal range. This is contrary to the time-honored patterns of intraoperative management that have characteristically emphasized *hypo*tension. However, neurosurgeons are becoming increasingly concerned about the potential for induced hypotension to cause or to aggravate cerebral ischemia in the patient with vasospasm. This concern extends to the World Federation of Neurosurgeons grade I patient who may have regions of cerebral ischemia [40] that are subclinical when the patient is normotensive.

Vasospasm is thought to be caused by the breakdown products of oxyhemoglobin in the blood that has accumulated around the vessels at the base of the brain. Whereas current suspicion is focused on the binding of nitric oxide by exposed heme groups, the specific mechanism/mediator has not been identified.

In the ICU, the regimens employed to treat vasospasm usually involve some combination of hypervolemia, hemodilution, and hypertension. The science behind hypervolemic-hypertensive therapy is "soft." It is not clear whether the rheologic or the pressure effects are the more important, although there is evidence of the relevance of blood pressure elevation in isolation. [146] Empirically, it appears to work. The favored pressor is dopamine. The end point for dopamine administration varies. It may be an increase in MAP of
20 to 30 mm Hg higher than "baseline" systolic pressure. Other surgeons are content to achieve merely a substantial increase in cardiac output, although the available data argue that blood pressure is the important determinant of CBF. [147] Some clinicians believe that the hematocrit should be reduced to the low 30s. Commonly, hematocrit reduction occurs secondarily as a result of attempts to produce hypervolemia (usually with colloid solutions), as part of the effort to raise blood pressure.

Calcium Channel Blockers.

Calcium channel blockers are an established part of the management of SAH. Administration of nimodipine has been shown to decrease the incidence of morbidity from cerebral ischemia after SAH. [148] [149] [150] However, these studies have failed to demonstrate any reduction in the incidence of vasospasm as detected by angiography. [149] This finding suggests that the beneficial effect of these agents may be the result of effects on neurons rather than on vascular smooth muscle. Patients can be expected to come to the operating room after having received nimodipine. The available information suggests that the use of nimodipine causes very little hemodynamic disturbance. [151] Nimodipine must be administered orally, and nicardipine has been evaluated as an intravenous alternative. A multicenter nicardipine trial [152] [153] revealed a reduced incidence of symptomatic vasospasm, but it showed no improvement in outcome. As a consequence, nimodipine is more commonly employed.

Tirilazad.

In a multicenter trial conducted in Europe, Australia, and New Zealand, a better neurologic outcome

and a reduced incidence of the need for hypervolemic-hemodilutional-hypertensive therapy were observed in men who received tirilazad, a free radical scavenger. [154]

The absence of a benefit in women has been attributed to a more rapid rate of metabolism associated with the presence of estrogens. The North American limb of that trial revealed no benefit in either sex. [155] It has been speculated that the absence of a protective effect in North America was the result of a greater frequency of use of anticonvulsants, with the attendant possibility of an increased rate of metabolism of tirilazad in both male and female patients. A follow-up trial using 10 to 15 mg/kg/d is under way.

Antifibrinolytics.

Antifibrinolytics were employed in the past in an attempt to reduce the incidence of rebleeding. Although they accomplish the latter, the overall morbidity is nonetheless worse as a result of an increase in the incidence of ischemic symptoms [156] and hydrocephalus.

ECG Abnormalities.

ECG abnormalities can occur in patients who have sustained an SAH. In addition to the classic "canyon T waves" (Fig. 52-12) , nonspecific T-wave changes, QT prolongation, ST-segment depression, and U waves have been described. [157] The significance of these changes has been debated. It seems likely that the episode of extreme hypertension and autonomic discharge that occurs in association with the initial SAH event does, in fact, result in focal, probably subendocardial, myocardial injury, presumably because of the extreme myocardial wall tension that occurs. [158] Evidence of focal myocardial injury has been found in some, [159] but not all, [157] investigations. The relationship between the ECG changes and myocardial dysfunction is not clear. Davies et al [160] compared the 12-lead ECG and the 2-dimensional precordial echocardiogram in 41 patients with sustained SAH. These authors concluded that myocardial dysfunction was more likely to occur with increasing severity of neurologic condition and that the ECG itself was not an accurate predictor of myocardial dysfunction. Szabo et al [161] observed thallium scan abnormalities in one-third of patients after SAH. However, there was no identifiable relationship between the scan abnormalities and the ECG changes. By contrast to the preceding two studies, Mayer et al [162] did identify an association between impaired left ventricular function and ECG abnormalities including T-wave inversion and QTc prolongation. In either case, it appears that, when ECG patterns other than those that are typical of myocardial ischemia are observed, no specific interventions or modifications of patient management approach are warranted. Brouwers et al [163] followed the clinical course of 61 patients who had at least one abnormal ECG following

Figure 52-12 Electrocardiographic abnormalities associated with subarachnoid hemorrhage. This tracing demonstrates the "canyon" T waves that may be seen after subarachnoid hemorrhage.

SAH. Cardiac dysfunction did not appear to contribute to morbidity or mortality in any of these patients, and these workers concluded that "in patients with aneurysmal SAH, ECG abnormalities do not herald impending cardiac disease." Although the nonspecific ECG changes do not appear to have important implications with respect to myocardial function, they may indicate a risk of dysrhythmias. In particular, an increased Q-T interval (>550 ms) has been associated with an increased incidence of malignant ventricular rhythms including torsades de pointes. [164]

Anesthetic Technique.

The important considerations include the following:

1. The absolute avoidance of acute hypertension with its attendant risk of recurrent rupture.
2. The provision of intraoperative brain relaxation to facilitate surgical access to the aneurysm.
3. The maintenance of a high-normal MAP in order to prevent critical reduction of CBF in recently insulted and now marginally perfused areas of brain.
4. The preparedness to perform precise manipulations of MAP as the surgeon attempts to clip the aneurysm and/or control bleeding from a ruptured aneurysm.

Monitoring.

An arterial line is invariably appropriate. A CVP may be relevant if the institutional practices involve large doses of mannitol to promote brain relaxation, and it may be chosen in older patients to guide volume replacement in the event of bleeding.

Agent Selection.

Any technique that permits proper control of MAP is acceptable. However, in the face of an increased ICP or a tight surgical field, an inhaled agent technique may be less suitable. The prevention of paroxysmal hypertension is the only absolute requirement in patients undergoing aneurysm clipping. Rebleeding kills, [134] and the poorly organized clot over the aneurysms of patients undergoing early post-SAH clipping makes them particularly prone to rebleeding. Rebleeding at induction is an almost invariably fatal event. The escaping arterial blood is more likely to penetrate brain substance because it cannot dissect through the CSF space (filled with clot), and the ICP increase is extreme because of the poor compliance of the intracranial space (swollen brain, hydrocephalus).

Induced Hypotension.

The routine use of induced hypotension is diminishing (see earlier). Nonetheless, the anesthesiologist should be prepared to lower the patient's blood pressure immediately and precisely if called on to do so. Preparation must occur before the episode of bleeding. We prepare a sodium nitroprusside infusion prior to induction. It is placed in line at a Y-injection port at the hub of the CVP or intravenous catheter. A carrier drip flows steadily such that any change in nitroprusside infusion rate is reflected as rapidly as possible in the central compartment. There are theoretical pros and cons for the use of various hypotensive agents. The data indicate that regimens that entail the use of an agent that is also a cerebral vasodilator (isoflurane, nitroprusside) are preferable in terms of brain oxygen delivery to approaches that do not involve cerebral vasodilation (trimethaphan, controlled hypovolemia). [165] Deep isoflurane and nitroprusside are the most commonly used regimens, although other agents may be suitable. The choice should ultimately be made on the basis of which regimen, in the hands of the individual practitioner, results in the most precise control of MAP. There are occasions when the anesthesiologist is asked to control MAP in the range of 30 to 50 mm Hg, in the face of active arterial bleeding. This can be extremely difficult in a patient who is hypovolemic at the beginning of the bleeding episode. Accordingly, it is our practice to maintain normovolemia.

Induced Hypertension.

Hypertension may be requested during periods of temporary arterial occlusion (see the discussion of trapping later) to augment collateral CBF. [117] In addition, following clipping of the aneurysm, some surgeons puncture the dome of the aneurysm to confirm adequate clip placement and may request transient elevation of the systolic pressure to 150 mm Hg. Phenylephrine is suitable in either instance.

Hypocapnia.

Hypocapnia has traditionally been employed as an adjunct to brain relaxation. This, too, has been questioned on the basis of the concern that it will aggravate ischemia (see earlier). The ICP/brain relaxation circumstances should probably dictate its use or avoidance.

Lumbar CSF Drainage.

Some surgeons employ elective drainage to facilitate exposure of the operative site. It is extremely effective, effective to the point that the energetic application of other brain-volume-reducing techniques is almost unnecessary. It is appropriate, when placing a lumbar CSF drain, to avoid excessive loss of CSF. Sudden reduction of the transmural pressure gradient across the dome of the aneurysm (by sudden reduction of ICP consequent on substantial CSF drainage) should be avoided lest this decompression encourage rebleeding. [166] The common practice is, having verified the patency of the lumbar drainage system, to leave it closed until such time

as the surgeon is completing the dural opening. The drain may then be opened and allowed to drain freely with the bag at floor level. Drainage should be discontinued promptly after final withdrawal of the retractors in order to allow CSF to reaccumulate and thereby to reduce the size of the potential pneumocephalus. The drain is usually removed immediately postoperatively.

Mannitol.

Some surgeons make relatively aggressive use of mannitol (e.g., 2 g/kg). In part, it is used to shrink the brain and thereby to facilitate exposure and to reduce retractor pressures. There is evidence that it may have additional benefits. Specifically, there are data derived in both animals and humans that indicate that mannitol may have a CBF-enhancing effect in regions of moderate CBF reduction. [167] [168] [169] The mechanism is not defined. However, reduction of interstitial tissue pressure around capillaries and/or an alteration of blood rheology have been proposed to contribute to this effect.

Trapping.

It is occasionally necessary for the surgeon to "trap" the aneurysm (i.e., to occlude the vessel temporarily on either side of the aneurysm) in order to complete dissection of the neck and to apply the clip. This is more common with larger aneurysms. With giant aneurysms in the vicinity

of the carotid siphon, the inferior occlusion may be performed at the level of the internal carotid artery via a separate incision in the neck. A clinical survey by Samson et al [170] of the results of temporary occlusion in normothermic adults revealed that occlusions of less than 14 minutes were invariably tolerated. The likelihood of an ischemic injury increased with longer occlusion times to 100 percent at more than 31 minutes. [170] In another institution, the threshold for ischemic injury was 20 minutes. [117] Typically, it is appropriate to support MAP at high-normal levels during periods of occlusion to facilitate collateral CBF.

Brain Protection.

Maintenance of MAP to ensure collateral flow and perfusion under retractors, efficient brain relaxation to facilitate surgical access and to reduce retractor pressures, limiting the duration of episodes of temporary occlusion, and perhaps mild hypothermia (see earlier) are the important brain-protection techniques. Specific anesthetic agents have also been used to protect the brain (Ch. 19) . Etomidate and propofol are used currently. However, there have been no convincing laboratory demonstrations that either drug provides any greater tolerance to a standardized ischemic insult than does anesthesia with a volatile agent. With respect to the volatile agents, attempts in the laboratory to confirm the once suspected protective efficacy of isoflurane have demonstrated that there are no differences among the various volatile agents in terms of their influence on outcome after focal or global ischemia in the laboratory. [171] [172] Nor has there been any demonstration of greater protective efficacy with concentrations of volatile agents sufficient to cause EEG suppression as opposed to more modest, levels, such as 1.0 MAC. It may evolve from ongoing investigative work that there is an advantage to a volatile agent technique over a narcotic-based technique, [173] but that issue remains to be defined. Among anesthetic agents, it is only the barbiturates for which additional protective efficacy has been demonstrated convincingly (Ch. 19) . Because of their potentially adverse effects on hemodynamics and arousal, these drugs are not ideal for routine administration. They should probably be reserved for situations in which a prolonged vessel occlusion is unavoidable, and in that circumstance, it would be ideal that the ischemic hazard be first confirmed by observation of the EEG response to a temporary occlusion.

Hypothermia.

As noted earlier, there has been no con-firmation in humans of the efficacy of mild hypothermia. Nonetheless, neurosurgical teams in many institutions are lowering body temperature to the range of 32 to 34°C for procedures in which vessel occlusion may occur. The institutions using the lower temperatures are those in which the team is willing to accept a delay in emergence from anesthesia as a result of the need to maintain anesthesia long enough to achieve rewarming in order to avoid the extreme hypertension that can occur when a patient is awakened at low body temperatures. It has been confirmed by Crowder et al [120] that the systemic temperature reduction does result in a concomitant decrease in brain temperature. In that investigation, during moderate hypothermia with the dura open, cortex temperature was approximately 0.5°C less than tympanic membrane temperature and about 1°C lower than esophageal, pulmonary artery, or jugular bulb temperature. [120]

Neurophysiologic Monitoring.

Both evoked responses and EEG have been employed, [174] [175] although neither is used widely. EEG monitoring can be used as a guide to management during the period of flow interruption and/or to guide the administration of CMR-reducing anesthetic agents given prior to occlusion. [175] At some institutions, the surgeon places an electrode strip over the region of cortex at risk during the intended occlusion. However, the more commonly used skin-surface frontal-mastoid derivation is probably sufficient to reveal a major ischemic event. The EEG can be either the conventional "raw" polygraph or a processed derivative. In most circumstances, if occlusion is deemed necessary, a temporary occlusion is performed, and the EEG is observed. If the EEG shows significant slowing, the usual practice is to reposition the clip and/or elevate MAP by some combination of phenylephrine and lightening of anesthesia in order to find a way of temporary clipping without a major EEG disturbance. If this cannot be accomplished, and if a sustained period of occlusion seems likely, then it may be appropriate to administer barbiturates (see earlier) to produce burst suppression.

Intraoperative Angiography.

Intraoperative angiography is an increasingly common component of the management of intracranial aneurysms. It does not have substantial implications for the anesthesiologist. However, apparatus around the patient's head must be organized so as to allow C-arm access without snagging of airway and monitoring equipment. In addition, the radiologist must have access to the patient's groin vessels. The vascular access sheath, for a patient who will ultimately be in the lateral position, is easiest to use when the nondependent femoral artery is chosen. The rate of administration of heparin "flush" via the vascular access sheath should be monitored.

Special Considerations for Specific Aneurysms.

The most common procedures are performed for aneurysms arising in or close to the circle of Willis. The vessel of origin may be the middle cerebral artery, the anterior communicating artery, the anterior cerebral arteries, the ophthalmic artery, the tip of the basilar artery, the posterior communicating artery, or, less frequently, the posterior cerebral artery. These procedures are all relatively similar for the anesthesiologist.

Ophthalmic Artery Aneurysms.

These aneurysms frequently require temporary vascular occlusion. Access to the origin of the ophthalmic artery is made difficult by the anterior clinoid process and the optic nerve. Surgeons commonly first expose the carotid artery in the patient's neck. When they reach the stage of seeking definitive access to the neck of the aneurysm, they occlude first the carotid artery in the neck and then the intracranial portion of the carotid artery immediately proximal to the origin of the posterior communicating artery. Surgeons may also place the isolated segment to suction, which entails a modest ongoing blood loss as a consequence of retrograde flow from meningeal and hypophyseal vessels.

Vertebrobasilar Aneurysms.

These procedures are typically performed with the patient in the lateral position. The exposure may involve a combined middle and posterior

fossa approach, with some attendant, although minor, risk of VAE. Cortical or skin-surface EEG monitoring is of less relevance with vertebrobasilar aneurysms.

Auditory and/or somatosensory evoked responses have been employed [176] (Ch. 35) . As in any other procedure involving the potential for mechanical or vascular injury to the brain stem, cardiovascular responses should be monitored, and sudden changes in response to surgical manipulation should prompt immediate notification of the surgeon. Spontaneous ventilation has also been shown to play an important role during surgical manipulation of the vertebral arteries, the vertebrobasilar junction, and the middle portion of the basilar artery. Apnea, gasping, and other sudden changes in ventilatory pattern during manipulation of the vasculature provide important, although somewhat nonspecific, warnings of compromise of the vascular supply of the brain stem. [177] [178]

Vein of Galen Aneurysms.

These "aneurysms" are more appropriately managed according to considerations relevant to AVM. These considerations include anticipation of the possibility of the cerebral dysautoregulation phenomenon and are considered later.

Arteriovenous Malformations

For the majority of intracranial AVMs, the general considerations are similar to those appropriate to aneurysm surgery: avoidance of acute hypertension and the capability to manipulate blood pressure accurately in the event of bleeding. A problem that is specific to AVM is the phenomenon known as perfusion pressure breakthrough or cerebral dysautoregulation. [179] It is characterized by an often sudden engorgement and swelling of the brain, sometimes with a relentless cauliflower-like protrusion from the cranium. It tends to occur in the advanced stages of lengthy procedures on large AVMs. The phenomenon is not entirely understood. However, it has been attributed to the acute obliteration of the high-volume, low-resistance pathway (the AVM) that, for many years, has been stealing blood from the surrounding tissue. The result is the abrupt diversion of the AVM's flow to the vasculature in adjacent and previously marginally perfused brain. It is presumed that these tissues have long been maximally vasodilated without the need ever to vasoconstrict and that they are incapable of doing so (although not all the available information is consistent with this premise [180] [181] . Accordingly, the phenomenon is also referred to as "autoregulation breakthrough" or dysautoregulation.

Anesthetic Technique.

The management constraints are essentially the same as those relevant to aneurysm surgery. Institutional practices vary. We do not employ induced hypotension unless required to by the patient's bleeding. The surgeon reasons that the effects on the surrounding brain of devascularizing the AVM will be best appreciated if the devascularization occurs at normal pressures. If refractory brain swelling occurs, we may also lower pressure as part of our attempts to control the swelling, reasoning that blood flow through the involved area is pressure passive and will decrease as MAP declines. With severe episodes of swelling, we have employed (in addition to hypotension, which we use cautiously because of the associated ischemia risk) hypocapnia, hypothermia, and barbiturates. The last three techniques probably serve to reduce the bulk of only normal brain tissue, with hypocapnia acting via a direct effect on CBF, and barbiturates and hypothermia via the coupled effects of reduction of CMR on CBF. Induced hypothermia is also an adjunct to minimizing the barbiturate doses.

Head Injury

Intubating the Trachea of a Head-Injured Patient

The anesthesiologist's first "interface" with the head-injured patient may come as a result of a request for assistance with airway management. It has been determined empirically that patients with Glasgow Coma Scale scores of 7 to 8 (Table 52-11) or less eventually require intubation and controlled ventilation for ICP and/or airway control. Accordingly, these patients are almost invariably intubated promptly. Patients with less severe head injuries may also require intubation because of trauma-related cardiopulmonary dysfunction or, when uncooperative, to facilitate diagnostic procedures. The anesthesiologist, in choosing the intubation technique, may encounter a number of conflicting constraints. These include (1) elevated ICP, (2) a full stomach, (3) an uncertain cervical spine, (4) an uncertain airway (presence of blood, possible laryngeal-tracheal injury, possible skull base fracture), (5) an uncertain volume status, (6) an uncooperative/combative patient, and (7) hypoxemia. There is no "correct" way, and the "best" approach is determined by the relative weight of these various factors, along with the degree of urgency. However, the anesthesiologist must not become distracted by an excessive initial emphasis on ICP and must keep sight of the ABCs of resuscitation: securing the airway, guaranteeing gas exchange, and stabilizing the circulation are higher initial priorities than ICP. One must not risk losing the airway or causing severe hypotension for the sake of preventing coughing while the patient is intubated or brief hypertension with intubation.

Cervical Spine

The possibility of causing or aggravating an injury to the cervical spine is a relevant concern. Approximately 2 percent of patients with a closed head injury who survive to reach a hospital have a fracture of the cervical spine. [182] Somewhat surprisingly, the incidence of cervical spine injury is similar (1.8-6.0%) for all blunt trauma victims with or without an associated head injury [182] [183] [184] [185]). This incidence suggests that a thiopental-succinylcholine-direct laryngoscopy-endotracheal intubation approach for all patients with a closed head injury may convey a measurable risk of injuring the cervical spinal cord. Nonetheless, although the literature contains contradictions, several published series have concluded that such an approach does not convey significant risk of neurologic injury. [185] [186] [187] [188] [189] However, it is possible that the incidence of intubation-related neurologic injury is underreported. An informal survey reported by Criswell et al [185] indicated that there have been more such events than one can infer from the published literature. [190] Nonetheless, the literature argues that clinicians manage to succeed most of the time, and there are certainly units in which the majority of patients requiring airway control are intubated using a hypnotic-relaxant-direct laryngoscopy sequence. However, it is the (probably minority) opinion of these authors that the possibility of devastating spinal cord injury exists, probably mostly with injuries in the atlantooccipital (A-O) region, which are also difficult to identify radiologically, [191] and that the anesthesiologist should seek to identify circumstances in which time latitudes allow more detailed examination or radiologic evaluation. When there is any uncertainty regarding the airway or the cervical spine, direct laryngoscopy (with vigorous A-O extension) should probably be avoided unless the exigencies of airway control demand it. The bias of the authors of this chapter is in favor, when feasible, of intubation techniques that allow the preservation of muscle tone, that maintain access to the patient's subjective and objective responses to airway maneuvers, and that make use of in-line stabilization or minimize A-O extension. The nasal route can be used in spite of concerns about entering the cranial vault via

a skull base fracture. However, one must use discretion (e.g., in the presence of an obvious facial crush injury it should be avoided) and be sensitive to unusual resistance in passing the endotracheal tube.

When a hypnotic-relaxant sequence is used, the standard approach includes the use of cricoid pressure and in-line axial stabilization. In-line traction was once favored, but it has been supplanted by stabilization because of the perceived risk of overdistraction and spinal-cord injury in the event of gross instability. * The largest of the clinical series that concluded that oral intubation with anesthesia and relaxation is reasonable [186] used in-line stabilization with the patient's occiput held firmly on the backboard, thus limiting the amount of "sniff" that was feasible (Fig. 52-13) (Figure Not Available) . There is no question that in-line stabilization, properly performed, makes laryngoscopy

Figure 52-13 (Figure Not Available) Intubating the patient who has undergone acute trauma and whose cervical spinal status is uncertain. A hypnotic and a relaxant have been administered. One assistant maintains in-line axial stabilization with the occiput held firmly to the backboard; a second assistant applies cricoid pressure. The posterior portion of the cervical collar remains in place. *(From Stene [186])*

somewhat more difficult. However, it serves to decrease the amount of A-O extension necessary to achieve visualization of the glottis. [192] This is probably because performing the laryngoscopy against the assistant's counterpressure results in greater compression of the soft tissue structures of the tongue and floor of mouth. Some clinicians recommend leaving the back half of the Philadelphia collar in place during laryngoscopy (see Fig. 52-13) (Figure Not Available) because it functions as a "strut" between the shoulder and the occiput that serves to limit A-O extension further.

In the resuscitation situation, before initiating a hypnotic-relaxant sequence, the anesthesiologist should confirm the availability both of cricothyrotomy equipment and of someone to make immediate, skilled use of it if necessary. The recently injured brain is very intolerant of hypoxia and hypotension. [193]

As noted in Chapter 19 , whereas succinylcholine can cause ICP increases, these increments are small and may not, in fact, occur at all in patients with serious cerebral injuries. [5] Accordingly, succinylcholine should not be viewed as contraindicated in the victim of head injury. If and when there is an urgent need to secure the airway (in order to control P CO_2 and guarantee oxygenation), and if succinylcholine is in other respects the appropriate drug to achieve that end, it should be used.

In two clinical surveys, alert, nonintoxicated patients with a cervical spine fracture invariably had pain, tenderness, or neurologic signs. [183] [194] Accordingly, in spite of the frequency with which clinicians meet patients still wearing their Philadelphia collars because their neck has not yet been "cleared," no special precautions appear warranted in the asymptomatic, alert patient. Note also that, if the clinical situation or examination suggests a cervical spine injury, a normal lateral x-ray film (the anteroposterior and through-the-mouth odontoid views are frequently not taken during initial evaluation) cannot provide complete reassurance. The lateral radiograph has been reported not to show between 15 percent [195] and 26 percent [183] of fractures.

*Is it not remarkable that in-line traction is considered ill-advised because of the possibility of instability but relaxation and direct laryngoscopy are viewed as begin?

Anesthetic Technique

Choice of Anesthetic Agents.

Craniotomies most commonly are performed for the evacuation of subdural, epidural, or intracerebral hematomas. The anesthetic approach is similar for all three procedures. The guiding principles are discussed earlier. In general, agents that are known to be cerebral vasoconstrictors are preferable to those that have the potential to dilate the cerebral circulation. All the intravenous anesthetic agents except perhaps ketamine cause some cerebral vasoconstriction and are reasonable choices, provided they are consistent with hemodynamic stability. All the inhaled agents (N_2O and all the vapors) have some cerebral vasodilatory effect. Although their administration is frequently consistent with acceptable ICP levels and/or appropriate conditions in the surgical field, when the ICP is out of control (or unknown) or when the surgical field is "tight," eliminating the inhaled agents in favor of fixed agents is appropriate. For patients who are likely to remain intubated postoperatively, an anesthetic regimen based primarily on a narcotic, such as fentanyl, and a muscle relaxant usually serves well. Any muscle relaxant is acceptable, with the provision that drugs that can release histamine should be titrated in careful increments. When immediate extubation is a possibility, such as the patient with an acute epidural hematoma who had a lucid interval before witnessed deterioration, the technique should be modified after opening of the cranium. Introduction of inhaled agents and/or the use of shorter-acting intravenous agents can be undertaken as guided by observation of the surgical field. If N_2O is contemplated at any time, one should remember the possibility, in the setting of missile injury or compound skull fracture, of intracranial air.

Monitoring.

The anesthesiologist should appreciate that the priority is to open the cranium as rapidly as possible. Once intravenous access is achieved, the craniotomy should never be delayed significantly by line placement. An arterial line is appropriate for essentially all craniotomies in patients who have undergone acute trauma. The decision to achieve central venous access can be made on the basis of the patient's hemodynamic status. Infrequently, management of a depressed skull fracture over the sagittal sinus justifies a precordial Doppler image and, subject to the surgeon's opinion of VAE risk, a right heart catheter.

Blood Pressure Management.

The concept that the injured brain is extremely vulnerable to what would otherwise be a minor insult, such as modest hypotension or moderate hypoxia, has been well confirmed in the laboratory. [196] [197] Although there are as yet no completely conclusive data derived in humans, several clinical surveys are strongly supportive of the adverse effect of minor degrees of hypotension in the period after head injury. [193] [198] [199] [200] The explanation for this vulnerability to hypotension probably resides, in part, in the observation that some patients in the postinjury period have regions of brain with precariously low CBF, [24] [35] in which autoregulation may also be defective. [201] In addition, there is ample evidence that the low postinsult CBF values correlate with a poor eventual outcome, [24] [202] [203] and a large percentage of patients who die after head injury have pathologic changes consistent with ischemia. [121] These observations have resulted in a much greater emphasis by many, although not all, neurosurgeons on aggressive support of blood pressure in the head-injured patient.

What constitutes appropriate blood pressure? Systematic studies, in particular those conducted at the University of Edinburgh, have revealed evidence that indexes of the adequacy of cerebral perfusion derived from Sjv O_2 and TCD data begin to deteriorate below mean CPP of 70 mm Hg [199] [204] [205] (recall that CPP = MAP - ICP). Some neurosurgeons have therefore adopted 70 mm Hg as the target CPP. However, an expert panel convened to generate recommendations for the treatment of head injury [206] found the data insufficient to justify establishing 70 mm Hg as the "standard" CPP target, but instead identified it as a reasonable management "option."

Added to this discussion are two alternative opinions regarding blood pressure management (Fig. 52-14) . The first, promoted by the neurosurgery group at the University of Alabama, Birmingham, is that induced hypertension can be employed as an adjunct to ICP control. [24] [207] [208] This idea is based on the beliefs that autoregulation is at least partially preserved after head injury, and an increased CPP results in autoregulation-mediated vasoconstriction with a concomitant reduction in CBV and therefore ICP. These physicians make aggressive use of volume expansion and vasopressors (phenylephrine, dopamine) to maintain a high CPP. They report a very satisfactory local experience with this approach, [208] but it has not been applied widely. The second alternative is the so-called "Lund concept," which is based on the premise that hyperemia commonly makes a substantial contribution to the increased ICP associated with head injury. [209] [210] Patients are managed by relative dehydration, by relative hyperosmolarity, and with a CPP target of 50 to 55 mm Hg using metoprolol, clonidine, and dihydroergotamine to lower blood pressure.

Figure 52-14 The relation of cerebral blood flow (CBF) to blood pressure after head injury. There are three cerebral perfusion pressure (CPP) management strategies (see text), driven by differing beliefs about common pathophysiologic derangements. The most commonly held, "Edinburgh," emphasizes low postinjury CBF, impaired autoregulation, and the necessity to support CPP (mean arterial pressure [MAP] - intracranial pressure [ICP]) to 70 mm Hg. The "Lund concept" emphasizes the contribution of hyperemia to the occurrence of elevated ICP and uses antihypertensive agents to achieve a CPP of 50 to 55 mm Hg. The "Birmingham" approach, which entails pharmacologically induced hypertension, is based on the belief that autoregulation is largely intact and that hypertension will result in cerebral vasoconstriction with concomitantly reduced cerebral blood volume (CBV) and ICP.

Which approach is correct? In particular, can the seemingly opposite objectives of the Edinburgh and Lund approaches be reconciled? In fact, it is possible that they both may be applicable in different patients or perhaps at different times in a given patient's course. Although an initially low postinjury CBF is probably the most common clinical occurrence, hyperemia does occur. [211] [212] [213] It tends to occur in patients with mass lesions rather than contusions, although even those patients have an immediate postinjury period of low CBF, with delayed hyperemia peaking at 24 hours or later. [36] [37] [202] [212] [213] Hyperemia may also be common in children. [214] A triphasic CBF pattern has been noted in some adult patients, in particular those with subarachnoid blood. That pattern is characterized by a period of initially low CBF (day 0), followed by a hyperemic phase (days 1 to 3), followed, in turn, by a period of reduced flow apparently occurring as a result of vasospasm (days 4 to 10). [37] [211] [215]

What is the clinician to do? It has been suggested that management targeted to the pathophysiologic features that prevail in the individual patient is the ideal. [216] However, the ability to discriminate the various flow states (CBF measurement, TCD, Sjv O_2) is not universally available or applied (or yet proven to lead to improvement in outcome). Clearly, convictions vary, and anesthesiologists should come to an understanding with local trauma specialists and neurosurgeons about blood pressure targets. It is likely that the majority of North American practitioners will encounter (and should place) a greater emphasis on the rigid maintenance of normotension in order to maintain a generous CPP, such as 70 mm Hg, in recently head-injured patients. [204] [205] [207] [217] The common view probably is that MAPs that are perfectly acceptable for elective noncranial surgery in young adults, such as 60 mm Hg, are likely to be deleterious in a recent head-injury victim. If the ICP is 20 mm Hg in a head-injured patient (and it may be much higher), an MAP of 60 mm Hg will yield a CPP of 40 mm Hg, which most centers view as much too low immediately after head injury.

Hyperventilation.

The use of hypocapnia is reviewed in detail earlier in this chapter. Hyperventilation has long been a standard component of the management of the head-injured patient who is perceived to be at risk of increased ICP. However, there is an increasing perception that hyperventilation is potentially deleterious, [22] [23] [24] [26] [28] [33] and it should not be overused. The evidence is that hyperventilation and the concomitant vasoconstriction can result in ischemia, [21] [34] especially when baseline CBF is low, [34] as is likely to be the case in the first 24 hours after head injury. [24] [35] We believe that the evolving information argues that hyperventilation should be used selectively, rather than routinely, in the management of head-injured patients. Maintaining ICP at less than 20 mm Hg, preventing or reversing herniation, minimizing retractor pressure, and facilitating surgical access are still important objectives in the management of the head-injured patient, and to the extent that hyperventilation contributes to these objectives, it is still appropriate. Once again the anesthesiologist should agree on management parameters with the surgical team at the outset of a procedure.

Fluid Management.

Fluid management of the head-injured patient is addressed earlier. The important principles are that fluids should be chosen invariably to prevent reduction of serum osmolarity and should probably be chosen to prevent profound reduction of colloid oncotic pressure; that is, in the circumstances of a large volume resuscitation (arbitrarily, greater than half a circulating volume), a mixture of colloids and crystalloids is probably appropriate. The severely injured brain can liberate sufficient thromboplastin into the circulation to result in consumptive coagulopathy. Appropriate laboratory tests and replacement should be performed. [218] The clinician may also find a serum osmolarity determination early in the course of anesthetic management useful in appreciating the cumulative effects of prior mannitol administration. The use of hypertonic solutions and the relevant attributes of colloid solutions are also discussed earlier.

Jugular Venous Oxygen Saturation

Several centers have evaluated the use of Sjv O_2 monitoring as a guide to the clinical management of head-injured patients. [27] [34] [38] [39] [205] [219] The underlying concept is that a marginal or inadequate CBF results in an increasing oxygen extraction, a widening arteriovenous content difference, and a falling jugular venous Pv O_2 or Sjv O_2. There have been numerous reports of improvements in Sjv O_2 as a consequence of reducing hyperventilation, increasing MAP, or inducing hypervolemia. [220] The availability of intravascular catheters that permit the continuous monitoring of Sjv O_2 has made the technique more practical. [221] Even though a method that makes an assessment of *global* oxygen extraction has only limited sensitivity to highly *focal* events, the early experience appears to justify further evaluation.

There are some limitations with the technique. Catheter placement must be very precise to avoid contamination by noncerebral venous blood or attenuation of light return (with optical catheters) because of vessel wall abutment. Even in experienced hands, there can be a significant false-positive rate. [34] An additional limitation inherent to the unilateral placement of the catheter is the observations by Stocchetti et al [222] that there was an average side-to-side difference between simultaneous jugular bulb saturations of 5.3 ± 5 percent, and that side-to-side differences in hemoglobin saturation of up to 15 percent were common. These and other authors have questioned the reliability of data obtained from a unilateral Sjv O_2 catheter. [222] [223] The next clinical problem is the matter of what constitutes an abnormal value. Normal subjects at rest may have Sjv O_2 values between 50 and 75 percent. A currently employed definition of abnormal is less than 50 percent for 5 minutes. [224] However, there has been limited opportunity to correlate Sjv O_2 threshold values with outcome.

In spite of the reported successes with Sjv O_2 monitoring, [39] [220] [225] we do not believe that the method is sufficiently well defined to justify advocating widespread intraoperative application. Further experience and clinical investigation are required to define the correct role and mode of application of Sjv O_2 monitoring. At present, it appears potentially useful as a trend monitor that may serve to identify the level of CPP below which cerebral perfusion *begins* to be compromised. However, the Sjv O_2 level at which that compromise is critical has not been identified. The

technique also has a potential use beyond identifying patients with low Sjv O_2 and inadequate CBF. High Sjv O_2 values may serve to identify the patient with elevated ICP in whom hyperemia is an important contributing factor and in whom aggressive attempts to decrease CBF, such as via hyperventilation and barbiturates, may be beneficial.

Hypothermia

Mild induced hypothermia has already crept into the management of neurosurgical procedures in which there is a perceived risk of ischemic injury. To date, this has encompassed principally aneurysm surgery. However, the efficacy of this technique in reducing damage when induced after experimental head injury has also been demonstrated, [122] and its relevance to the management of the head-injured patient has been the subject of small, prospective controlled trials in at least four centers. [123] [124] [125] [126] These single center trials appear to indicate good patient tolerance of sustained mild hypothermia (32-34°C) as well as improvement in ICP, cerebral oxygen supply/demand, and outcome. A multicenter trial sponsored by the National Institutes of Health is under way. The results of that trial, due late in 1999, will determine the role of hypothermia.

Intracranial Pressure Monitoring for Nonneurologic Surgery in the Head-Injured Patient

In the ideal, neurosurgical consultation will be readily available and, appropriately, the anesthesiologist will rarely have to make this decision. It may, however, be necessary for the anesthesiologist to participate in this decision. The relevant variables include the following:

1. Level of consciousness. If there has been a loss of consciousness at any time or if the GCS score is less than 15, a CT scan should be obtained. If the CT scan reveals compressed basal cisterns (indicative of an exhaustion of supratentorial compensatory latitudes), midline shift, or effaced ventricles and probably any intracranial lesion (contusion, small subdural), an ICP monitor should be placed. Excessive comfort should not be taken from a good GCS score. Patients with a good GCS score can "talk and deteriorate" or "talk and die" following a head injury associated with loss of consciousness. Delayed deterioration has been observed up to as much as 48 hours after the initial injury (average, 17 h). [226] Patients with lesions, usually contusions, in the frontotemporal region and especially those with medial temporal lesions are most at risk for this phenomenon. Modest expansion of lesions in this location (i.e., close to the uncus and the incisura, where herniation occurs) can result in herniation even at relatively low ICP (e.g.,

20 mm Hg). At our institution, neurosurgeons recommend avoiding anesthesia in these patients and certainly advise ICP monitoring when general anesthesia is unavoidable.

2. Time since injury. The longer the patient has had to declare a clinical course, the less pressing is the need for ICP monitoring. However, delayed deterioration, as noted earlier, has been observed for up to 48 hours, and a patient with a demonstrable CT lesion is a candidate for a monitor for at least this period of time.
3. Intended aortic occlusion, that is, repair of a ruptured aorta. Dramatic increases in ICP have been associated with aortic occlusion. This may, in large part, be the result of the abrupt increase in blood pressure and/or the agents used to control it. In addition, the increased airway and venous pressures associated with the lateral position and one-lung ventilation plus occasional difficulties in maintaining hypocapnia during one-lung ventilation should result in a low threshold for ICP monitoring in this situation. Note, however, that the intent to heparinize systemically essentially precludes the placement of a monitor.
4. Nature and duration of the intended procedure. The risks of an untoward ICP event are inevitably greater in a 6-hour Edward instrumentation in the prone position than for a 20-minute debridement and suturing of an arm laceration.

TABLE 52-12 -- Considerations Relevant to Posterior Fossa Procedures

Hemodynamic effects of the sitting position
Venous air embolism
Paradoxic air embolism
Hemodynamic effects of brain-stem or cranial nerve manipulation
Quadriplegia
Macroglossia
Pneumocephalus

Posterior Fossa Procedures

Most of the topics relevant to posterior fossa procedures (Table 52-12) are discussed in preceding sections. These include the sitting position and its cardiovascular effects and complications (quadriplegia, macroglossia), pneumocephalus. Those sections should be read in conjunction with this segment. The use of the sitting position to facilitate surgery in the posterior fossa increases the likelihood of all of these phenomena, although they are relevant to nonsitting positions as well. This section reviews the cardiovascular events associated with direct stimulation of the brain stem and their possible implications for postoperative management.

Brain-Stem Stimulation

Irritation of the lower portion of the pons and of the upper medulla and of the extra-axial portion of the fifth cranial nerve can result in a number of cardiovascular perturbations. The former two areas are most often stimulated during procedures on the floor of the fourth ventricle and the last during surgery at or near the cerebellopontine angle, such as for acoustic neuromas and microvascular decompression of the fifth (tic douloureux), seventh (hemifacial spasm), or ninth (glossopharyngeal neuralgia) nerves. The cardiovascular responses may include bradycardia and hypotension, tachycardia and hypertension, bradycardia and hypertension, and ventricular dysrhythmias. [227] Meticulous attention to the ECG and a directly transduced arterial pressure during manipulation in this region is necessary in order

to provide the surgeon with immediate warning of the risk of damage to the adjacent cranial nerve nuclei and respiratory centers. Pharmacologic treatment of the dysrhythmias that occur may serve to attenuate the very warning signs that should be sought.

Balloon compression of the trigeminal ganglion is another situation in which a dysrhythmia may occur. The procedure attempts to produce a neuropraxia of the fifth cranial nerve by the rapid inflation of a Fogarty-type balloon within the Meckel cave. [228] The balloon is introduced percutaneously through the cheek and beneath the maxilla. A relatively profound, albeit transient, bradycardia occurs and is, in fact, sought as confirmation of adequate compression. External pacemaker pads have been advocated, but they are, in our experience, unnecessary.

Irritation and injury of posterior fossa structures that may have occurred during surgery should be taken into account in planning extubation and postoperative care. In particular, procedures involving dissection on the floor of the fourth ventricle entail the possibility of injury to cranial nerve nuclei and/or postoperative swelling in that region. There should be attention to the fact that cranial nerve dysfunction, particularly of 9, 10, and 12, can result in loss of control/patency of the upper airway and that swelling of the brain stem can result in impairment of both cranial nerve function and respiratory drive. The posterior fossa is a relatively small space, and its compensatory latitudes are even more limited than those of the supratentorial space. Relatively little swelling can result in disorders of consciousness, respiratory drive, and cardiomotor function. There should be an interaction between the anesthesiologist and the surgeon to make decisions about whether extubation is appropriate and where postoperative observation should occur, that is, ICU or non-ICU.

Spontaneous ventilation was once advocated for procedures that entailed a risk of damage to the respiratory centers. Spontaneous ventilation is now rarely used because the proximity of the cardiomotor areas to the respiratory centers should permit cardiovascular signs to serve as an indicator of impending injury to the latter. It is our opinion that respiratory pattern is more likely to be a relevant monitor when the "threat" to the brain stem is the result of vessel occlusion (as may occur with accidental interruption of perforating vessels during vertebrobasilar aneurysm surgery [177]) than when it is because of direct mechanical damage caused by retraction of or dissection in the brain stem.

Various electrophysiologic monitoring techniques may be used during posterior fossa surgery. These include somatosensory evoked responses, brain-stem auditory evoked responses, and EMG monitoring of the facial nerve. The last technique requires that the patient not be paralyzed or have a constant state of incomplete paralysis. Somatosensory evoked response monitoring imposes some constraints with respect to the selection of anesthetic agents. These are discussed in Chapter 35 .

Transsphenoidal Hypophysectomy

The transsphenoidal approach to the pituitary is used for the excision of tumors that lie within the sella or that have extension to the immediate suprasellar area. The most common lesions are prolactin-secreting microadenomas (Table 52-13) . These patients are usually women who present with secondary amenorrhea. There are three other less common pituitary tumors: growth hormone-secreting lesions result in acromegaly; adrenocorticotropic hormone (ACTH)-secreting tumors cause Cushing disease; and a very rare thyroid-stimulating hormone (TSH)-secreting lesion that results in hyperthyroidism.

Preoperative Evaluation

The important preoperative considerations relate to the patient's endocrine status. In general, as a pituitary lesion expands and compresses the pituitary tissue, the sequence in which hormonal function is lost is as follows: (1) gonadotropins; (2) growth hormone; (3) ACTH; and (4) TSH. The precise definition of the adrenal status of these patients is often not important because, in general, they all receive adrenal hormone supplementation at least temporarily. However, profound hypocortisolism, with associated hyponatremia, should be corrected preoperatively. It is, in fact, uncommon for thyroid deficiency to occur. However, hypothyroidism should be sought and corrected preoperatively because hypothyroid patients have a diminished tolerance for the cardiovascular-depressant effects of anesthetic agents. Patients with advanced acromegaly can develop an enlarged tongue, and the airway should be evaluated.

TABLE 52-13 -- Tumors of the Pituitary Region

LOCATION	HORMONE SECRETED	CLINICAL PRESENTATION	COMMENT

Anterior pituitary	Prolactin	Galactorrhea, amenorrhea hypogonadism, infertility	Bromocriptine sensitivity
	Adrenocorticotropin	Cushing disease (hypercortisolism)	Basophilic adenoma
	Growth hormone	Acromegaly/gigantism, glucose intolerance	Eosinophilic adenoma, difficult airway
	Nonsecretory	Mass effect, panhypopituitarism	Chromophobe adenoma, preoperative hormones?
Suprasellar	Nonsecretory	Panhypopituitarism, syndrome of inappropriate antidiuretic hormone, visual (optic chiasm) symptoms	Craniopharyngioma or suprasellar extension of pituitary lesion

Monitoring

Many practitioners place an arterial catheter, but it is not absolutely necessary. Blood sampling access is a valuable adjunct to postoperative care if diabetes insipidus develops. Blood loss is usually modest. However, the cavernous sinus is an immediate lateral relation of the pituitary and may be entered during the resection of large tumors. In addition, in some patients, there is a venous sinusoid that lies in front of the pituitary gland and connects the two cavernous sinuses. This can be the origin of substantial blood loss. It has, on occasion, actually precluded this approach to the pituitary gland.

Anesthetic Technique

The latitudes are broad with respect to choice of agent, although tumors with suprasellar extension can cause hydrocephalus and thereby can add increased ICP constraints to the anesthetic technique. The procedure is performed with the patient in a supine position, usually with some degree of head-up posture to avoid venous engorgement. A pharyngeal pack prevents an accumulation of blood in the stomach (which causes vomiting) or in the glottis (which contributes to coughing at extubation). An RAE-type tube secured to the lower jaw at the corner of the mouth opposite the surgeon's dominant hand, such as the left corner of the mouth for a right-handed surgeon, is suitable. A small esophageal stethoscope and a temperature probe can lie with the endotracheal tube. Covering the entire bundle with a towel drape (a plastic sheet with an adhesive edge) placed just below the patient's lower lip so that it hangs from the lower jaw like a veil protects it from the preparation solutions.

The procedure requires a C-arm image intensifier (lateral views), and the patient's head and arms are relatively inaccessible once the patient is draped. It is appropriate to establish the nerve stimulator at a lower extremity site. The surgical approach is via the nasal cavity through an incision made under the upper lip. During the approach, the mucosal surfaces within the nose are infiltrated with a local anesthetic and epinephrine solution, and the patient should be observed for the occurrence of dysrhythmias.

Surgical preferences for CO_2 management vary. In some instances, hypocapnia is requested to reduce brain volume and thereby to minimize the degree to which the arachnoid bulges into the sella. One of the important surgical considerations is the avoidance, when possible, of opening the arachnoid. Postoperative CSF leaks can be persistent and are associated with a considerable risk of meningitis. By contrast, when there is suprasellar extension of a tumor, a normal or increased CO_2 helps to deliver the lesion into the sella for excision. As an alternative way to accomplish this, some surgeons have resorted to pumping of saline or air into the lumbar CSF space. [229] [230]

Diabetes insipidus is a potential complication of this procedure. The antidiuretic hormone (ADH) is synthesized in the supraoptic nuclei of the hypothalamus and is transported down the supraoptic-hypophyseal tract to the posterior lobe of the pituitary. This portion of the pituitary gland is frequently spared. Even when it is excised, water homeostasis commonly normalizes, presumably because the ADH is released from the cut end of the tract. However, even when the posterior lobe of the pituitary is left intact, transient diabetes insipidus may occur. This disorder usually occurs 4 to 12 hours postoperatively and very rarely arises intraoperatively. The clinical picture is one of polyuria in association with a rising serum osmolality. The diagnosis is made by comparison of the osmolalities of urine and serum. Hypo-osmolar urine in the face of an elevated and rising serum osmolality strongly supports the diagnosis. Urine specific gravity is a useful bedside test. In the presence of bona fide diabetes insipidus, specific gravity is low, that is, less than or equal to 1.002.

When the diagnosis of diabetes insipidus is established, an appropriate fluid management regimen is hourly maintenance fluids plus two-thirds of the previous hour's urine output. (An acceptable alternative is the previous hour's urine output minus 50 mL plus maintenance.) The choice of fluid is dictated by the patient's electrolyte picture. In general, the patient is losing fluid that is hypo-osmolar and relatively low in sodium. Half-normal saline and 5 percent dextrose in water (D_5W) are commonly used as replacement fluids. Beware of hyperglycemia when large volumes of D_5W are employed. An *un*acceptable fluid regimen that has been employed calls for maintenance fluids plus the previous hour's urine output. This regimen has the potential to create a vicious circle. Should the patient become iatrogenically fluid overloaded, this regimen precludes a return to isovolemia, and, in fact, when the maintenance fluid allowance is generous, it guarantees that the patient will become increasingly hypervolemic. If the hourly requirement exceeds 350 to 400 mL, ADH is usually administered.

A smooth emergence from anesthesia (see earlier) is desirable especially if the CSF space has been opened (and resealed with fibrin glue or by packing the sphenoid sinus with fat or muscle). Repeated, intense Valsalva maneuvers, such as with coughing or vomiting, may contribute to the reopening of a CSF leak and may worsen the risk of subsequent meningitis. The airway should be cleared of debris including formed clot. Some clinicians routinely inspect the pharynx using a laryngoscope. This also permits one to assess whether or not there is still active bleeding. This allows one more confidently to extubate the patient promptly at the first signs of reactivity to the endotracheal tube. In situations in which there is concern that a persistent CSF leak may occur, some surgeons place a lumbar CSF drain to maintain CSF decompression in the early postoperative period.

Seizure Surgery/Awake Craniotomy

Awake craniotomies are performed when tumors or epileptic foci lie close to cortical areas required for either speech or motor function or to mesial temporal structures critical to short-term memory. The majority of patients will have so-called temporal lobe epilepsy. There is commonly a structural lesion visible on magnetic resonance imaging (MRI). Sometimes there is a history of trauma. More commonly, the cause is presumed to be an asphyxial birth injury.

Presurgical Evaluation

Prior to the resection, most patients have undergone either or both a Wada test and videotelemetry. The Wada test

involves selectively anesthetizing the cerebral hemispheres by injection of sodium amytal into the carotid artery to localize the hemisphere that controls speech and/or to confirm that there is bilateral representation for short-term memory. Speech is an issue when the lateral portions of the temporal lobe are involved, and memory is the concern when the involvement is medial.

Anesthesia for EEG Electrode Placement

Videotelemetry is performed to permit localization of the seizure focus that is responsible for the clinically problematic events. This usually requires prior placement of either subdural strip electrodes (via bur holes) or a subdural electrode grid (requiring a craniotomy). Occasionally, electrodes are placed deep into parenchyma, usually within the temporal lobe (placed stereotaxically via bur holes), or they are positioned so as to "look at" the inferior surfaces of the temporal lobe. The latter is commonly accomplished with so-called foramen ovale electrodes. These are placed using a needle similar to an epidural needle. The point of entry is about 2 cm lateral to the angle of the mouth. The needle is passed through soft tissue, under the temporal process of the zygomatic bone and medial to the ramus of the

mandible, up to the base of the skull in the vicinity of the foramen ovale. Typically, this procedure is performed as a "MAC," although doses of methohexital or propofol are usually required at the time of stimulation by the needle of the periosteum at the base of the skull. After placement of the relevant electrodes, the patient's seizure medication is discontinued, and the patient remains in an observation unit with EEG and behavior recorded continuously. In this manner, the EEG events associated with the clinically significant seizure events and their anatomic origin can be identified.

Preanesthetic Evaluation/Preparation

At the preoperative interview, the patient should be educated about the nature and duration of the procedure and the limitations on patient movement. The clinician should obtain a description of both the aura and the seizures to facilitate recognition of them. One should ascertain whether the patient is subject to grand mal convulsions. If intraoperative electrocorticography to identify seizure foci is intended, it is common to discontinue or to reduce by half the anticonvulsants according to the perceived risk of uncontrolled seizures. Premedicants with an anticonvulsant effect, such as benzodiazepines, should not be used because they may interfere with intraoperative EEG localization.

Anesthetic Technique

The objectives of the anesthetic technique are as follows:

1. To minimize patient discomfort associated with the potentially painful portions of the procedure and with the prolonged restriction of movement.
2. To ensure patient responsiveness and compliance during the phases of the procedure that require assessment of either speech or motor/sensory responses to cortical stimulation.
3. To select anesthetic techniques that produce minimal inhibition of spontaneous seizure activity.

There are probably many ways of providing sedation that are consistent with these objectives. Several active centers use a droperidol/synthetic narcotic combination [231] (e.g., droperidol, 2.5-7.5 mg; alfentanil, 5-10 mug/kg load, 0.25-0.5 mug/kg/min infusion; fentanyl, 0.7 mug/kg load, 0.7 mug/kg/h infusion). [232] Others use principally propofol by either physician-controlled or patient-controlled infusion. [232] Care should be taken in administering additional sedative agents, especially narcotics, whose respiratory-depressant effects may be synergistic with propofol. This is especially relevant when pin fixation is employed. Pin fixation severely restricts the anesthesiologist's capacity to intervene quickly in the event of excessive respiratory depression or loss of patency of the airway. Propofol, if used, should be discontinued at least 15 minutes before EEG recording. In spite of prompt awakening, propofol leaves a residual EEG "footprint" characterized by high-frequency, high-amplitude beta activity that can obscure the abnormal activity that is being sought in the cortical surface EEG. [233]

Routine, noninvasive monitors are almost always sufficient. Reliable capnography, to provide breath-by-breath confirmation of airway patency and respiratory drive, is an essential component of the technique if deep sedation is intended for any portion of the procedure. These procedures are often lengthy, and attention to the details of patient comfort (warming blankets, a sheepskin, room temperature) improve patient tolerance.

The uncomfortable phases of the procedure are pin head holder placement (Not all groups use a pin head holder) and the craniotomy. Many patients also find manipulation of the dura, in particular traction, painful. The actual manipulation of supratentorial brain parenchyma is painless. These procedures cannot be accomplished without thorough local anesthetic technique. Note that in some institutions, awake craniotomies are performed as straight local procedures without sedation. The anesthesiologist must not think that it is his or her responsibility to provide a general anesthetic-equivalent in a spontaneously breathing patient with an unprotected and all but inaccessible airway. The volume of local anesthetic used to infiltrate pin sites and to perform the field block of the scalp can be substantial. It is appropriate for the anesthesiologist, in particular the anesthesiologist working with surgical trainees, to keep track of the doses of local anesthetic agents used.

The anesthesiologist should participate actively at the time of head positioning. The more "sniff" that can be achieved before the final lock-down of the head holder, the wider the latitudes will be for sedating the patient while maintaining spontaneous ventilation and a patent airway. During positioning of the patient, there should also be attention to the need to maintain visual access to the face. A clear line of sight to the face is necessary both to present the patient with images to name as part of speech testing and to identify the occurrence of facial motor responses during mapping of the motor strip.

In general, after the dural opening is complete, cortical surface EEG recording is performed to locate the seizure

focus. If no seizure activity is observed, provocative maneuvers may be requested. Methohexital, in a dose of approximately 0.3 mg/kg, is in general safe and effective. Etomidate, approximately 0.05 to 0.1 mg/kg, has also been used. Seizure focus localization can also be accomplished during light general anesthesia, such as, N_2 O/fentanyl/low-dose isoflurane. During general anesthesia, alfentanil, in a bolus dose of 50 mug/kg, [234] and etomidate, in doses of 0.2 to 0.3 mg/kg, [235] [236] have been reported effective in activating seizure foci.

After localization by EEG, functional testing may be performed by stimulating the cortical surface electrically and observing for motor, sensory, or speech interruption effects. During stimulation, the anesthesiologist should be prepared to treat grand mal convulsions that are not self-limited. Thiopental in 1 mg/kg increments is appropriate. However, thiopental should be withheld until it is clear that the seizure is not going to terminate spontaneously because this drug may interfere with subsequent EEG localization of the seizure focus for some time. A comprehensive review of the anesthetic implications of epilepsy, status epilepticus, and epilepsy surgery has appeared. [237]

Neuroradiologic Procedures

Magnetic Resonance Imaging

The major constraints for this procedure are created by the powerful magnetic field employed. This procedure creates three conditions that have an impact on anesthetic technique. The first is that any ferromagnetic object that approaches the magnet has the potential to become a dangerous projectile. The second is that a wide variety of electronic instruments will not function properly in the vicinity of the magnet. These instruments include most notably those that contain oscilloscopes, solenoids (e.g., some noninvasive blood pressure devices), or galvanometer-type gauges. The third is that when moderately large metal objects, even nonferromagnetic objects, are brought into the vicinity of the magnet, they may degrade the image. The equipment limitations have largely been circumvented. At present, MRI-compatible oximeters, capnographs, noninvasive blood pressure monitors, and gas machines are available.

It is most frequently children, claustrophobic adults, and patients with painful conditions who require anesthesia. Sedation with propofol and an unprotected airway and general anesthesia with either a laryngeal mask airway or an endotracheal tube have all been employed successfully.

Interventional Neuroradiology

Many different procedures are performed for the evaluation and treatment of intracranial and extracranial disease. These include principally attempts to obliterate aneurysms or to devascularize tumors and AVMs using balloons, coils, or glue. Stenting of extracranial carotid disease is occasionally performed. Vasospasm can be treated by selective intra-arterial instillation of papaverine or more commonly by balloon dilation. The majority of these procedures can be accomplished without the involvement of an anesthesiologist. The duration of a procedure, individual patient factors, and, occasionally, the necessity for precise physiologic control may result in requests for monitored anesthesia care or general anesthesia. In addition, anesthesiologists may become involved during the resuscitation stage in the event of vascular rupture or of the migration of an intravascular device to an incorrect location. When detachable devices are misplaced and ischemia ensues, fluid loading and pressor administration may be requested to improve collateral CBF while the device is retrieved.

Hyperventilation may be appropriate in an attempt to divert flow away from normal brain and toward a lesion that is intended to receive the occlusive device or material. Occasionally, the anesthesiologist is asked to lower systemic blood pressure and, it is hoped, cardiac output, to facilitate the initial trapping of glue or coils within a vascular lesion by briefly reducing the flow through it. Adenosine has proven effective for this purpose. [238]

The anesthesiologist may also be asked to participate in test occlusions of various cerebral vessels that are candidates for sacrifice at a subsequent procedure. In these circumstances, it is on occasion necessary to manage a patient who is restless, confused, or abruptly unconscious.

Procedures that are likely to entail requests for blood pressure manipulation are best done with an arterial catheter in place. The radiologist's arterial line cannot be dedicated to blood pressure monitoring, and accordingly, an independent arterial catheter should be placed.

Cerebrospinal Fluid Shunting Procedures

CSF shunts are inserted for the relief of a variety of hydrocephalic states and pseudotumor cerebri. Hydrocephalus can be communicating or noncommunicating. In noncommunicating hydrocephalus, CSF egress from the ventricular system is obstructed. This can occur as a result of blood or infection in the ventricular system or tumors in or adjacent to the ventricular system. In communicating hydrocephalus, the CSF escapes from the ventricular system but is not absorbed by the arachnoid villi. This occurs most commonly secondary to infection or blood in the CSF space. Some degree of communicating hydrocephalus is particularly common after SAH.

The ventriculoperitoneal shunt is the most commonly employed device. Usually, a catheter is inserted via a bur hole into the frontal horn of the lateral ventricle on the nondominant (usually the right) side. A reservoir is placed subcutaneously adjacent to the bur hole, and the drainage limb passes via a subcutaneous tunnel to a point near the epigastrium, where it is inserted into the peritoneal space via a very small laparotomy. A moderate degree of muscle relaxation may be helpful. A distended stomach can result in an inadvertent "gastrostomy." Occasionally, most commonly in pediatric patients, there may be an obstruction at more than one level in the ventricular system, and a so-called "double-barreled" shunt becomes appropriate. In this instance, there are two proximal ends, usually one in the lateral ventricle and one in the fourth ventricle. This latter procedure is usually performed with the patient in the prone position,

whereas most ventriculoperitoneal shunts are done with the patient supine.

Occasionally, when there is a communicating hydrocephalus, a lumboperitoneal shunt is inserted. The patient is placed in a lateral position, and a catheter is put in the lumbar CSF space via a Tuohy-type needle. The catheter is then tunneled subcutaneously around to the anterior abdominal wall and is inserted into the peritoneal space via a small laparotomy. In the past, ventriculoatrial shunts were employed, though they have largely been abandoned because of the occurrence of pulmonary embolus. For these shunts, the noncerebral end is inserted into the venous system via the jugular vein. The atrial location of the noncerebral end is confirmed using the same ECG technique that is employed to place VAE recovery catheters (see earlier).

Anesthetic Management

Invasive monitoring is generally not required. The anesthetic technique should be chosen to avoid further increases in ICP. Moderate hyperventilation (Pa CO_2 , 25-30 mm Hg) is customary. However, aggressive ICP reduction measures are not warranted because collapsing the ventricles may render them more difficult to "hit" with the ventricular catheter. Ventriculoperitoneal shunting is usu-ally performed with the patient supine, with the table turned 90 degrees and the patient's head turned toward the anesthesiologist. Blood pressure may drop abruptly (as brain-stem pressure is relieved) when the ventricle is first cannulated. Infrequently, brief pressor support is required. Burrowing the subcutaneous tunnel can produce a sudden painful stimulus. There is only minor postoperative discomfort.

Unlike the majority of neurosurgical patients, patients with shunts are often nursed flat following their procedures in an attempt to prevent an excessively rapid collapse of the ventricular system. Empirically, there is a small incidence of subdural hematoma following shunting, and the tearing of bridging veins at the time of rapid brain shrinkage is a suspected cause.

TABLE 52-14 -- Common Pediatric Neurosurgical Problems and Their Anesthetic Considerations

AGE GROUP	LESION	PATHOGENESIS	ANESTHETIC CONSIDERATIONS
Neonates	Intraventricular hemorrhage	Subependymal vascular rupture	Associated problems of prematurity
	Depressed skull fracture	Forceps injury	Associated cerebral edema
Infants	Hydrocephalus	Varied	Increased ICP, especially dangerous in shunt-dependent revisions
	Meningocele	Outpocketing of meninges through skull defect	Large size creating airway management problems Prone-lateral position Substantial blood loss Repair may increase ICP
	Encephalocele	Outpocketing of meninges through skull defect with brain tissue enclosed	
	Myelomeningocele	Projection of spinal meninges and roots through spina bifida	Prone or lateral Substantial blood loss Respiratory restriction after covering large defects
	Arnold-Chiari malformation	Impaction of posterior fossa contents into foramen magnum	Brain-stem compression with head flexion
		±Hydrocephalus	Increased ICP; latex allergy
		±Myelomeningocele	Postoperative respiratory depression
	Craniosynostosis	Premature cranial suture fusion	Substantial blood loss Air embolism Supine or prone
	Craniofacial dysostosis	Developmental abnormality	Lengthy procedures Substantial blood loss Brain retraction Air embolism Endotracheal tube damage
	Vascular malformations	Varied	Congestive heart failure Large blood loss Elective hypotension
	Subdural hematoma/effusion	Trauma	Associated injuries
Older pediatrics	Posterior fossa tumors	Ependymoma	Malnutrition-dehydration

		Astrocytoma	Hydrocephalus Increased ICP Prone or sitting position Air embolism Brain-stem compression Postoperative cranial nerve dysfunction or brain-stem swelling or compression

ICP, intracranial pressure

Pediatric Ventriculoperitoneal Shunts

Shunts are probably more commonly performed in children than adults. Common indications are hydrocephalus occurring in association with meningomyelocele, neonatal intraventricular hemorrhage, and posterior fossa tumors. Although one can never be casual about the management of these patients, open fontanelles seem to provide some margin for error in younger patients, and, in addition, palpation of the fontanelles provides on-line trend monitoring of "ICP." In spite of the theoretical considerations, inhalation inductions using volatile agents are empirically well tolerated even in children with closed fontanelles. However, we avoid that induction technique in a child who is already stuporous. When an intravenous line is available, we usually employ a thiopental-relaxant induction sequence. For children in whom cannulation of a peripheral vein cannot be accomplished readily, an inhalation induction with halothane or sevoflurane is the common approach.

If, in the absence of sevoflurane, halothane were employed for induction, immediately following loss of consciousness, we would generally change to isoflurane and control ventilation manually using the bag and mask. If an assistant is available, an ideal course at this point is to establish an intravenous line and to administer a muscle relaxant (with or without atropine according to personal bias) and perhaps thiopental and to intubate the patient in these optimal circumstances. Anesthesia is most commonly maintained thereafter with 60 to 70 percent N_2O, mechanical hyperventilation, and isoflurane or sevoflurane, as required. For children older than 6 months of age who are not stuporous at the outset, we commonly administer 2 to 3 mug/kg of fentanyl in the belief that this procedure is not entirely pain-free postoperatively and, in addition, that a smoother emergence from anesthesia can be accomplished with a narcotic background.

Pediatric Neurosurgery

Table 52-14 identifies common pediatric procedures and their anesthetic considerations. The most frequent procedures

TABLE 52-15 -- Anesthetic Considerations and Position Requirements Associated With Various Spinal Surgical Procedures

SPINAL REGION OR SURGICAL CONDITION	PROBLEMS/CONSIDERATIONS	POSITIONS USED AND COMMENTS
Lumbar region: degenerative disease, spinal stenosis, trauma	Major position change	Prone, lateral, or knee-chest
	Awake intubation and position	If unstable after trauma and major position change required
	Blood loss	Especially with repeat procedures, instrumentations and spinal stenosis; risk of occult aortoiliac or major venous tear
	Air embolism	Infrequent; perhaps with knee-chest and Relton-Hall frames
	Anaphylaxis with chymopapain chemonucleolysis	Infrequently done because of anaphylaxis and neurologic injury if intrathecal injection
Cervical region: degenerative disk disease, stenosis, trauma	Maintenance of neutral neck position to avoid cord compression	Supine/anterior approach for most diskectomies; posterior approach (prone or sitting) for laminectomy and occasional diskectomy
	Maintenance of perfusion pressure	If existing cord compression, recent cord injury, or if cord retraction required
	Hypotension (spinal shock)	Occurs with complete cervical cord injury
	Postoperative respiratory insufficiency	Occurs with cervical cord injury
	Methylprednisolone [241] [242]	30 mg/kg over 1 hr, then 5.4 mg/kg/h for 23 h
	Air embolism	With sitting laminectomies
Anterior cervical diskectomy	Traction required for anterior graft insertion? Retractor compression of airway Postoperative swelling/airway compression Postoperative cranial nerve dysfunction	
Cervical instability	Awake intubation Awake positioning	Prone or supine
	Axial stabilization for intubation	(If awake intubation not feasible)
Vertebral metastasis	Large blood loss	Prone or anterolateral/retroperitoneal Double-lumen tube for lesions above L1
Spinal cord tumors	Maintain perfusion pressure during retraction Methylprednisolone	Prone
Procedures with major neurologic risk	Wake-up test	Prone; rehearse with patient
	Somatosensory evoked responses	Anesthetic agent restrictions
	Motor evoked responses	Anesthetic/relaxant restrictions

are probably the placement and revision of CSF shunts. These are discussed earlier. Most pediatric tumors occur in the posterior fossa. Most are near the midline, and many are associated with hydrocephalus. For pediatric posterior fossa procedures, VAE risk, monitoring, and treatment are similar for adults and children, as discussed earlier. A Doppler study is invariably indicated, and right heart catheters are generally placed when procedures are done with the patient in the sitting position. Craniosynostosis procedures have the potential for a substantial blood loss that is roughly proportional to the number of sutures involved. There is a small risk of VAE that justifies the use of a precordial Doppler.

Spinal Surgery

Table 52-15 surveys the many issues that may arise in the context of spinal-cord and column procedures undertaken by neurosurgeons. The spinal cord has been described as a microcosm of the brain because its physiology is, in general, similar to that of the brain: CO_2 responsiveness, blood-"brain" barrier, autoregulation,

high metabolic rate and blood flow (although somewhat less than the brain), and substantial ischemic vulnerability of gray matter. Measures to reduce spinal cord swelling, analogous to ICP reduction maneuvers are, however, rarely used.

ACKNOWLEDGMENT

The authors gratefully acknowledge the contribution of Harvey M. Shapiro to the development of this chapter.

Chapter 53 - Anesthesia and the Renal and Genitourinary Systems

Vinod Malhotra
Sudhir Diwan

INTRODUCTION

Patients requiring anesthesia for renal and genitourinary surgery belong frequently to the extremes of age. Concomitant cardiovascular and respiratory disease is common in the elderly in addition to the physiologic changes of aging. Medical history, physical examination, and appropriate laboratory tests are necessary to evaluate concomitant disease. In the pediatric urologic patient, upper respiratory infections are not uncommon. Careful history should be obtained to exclude other congenital lesions if the urologic procedure is planned for congenital urologic anomalies such as exstrophy of the bladder or Wilms tumor. [1]

Urologic procedures are mostly performed on the kidneys, adrenals, ureters, urinary bladder, prostate, urethra, penis, scrotum, testis, and spermatic cord. Because their sensory nerve supply is primarily thoracolumbar and sacral outflow (Table 53-1) , these structures are well adapted for regional anesthesia.

INNERVATION OF THE GENITOURINARY SYSTEM

The parts of the genitourinary system that are in the abdomen receive their nerve supply from the autonomic nervous system via both sympathetic and parasympathetic pathways. The pelvic urinary organs and the genitalia are supplied by the somatic in addition to the autonomic nerves. Table 53-1 summarizes the pain conduction pathways and spinal levels of the genitourinary system.

Kidney and Abdominal Ureter

Sympathetic nerves to the kidney originate as preganglionic fibers from the eighth through the first lumbar segments and converge to the celiac plexus and the aorticorenal ganglia (Fig. 53-1) (Figure Not Available) . Postganglionic fibers to the kidney arise mainly from the celiac and aorticorenal ganglia. Some sympathetic fibers may reach the kidney via the splanchnic nerves. Parasympathetic input is from the vagus nerve. [2] Sympathetic fibers to the ureter originate from the tenth thoracic through the second lumbar segments and synapse with postganglionic fibers in the aorticorenal and superior

TABLE 53-1 -- Pain Conduction Pathways and Spinal Segment Projection of Pain of the Genitourinary System

ORGAN	SYMPATHETICS, SPINAL SEGMENTS	PARASYMPATHETICS	SPINAL LEVELS OF PAIN CONDUCTION
Kidney	T8-L1	X (vagus)	T10-L1
Ureter	T10-L2	S2-S4	T10-L2
Bladder	T11-L2	S2-S4	T11-L2 (dome)
			S2-S4 (neck)
Prostate	T11-L2	S2-S4	T11 to L2, S2-S4

Scrotum	NS	NS	S2-S4
Testes	T10-L2	NS	T10-L1

NS, not significant for nociceptive function

and inferior hypogastric plexus. Parasympathetic input is from second through fourth sacral spinal segments. [2] Nociceptive fibers travel along the sympathetics to the same spinal segments. Pain from the kidney and ureter, therefore, is referred mainly to the somatic distribution of the tenth thoracic through the second lumbar segments, namely, the lower back, flank, ilioinguinal region, and scrotum or labia. Effective neural block of these segments is necessary to provide adequate analgesia or anesthesia.

Figure 53-1 (Figure Not Available) Autonomic and sensory innervation of the kidney and ureters. Solid line = preganglionic fibers; dashed line = postganglionic fibers; dotted line = sensory fibers. *(From Gee WF, Ansell JF: Pelvic and perineal pain of urologic origin. In Bonica JJ [ed]: The Management of Pain. 2d ed. Philadelphia, Lea & Febiger, 1990: 1368-1378.)*

Bladder and Urethra

Sympathetic nerves to these organs originate from the eleventh thoracic to the second lumbar segments, travel through the superior hypogastric plexus, and supply the bladder via the right and the left hypogastric nerves. [3] Parasympathetic nerves arise from the second through the fourth sacral segments and form the pelvic parasympathetic plexus, which is joined by the hypogastric plexus. Vesical branches then proceed toward the bladder base, where they provide the nerve supply to the bladder and the proximal urethra (Fig. 53-2) (Figure Not Available) . Parasympathetic fibers are the main motor supply to the bladder (with the exception of the trigone) and hence far outnumber the sympathetic fibers in the bladder. [3]

The afferents carrying sensations of stretch and fullness of bladder are parasympathetic, whereas pain, touch, and temperature sensations are carried by the sympathetic nerves. Sympathetic fibers are predominantly alpha-adrenergic in the bladder base and the urethra and beta-adrenergic in the bladder dome and lateral wall. Knowledge of these aspects of neuroanatomy is important to appreciate the pharmacologic effects on the urologic system of neural ablation or regional block and of drugs with adrenergic or cholinergic effects. [3]

Prostate and Prostatic Urethra

The prostate and prostatic urethra receive both sympathetic and parasympathetic supply from the prostatic plexus arising from the pelvic parasympathetic plexus, which is joined by the hypogastric plexus. The spinal origin of the nerve supply is primarily lumbosacral (see Fig. 53-2) (Figure Not Available) . [3]

Penis and Scrotum

The autonomic supply to the penile urethra and the cavernous tissue comes from the prostatic plexus. Somatic fibers from the pudendal nerve (S2-S4) supply the external sphincter. The dorsal nerve of the penis, the first branch of the pudendal nerve, is its main sensory supply. The scrotum is innervated anteriorly by the iliolingual and genitofemoral nerves (L1 and L2) and posteriorly by the perineal branches of the pudendal nerve (S2 and S4). [3]

Figure 53-2 (Figure Not Available) *A.* Nerve supply of the urinary bladder and prostate showing the relationship of the various nerve structures to the large intestine and their distribution in the bladder and prostate. *B.* Schematic illustration showing the segmental nerve supply to the bladder, penis, and scrotum. Solid lines = preganglionic fibers; dashed lines = postganglionic fibers; dotted lines = sensory fibers. *(From Gee WF, Ansell JS: Pelvic and perineal pain of urologic origin. In Bonica JJ [ed]: The Management of Pain. 2d ed. Philadelphia, Lea & Febiger, 1990: 1368-1378.)*

Testes

The testes descend from their intra-abdominal location to the scrotum during fetal development. Because they share their embryologic origin with the kidney, their nerve supply is similar to that of the kidney and upper ureter and extends up to the T10 spinal segment. [3]

Although knowledge of the neuroanatomy is essential to provide adequate anesthesia, a thorough understanding of renal physiology and pharmacology is equally important. Frequently the genitourinary surgical patient has mechanical or functional renal disease. Anesthetics and surgery will significantly alter renal function. Conversely, renal dysfunction will significantly affect the pharmacokinetics and pharmacodynamics of anesthetics and adjuvant drugs. The evaluation of a patient with renal disease is discussed later.

Renal Blood Flow

Kidneys receive approximately 15 to 25 percent of total cardiac output or 1.0 to 1.25 L blood/min via renal arteries depending on the state of body. Most of the blood is received by renal cortex, and only 5 percent of cardiac output flows through renal medulla, which makes renal papillae vulnerable to ischemic insults. Renal blood flow is regulated by a variety of mechanisms that control activity of vascular smooth muscles and thereby alter vascular resistance. The sympathetic tone of renal vessels increases during exercise to shunt renal blood flow to exercising skeletal muscle, similarly renal blood vessels relax during the resting condition of the body. Sympathetic stimulation due to surgery can increase the vascular resistance to reduce the renal blood flow, whereas anesthetic may reduce the renal blood flow by decreasing cardiac output. Glomerular capillaries separate afferent arterioles from efferent arterioles. The glomerular capillaries are high pressure systems, whereas peritubular capillaries are low pressure systems. So the glomerular capillaries are a fluid-filtering system, whereas peritubular capillaries are a fluid-absorbing system. Vasa recta are a specialized portion of peritubular capillaries that are formed from efferent arterioles and are important in the formation of concentrated urine by countercurrent mechanism. An intrinsic mechanism that causes vasodilation and vasoconstriction of renal afferent arterioles regulates the autoregulation of renal blood flow. A fall in mean arterial pressure will also decrease renal blood flow and eventually affect glomerular filtration rate (GFR) when the pressure decreases below 60 mm Hg. The persistent low mean arterial pressure above 60 mm Hg affects renal blood flow but does not affect the GFR due to the intrinsic mechanism of autoregulation (Fig. 53-3) (Figure Not Available) . This autoregulation is maintained between 60 and

---

Figure 53-3 (Figure Not Available) Autoregulation of renal blood flow (RBF) and glomerular filtration rate (GFR). The relationships between RBF, GFR, and urine flow rate (UFR) and mean renal arterial pressure in dogs are shown as renal arterial pressure is varied from 20 to 280 mm Hg. Autoregulation of RBF and GFR is observed between about 80 and 180 mm Hg. *(From Hemmings HC: Anesthetics, Adjuvants and Drugs and the Kidney. In Malhotra V [ed]: Anesthesia for Renal and Genitourinary Surgery. New York, McGraw-Hill, 1996, p 18.)*

160 mm Hg mean arterial pressure (MAP) in intact as well as denervated kidneys. [4]

Although knowledge of the neuroanatomy and renal blood flow is essential to provide adequate anesthesia, a thorough understanding of renal physiology and pharmacology is equally important. Frequently the genitourinary surgical patient has mechanical or functional renal disease. Anesthetics and surgery will significantly alter renal function. Conversely, renal dysfunction will significantly affect the pharmacokinetics and pharmacodynamics of anesthetics and adjuvant drugs. The evaluation of a patient with renal disease is discussed later.

ANESTHESIA FOR THE PATIENT WITH RENAL DISEASE

Evaluation of Renal Function

The best indication that a patient has renal disease is usually obtained from the medical history (Ch. 34) . Physical findings often are minimal until renal disease is far advanced unless hypertension is present. Urinalysis is sufficient laboratory screening for identification of kidney disease if the patient does not have a history of genitourinary abnormalities. If renal disease is thought to be present, more precise methods of assessing renal function are necessary. Laboratory tests useful in evaluating renal function are described next (Table 53-2) (Table Not Available) .

Urinalysis

Gross and microscopic observation of the urine and its sediment, with determination of urinary pH, specific gravity,

TABLE 53-2 -- Commonly Ordered Renal Function Tests

(Not Available)

From Miller ED Jr: Understanding renal function and its preoperative evaluation. In Malhotra V (ed): Anesthesia for Renal and Genitourinary Surgery. New York, McGraw-Hill, 1996, p 9.

protein content, and sugar content, is one of the most readily available, inexpensive, and informative laboratory tests.

Appearance

The gross appearance of the urine may indicate the presence of bleeding or infection in the genitourinary tract. Microscopic examination of urinary sediment may reveal the presence of casts, bacteria, and various cell forms, supplying diagnostic information in patients with renal disease.

pH Value

Urinary pH is a measure of the ability of the kidneys to acidify urine. The kidneys share regulation of acid-base balance with the lungs and provide the sole pathway of excretion for the 60 mEq of hydrogen ion (nonvolatile acid) produced each day by normal metabolism. [5] The three renal mechanisms that prevent the development of acidemia are the reabsorption of filtered bicarbonate, the acidification of buffers in the tubular urine (i.e., the excretion of titratable acid) and the production of ammonia in tubular cells and its excretion as ammonium ion. The inability to excrete an acid urine in the presence of systemic acidosis is indicative of renal insufficiency.

Concentration

Urinary specific gravity is an index of concentrating ability, specifically, renal tubular function. Determination of urinary

osmolality, that is, measurement of the number of moles of solute (osmoles) per kilogram of solvent, is a similar, more specific test. Excretion of concentrated urine (specific gravity 1.030, 1050 mOsm/kg) is indicative of excellent tubular function, whereas urinary osmolality fixed at that of plasma (specific gravity 1.010, 290 mOsm/kg) is indicative of renal disease. The urinary dilution mechanism persists after concentrating defects are present, so that a urinary osmolality of 50 to 100 mOsm/kg may still be consistent with advanced renal disease.

Protein

Patients without renal disease may excrete up to 150 mg of protein per day; greater amounts may be present after strenuous exercise or after standing for several hours. Massive proteinuria (i.e., >750 mg/d) is always abnormal and is usually indicative of severe glomerular damage. However, proteinuria also may be due to (1) failure of tubular reabsorption of the small amount of protein that is normally filtered, (2) abnormally increased concentrations of normal plasma proteins, or (3) the presence of abnormal plasma proteins, which are then excreted in the urine.

Sugar

Glucose is freely filtered at the glomerulus and subsequently is reabsorbed in the proximal tubule. Glycosuria signifies that the ability of the renal tubules to reabsorb glucose has been exceeded by an abnormally heavy glucose load and is usually indicative of diabetes mellitus. However, glycosuria also may be present in hospitalized patients without diabetes who are receiving intravenous glucose infusions.

Complete Blood Count

Anemia may be present in patients with renal disease because of abnormalities in production of erythropoietin (erythropoiesis-stimulating factor [ESF].) The exact mechanism of ESF formation is unknown. [6] [7] [8] One view is that in response to hypoxia, the kidney elaborates a precursor of ESF, which combines with a plasma protein to form active ESF. [7] Another theory is that the kidney produces an enzyme, renal erythropoietic factor, which converts a precursor in plasma to ESF. [7] In advanced renal disease there appears to be decreased ESF activity and hence anemia. [8] The absence of ESF, as may occur in the anephric patient, results in hemoglobin levels of 6 to 8 g/100 mL. Recently available commercial preparation of erythropoietin has been effective in alleviating the chronic anemia associated with end-stage renal disease. Hemoglobin concentrations of 10 g/100 mL or greater are not uncommon in patients with end-stage renal disease treated with recombinant erythropoietin. White blood cell and platelet counts are of particular importance in patients who have a transplanted kidney, as immunosuppressive therapy may cause bone marrow suppression.

Creatinine and Urea Concentrations and Clearances

Measurements of creatinine and urea concentrations and clearances provide valuable information regarding general kidney function. Creatinine in the serum results

from the turnover of muscle tissue and is dependent on daily dietary intake of protein; normal values are in the range of 0.5 to 1.5 mg/100 mL, with values of 0.5 to 1.0 mg/100 mL present during pregnancy. Creatinine is freely filtered at the glomerulus and apart from an almost negligible increase in content due to secretion in the distal nephron; it is neither reabsorbed nor secreted. Therefore, serum creatinine measurements reflect glomerular function [9] (Fig. 53-4) (Figure Not Available) , and creatinine clearance is a specific measurement of GFR. Because there is such a wide range in normal values, a 50 percent increase in serum creatinine concentration, indicative of a 50 percent reduction in GFR, may go undetected unless baseline values are known. It also should be apparent that the excretion of drugs dependent on glomerular filtration may be significantly decreased despite what might seem to be only slightly elevated serum creatinine values (1.5-2.5 mg/100 mL). Serum creatinine concentration and clearance are better indicators of general kidney function and GFR than similar measurements of urea nitrogen. Urea nitrogen concentration and clearance are subject to wide intraindividual variations secondary to changes in hydration, rate of urine flow, and dietary protein intake.

Creatinine clearance measurement is made over a 24-hour period and calculated as follows:

A 24-hour clearance is more accurate than a 2-hour creatinine clearance test, which is frequently used because it is more convenient. Normal values are 85 to 125 mL/min in women and 95 to 140 mL/min in men. Creatinine clearance decreases with age and the value approaches 70 at age 70.

Serum Electrolytes

Sodium, potassium, chloride, and bicarbonate concentrations should be determined if impairment of renal function is suspected. However, these tests usually remain normal until frank renal failure is present, and hyperkalemia does not occur until patients are uremic. [10]

pH and Blood Gases

If significant renal disease is present, patients consuming a diet high in animal protein may have metabolic acidosis

---

Figure 53-4 (Figure Not Available) Theoretical relationship between blood urea nitrogen (BUN) and creatinine versus glomer-ular filtration rate (GFR). *(From Kassirer JP: Clinical evaluation of kidney function--glomerular function. N Engl J Med 285:385, 1971. Copyright 1971, Massachusetts Medical Society. All rights reserved.)*

due to the inability to excrete nonvolatile acid metabolites. Arterial blood pH, bicarbonate, and P_{CO_2} should be determined to measure the extent of acid-base imbalance (Ch. 38) .

Chest Radiograph

Standard posteroanterior and lateral radiographic exposures (Ch. 23) of the chest may be of value in determining the presence and extent of hypertensive cardiovascular disease, pericardial effusion, and uremic pneumonitis.

Electrocardiogram

The electrocardiogram (ECG) (Ch. 32) reflects the toxic effects of potassium excess more closely than does determination of serum potassium concentration. As hyperkalemia progresses, tall peaked T waves, depression of the ST segment, and widening of the QRS complex are seen. When potassium values increase above 8.0 mEq/L, ventricular standstill and bizarre arrhythmias may occur. Digitalis toxicity is a real danger in patients with advanced renal disease, particularly if electrolyte imbalance is present; it is best detected with the ECG. Digitalis will shorten the Q-T interval, depress the ST segment, and cause ventricular premature contractions that may be coupled or tripled, producing bigeminal or trigeminal rhythms. Hypocalcemia is associated with prolongation of the Q-T interval on the ECG. Hypocalcemia, hyperkalemia, and digitalis excess are the most likely causes of arrhythmias during anesthesia in uremic patients. Finally, the ECG may be of value in diagnosing hypertensive and ischemic heart disease.

These laboratory tests will define the degree of acute or chronic renal impairment that is present. Until approximately 50 percent of renal function is lost, the usual biochemical indices of renal function, except for creatinine clearance, are within normal limits; other signs and symptoms of renal impairment are absent. Patients with this degree of impairment are said to have decreased renal reserve [10] ; their anesthetic management is no different from that of patients with normal renal function.

Renal insufficiency is said to be present when patients have mild azotemia, nocturia, decreased maximum urinary concentrating ability, and slight anemia. Patients in this category require special attention, as further small decrements in renal function could lead to significant deterioration of their condition. Drugs excreted primarily by the kidney may have a clinically discernible, prolonged duration of action.

Renal failure is characterized by progressive anemia, hypocalcemia, hyperphosphatemia, and loss of urinary concentrating and diluting ability. Polyuria, hyponatremia, and hyperchloremia may be present, but hyperkalemia is rare. Creatinine levels in the range of 3.5 to 4.0 mg/100 mL are common, as are creatinine clearance values of 15 to 20 mL/min. The clinical condition of these patients is precarious, and management must be directed at avoiding further loss of renal function. They are unable to adapt to rapid and significant changes in fluid balance, and they run the risk of becoming acutely hypovolemic or fluid overloaded. Further deterioration in renal function will cause them to become grossly uremic and to require hemodialysis to control the signs and symptoms of renal failure. Drugs excreted primarily by the kidney should be avoided, or if they must be given, they should be administered in decreased dosage and/or at prolonged intervals.

Effects of Drugs in Patients With Reduced Renal Function

Most drugs are weak electrolytes and lipid-soluble in the un-ionized state; thus, they are extensively reabsorbed by renal tubular cells (Chs. 18 and 34) . Termination of their action is not dependent on renal excretion; redistribution and metabolism produce this effect. After biotransformation, these drugs are excreted in the urine as water-soluble, polar forms of the parent compound. They are usually pharmacologically inactive, and their retention is not harmful. [11] The majority of drugs with prominent central and peripheral nervous system activity fall into this category, including most narcotics, barbiturates, phenothiazines, butyrophenone derivatives, benzodiazepines, ketamine, and local anesthetics. [11] [12] [13] However, several drugs are relatively lipid-insoluble or are highly ionized in the physiologic pH range and are eliminated unchanged in the urine. Their duration of action may be extended in patients with impaired renal function. Drugs in this category include muscle relaxants, cholinesterase inhibitors, thiazide diuretics, digoxin, and many antibiotics [12] (Table 53-3) (Table Not Available) .

Because patients with severe renal disease often are debilitated, caution should be exercised when administering any therapeutic agent; dosage reductions of 25 to 50 percent are appropriate in most cases. At times, it may not be possible to avoid the administration of certain nonanesthetic drugs, such as digitalis or aminoglycoside antibiotics, excreted primarily or solely by the kidney. Blood concentration determinations of many of these agents are regularly performed in many hospitals. When levels cannot be determined, formulas have been derived for calculation of dosage, based on serum creatinine concentration or creatinine clearance, so that nontoxic therapeutic levels may be maintained. [13] Drugs frequently used by anesthesiologists are considered next.

Drugs Used for Premedication

Barbiturates

Except for phenobarbital, which is still used for premedication for epileptic adults and children, barbiturates are rarely used today (Ch. 8) . Approximately 24 percent of

phenobarbital is excreted in the urine in unchanged form. [14] Little problem is encountered when it is used in this circumstance.

Belladonna Alkaloids (and Their Substitutes)

Approximately 20 to 50 percent of a dose of atropine is recovered unchanged in the urine or in the form of active metabolites. [15] [16] The same is true for quaternary ammonium atropine-like compounds such as glycopyrrolate. [13] Thus, there is a potential for accumulation of these drugs in patients with renal failure, but a single dose will not cause clinical difficulties. Only one-tenth as much scopolamine is recovered from urine as atropine [16] ; however, because of its

TABLE 53-3 -- Drugs Used or Encountered in Anesthesia Practice for Which Renal Excretion Is a Significant Elimination Pathway

(Not Available)

Modified from Prescot LF: Mechanisms of renal excretion of drugs (with special reference to drugs used by anaesthetists). Br J Anaesth 44:246, 1972.

untoward central nervous system (CNS) effects, scopolamine should not be substituted for atropine or glycopyrrolate when large or repeated doses of an antimuscarinic agent are required. As a premedicant, scopolamine is satisfactory for patients with renal failure.

Phenothiazine and Benzodiazepine Compounds

Both phenothiazine and benzodiazepine derivates (Ch. 9) are extensively metabolized in the liver before excretion. [17] [18] Thus, any apparent increased duration or intensity of action associated with their administration is probably related to the general systemic effects of renal failure rather than to specific drug actions. A possible disadvantage of the phenothiazine derivatives is that they produce alpha-adrenergic blockade; this could accentuate cardiovascular instability in recently dialyzed patients who may be hypovolemic.

Opioids

Protein binding of morphine decreases by approximately 10 percent in chronic renal failure (Ch. 10) . [19] This does not result in a significant alteration in the free-fraction of morphine, as it usually is protein-bound to only a small extent (23-42%), and it has a large volume of distribution. [20] Morphine is almost completely metabolized in the liver mostly to the inactive glucuronide, which is then excreted in the urine. [21] [22] Thus, its administration to patients with renal failure, particularly in analgesic doses, should not cause prolonged depression. Nevertheless, a report of severe respiratory and cardiovascular depression in a patient with renal failure was attributed to administration of a single 8-mg dose of morphine. [23] This can be attributed to the accumulation of morphine-6-glucuronide, which possesses opioid activity and is excreted by the kidney. The distribution, protein binding, and excretion of meperidine are similar to those of morphine. [24] [25] Accumulation of its metabolite normeperidine can produce excitatory central nervous system (CNS) effects including convulsions in extreme cases. Fentanyl also is metabolized in the liver, with only 7 percent excreted unchanged

in the urine. [26] [27] It is moderately bound to plasma protein (free fraction, 19 percent), and its volume of distribution is large. [26] [27] Thus, fentanyl should be suitable for premedication of patients with renal failure. The pharmacokinetics and pharmacodynamics of sufentanil and alfentanil are not significantly different in patients with reduced renal function as compared with normal individuals. [28] [29] An ester linkage in remifentanil renders it susceptible to rapid metabolism by blood and tissue esterases. Therefore, the pharmacokinetics and pharmacodynamics of remifentanil are unaltered in patients with renal disease. Although the renal elimination of its principal metabolite is reduced, it is of no clinical significance. [30]

Anesthetic Agents and Adjuvant Drugs

Inhaled Anesthetics

All inhaled anesthetics (Chs. 4 and 6) are biotransformed to some extent, with the nonvolatile products of metabolism eliminated almost entirely by the kidney. [31] However, reversal of the CNS effects of inhaled anesthetics is dependent on pulmonary excretion, so that impaired kidney function will not alter the response to these agents. From the viewpoint of selecting an anesthetic agent that will not be harmful for patients with mild or moderate impairment of renal function, all the modern potent agents are suitable. Methoxyflurane, an inhaled anesthetic of the 1960s and 1970s, was contraindicated in patients with renal disease because of its extensive biotransformation to nephrotoxic inorganic fluoride and oxalic acid. [32] [33] Enflurane is also biotransformed to inorganic fluoride, but levels after 2 to 4 hours of anesthesia average only 19 muM in patients with mild to moderate kidney disease, [34] significantly lower than the nephrotoxic threshold of 50 muM. [33] This level of fluoride should not cause further renal impairment. Fluoride levels after isoflurane increase by only 3 to 5 muM [35] and by only 1 to 2 muM [32] [33] after halothane, so these agents have no nephrotoxic potential.

Desflurane and sevoflurane, the two new inhaled anesthetics, are remarkably different in their molecular stability and biotransformation. Desflurane is highly stable and resists degradation by soda lime [36] and the liver. Even in enzyme-induced animals, the excretion of organic or inorganic fluoride has been shown to be minimal. [37] [38] Mean inorganic fluoride concentration after 1.0 MAC (minimum alveolar concentration)-hour exposure to desflurane was less than 1 mumol/L. [39] In addition, recently developed, more sensitive indices of renal function, namely urine retinol-binding protein and beta-N-acetylglucosaminidase, showed no evidence of renal damage. Prolonged exposure to desflurane (7.0 MAC-hours) has been associated with normal renal function. [40]

Sevoflurane, on the other hand, is not very stable. Soda lime causes its decomposition, [41] and it is biotransformed by the liver to an extent similar to enflurane. There have been reports of plasma inorganic fluoride concentrations approaching nephrotoxic levels (50 mumol/L) [42] [43] after prolonged inhalation of sevoflurane. However, there is no evidence of gross changes in renal function in humans. [44]

Inhaled anesthetics cause a transient reversible depression of renal function. GFR, renal blood flow, urine output, and urinary excretion of sodium are decreased (Table 53-4) (Table Not Available) . Likely mechanisms include reduced renal blood flow, loss of renal autoregulation, neurohumoral factors (e.g., antidiuretic hormone, vasopressin, renin), or neuroendocrine responses. Although most inhalation anesthetics have been shown to reduce GFR and urinary excretion of sodium, their

TABLE 53-4 -- Effects of Various Anesthetics on Renal Function

(Not Available)

From Hemmings HC Jr: Anesthetics, adjuvant drugs and the kidney. In Malhotra V (ed): Anesthesia for Renal and Genitourinary Surgery. New York, McGraw-Hill, 1996 p 20.

effects on renal blood flow have yielded conflicting results. This can be explained by differences in experimental methodology. Data suggest that renal blood flow is maintained with halothane, isoflurane, and desflurane [45] [46] [47] but decreased with enflurane and sevoflurane. [48] [49]

Patients with severe renal disease frequently have hemoglobin levels of 6 to 8 g/100 mL. Although oxygen-carrying capacity may be adequate in the unanesthetized state, intrapulmonary shunting and reduced cardiac output may occur during general anesthesia. Therefore, to avoid intraanesthetic hypoxemia, it is advisable not to administer high concentrations of nitrous oxide, as might be necessary with balanced anesthetic techniques, unless arterial oxygen saturation can be continuously monitored.

Intravenous Anesthetics

Reversal of CNS effects after administration of ultrashort-acting barbiturates, such as thiopental and methohexital, occurs as a result of redistribution (Chs. 8 to 10) ; hepatic metabolism is the sole route of elimination of these drugs. Thiopental is 75 to 85 percent bound to albumin, [50] the concentration of which may be markedly reduced in uremia. Because it is a highly bound drug, reduced binding permits a greater proportion of an administered dose of thiopental to reach receptor sites. In addition, thiopental is a weak acid, with its pKa in the physiologic range; acidosis will result in more un-ionized, nonbound, active thiopental. In combination, these changes produce an increase in the free fraction of thiopental from 15 percent in normal patients to 28 percent in patients with chronic renal failure. [51] Because the metabolism of thiopental is essentially unchanged in renal disease, the amount of thiopental necessary to produce and maintain anesthesia is reduced. [51] [52] The same considerations are true for methohexital, [53] although metabolism plays a slightly greater part in termination of its therapeutic effect. [54]

There are no reports of the disposition of narcotics and tranquilizers when used in high dosage for anesthesia in uremic patients. These agents are extensively metabolized before excretion so that, in combination with 30 to 50 percent nitrous oxide, they should not have a particularly prolonged effect. Of course, the benzodiazepines, especially diazepam, [18] have a long half-life so they will tend to accumulate in any case. Because uremic patients are anemic and may require high inspired oxygen concentrations and because of the greater ease of reversibility of the potent inhaled anesthetics as compared with the intravenous drugs, inhaled anesthetics may be preferable for the production of general anesthesia.

Muscle Relaxants and Their Antagonists

Succinylcholine has been used without difficulty in patients with decreased or absent renal function (Ch. 12) . Its metabolism is catalyzed by pseudocholinesterase, yielding the nontoxic end products succinic acid and choline. The metabolic precursor of these two compounds, succinylmonocholine, is excreted by the kidney. Thus, large doses of succinylcholine, which might result from prolonged administration of an infusion, should be avoided in patients with renal failure. It has been reported that pseudocholinesterase levels are reduced in uremia. [55] [56] However, values are rarely so low as to cause prolonged block. Hemodialysis has been reported to have no effect on cholinesterase levels. [57] [58]

Succinylcholine administration causes a rapid, transient rise in serum potassium concentration of 0.5 mEq/L. In traumatized, burned, or neurologically injured patients, the increase may be as great as 5 to 7 mEq/L, probably as a consequence of denervation supersensitivity of the muscle membrane to succinylcholine and to acetylcholine. [59] [60] In some instances, cardiovascular collapse has occurred. [59] An exaggerated rise in serum potassium could be particularly dangerous in uremic patients with elevated potassium levels, so that the use of succinylcholine is inadvisable unless the patient has undergone dialysis within 24 hours before operation. If the patient has recently undergone dialysis, the use of succinylcholine is reported to be safe. [61] [62]

The disposition of the nondepolarizing muscle relaxants has been well studied in recent years. In patients with normal renal function, the largest excreted fraction of a dose of *d*-tubocurarine (dTc) is found in the urine (i.e., 45 percent is recovered in 24 hours, with an additional 12 percent recovered in bile. [63] As can be appreciated from examination of the pharmacokinetic data in Table 53-3 (Table Not Available) , excretion of dTc is delayed in patients with renal failure. [64] Clearance is reduced and volume of distribution is unchanged--hence the increased terminal elimination half-life. Because protein binding [65] and sensitivity of the neuromuscular junction to dTc [66] are unchanged in patients with renal failure, the consequence of delayed excretion would be prolonged duration of action. However, this would not be apparent after administration of a single small dose, as redistribution rather than excretion is responsible for termination of action. [67] On the contrary, recovery after a single large dose or several small doses of dTc is directly related to the terminal elimination half-life. Thus, maintenance doses for patients with decreased renal function should be smaller than for patients with normal renal function, the interval between doses should be increased, [20] and administration should be monitored with a nerve stimulator.

Pharmacokinetic data for metocurine [68] and gallamine [69] (Table 53-5) indicate that these agents differ quantitatively rather than qualitatively from dTc. More than 90 percent of an injected dose of gallamine is eliminated unchanged in the urine within 24 hours, whereas only 43 percent of a dose of metocurine is excreted unchanged in that time. Recovery from a small dose of gallamine occurs by redistribution, so theoretically it could be used in patients with reduced renal function. However, prolonged paralysis requiring hemodialysis for reversal has been reported after gallamine administration to a patient with renal failure. [70] The availability of other more suitable muscle relaxants (see later) argues against its use.

Approximately 40 to 50 percent of pancuronium is excreted in the urine. A portion of this occurs after biotransformation to the less active metabolite 3-hydroxypancuronium. [20] [71] [72] Pancuronium has a prolonged terminal elimination half-life in patients with reduced renal function (Table 53-5) , [73] [74] so it should be administered cautiously, particularly when several doses are required.

TABLE 53-5 -- Pharmacokinetic Data for Nondepolarizing Muscle Relaxants in Normal and Anephric Patients

DRUG	PATIENTS STUDIED	ELIMINATION HALF-LIFE (h) (t½ s)	CLEARANCE (L/kg/min)	VOLUME OF DISTRIBUTION (L/kg)	REFERENCE
Vecuronium	Normal	0.9	5.3	0.20	[80]
	Anephric	1.4	3.1	0.24	
Atracurium	Normal	0.3	6.1	0.18	[76]

	Anephric	11.4	0.4	0.48	
Gallamine	Normal	2.2	1.2	0.24	[69]
	Anephric	12.5	0.2	0.28	

Two nondepolarizing muscle relaxants, atracurium and vecuronium, were introduced into clinical practice during the early 1980s. After initial reports that the action of neither drug was prolonged in patients with decreased renal function, [75] [76] [77] [78] [79] it now appears that this is only true for atracurium. [80] [81] Atracurium and cisatracurium are broken down by enzymatic ester hydrolysis and by nonenzymatic alkaline degradation (Hofmann elimination) to inactive products and are not dependent on renal excretion for termination of action. [75] Predictably, their terminal elimination half-life (Table 53-5) and indices of neuromuscular block (onset, duration, and recovery) are the same in patients with normal and with absent renal function. [76] [77] Although atracurium may cause histamine release in patients undergoing renal transplantation, this usually does not result in clinical signs or symptoms with doses less than 0.4 mg/kg. [78]

The pharmacokinetics and pharmacodynamics of vecuronium in patients with normal renal function and with renal failure have recently undergone reexamination. [80] [81] There now appears to be general agreement that about 30 percent of a dose of vecuronium is eliminated by the kidneys. Thus, it is not surprising that Lynam et al [80] found that the duration of neuromuscular blockade after administration of vecuronium was longer in patients with renal failure than in those with normal renal function (99 versus 54 minutes), secondary to longer elimination half-life (83 versus 52 minutes) and lower plasma clearance (3.1 versus 5.3 mL/kg/min). In a related area, an interaction between the solvent of cyclosporin, cremophor, and both atracurium and vecuronium, which potentiates the action of these muscle relaxants in

cats, has been reported [82] ; it is not known if this also occurs in human renal transplant recipients.

Of the newer relaxants, doxacurium is a long-acting muscle relaxant, whose duration of action is further prolonged in patients with renal failure. [83] [84] The duration of action of another long-acting muscle relaxant, pipecuronium, shows a large variability in patients with renal failure. [85] The new short-acting drug mivacurium is metabolized by plasma pseudocholinesterase. Its effect has been shown to be lengthened by 10 to 15 minutes in patients with end-stage renal disease; this is most likely due to a decrease in plasma cholinesterase activity in these patients associated with uremia or after hemodialysis. [86] [87] [88] Phillips and Hunter [87] demonstrated a decrease in mivacurium requirement by infusion in the anephric patient.

The elimination half-life of rocuronium is increased in renal failure due to an increase in volume of distribution with no change in clearance. This may explain a somewhat longer duration of action in anephric patients, although its clinical significance is uncertain. [89]

In summary, the pharmacokinetic data in Table 53-3 (Table Not Available) indicate that for agents excreted by the kidney (i.e., all drugs except cisatracurium and atracurium) lower doses and a longer dosing interval are appropriate for maintenance of neuromuscular blockade in patients with abnormal renal function. Additionally, a clinical monitor of neuromuscular function, such as a train-of-four nerve stimulator, is useful in most cases.

Pharmacokinetic data for the cholinesterase inhibitors neostigmine, pyridostigmine, and edrophonium for normal, anephric, and renal transplant recipients are presented in Table 53-6 ; there are no major differences among the three drugs. [90] [91] [92] Renal excretion is of major importance for the elimination of all three agents, with approximately 50 percent of neostigmine and 70 percent of pyridostigmine and edrophonium excreted in the urine. The excretion of all the cholinesterase inhibitors is delayed in patients with impaired renal function to the same or perhaps to a slightly greater extent than is the elimination of the muscle relaxants. Thus, "recurarization" after reversal of neuromuscular block in a patient with renal failure in most cases is due to some other cause, such as an interaction of the residual muscle relaxant with an antibiotic or a diuretic. Of interest in Table 53-4 (Table Not Available) are the data that indicate that the pharmacokinetics of all the cholinesterase inhibitors are similar in normal patients and in those with well-functioning newly transplanted kidneys. Similar findings have been reported for dTc pharmacokinetics, [66] and they probably also hold for pancuronium disposition. Thus, as a category, transplant recipients with well-functioning kidneys can be considered normal in the way they eliminate renally excreted drugs. However, there is sufficient interindividual variability in

TABLE 53-6 -- Pharmacokinetic Data for Cholinesterase Inhibitors in Normal, Anephric, and Renal Transplant Patients

DRUG	PATIENTS STUDIED	ELIMINATION HALF-LIFE (h) ($t_{½}$ s)	CLEARANCE (mL/kg/min)	VOLUME OF DISTRIBUTION (L/kg)	REFERENCE
Neostigmine	Normal	1.3	8.4	0.7	[90]

[a] $P < .05$ versus normal.

these data to indicate that treatment with muscle relaxants and their antagonists should be individualized, as indicated by clinical signs and by the results of tests with a nerve stimulator.

Digitalis

Digoxin is the most frequently used digitalis glycoside in both uremic and nonuremic patients. Approximately 72 percent of a parenteral dose is excreted unchanged in the urine. [93] Thus, its administration to patients with reduced renal function is potentially dangerous, and maintenance doses must be reduced in proportion to the reduction in renal function. Ultimately, blood digoxin levels are the most reliable guide to therapy (therapeutic level, >0.8 ng/mL; toxic level, >1.8 ng/mL). [94] Whenever possible, initial digitalization or changes in digitalis dosage should be avoided immediately before surgery.

Vasopressors and Antihypertensive Agents

Patients with severe renal disease frequently are given antihypertensive and other cardiovascular medications (Ch. 14) . More than 90 percent of the thiazides [14] [95] and 70 percent of furosemide [91] are excreted by the kidney and have prolonged durations of action in patients with abnormal or absent renal function. Propranolol is almost completely metabolized in the liver, and esmolol is biodegraded by the esterases in the cytosol of red blood cells, so their effects are not prolonged in patients with abnormal or absent renal function. [97] The calcium channel blocking agents nifedipine, verapamil, and diltiazem are extensively metabolized in the liver to pharmacologically inert products; they may be administered in usual doses to patients with renal insufficiency. [98] Among the older agents, methyldopa may have a prolonged duration of action because it is excreted unchanged in the urine. [99] Methyldopa acts by reducing both central and peripheral norepinephrine levels; it interacts with anesthetic agents to cause a reduction in MAC. [100] Guanethidine is excreted almost completely by the kidney, much of it in active form. [101] Guanethidine administration results in a reduction of peripheral, but not central, norepinephrine stores; it does not alter MAC.

During anesthesia, if arterial blood pressure reduction is necessary, several drugs may be used safely. Trimethaphan (Arfonad), a ganglionic blocking agent, is suitable because its action is terminated enzymatically rather than by renal excretion. Nitroglycerin is useful as it is rapidly metabolized, with less than 1 percent excreted unchanged in the urine. [102] Sodium nitroprusside has had a resurgence in use because its initial introduction as a hypotensive agent in the 1920s. Cyanide is an intermediate in the metabolism of sodium nitroprusside, with thiocyanate the final metabolic product. Whereas cyanide toxicity as a complication of sodium nitroprusside therapy is well described, [103] it is less well appreciated that thiocyanate is also potentially toxic. The half-life of thiocyanate is normally more than 4 days, and it is prolonged in patients with renal failure. [103] Hypoxia, nausea, tinnitus, muscle spasm, disorientation, and psychosis have been reported when thiocyanate levels exceed 10 mg/100 mL. Thus, sodium nitroprusside is less desirable for prolonged administration than either trimethaphan or nitroglycerin. Hydralazine is slower acting than the other three agents discussed previously, but it is often used for postoperative blood pressure control. Its action is terminated by hydroxylation and subsequent glucuronidation in the liver, with approximately 15 percent excreted unchanged in the urine. [104] The elimination half-life of hydralazine is prolonged in uremic patients, so caution is required when it is administered. [105] Following a single intravenous dose of 0.5 mg/kg of labetolol, the volume of distribution, clearance, and the elimination half-life were similar in patients with end-stage renal disease and normal volunteers. [106] Esmolol is independent of renal function as it is metabolized by red blood cell cytosol esterases. [107]

If administration of a vasopressor is necessary, a direct alpha-adrenergic-stimulating drug, such as phenylephrine, will be effective. Unfortunately, this type of vasopressor causes the greatest interference with renal circulation. Although beta-adrenergic-stimulating drugs, such as isoproterenol, maintain heart and brain perfusion without renal vasoconstriction, they also increase myocardial irritability. Therefore, when possible it is best to substitute simple measures

such as blood volume expansion for drug therapy. If these measures are inadequate, alpha-adrenergic-stimulating drugs or dopamine should be used.

Psychotropic Drugs

Monoamine oxidase inhibitors occasionally are used by patients with renal disease to counteract mental depression. Cardiovascular instability may occur in anesthetized patients treated with these drugs. [108] Their effect in uremic anesthetized patients is unknown.

Acute Renal Failure and Hemodialysis

Acute Renal Failure

The following material is provided as background information for consideration of the anephric patient and the patient undergoing renal transplantation.

Acute renal failure is defined as the sudden inability of the kidneys to vary urine volume and content appropriately in response to homeostatic needs. Synonymous terms are acute tubular necrosis and lower nephron nephrosis. The three major types of acute renal failure when classified according to their predominant etiologic antecedents are prerenal (i.e., owing to acute circulatory problems that impair renal perfusion); renal, (i.e., owing to primary or secondary renal disease, toxins, and pigments); and postrenal (i.e., owing to obstruction of the urinary tract.) [109] Common prerenal, renal, and postrenal causes of perioperative oliguria are listed in Table 53-7 (Table Not Available) . Prerenal failure is usually reversible if the circulatory status is promptly improved; postrenal failure is reversible when the obstruction is removed. Acute renal failure due to primary renal disease is the most serious of the three types and most often requires hemodialysis. [110]

Renal failure also is classified according to urine flow rates, so the terms *oliguric, nonoliguric,* and *polyuric renal failure* often are encountered. The diagnosis of acute oliguric renal failure is made when creatinine and blood urea nitrogen concentrations progressively increase while urine flow remains below 20 mL/h in an adequately hydrated patient who has a stable blood pressure and a patent urinary outflow tract. Urine and blood chemistry values are as indicated in Table 53-8 . In some cases, patients with acute renal failure may have normal or high (>2.5 L/d) urine flow rates, but they have biochemical abnormalities that are similar to

TABLE 53-7 -- Perioperative Causes of Oliguria

(Not Available)

those occurring in patients with low urine output. [111] Their management is less complex than that of oliguric patients because adequate drug therapy and proper nutrition are easier to maintain owing to the less stringent limitations on daily fluid intake.

The major problem arising from acute renal failure is the inability to maintain the dynamic balance between dietary intake of essential substances and production of waste products. This results in (1) a progressive rise in serum urea, creatinine, uric acid, magnesium, sulfate, phosphate, some amino and organic acids, and polypeptides; (2) a daily rise in serum potassium of 0.3 to 3 mEq/L except when there is concomitant potassium loss from diarrhea or vomiting (greater increases may occur in traumatized or postsurgical patients); (3) a decrease in serum sodium and calcium; (4) a decrease in serum proteins, particularly albumin; (5) a consistent increase in total reducing substance in the serum, frequently occurring with true hyperglycemia, which may be either sensitive or resistant to insulin; (6) elevation of total

TABLE 53-8 -- Urinary Composition in Oliguria

	PHYSIOLOGIC OLIGURIA	PRERENAL FAILURE	ACUTE TUBULAR NECROSIS
Urinary sodium	<10 mEq/L	<25 mEq/L	>35 mEq/L
Urinary specific gravity	>1.024	>1.015	1.010-1.015
Urinary osmolality	>700 mOsm/kg	>500 mOsm/kg	<350 mOsm/kg
Urinary/plasma osmolality	>2.5:1	>1.8:1	1.1:1
Urinary/plasma urea	>100:1	>20:1	3:1, rarely >10:1
Urinary/plasma creatinine	>60:1	>30:1, rarely <10:1	<10:1
Fractional sodium excretion	>0.5	<1	>1

lipids, cholesterol, phosphorus, and neutral fats; and (7) metabolic acidosis. The kidney functions both as an endocrine and as an excretory organ. Thus, disorders of renin-angiotensin and aldosterone secretion occur, contributing to the hypertension that develops in patients with severe renal disease. Reduced erythropoietin production leads to anemia. Heart failure and abnormalities in liver function and blood coagulation also may occur in patients with renal shutdown. Infection is common and difficult to treat because the altered excretion of antibiotics leads to rapid development of toxic levels of these drugs.

Once established, oliguria is usually present for 10 to 18 days but may persist for as long as 30 to 45 days. During this period, hemodialysis is required every 2 to 4 days. When diuresis occurs, the beginning of the recovery phase is signaled. During the diuretic phase, urine volume gradually increases until as much as 5 to 6 L of urine is produced daily. Management of the patient is directed at maintaining fluid and electrolyte balance in the face of these large losses. Finally, concentrating ability gradually returns toward normal. There is a complete return of all measurable parameters of renal function in approximately two-thirds of patients who survive. However, 50 to 60 percent of patients with acute renal failure do not survive long enough to recover or to develop chronic renal failure. [112] Arrhythmias, bleeding, and infection are the most frequent causes of death. Analyses of outcome indicate that the overall mortality rate from acute renal failure has not been significantly reduced in recent years despite earlier and more frequent dialysis. In fact, it is likely that there has been an increase in the survival rate of some categories of patients with the absence of a change in the overall rate due to an increase in the proportion of seriously ill patients who are now treated in dialysis units. This conclusion is suggested by the steady improvement in mortality data of obstetric patients with renal failure. The low (15%) mortality rate for this group emphasizes that the most significant feature determining survival is the physical status of the patient before the onset of renal failure.

As noted earlier, many patients with acute renal failure [111] have normal or high urinary flow rates. In these patients, the antecedent cause of renal failure may be the same as in patients with classic oliguric renal failure, but an oliguric or anuric phase is not identifiable. Patients are unable to alter urinary volume and content appropriately, with average daily output often in excess of 2.5 L/d. The higher incidence of nonoliguric and polyuric renal failure in recent years as compared with the 1940s and 1950s is thought to be due, in part, to more vigorous early treatment of patients with incipient oliguric renal failure. The majority of patients who suffered renal dysfunction following methoxyflurane anesthesia had normal or high urinary output. [33] [113]

Hemodialysis

The steady improvement in hemodialysis techniques (Ch. 55) from the first artificial kidney developed in 1944 by Kolf and Berk [114] to the current practice of home dialysis has resulted in additional years of productive life for patients with chronic renal failure. That, coupled with the 1976 federal legislation that extended Medicare coverage to renal failure patients, has resulted in a large increase in the number of hemodialysis patients in recent years. Many of these patients ultimately require anesthesia not only for renal transplantation but for surgical procedures unrelated to their renal disease. Dialysis improves most of the signs and symptoms of uremia (e.g., volume overload, acid-base and electrolyte imbalance, abnormal mental function, peripheral neuropathy, muscle weakness, and defective coagulation). Hypertension is improved except in those patients with high renin levels. Some patients have been hemodialyzed for more than 10 years. The 3-year survival rate for

U.S. patients aged 20 to 25 years treated by hemodialysis is 85 percent; for those aged 60 to 65 it is 60 percent.

Presently, two basic dialysis techniques are used: peritoneal dialysis, either chronic intermittent or continuous ambulatory, both performed at home; and chronic intermittent hemodialysis, performed at home or at a dialysis center. In most circumstances, hemodialysis is used, and it is generally the method of choice. However, peritoneal dialysis is preferred for patients who have had (1) recent cerebral surgery or a cerebral vascular accident or trauma, as the risk of fluid shifts or bleeding following heparinization is greater with hemodialysis; (2) recent cardiac surgery or a myocardial infarction, as the risk of hypotension and arrhythmias is greater with hemodialysis; (3) a recent acute hemorrhage; or (4) a severe coagulopathy. It also is frequently used in children.

The dialysis principle involves equilibration of waste products in the patient's blood across a semipermeable membrane to the dialysis bath. Peritoneal dialysis relies on the patient's peritoneum as the exchange membrane, avoiding the need for vascular cannulae and expensive equipment. Exchange volumes during peritoneal dialysis are 1 to 3 L/h. Clearance of small molecules is less than with hemodialysis (e.g., urea, 25 mL/min versus 150 mL/min), but clearance of large molecules is greater. The ionic content of the dialysate may be altered to suit the patient's needs, and the fluid may be hypertonic or hypotonic to plasma to remove or add fluid to the patient's extracellular fluid volume, respectively. Peritoneal dialysis is less efficient than hemodialysis, so dialysis times are longer. Also, peritonitis is a danger, and pain during dialysis may be severe. Future refinements may make this a more acceptable form of chronic dialysis.

Hemodialysis is by far the most common dialysis technique used today. Originally, Teflon shunts were inserted between the radial artery and a forearm vein with a connector between them, allowing access to the circulation. Today, vascular access is usually obtained by creation of an end-to-side arteriovenous fistula in the forearm or by insertion of a prosthetic arteriovenous (AV) graft when the vessels are inadequate. During hemodialysis, which is performed two or three times weekly, both the patient and the external circuit are heparinized to prevent clotting. Flow rates are usually 500 mL/min, so the patient's blood is exposed to 120 L of fluid during a standard 4-hour dialysis. Variation of the ionic content and osmolarity of the dialysate permit correction of abnormalities in fluid and electrolyte balance. However, if fluid and electrolyte shifts are too rapid, dialysis disequilibrium may occur. This syndrome is characterized by weakness, nausea, vomiting, and occasionally, convulsions and coma. In the interval between treatments, clotting does not occur because the shunted circuit is short and blood flow is rapid (150-300 mL/min).

Local infiltration, axillary block, and general anesthesia have been successfully used for creation of AV fistulas (Chs. 42 and 43) . Several anesthetic precautions are appropriate. Uremic patients may be debilitated, in which case smaller doses of all drugs, including local anesthetics, should be administered. Hyperkalemia, acidosis, and overhydration can combine to cause myocardial irritability; therefore, local anesthetic solutions that contain epinephrine should be used with caution. If epinephrine is used, concentrations greater than 1,200,000 are not necessary and solutions as dilute as 1,400,000 are probably adequate. Brachial plexus block may greatly facilitate introduction of cannulae by producing analgesia combined with peripheral vasodilation. Of interest, Bromage and Gertel [115] reported that brachial plexus block had a 38 percent shorter duration in renal failure patients than in those with normal renal function. However, this finding could not be confirmed in a recent study of renal failure patients. [116]

RENAL AND GENITOURINARY PROCEDURES

Transurethral Resection of the Prostate

Transurethral resection of the prostate (TURP) is one of the most commonly performed surgical procedures in men older than 60 years of age. The operation is performed through a modified cystoscope and consists of excising the hypertrophied lateral and median lobes of the prostate gland with an electrically energized wire loop; bleeding is controlled with a coagulating current. Continuous irrigation is used to distend the bladder and to wash away blood and dissected prostatic tissue.

Absorption of Irrigating Solution

Because the prostate gland contains large venous sinuses, it is inevitable that irrigating solution will be absorbed. Simple principles govern the amount of absorption: (1) the height of the container of irrigating solution above the surgical table determines the hydrostatic pressure driving fluid into prostatic veins and sinuses, and (2) the time of resection is proportional to the quantity of fluid that is absorbed. On average, 10 to 30 mL of fluid is absorbed per minute of resection time, with as much as 6 to 8 L absorbed in some cases lasting up to 2 hours. [117] [118] Whether patients suffer complications as a consequence of absorption of irrigating fluid depends on the amount and type of fluid absorbed. [119]

For many years distilled water was used for bladder irrigation during TURP, as it interfered least with visibility. However, absorption of large quantities of water led to dilutional hyponatremia, which resulted in hemolysis of red blood cells and CNS symptoms, ranging from confusion to convulsions and coma. Because of this, distilled water was abandoned in favor of isosmotic or near isosmotic solutions for TURP. Solutions such as normal saline and Ringer lactate would be well tolerated when absorbed intravascularly, but these electrolyte solutions are highly ionized and facilitate dispersion of high-frequency current from the resectoscope. Thus, solutions of nonelectrolytes, such as glucose, urea, glycine, mannitol, sorbitol, or Cytal (a combination of mannitol and sorbitol), have replaced distilled water. Today, glycine and Cytal are the two most commonly used irrigating solutions for TURP. [120] [121]

Replacement of distilled water with near isosmotic solutions has eliminated hemolysis and its sequelae as a complication of TURP. Also, the incidence of severe CNS problems, such as convulsions and coma, associated with extreme hyponatremia has been reduced. However, the other major problem associated with absorption of large volumes of irrigating solution, overhydration, still remains. Under usual conditions, only 20 to 30 percent of a load of crystalloid solution remains in the intravascular space; the remainder enters the interstitial space. When intravascular pressure is increased, movement of fluid into the interstitial space and development of pulmonary edema are favored. Whether a given patient will develop symptoms of circulatory overload depends on his or her cardiovascular status, the amount and rapidity of absorption of irrigating fluid, and the extent of surgical blood loss. It is obvious that the situation is dynamic and that patients must be monitored carefully. In this regard, spinal or epidural anesthesia, supplemented with only light intravenous sedation, has the advantage of allowing the patient's subjective judgment to contribute to the assessment of his or her condition during operation. In addition, cardiovascular depression associated with administration of the potent inhaled anesthetics is avoided. Another advantage of regional anesthesia is that the sympathetic block it produces increases venous capacitance and tends to mitigate intraoperative fluid overload. A note of caution: when the block dissipates, venous capacity acutely decreases and circulatory overload can occur.

Yet another advantage of regional anesthesia for TURP is that it allows early recognition of bladder perforation, which occurs in less than 1 percent of cases. If bladder perforation occurs, patients complain of back pain, abdominal pain, or shoulder pain, depending on the site of perforation and the resultant collection of fluid intra- or retroperitoneally. It is of utmost importance to the spinal block level to T10 or below or else this very advantage is lost because the patients would no longer sense the abdominal or back discomfort. The use of nonelectrolyte isosmotic irrigating solutions has reduced the incidence of severe CNS complications because extreme extracellular fluid hypoosmolality does not occur and the subsequent development of cerebral edema is avoided. That CNS symptoms occur at all is probably because the incidence and extent of hyponatremia are unchanged. It is now proposed that the TURP syndrome occurs if hyponatremia is accompanied by hypoosmolality and that CNS signs and symptoms usually do not manifest themselves if the osmolality remains normal. Glycine, urea, mannitol, and sucrose found in irrigating solutions tend to retain near normal osmolality. [122] The concentration of extracellular sodium must be in the physiologic range for depolarization of excitable cells and for production of the action potential. When extracellular sodium levels fall below 100 mEq/L, consciousness is lost and convulsions may ensue. [123] Signs and symptoms of cardiovascular dysfunction secondary to hyponatremia also may occur, such as arrhythmias, hypotension, and pulmonary edema. [124] However, it is often impossible to separate the latter events from those due to fluid overload.

Since the early 1980s, attention has turned to the absorption of glycine (HO_2-CCH_2-NH_2), a nonessential amino acid, as a possible cause of some of CNS symptoms associated with TURP. For example, in one publication, five cases of transient blindness were attributed to glycine toxicity. [125] Glycine has a distribution similar to that of gamma-aminobutyric acid, the latter an inhibitory transmitter in the brain; it has been suggested that glycine also is a major inhibitory transmitter acting in the spinal cord, brain stem, and retina. Glycine induced blindness is usually partially accompanied by widely dilated pupils, absent light and accommodation reflexes but preserved blink reflex. In contrast, cortical blindness is total with loss of blink reflex but preservation of light and accommodation reflexes. [126] Normal plasma glycine levels are 13 to 17 mg/L, whereas levels as high as 1,029 mg/L were measured during one episode of blindness. [125] Twelve hours later, the glycine level in this case had fallen to 143 mg/L, by which time vision had returned. However, an overall correlation between plasma glycine levels and CNS toxicity has not been established, so the relationship, although interesting, must still be considered speculative.

Absorption of glycine may result in CNS toxicity as a result of its oxidative biotransformation to ammonia. [127] [128] In a report of delayed awakening after TURP in three patients, [127] an association with elevated blood ammonia concentrations was noted. Blood ammonia levels as high as 500 muM were noted in this and in another case report. [128] Deterioration of CNS function is said to occur when ammonia levels exceed 150 M. In a prospective study examining glycine metabolism, blood ammonia levels were increased postoperatively in 12 of 26 patients in whom 1.5 percent glycine was used as the irrigating solution for TURP. [127] Blood glycine levels also were measured. Interestingly, glycine and ammonia levels did not correlate; in fact, the opposite relationship was prevalent. Furthermore, high ammonia levels were not necessarily associated with CNS symptoms of toxicity. Although the investigators postulated that delayed awakening and other CNS symptoms were due to ammonia toxicity, it is not at all clear that this is correct.

Perforation

Another relatively common complication of TURP is perforation of the bladder. [129] Perforations usually occur during difficult resections and are most often made by the cutting loop or knife electrode. Some, however, are made by the tip of the resectoscope, whereas others may result from overdistention of the bladder with irrigation fluid. Most perforations are extraperitoneal, and in the conscious patient they result in pain in the periumbilical, inguinal, or suprapubic regions; additionally, the urologist may note the irregular return of irrigating fluid. Less often, the perforation is through the wall of the bladder and is intraperitoneal, or a large extraperitoneal perforation may extend into the peritoneum. In such cases, pain may be generalized, in the upper abdomen, or referred from the diaphragm to the precordial region or the shoulder. Other signs and symptoms such as pallor, sweating, abdominal rigidity, nausea, vomiting, and hypotension have been reported;

their number and severity depend on the location and size of the perforation and the type of irrigating fluid. In an early series of 2,015 cases that examined the incidence of complications of TURP, perforation occurred in 25 patients (1.1 percent). [130] A multicenter study conducted 25 years later confirms this. Four deaths and five additional major complications occurred in the 12 patients in whom suprapubic cystostomy was delayed more than 2 hours after perforation. Distilled water was the bladder irrigant in most of these cases, so it is not clear whether these morbidity and mortality data still are relevant. The subject of complications associated with transurethral surgery was reviewed by Marx and Orkin [117] in 1962; their discussion of the topic is still valid today. [131]

Transient Bacteremia and Septicemia

The prostate harbors many bacteria, which can be a source of intraoperative and postoperative bacteremia via the prostatic venous sinuses. This risk is further increased by the presence of an indwelling urinary catheter. Bacteremia is usually asymptomatic and easily treated with commonly used antibiotic combinations that are effective against gram-positive and gram-negative bacteria. In 6 to 7 percent of patients, however, septicemia may occur. [132] Common manifestations include chills, fever, and tachycardia. In severe cases, bradycardia, hypotension and cardiovascular collapse may occur, with mortality rates between 25 and 75 percent.

Irrigating fluids stored at room temperature are frequently used during TURP. Heat loss due to irrigation and significant absorption of this fluid may result in a decrease in the patient's body temperature and cause shivering (Ch. 37) . [133] Use of warmed irrigating solutions has been shown to be efficacious in reducing this heat loss and the resultant shivering. [134] Although one may believe that warming of fluids might cause increased bleeding due to vasodilation, such is not the case, as shown by the study of Heathcote and Dyer. [135]

Bleeding and Coagulopathy

Hypertrophied prostate is highly vascular, and operative bleeding is usually significant (Ch. 46) . The blood is washed into the draining bucket and mixed with ample quantities of irrigant fluid. Hence, estimation of blood loss is quite inaccurate and extremely difficult. Efforts have been made to quantify blood loss based on resection time (2-5 mL/min of resection time) and size of the prostate in grams (20-50 mL/g). However, these guidelines are rough estimates at best, and the patient's vital signs and serial hematocrit levels should be followed to better assess the blood loss and the need for transfusion. Because alpha-adrenergic receptors are abundant in the prostate tissue, the use of alpha-adrenergic agonists would cause vasoconstriction of prostatic blood vessels and a decrease in blood loss. In a 1993 study, the blood loss during TURP was reduced by 50 percent with preoperative use of methoxamine. [136]

Abnormal bleeding after TURP occurs in less than 1 percent of cases. It is believed by some to be due to systemic fibrinolysis caused by plasmin. The prostate releases plasminogen activator, which converts plasminogen into plasmin. Others believe that the fibrinolysis is secondary to disseminated

intravascular coagulation triggered by the systemic absorption of resected prostate tissue, which is thromboplastin-rich. [131] If primary fibrinolysis is suspected, aminocaproic acid may be effective when given intravenously in a dose of 4 to 5 g in the first hour followed by 1 g/h. [131]

TURP Syndrome

TURP syndrome is a term applied to a constellation of symptoms and signs caused primarily by excessive absorption of the irrigating fluid. Neurologic manifestations such as restlessness, agitation, confusion, altered sensorium, seizure, and coma result from water intoxication and dilutional hyponatremia, which collectively produce cerebral edema. Neurotoxic effects of glycine and ammonia may further compound the clinical situation. The cardiovascular effects reflect volume overload and hyponatremia. Hypertension and bradycardia are frequently seen because of acute hypervolemia. If serum sodium levels rapidly decrease to less than 120 mEq/L, negative inotropic effects are manifest as hypotension and ECG changes of widened QRS complexes and ventricular ectopy. [131] [137] Pulmonary edema, congestive heart failure, and cardiorespiratory arrest have been reported in these patients.

The treatment of TURP syndrome consists of fluid restriction and a loop diuretic such as furosemide. Hypertonic saline (3 percent sodium chloride) is rarely if ever necessary and should be considered only in cases of severe hyponatremia. CNS complications of hypertonic saline include cerebral edema and pontine myelinolysis. [131] [137] [138]

Anesthetic Technique

Spinal anesthesia is the most frequently used anesthetic for TURP in the United States [138] and is believed to be the technique of choice by many. Anesthetic level to T10 is required. A spinal anesthetic provides adequate anesthesia for the patient and good relaxation of the pelvic floor and the perineum for the surgeon. The signs and symptoms of water intoxication and fluid overload can be recognized early because the patient is awake. Accidental bladder perforation also is recognized easily if the spinal level is limited to T10 because the patient would experience abdominal or shoulder pain.

General anesthesia may be necessary in patients who require ventilatory or hemodynamic support. In a 1990 study, [139] blood loss was less with spinal than with general anesthesia. However, short-term morbidity and mortality and long-term outcome for TURP are similar for both regional and general anesthesia. [140] [141]

Anesthetic considerations for TURP should include positioning. TURP is usually performed in the lithotomy position with a slight Trendelenburg tilt. This would result in changes in pulmonary blood volume, a decrease in pulmonary compliance, a cephalad shift of the diaphragm, and a decrease in lung volume parameters such as residual volume, functional residual volume, tidal volume, and vital capacity. Cardiac preload may increase. Nerve injuries to the common peroneal, sciatic, and femoral nerves are likely (Ch. 26) .

Laser Surgery

Lasers (Ch. 64) have recently been introduced into urologic surgery and are being used increasingly. Anesthetic considerations for laser surgery are considered elsewhere; specific concerns pertaining to urologic surgery are discussed here.

Laser Lithotripsy

Laser lithotripsy is used for ureteral stones that are low in the ureter and not amenable to extracorporeal shock wave lithotripsy. Pulsed dye laser is generated with a laser beam of 504 nm wavelength passing through an organic green dye. [142] This laser beam is easily absorbed by the stones, releasing pulsatile energy that causes their disintegration. The beam is carried over a bare wire passed through a rigid ureteroscope, which is longer and more pointed than a cystoscope, so that the risk of ureteral perforation exists. General anesthesia should be maintained to avoid patient movement. For regional anesthesia, a spinal level of T8 to T10 is required. The bare laser wire is sharp and can cause mucosal injury to the ureter. However, these lasers are not well absorbed by the red blood cells or other tissues, which provides safety against tissue coagulation or thermal injury. Because the laser beam is reflective, the user, the other personnel, and the patient should wear protective eyeglasses. Some hematuria always occurs; hence, good intravenous hydration is recommended. [143]

Laser Prostatectomy

Recently approved by the Food and Drug Administration for clinical use, laser prostatectomy is being conducted in several centers in clinical trials. Based on initial experience, it promises to replace conventional TURP in many cases in the near future. The neodymium: yttrium-aluminum-garnet (Nd:YAG) laser is used, which produces coagulation and vaporization of prostate tissue. The main advantages over conventional TURP include minimal blood loss (as little as 50-70 mL) and minimal fluid absorption, which should nearly eliminate these two major complications of TURP. For these reasons, laser prostatectomy is frequently conducted in patients otherwise considered too ill to undergo TURP. In critically ill patients, caudal anesthesia has been successfully used for laser prostatectomy because the use of continuous irrigation combined with minimal bleeding obviates copious irrigation and minimizes bladder distention. [144] However, other potential complications are introduced, including coagulation through the prostatic fossa and sloughing of prostatic debris in the postoperative period, with urinary obstruction and urinary retention. Once again, protective eyewear should be used, and a means to evacuate the smoke plume should be used.

Pelvic lymph node dissection is the most commonly performed laparoscopic urologic procedure in adults. Other

urologic procedures for which laparoscopy has been used include variocelectomy, hernia repair, adrenalectomy, percutaneous stone retrieval from the renal pelvis or ureter, and nephrectomy. Although all the conventional complications and concerns of laparoscopy are applicable to the urologic procedures (Ch. 56) , two unique problems are also identified. First, because the urogenital system is mainly retroperitoneal, the large retroperitoneal space and its communications with thorax and the subcutaneous tissue are exposed to the insufflated carbon dioxide. Subcutaneous emphysema in these patients is frequent and may extend all the way up to the head and neck. The upper airway is at risk of compromise in the most severe cases because of pharyngeal swelling due to submucous carbon dioxide. This should be kept in mind before extubation of these patients. Second, the procedures tend to be lengthy, thus allowing for sufficient absorption of carbon dioxide to result in acidemia and marked acidosis. [145] Because of significant increases in intra-abdominal and intrathoracic pressures due to insufflated carbon dioxide, a steep Trendelenburg position, and lengthy procedures, general anesthesia with controlled ventilation is the method of choice. Despite adequate hydration, intraoperative oliguria may occur followed by diuresis in the immediate postoperative period. While the exact mechanism for this is unclear, it is believed to be due to an increased perirenal pressure exerted by the insufflated gas in the retroperitoneal space.

Extracorporeal Shock Wave Lithotripsy

Extracorporeal shock wave lithotripsy (ESWL) was first conducted in Munich, Germany in 1980, and in 1984 the lithotripter was introduced into the United States. Since then, ESWL has become the treatment of choice for disintegration of urinary stones in the kidney and upper ureter. The first clinical model of the lithotripter introduced into common practice (Dornier HM-3) uses a water bath in a steel tub and a metal gantry chair to support the patient suspended in a sitting position. This, the first-generation lithotripter, is still commonly used and presents complex challenges of immersion physiology and monitoring difficulties. Second- and third-generation lithotripters (Siemens, Lithostar, Wolf Piezolith, Dornier HM-4, MFL 5000, etc.) have since been developed and introduced into clinical practice. They have evolved mainly in the direction of eliminating the water bath and producing a pain-free lithotripter. However, all lithotripters share similar technologic principles in having three main components: (1) an energy source, most commonly a spark plug (alternatively an electromagnetic membrane or piezoelectric elements may be used in some machines); (2) a system to focus the shock wave, such as an ellipsoid or reflecting mirrors; and (3) a system to visualize and localize the stone in focus, namely fluoroscopy or ultrasound. [146]

Technical Aspects

The Dornier HM-3 lithotripter, the gold standard, uses a water bath for treatment and x-ray equipment to localize the stone. These are contained in the all too familiar steel tub. The patient is strapped in a gantry chain in a semisitting position, with support under the shoulders and hips and with the flank exposed. The chair is hoisted to the ceiling, travels on ceiling rails, and is then slowly lowered into the tub. The patient is immersed in the water up to the clavicles. An electrode (or spark plug) is placed in the water at the base of the tub in an ellipse and is connected to a generator that supplies 16 to 24 kV of electricity. The electrical energy creates a spark across the gap in the electrode with generation of a loud noise, intense heat, and explosive vaporization of water. The sudden expansion of air bubbles thus created sets up a pressure wave (shock wave) with distinct mechanical and acoustic properties. The shock wave is focused by the ellipse to a focal point called the Fz focus (the tip of electrode is the first focus). The shock wave travels through water and body tissues without significant localized dissipation of energy because the acoustic impedance of the two media is similar. However, when the shock wave arrives at the entry surface of the stone, it encounters a sudden change in impedance, causing it to release compressive energy of the magnitude of several atmospheres. Similarly, when the wave exits on the opposite surface of the stone, an interface is again encountered, and shock wave energy is released in a blast. Repeat applications cause the stone to disintegrate. Shock wave energy is most concentrated in the Fz focal zone and rapidly decreases beyond it. [147] [148] [149] These physical properties of the shock wave must be understood to prevent injury to tissue or to any prostheses and to ensure that the shock wave passes unimpeded to its focal point for most effective lithotripsy results. The following discussion elucidates this further.

Biomechanical Effects of Shock Wave

For shock waves to be most effective, the stone should remain in the Fz focus during treatment. [149] Pressure energy measurements show an exponential decrease beyond this small focal zone. The kidneys and hence the kidney stone follow the up-and-down movements of the diaphragm during respiration. It is likely, therefore, that the stone will move in and out of focus during respiration. This issue has been studied, and innovative ventilatory techniques have been tried to minimize stone movement during ventilation. [150] [151] [152] [153] [154] [155] High-frequency jet ventilation has been shown to decrease stone movement and has been claimed to increase the efficacy of the treatment. [151] High-frequency conventional ventilation using fast respiratory rates and small tidal volumes has also been effective in decreasing stone excursions during respiration. [155] However, other data [156] and wide clinical experience with success rates of lithotripsy do not support or justify the routine use of these techniques, which add their own complexity and complications to the procedure. [153] Furthermore, regional anesthesia and analgesia-sedation are frequently used for lithotripsy, in which case spontaneous ventilation is the only option. Studies in sedated patients with intercostal block and local infiltration anesthesia have documented that the stone movement with spontaneous respiration is mainly restricted to the Fz focal zone during ESWL. [157] Therefore, conventional ventilation during general anesthesia or spontaneous respiration during

regional anesthesia is acceptable for lithotripsy. Occasionally in an awake patient, one may have to carefully titrate sedation or, if the patient is under general anesthesia, may need to manipulate respiratory parameters to decrease abnormally large stone movement.

For effective stone disintegration, shock waves should reach the stone with very little loss of energy. Therefore, the flank area should be kept free of any medium that would provide an interface for dissipation of shock wave energy. For example, nephrostomy dressings should be removed and the nephrostomy catheter should be taped clear of the blast path. If epidural anesthesia is used, great care should be taken that the catheter and the gauze are taped well clear of the blast path in the flank on the side being treated. Pandit et al [158] [159] noticed an unusually high rate of failure of lithotripsy in their patients receiving epidural fentanyl analgesia. They discovered that the foam tape placed to secure the epidural catheter was frequently in the blast path of the shock waves and could absorb up to 80 percent of the shock wave energy.

Except when piezoelectric lithotripters or lithotripters with very low shock-wave energy are used, the procedure is painful and requires some form of anesthesia. Shock waves produce sharp stinging pain at the entry site in the flank combined with a sensation of deep visceral pressure discomfort.

Although shock waves pass through most tissues relatively unimpeded, they do cause tissue injury, the extent of which depends on the tissue exposed and the shock wave energy at the tissue level. For example, skin bruising and flank ecchymoses are not uncommon at the entry site. Painful hematoma in the flank muscles may occur. Hematuria is almost always present at the end of the procedure and results from shock wave-induced endothelial injury to the kidney and ureter. [147] [148] Adequate hydration is necessary to prevent clot retention. A decrease in postoperative hematocrit should arouse suspicion of a large perinephric hematoma. Punctate hemorrhages have been observed in the stomach and bowel; and this injury might be responsible for abdominal distention, nausea, and vomiting in some patients.

Lung tissue is especially susceptible to injury by shock waves. Air trapped in alveoli presents the classic water (tissue)-air interface to the shock wave, causing dissipation of energy with alveolar rupture and hemoptysis. Massive hemoptysis and death from pulmonary damage have been reported in laboratory animals after a single exposure of the thorax to shock wave. [160] Shock wave-induced hemoptysis in a child and a pulmonary contusion with life-threatening hypoxemia in an adult have been reported. [161] [162] Children are more likely to suffer pulmonary damage from shock waves because of the shorter distance of the lung bases from kidneys as compared with adults. It is recommended that a Styrofoam sheet or Styrofoam board be placed under the back in children to shield the lung bases from shock waves during ESWL. [163]

Shock wave-induced cardiac arrhythmias occur in 10 to 14 percent of patients undergoing lithotripsy despite the fact that shock waves are synchronized with the patient's ECG and are delivered in the refractory period of the cardiac cycle. [164] These arrhythmias are believed to be due to mechanical stresses on the conduction

system exerted by the shock waves. Even though the shock waves are produced

TABLE 53-9 -- Changes on Immersion During Lithotripsy

Cardiovascular	Increased	Central blood volume
		Central venous pressure
		Pulmonary artery pressure
Respiratory	Increased	Pulmonary blood flow
	Decreased	Vital capacity
	Decreased	Functional residual capacity
	Decreased	Tidal volume
	Increased	Respiratory rate

by electrical energy, the intricate grounding system of the lithotripter is such that the current density reaching the myocardium is minuscule compared with other sources (e.g., cardiac pacemakers). Hence, current-induced arrhythmias are unlikely. As mentioned previously, arrhythmias do occur frequently and are due to mechanical effects of shock waves. Atrial and ventricular premature complexes, atrial fibrillation, and supraventricular and ventricular tachycardia have been reported. [164] [165] [166] ECG artifacts are also common. Artifacts and arrhythmias usually disappear once the lithotripsy is stopped. Occasionally, however, arrhythmias may persist, requiring treatment.

Physiologic Changes During Immersion Lithotripsy

Water immersion with the Dornier HM-3 lithotripter produces significant changes in the cardiovascular and respiratory systems (Table 53-9) . Cardiovascular changes include an increase in central blood volume, with an increase in central venous and pulmonary artery pressures. [167] [168] [169] [170] [171] [172] Weber et al [167] observed that increases in central venous pressure and pulmonary artery pressure were directly correlated with the depth of immersion. On the other hand, the sitting position, together with general or epidural anesthesia, would tend to cause peripheral pooling and decreased venous return. A 1987 study noted a decrease in cardiac output and an increase in systemic vascular resistance during ESWL under general anesthesia. [172] Respiratory changes with immersion up to the clavicles are significant: functional residual capacity and vital capacity are reduced by 20 to 30 percent; pulmonary blood flow has been shown to increase [170] [171] [172] [173] [174] ; and tight abdominal straps and the hydrostatic pressure of water on the thorax impart a characteristic of shallow, rapid breathing pattern. [174] Ventilation/perfusion mismatch and hypoxemia are thus more likely. The renal effects of immersion include diuresis, natriuresis, and kaliuresis. A decrease in antidiuretic hormone and renal prostaglandins occurs. The temperature of the bath water can cause profound changes in the patient's temperature. This heat transfer is further augmented by vasodilation produced by general or epidural anesthesia. Both hypothermia and hyperthermia have been reported. [175] [176]

Anesthetic Choices for Lithotripsy

Anesthetic regimens successfully used for lithotripsy include general anesthesia, epidural anesthesia, spinal anesthesia,

flank infiltration with or without intercostal blocks, and analgesia-sedation. [177] [178] [179] [180] [181] [182] [183] [184] General anesthesia offers the advantages of rapid onset and control of patient movement. Ventilatory parameters can be controlled to decrease stone movement with respiration. Extra-long circuit tubing and monitoring cables are required. Disadvantages include a likelihood of positional injury and the possible need to transport an anesthetized patient to other locations if adjunctive procedures become necessary.

Epidural anesthesia offers the advantage that the patient is awake and can help with transfer in and out of the gantry chair, thus reducing the likelihood of injury. With epidural anesthesia and use of loss of resistance to air for identifying the epidural space, only the smallest amount of air necessary should be injected. Air in the epidural space will provide an interface and cause dissipation of shock wave energy resulting in local tissue injury. Korbon et al [185] found a decrease in epidural compliance and pain on injection in repeat epidurals for subsequent lithotripsies in their patients. In animal experiments, they were able to show epidural tissue damage following injection of air and exposure to shock waves. [186] It is reassuring, however, that in the vast number of lithotripsies performed under epidural anesthesia worldwide, neurologic injury has not been a problem.

The main disadvantage of epidural anesthesia is its slow onset. Spinal anesthesia offers a reasonable alternative with its rapid onset. However, the incidence of hypotension (the patient is in sitting position for treatment) is higher. In one series, the incidence of hypotension with general, epidural, and spinal anesthesia was 13, 18, and 27 percent, respectively. [187] Local anesthetic infiltration of the flank with or without intercostal blocks provides adequate anesthesia when combined with intravenous sedation and avoids hypotension. [178] Intravenous analgesia-sedation in various combinations has been successfully used by many anesthetists. [180] [181] [182]

Newer Lithotripters

The second- and third-generation lithotripters offer many advantages. First, there is no water bath; hence all the problems of immersion are avoided. Second, they tend to use multifunctional tables allowing other procedures such as cystoscopy and stent placement to be accomplished without moving the patient off the table. Third, the shock waves are focused, so that they cause less pain at the entry site. With the exception of the piezoelectric lithotripters (Wolf, EDAP, Diasonic) and the use of lowest energy levels with the other lithotripters, ESWL is not pain-free and intravenous analgesia-sedation is the mainstay of anesthesia with these newer lithotripters. Other incidental interventions such as cystoscopy, stone manipulation, or stent placement will alter anesthetic requirements. Many of these newer lithotripters have a much smaller focal zone for the shock waves. Hence, it is even more imperative with these to provide adequate analgesia and sedation so that the stone excursions with respirations are limited to the focal zone. Most analgesiasedation combinations are adequate. Even patientcontrolled analgesia with alfentanil has been used. [188] [189]

Contraindications

Pregnancy and untreated bleeding disorders and abdominally placed pacemakers are the only absolute contraindications to lithotripsy. Women of childbearing age must have a pregnancy test that is documented negative before lithotripsy. Standard tests of coagulation such as platelet count, prothrombin time, and partial thromboplastin time should be obtained. Other conditions that were labeled previously as absolute contraindications are no longer believed to be so provided that appropriate precautions are taken. These conditions include pacemakers, automatic implanted cardioverter defibrillators (AICD) abdominal aortic aneurysm, orthopedic prostheses, and obesity.

Patients with pacemakers can be treated safely if the pacemaker is pectorally placed and the following precautions are observed. [190] [191] [192] Pacemaker programmability should be established prior to the treatment, and a programmer should be available to switch the pacemaker to a nondemand mode should the shock waves interfere with pacemaker function. Alternating means of pacing should be available. Although most pacemakers located pectorally are at a safe distance from the blast path, some may be damaged. Weber et al [190] examined 43 different pacemakers and found that 3 were affected. Dual-chamber pacemakers tend to be more sensitive to interference. Treatment must be started at the lowest energy level and gradually increased while observing pacemaker function.

Manufacturers of AICDs and lithotripters generally consider an AICD a contraindication for lithotripsy. Patients with AICDs have been treated successfully with lithotripsy, however. [193] Transvenous AICDs are less of a concern than the older abdominally implanted defibrillators. AICD devices should be shut off immediately before lithotripsy and then reactivated immediately after the treatment.

Patients with small aortic aneurysms have been treated safely provided that the stone is not close to the aneurysm. Orthopedic prostheses such as hip prostheses and even Harrington rods are not a problem if they are not in the blast path, which is usually the case. Positioning of these patients may sometimes be problematic.

Not only do extremely obese patients present with anesthetic challenges related to obesity, but focusing of the stone may be extremely difficult in the very obese, and it is not uncommon for the procedure to be abandoned in these patients because of inability to bring the kidney stone in the Fz focal zone. It is prudent, therefore, that focusing of the stone be attempted before administering any anesthetic in this high-risk population. With the newer lithotripters, some of these patients may have to be placed prone, a position that they may not be able to tolerate safely.

Renal Tumors

Procedures associated with recent changes in anesthetic management include operations for renal cell carcinoma. [194] Of those patients with tumors of the vena cava, some may have tumors that extend above the insertion of the hepatic vein and into the right atrium. Several problems can occur in these patients, ranging from circulatory failure due to

complete occlusion of the vena cava by tumor to acute pulmonary embolization of tumor fragments during operation. To operate safely on these patients, the extent of the lesion must be defined preoperatively. Approximately 10 to 15 percent of lesions extend into the atrium. [194] Cardiopulmonary bypass is required in these cases to prevent tumor embolization; it may also be necessary in some cases with extension into the upper portion of the hepatic vena cava or when venous return is significantly compromised. Right-heart catheterization is potentially hazardous, because there is a danger that a part of the tumor may be dislodged and embolize. Some use a central venous pressure (CVP) catheter inserted via left internal jugular or external jugular vein so as not to place it beyond the superior vena cava. CVP in such case may not reflect intravascular volume accurately because the venous return via the inferior vena cava is impaired by the thrombus. This decrease in venous return also predisposes the patient to hypotension during induction of anesthesia. Furthermore, the venous obstruction leads to dilation of epidural veins and development of abdominal wall and retroperitoneal collaterals. Again, the emphasis is on appropriate preoperative preparation, which is possible only when the full extent of the lesion has been defined. [195]

Radical Surgery in Urology

Radical surgery is becoming commonplace in the urologic suite with the introduction of radical nephrectomy, radical cystectomy, and radical retropubic prostatectomy. Common features are that the procedures tend to be lengthy, may be associated with sudden and significant blood loss, and require special attention to preservation of renal function. With radical nephrectomy, significant cardiorespiratory changes attendant to the flank position are a concern. Respiratory changes include decreases in thoracic compliance, tidal volume, vital capacity, and functional residual capacity. Dependent atelectasis is common and may lead to hypoxemia. Pneumothorax may occur and can have significant respiratory and hemodynamic consequences intraoperatively. It is not uncommon to see a decrease in blood pressure when the kidney rest is raised. This is usually due to inferior vena cava compression. In addition, hepatic encroachment on the vena cava and mediastinal shift may further reduce venous return and stroke volume. Cervical plexus, brachial plexus, and common peroneal neuropathies may occur due to stretch or compression of the nerves in the lateral position.

Radical Prostatectomy

Localized prostate cancer is treated with either radiation therapy or radical prostatectomy. Radical prostatectomy is now more commonly used because the popularization of the nerve-sparing surgery that reduces the risk of impotence. The most common intraoperative problem is hemorrhage and massive blood loss. Most patients require blood transfusion. Autologous predonation and isovolemic hemodilution are commonly practiced to reduce the patient exposure to allogenic blood. Early postoperative complications include deep venous thrombosis, pulmonary embolism, and wound infection and occur in 0.5 to 2 percent of cases. [196] Death within 30 days has been reported by several centers to be approximately 0.2 percent. [197] Late complications include incontinence, impotence, and bladder neck contracture.

Patients undergoing radical prostatectomy are placed supine in the Trendelenburg position with the back extended, which places the pubis above the head. Air embolism from the prostatic fossa due to a gravitational gradient between the prostatic veins and the heart has been reported. [198]

Epidural anesthesia, spinal anesthesia, general anesthesia, and combined epidural and general anesthesia has been used for this surgery. A decrease in intraoperative blood loss, operative time, and thromboembolic complications with epidural anesthesia has been reported. [199] Others have reported no difference in postoperative morbidity comparing epidural anesthesia and general anesthesia for this procedure. [200] There is no reported benefit of combining the two techniques over either technique used alone. Postoperative pain is well controlled with patient controlled analgesia, epidural analgesia, or a combination of ketorolac and rescue opiates.

UROGENITAL PAIN SYNDROMES

The pain syndromes of the urogenital system result from inflammatory disease, anatomic anomalies, obstructive uropathies, and malignancies. The visceral type of renal pain is frequently caused by pyelonephritis or ischemic events due to an embolus or a thrombus. Hematuria in sickle cell disease or trait is typically painless. The site of pain, characteristics of referred pain, and the quality of pain help the clinician to identify the source of pain.

Benign Renal Neoplasms

Flank pain is a common symptom in adults with angiomyolipoma (more common in women than men), and in children with mesoblastic nephroma and Wilms tumor or nephroblastoma. Nephroblastomas may be combined with several congenital malformations such as sporadic anidria (lack of sweating), microcephaly, mental retardation, and spina bifida. Treatment consists of surgical resection of the tumor supplemented by chemotherapy and adequate pain management. Opiates are the mainstay of pain management.

Renal Cell Carcinoma

Renal cell carcinoma, also known as hypernephroma, presents with the classic triad of hematuria, flank pain, and a renal mass. The development of pain may be a warning sign for metastatic disease. Pain control becomes an important issue in the metastatic disease. Intrathecal implantable pump or a permanent epidural catheter placement for continuous delivery of pain medications may be indicated. Fewer than 5 percent of tumors of the renal origin are sarcomas.

The majority of them are leiomyosarcomas. The peak age is the fourth and fifth decade of life. Flank pain is usually the presenting symptom. Pain is mainly due to stretching of the Gerota fascia and/or compression and invasion of intercostal nerves.

Inflammatory Renal Diseases

Inflammatory renal diseases commonly producing flank pain include acute pyelonephritis, pyelitis, renal carbuncle, and perinephritic abscess. Spiking fever is an important associated finding to suggest presence of infection. The most prominent sign is the tenderness in the flank. As kidneys are retroperitoneal organs, peritoneal signs develop very late. Differential diagnosis must include pneumonitis, pancreatitis, appendicitis, and cholecystitis. Oral or parenteral narcotics are very effective for pain control. Systemic antibiotics and fluid resuscitation are important for management of renal infections.

Perinephritic fasciitis is an inflammation of renal capsule and fascia of Gerota and it may follow perinephritic abscess. Depression of the immune system (due to human immu-nodeficiency virus infection, chemotherapy, radiotherapy) and sickle cell disease are the major risk factors. Peri-nephritic abscess needs to be drained. Nonsteroidal antiinflammatory drugs (NSAIDs) are effective in treating associated reflex skeletal muscle spasm.

Idiopathic nephralgia is a rare condition that mimics renal pain and other urologic symptoms. The pain is thought to originate from incoordinated hyperactivity and spasms of calyces and renal pelvis. A comprehensive psychologic evaluation may be required to eliminate psychologic factors as a source of pain. Diagnostic and therapeutic paravertebral blocks may help diagnose and treat this disabling pain condition.

Pseudorenal pain syndromes are caused by genital nerve entrapment and ilioinguinal neuropathy following inguinal surgery and may mimic renal pain. The referred pain in the dermatomal distribution is very characteristic of these conditions. Diagnostic and therapeutic ilioinguinal or genitofemoral nerve blocks help establish the diagnosis and treat this pain. In congenital polycystic kidney disease, renal pain is caused by distention of the cysts and stretching of the Gerota fascia. Hemorrhage in the cysts, rupture of the cysts, or infection produce exacerbation of pain. Surgical intervention including percutaneous drainage of solitary renal cyst may relieve symptoms. Renal vein thrombosis and renal infarctions cause acute or acute-on-chronic pain syndromes. Along with treatment of shock and embolectomy, narcotics are used to control pain.

Obstructive Uropathy

Obstruction of the urinary tract causes severe pain in the flank. Chronic conditions cause constant dull ache as compared with spasmodic episodic pain in acute obstruction. Surgery may be indicated. As a general rule, pain from the upper one-third of the ureter is referred to the loin, from the middle one-third to the iliac fossa, and from the lower one-third to the suprapubic and groin area. The pain due to ureteric calculi is often felt in the upper and inner thigh and ipsilateral testicle in males and labia majora in females. NSAIDs are helpful in relieving pain. This is believed to be due to the antiprostaglandin effect of NSAIDs. Calcium channel blockers (verapamil, diltiazem, and nifedipine) have been effective in treating ureteric colic. Although there are some controversies that morphine and meperidine may have a spasmogenic effect on the ureter, opiates remain the mainstay of treatment of ureteric colic.

Bladder Pain

Bladder pain is mostly dull ache and usually localized to the suprapubic region. Most common causes of pain are bladder distention by obstruction and cystitis. Bladder distention accompanied with acute or chronic inflammation presents with severe suprapubic spasmodic pain, urinary frequency, and dysuria. The treatment of the cause of inflammation (e.g., obstruction, stone, enlarged prostate, vesicoureteral reflux) is the treatment of choice for pain. Untreated cystitis may result in upper urinary tract infection. Pregnancy, diabetes mellitus, and immune deficiency are additional risk factors.

Interstitial cystitis is a condition with unknown etiology that frequently poses a challenge to the physicians. The pathologic features of interstitial cystitis are nonspecific chronic inflammatory infiltrate, edema, and vasodilation. Suprapubic pain is due to bladder spasm or incoordinated detrusor muscle contraction. Suprapubic pain and frequency of micturition may become so incapacitating that a cystectomy may be required in extreme cases. Options of pain control include bladder denervation (rhizotomy), transurethral electrocautery, cystolysis, presacral nerve blocks, and neurolytic blocks. Medical management includes antihistamine, corticosteroids, anticholinergics, and calcium channel blockers. [201] [202]

Urothelial Tumors

The most common urothelial tumor is the transitional cell carcinoma of the urinary bladder. Painless hematuria is the most common presentation. Thirty percent of patients may present with bladder irritability, which is thought to be due to muscular involvement. Surgical treatment includes fulguration, transurethral resection, or

more extensive radical cystectomy with urinary diversion. Pain control is an integral part of treatment in the metastatic disease of the bladder.

Testicular Pain

Most common testicular congenital anomaly producing pain is cryptoorchidism. Pain in an undescended testis without trauma usually indicates infection or torsion. Emergency surgical exploration is the treatment of choice. The incidence of malignancy is 20 times higher in an undescended testis as compared with a descended testis. The bacterial or viral orchitis or epididymoorchitis is a painful condition that needs urgent attention.

Tumors of the testis are generally malignant; however, extratesticular tumors within the scrotum are usually benign. The earliest sign of the tumor is a painless, testicular mass. Pain is a late sign, usually described as dull ache, testicular heaviness, or dragging. The treatment of testicular tumor depends on the cell type and disease stage. Seminoma is generally radiosensitive.

Prostatic Pain

Acute or chronic prostatitis is very painful. Acute prostatitis is usually due to a bacterial infection and responds to antibiotic therapy. Chronic prostatitis is due to inadequate treatment of acute infection, recurrent infection, or prostatic uroliths. Treatment includes prostatic massage, NSAIDs, antibiotics, and surgical drainage.

Adenocarcinoma of the prostate is the most common male cancer and usually painless. Rectal or sacral pain with prostatic cancer may be a sign of metastatic disease. Patients with sacral or pelvic pain should be investigated for bone metastasis. Oral or parenteral high-dose opiates are the mainstay of treatment initially. Permanent epidural catheter or intrathecal implantable pump for continuous delivery of medications and radiation therapy should be considered for metastatic disease.

Priapism

Priapism is a prolonged pathologic and painful erection caused by engorgement and thrombosis of pelvic veins. It is seen in patients with metastatic malignant diseases like pancreatic cancer and leukemia, pelvic trauma, sickle cell disease, or spinal trauma. Pathology of corpora and local neurovascular abnormality can also cause priapism. Prompt therapy should be instituted to control pain and to prevent subsequent impotence from fibrosis of the corpora cavernosa. Cause of priapism may be important in defining the treatment. Sickle cell priapism is treated with hydration, alkalinization, and blood transfusion to increase hemoglobin to greater than 10 mg/dL. Priapism due to leukemia responds to radiation. Intracorporeal injection of phenylephrine is recommended for selected cases of priapism. Stepwise institution of pain medications from NSAIDs to opiates is recommended. Severe pain will warrant parenteral administration of morphine or hydromorphone.

Peyronie's disease is a sexually crippling condition that causes severe penile pain during sexual intercourse due to curvature. The treatment of choice is surgery and NSAIDS for pain.

Female Genital Pain

Vulvodynia is a chronic pain condition with unknown etiology associated with sexual inactivity or dysfunction, depression, anxiety, and obsessive behavior.

Vestibulitis is characterized by painful penetration during coitus. It is more common in Caucasian females and resistant to most of the medical treatment. Some success with tricyclic antidepressants and antihistamines has been reported. Heat treatment (sitz bath) is also helpful.

Chronic dysmenorrhea is a severe pain-producing condition caused by hypercontractility of uterine muscles during menstruation. Ovulation suppression and the use of NSAIDs are effective due to its antiprostaglandin effect. A 1987 study by Helms [203] found that acupuncture is effective in resistant cases. Presacral neurectomy can be considered as a last resort after other options have been tried and failed.

Incoordinated contraction of the muscles of the pelvic floor (levator ani, pubococcygeus, and deep transverse perineal) causes vaginismus. It produces extreme spasms and painful sexual dysfunction. Psychologic factors such as rigid sexual upbringing and traumatic sexual experience inadvertently reinforce the vaginal spasm. Treatment involves correction of any physical condition and then behavior modification that includes desensitization techniques.

Dyspareunia is defined as recurrent and persistent genital pain before or after intercourse that may be due to infection, trauma, or lack of lubrication. Treatment includes psychotherapy and systemic desensitization.

Chronic pelvic pain is also known as pelvic congestion, pelvic fibrosis, pelvic neurodynia, and pelvic sympathetic syndrome. Pain is often multifactorial and requires multidisciplinary pain management, which involves psychotherapy, medications, and trigger point injections. In selected cases, nerve root blocks and neuraxial opioid therapy are promising. Metastatic disease of the cervix and uterus can cause severe vulvovaginal pain syndrome and requires aggressive opioids and adjuvant pain treatment. [201]

General Considerations

General considerations for genitourinary pain management follow the same principles of pain management elsewhere. For nonmalignant acute pain, medical management is the first choice. Narcotics and nonnarcotic medications such as acetaminophen, aspirin and NSAIDs are indicated for the control of acute pain. When oral administration is not feasible, parenteral administration of narcotics should be used. Patient controlled epidural analgesia or continuous epidural infusion produces segmental dose-related analgesia and prevents atelectasis. Use of lipophilic versus hydrophilic narcotics depends on the segmental level of epidural catheter placement. Intravenous patient-controlled analgesia should be the next option. Meperidine should be avoided in the patients with compromised renal functions because the half-life of normeperidine (metabolite of meperidine, which lowers the seizure threshold and induces CNS excitability) is significantly prolonged. Hydromorphone, a semisynthetic opioid, is recommended for patients with renal failure because of lack of identifiable metabolites. Antiprostaglandin effect of NSAIDs affects the regulation of renal blood flow in susceptible patients. Therefore, patients requiring long-term NSAIDs should be appropriately monitored for renal function.

Interventional techniques are an integral part of pain control in chronic nonmalignant and malignant pain syndromes. Continuous epidural infusion of opioids causes minimum fluctuations of the drug level in the cerebrospinal fluid. Before consideration of a tunneled epidural catheter, pain should be treated aggressively with sustained release morphine preparations, methadone, and fentanyl transdermal

patches to optimize the medication requirement. If intractable pain persists despite aggressive systemic opioids and adjuvant drug therapy, treatment with an implantable drug delivery system should be considered. Because of the safety, efficacy, and relative ease of intraspinal administration of opioids for the control of intractable pain resulting from metastatic disease, implantable intrathecal and epidural drug administration systems are being used increasingly.

Chapter 54 - Anesthesia and the Hepatobiliary System

Mervyn Maze
Nathan M. Bass

INTRODUCTION

Mortality from liver disease has almost doubled in the last three decades in the United States and is increasing at an even faster rate in Canada, where it is now the fifth major cause of death for men in the productive ages from 25 to 64 years. [1] The most likely reason for this increase is the increasing consumption of alcohol, which has been found to parallel the rate of liver disease, especially cirrhosis, in all countries where statistics are kept. [2] Regardless of cause, more patients with liver disease are presenting for anesthesia and surgery than ever before and, with the advent of liver transplantation in many centers, an even greater number may be expected in the future.

Anesthesia and surgery may exacerbate liver dysfunction in patients with preexisting liver disease and in some cases may precipitate life-threatening hepatic failure. [3] [4] The degree to which this occurs depends more on the type and extent of the functional liver impairment than on its precise etiology. Accordingly, the preanesthetic work-up of patients with liver disease should focus on the pattern of liver injury and the severity of the functional abnormality present. In this chapter, the patterns of liver disease have been divided into parenchymal (acute and chronic) and cholestatic liver disease.

ACUTE PARENCHYMAL LIVER DISEASE

Hepatocellular damage is caused by a variety of drugs, toxins, and viruses. Viral or drug-induced hepatitis is commonly encountered in patients presenting for surgery. The cause of hepatitis is often difficult to ascertain from the clinical picture alone. Careful history, including specific questions about drug use, a sexual history, and an understanding of serologic markers are essential in differentiation of the various types of hepatitis.

Acute Viral Hepatitis

Acute viral hepatitis of any type has a broad clinical spectrum. Patients may be completely asymptomatic or critically ill. Many patients experience a nonspecific illness characterized by nausea, vomiting, anorexia, and malaise. Vague abdominal discomfort is more common than localized right upper quadrant pain; low-grade fever is common. Overt jaundice occurs in about half the patients with acute viral hepatitis. Extrahepatic manifestations such as arthralgias and myalgias may be present.

Hepatitis A is an enterovirus spread by the fecal-oral route. The virus is endemic throughout the world. In industrial nations, food-borne common-source outbreaks are an important source of virus. Viral outbreaks are also common in institutions and daycare centers. Hepatitis A is not usually a nosocomial problem because patients generally present themselves after the period of viral shedding, but hospital outbreaks have been reported. [5] Viral shedding in feces occurs as early as 9 days after exposure and decreases after the onset of jaundice; therefore, patients are highly infectious for several weeks.

Acute hepatitis A is diagnosed serologically by elevated titers of immunoglobulin M antihepatitis A virus (IgM anti-HAV). This marker peaks within a month of clinical illness then disappears by 3 to 6 months. IgG antibody develops several months after infection and persists indefinitely.

Most patients with acute hepatitis A recover within weeks, and no chronic carrier state has been reported. A rare cholestatic variant may cause persistent jaundice, [6] but these patients are not infectious. Acute fulminant hepatic failure from hepatitis A is an unusual presentation. Transfusion-acquired hepatitis A is an extremely rare disease. [7]

Hepatitis B is transmitted percutaneously via infected serum or blood or by sexual contact. Serologic diagnosis of acute hepatitis B is confirmed by the presence of hepatitis B surface antigen (HBsAg) and IgM antibody to hepatitis B core antigen (IgM anti-HBc). Hepatitis e antigen follows

TABLE 54-1 -- Serologic Status at Different Stages of HBV Infection

	ACUTE INFECTION		POSTINFECTION		PERSISTENT INFECTION	
	EARLY	LATE	EARLY	LATE	NONREPLICATIVE	REPLICATIVE
HBsAg	++	±	-	-	+	++
Anti-HBc	-	-	+	-	++	++
Anti-HBc IgM	-	+	-	-	-	-
Anti-HBs	-	±	+	+	-	-
HBV-DNA	+	-	-	-	-	+
HBeAg	+	-	-	-	-	+
HBcAg (liver)	+	-	-	-	-	-

the pattern of HBsAG, so that patients who recover normally should clear HBeAg by 6 months. [8] Antibody to the surface antigen (anti-HBs) is not present during the acute illness, developing instead about 6 months after exposure in patients who recover from the disease. This antibody is protective against future infection. Recovered patients also develop antibody to the E antigen (Table 54-1) .

Delta hepatitis or hepatitis D may complicate the course of patients with hepatitis B. The delta virus is an RNA strand that requires hepatitis B for replication. Hepatitis B and D may be acquired together, or delta hepatitis may be a superinfection in patients who are carriers of hepatitis B virus. The combination of hepatitis B and hepatitis D infection is a more severe illness than isolated type-B hepatitis. [9] IgM anti-HDV is present in patients with both acute and chronic delta infections, and high titers in chronic carriers may indicate a poor prognosis. [10] Chronically infected patients develop an IgG antibody. [11] Molecular hybridization assays may be the best way to monitor the hepatitis D viral RNA associated with viral replication. Alternatively, the hepatitis D antigen can be detected by immunoblotting. [12] Hepatitis D is largely confined to intravenous drug abusers and commonly leads to chronic liver disease.

Hepatitis C (formerly, non-A, non-B) virus infection occurs in 2 to 4 percent of patients receiving a transfusion with blood or blood products. The incubation period following transfusion can be from 1 to 4 months; an enteric form of hepatitis C viral infection is responsible for up to 40 percent of cases in which there is no association with transfusion of any kind. [13] Recently, the viral genome for hepatitis C virus has been cloned. This has resulted in the development of very sensitive and specific serologic tests that can diagnose more than 90 percent of the chronic and more than 60 percent of the acute cases. Since the development of the sensitive serologic tests for hepatitis, the incidence of posttransfusion hepatitis from any cause has dropped 10-fold to 6 percent. More recently, hepatitis C RNA by polymerase chain reaction (HCV RNA by PCR) has become available and is indicative of acute or chronic infection with hepatitis C.

Acute Drug-Induced Hepatitis

Drugs, including alcohol, are common causes of acute hepatic parenchymal injury. Toxins in the workplace, such as carbon tetrachloride and vinyl chloride, may also cause hepatocellular damage. Unfortunately, drinking histories are notoriously unreliable, so the diagnosis of alcoholic hepatitis often rests on a high index of suspicion and diagnostic laboratory tests. Similarly, a history of drug abuse may be difficult to elicit. Therapeutic drugs most frequently implicated in acute hepatitis include acetaminophen, isoniazid, methyldopa, rifampicin, acetylsalicylic acid, and other nonsteroidal anti-inflammatory drugs (NSAIDs). [14] The most common reaction leading to liver cell necrosis is the formation of covalent bonds between a reactive metabolite of the parent compound and the cell proteins or DNA.

If drug-induced hepatitis is suspected, it may be possible to assay for a particular drug in the plasma or urine. For example, because alcoholic hepatitis usually follows a period of particularly heavy drinking, alcohol may still be detected in the plasma. Serum salicylate concentrations above 250 ng/mL are associated with

abnormalities in liver function. [15] Acetaminophen levels above 4 to 5 ng/mL 24 hours after ingestion are associated with acute hepatitis. [16] Acute acetaminophen is particularly important to identify, because a specific antidote, N-acetylcysteine, may be life-saving therapy by restoring the available glutathione stores. [17] Acetaminophen hepatotoxicity is potentiated by alcohol. [18] Acute drug-induced injury to the liver is often mediated by cytochrome P-450, which is capable of transforming drugs into reactive electrophilic compounds or oxygen intermediates (such as the superoxide anion or free radicals and metabolites such as electrophiles or free radicals). These metabolites then induce a series of toxic reactions. [19]

Most drugs only rarely produce toxic reactions and may be related to enzyme polymorphism in which a genetic variant of P-450 contributes either to a lack of metabolism of the parent compound or excess formation of the toxic metabolite.

Acute Toxin-Induced Hepatitis

This is most commonly seen after exposure to toxins such as *Amanita phalloides*, a mushroom particularly prevalent in northern California in the winter and early spring. Patients suffering from acute liver cell failure may need urgent liver transplantation, and may also need intracranial pressure monitoring and hence care by an anesthesiologist. *Amanita* and other acute liver toxins can essentially ablate hepatic function a while, but the liver will eventually regenerate. Hence there has been successful use of auxiliary liver transplantation

in some patients. A left lateral segment of the left hepatic lobe is transplanted into the recipient after removal of the recipient's own left lobe. The recipient's own necrosed right lobe eventually regenerates and the transplanted left segment is allowed to reject and is then removed some days to weeks later. This procedure is referred to as a partial liver graft.

Assessment of Liver Function

Liver function (Ch. 25) tests in patients with acute parenchymal disease may reflect hepatocellular injury and abnormalities in hepatic synthetic function. Within the liver cells, the aminotransferases convert amino acids into their corresponding alpha ketoacids for further metabolism. Significant elevations of serum glutamic oxaloacetic transaminase (SGOT or aspartate aminotransferase [AST]) and serum glutamic pyruvic transaminase (SGPT or alanine aminotransferase [ALT]) are characteristic of hepatocellular damage. In most patients the AST/ALT ratio is 1:1. However, when the AST level is more than twice that of the ALT a diagnosis of alcoholic hepatitis is likely. [20] Although the extent to which the serum transaminase levels rise may reflect acuity and extent of injury, these levels do not correlate well with prognosis. SGPT is found predominantly but not exclusively in the liver, whereas SGOT is found in a variety of tissues, especially muscle. Lactate dehydrogenase (LDH) is abundant in the liver and is released into the blood during hepatocellular injury but may rise from many sources including red blood cells (RBC). Acute ischemic injury to the liver may also result in a picture similar to an acute viral or toxic hepatitis.

Prothrombin time is a useful test of liver cell function, as it reflects the impaired ability of the acutely damaged liver to synthesize clotting factors. Although synthesis of other products from the liver such as albumin may also be affected, albumin has a longer plasma half-life than the clotting factors; albumin levels may remain within normal limits for days even if hepatic production ceases entirely. The prothrombin time measures the rate of conversion of prothrombin to thrombin in the presence of thromboplastin, calcium ions, and several activated factors. A prothrombin time more than 4 seconds above control is distinctly abnormal (to standardize the prothrombin time, values are now expressed as an international normalized ratio [actual/control ratio]). In acute parenchymal injury, the prothrombin time reflects the severity of liver dysfunction and has definite prognostic significance. [21] [22]

In addition to elevated transaminases and abnormal prothrombin time, mild elevation of bilirubin and alkaline phosphatase are the rule. Hypoglycemia is also seen occasionally, especially if hepatic injury is severe.

Liver biopsy may be useful in establishing the qualitative pattern of injury, even in the case of acute drug-induced hepatitis. [19] In addition, in patients with fulminant hepatic failure, a quantitative estimate of hepatocyte damage can be made by examining a biopsy specimen; in the severest cases no hepatocytes are seen. In cases of acute alcoholic hepatitis, Mallory hyaline bodies may be present. [23] Viral inclusion bodies seen on pathologic examination of a biopsy specimen may point to a diagnosis.

Preoperative Considerations

The diagnosis of viral hepatitis is established by measuring viral proteins (antigens) in the blood and identifying characteristic immunologic responses (antibodies) during and after acute infection. Because of the risk to operating room personnel (Ch. 84) , the diagnosis of infectious hepatitis should be actively pursued in any patient with liver disease of unknown cause. If hepatitis B is suspected, serologic studies of the carrier may help determine the infectious risk to hospital personnel. [24] All patients with acute hepatitis B should be considered infectious.

Hepatitis B is an occupational risk for anesthesiologists. One multicenter study demonstrated a 12.7 percent rate of seropositivity in anesthesia residents and a 23.3 percent seropositivity in anesthesia faculty. [25] Hepatitis B vaccination is protective in the vast majority of health-care workers, [26] and vaccine responders are also protected against delta infection. The yeast-recombinant hepatitis B vaccine theoretically carries no risk of infection for vaccinated persons. [27] Vaccination for anesthesiologists is strongly recommended by the Centers for Disease Control and Prevention, [28] especially in light of a retrospective study suggesting that gloves are not sufficient protection for this disease. [29]

If a health-care worker is exposed to a needle stick, both the health-care worker and the source (contact) should be tested for HCV antibody and HBV serologic markers (surface antigen, surface antibody, core antibody, and E antigen). If the patient has markers for HBV infection (surface antigenemia), the health-care worker should receive a dose of HB immune globulin [30] , and a course of HBV vaccination should be commenced within 7 days. If the health-care worker is immune to HBV (surface antibody positive), no treatment is needed. With exposure by needle stick to HCV, the current recommendation is to monitor the health-care worker for seroconversion to HCV antibody positive status at 3 and 6 months. If seroconversion occurs, interferon at conventional dosage (3 million units three times a week) should be commenced. A more aggressive approach is to detect infection by performing HCV RNA by PCR at 3 and 6 months in addition to HCV antibody. If conversion occurs, interferon, 5 to 10 million units daily, has been recommended for a minimum of 6 months.

If possible, elective surgery should be postponed in patients with acute hepatocellular injury because of increased risk of morbidity and mortality. In particular, surgery carried out in the presence of acute viral hepatitis is associated with a higher than normal incidence of major complications. In one study, 9.5 percent of patients with acute viral hepatitis undergoing laparotomy died, and a further 12 percent developed significant morbidity. The unusual patient with a cholestatic pattern of injury associated with hepatitis probably should also not undergo elective surgery and anesthesia.

The preoperative management of a patient with acute parenchymal liver disease will depend on the severity of liver dysfunction. The clinical picture may be so mild that no treatment is required, or so severe that acute liver failure occurs and aggressive intervention is required. In patients with acute encephalopathy, sedative drugs for premedication may dramatically exacerbate encephalopathy and, therefore, should be avoided. Frequent blood glucose monitoring is important in preoperative management, as these

patients may rapidly develop hypoglycemia and secondary neurologic damage. Acid-base disturbances, particularly respiratory alkalosis, may be profound. Electrolyte disturbances may contribute to encephalopathy, and appropriate therapy should be initiated before the surgical procedure. Hypoxemia is a frequent finding [31] despite hyperventilation. Many patients with acute hepatocellular injury also develop renal insufficiency. [32] Damage to kidneys may be caused by the same toxin affecting the liver or, more commonly, is secondary to hepatic damage.

If coagulopathy is present, surgical bleeding may be severe. Correction of clotting factor deficits with vitamin K and fresh frozen plasma may be indicated. Similarly,

appropriately timed platelet transfusions may aid the surgeon. Patients with liver disease are also more susceptible to bacterial infection.

In the preoperative management of a patient with an isolated abnormality of liver function tests (Fig. 54-1) , one should never assume that the abnormality is definitely due to alcohol (e.g., an elevated alkaline phosphatase cannot be explained on the basis of alcohol). An isolated elevation of gamma-glutamyl transpeptidase is typical of most drinkers and does not imply liver disease. The degree to which the transaminase levels are elevated dictates further management; if less than twice normal values are observed, it is important to try to elicit whether there has been recent exposure to potentially

Figure 54-1 Algorithm for work-up of unexpected abnormality in transaminase levels.

hepatotoxic medications or toxins (especially alcohol), and what the risk factors are for the acquisition of infectious liver disease (viral hepatitis) in the individual patient. If the patient has a twice normal increase in aminotransferases and/or gamma-glutamyltransferase, complete abstinence should be advised and the tests should be repeated after a week. If the tests are still abnormal, a full work-up, including complete blood count (CBC) and platelets, viral serologies, autoantibodies, ceruloplasmin, and iron studies are indicated. A right upper quadrant ultrasound is also indicated in the work-up of a persistent abnormality. Tests that are abnormal only in the setting of drinking suggest that more alcohol ingestion is occurring than is admitted, and attempts to get the patient to stop drinking should be initiated. Caring for the problem drinker in the perioperative period is a challenging task. If alcohol abuse is suspected, a careful preoperative evaluation of alcohol-dependent patients should include a CBC, blood urea nitrogen, serum electrolyte levels, creatinine and glucose levels, liver function tests, coagulation studies, an electrocardiogram, and a chest radiograph. Smoking cessation and aggressive postoperative respiratory care are especially important for alcoholic patients who have chronic obstructive pulmonary disease. Elective surgery should not be considered in patients with acute hepatitis or cirrhosis, because the operative mortality rate is quite high in these patients. In the event that the liver function tests are markedly elevated (>3 times normal), elective cases that require general or regional anesthesia should be delayed until further work-up is completed, as each of these forms of anesthesia reduced hepatic blood flow by 30 to 50 percent, which may set the stage for rapid deterioration in liver function. [4] Patients undergoing exploratory laparotomy with unsuspected parenchymal liver disease have a 31 percent mortality rate. [33]

Intraoperative Considerations

The reason for the poor prognosis in patients undergoing surgery in the presence of acute viral hepatitis may be related to decreased total hepatic blood flow that accompanies all forms of anesthesia. Additionally, total hepatic necrosis may be precipitated by relative hypoperfusion in an already diseased liver. Thus, if the diagnosis is uncertain or emergency surgery is necessary in patients with acute parenchymal disease, attempts to maintain hepatic blood flow at near normal levels should be the goal of intraoperative therapy. Although the relationship between anesthetic-induced changes in liver blood flow and liver function is not clear, it seems reasonable to maintain liver blood flow as close to normal as possible. Isoflurane, in animal models, has no major deleterious effect on hepatic circulation. [34] Mechanical ventilation with positive pressure is theoretically more deleterious to liver blood flow than spontaneous ventilation. On the other hand, hypercarbia initiates sympathetic stimulation of the splanchnic vasculature, resulting in decreased portal blood flow. Because the nature and anatomic location of the surgery, anesthetic drugs, and techniques may all modify liver blood flow, CO_2 probably should be maintained in the range of 35 to 40 mm Hg.

Drug disposition in the presence of acute parenchymal disease may be difficult to predict because of the marked differences in liver response to high and low extraction ratio drugs. [35] For example, the half-life of meperidine is considerably prolonged in patients with parenchymal liver disease. [36] Furthermore, certain intravenous drugs such as chlorpromazine, which act on the central nervous system (CNS) have a more pronounced depressant effect in patients with hepatic impairment. [37] In addition, the liver synthesizes hydrolytic enzymes that catalyze the intravascular inactivation of certain local anesthetic esters and other drugs such as succinylcholine. Because pseudocholinesterase is relatively stable, prolonged apnea from pseudocholinesterase deficiency after succinylcholine administration is rare, even in patients with fulminant hepatic failure (Ch. 12) .

CHRONIC PARENCHYMAL LIVER DISEASE

This pattern of liver disease may produce little alteration in standard liver tests and may be clinically and biochemically undetectable. Hepatic reserve, however, may be limited and decompensation may occur when an additional insult, often iatrogenic, is introduced. Chronic parenchymal disease can be subdivided into two major categories: chronic hepatitis (precirrhotic) and cirrhosis.

Chronic hepatitis is an hepatic inflammatory process that has persisted for at least 24 weeks and has resulted in abnormalities in hepatic function. [38] Patients have been classified as having chronic persistent or chronic active hepatitis based on liver biopsy, but the distinction is often difficult to make. Chronic persistent hepatitis is the milder hepatic lesion, characterized by inflammation in the portal tracts with minimal cell necrosis and no disruption of the normal architecture. [39] Abnormalities in liver function are trivial, with modest elevations of transaminase being the only notable feature.

Liver biopsies of patients with chronic active hepatitis reveal scar tissue and inflammatory cells, which disrupt normal hepatic structure. Not surprisingly, patients with chronic active hepatitis have higher rates of morbidity and mortality than those with chronic persistent hepatitis. The estimated 5-year survival rate is 97 percent for patients with chronic persistent hepatitis, 86 percent for chronic active hepatitis, and 55 percent for chronic active hepatitis. [40] Despite these percentages, the natural history of chronic active hepatitis in an individual patient is extremely variable. Patients with chronic active hepatitis in remission may be totally asymptomatic, but most complain of fatigue and malaise. Stigmata of chronic liver disease should be sought on clinical examination. In symptomatic cases, liver function tests are usually markedly abnormal, with evidence of hepatocellular injury (high transaminases) and diminished synthetic function (low albumin, prolonged prothrombin time).

Patients with persistence of HBsAg 6 months after exposure are considered chronic carriers of hepatitis B (Table 54-2) . A chronic state develops in 5 to 10 percent of acutely infected patients. These patients do not develop the protective anti-HBs. Chronic carriers of virus have low, fluctuating, or absent titers of IgM anti-HBc. [41] Persistent high titers of IgG anti-HBc may indicate increased infectivity. The presence of hepatitis B DNA polymerase is considered a marker

TABLE 54-2 -- Serologic Markers of Hepatitis B Viral Infection

MARKER	DEFINITION	SIGNIFICANCE
HBsAg	HBV surface antigen	Acute or chronic infection
Anti-HBs	Antibody to HBV surface antigen	Past infection resolved, immune
Anti-HBc	Antibody to HBV core antigen	Acute, chronic, or past infection (not protective)
HBeAg	HBV e antigen	High state of viral replication (= host very infectious) - acute or chronic infection
Anti-HBe	Antibody to e antigen	Low state of viral replication
HBV-DNA	HBV genomic DNA	Same as HbeAg

of active viral replication and infectivity and may be assayed in the absence of conventional hepatitis B markers. [42] A chronic carrier state follows infection with hepatitis C virus in 40 percent of cases. These patients may be infectious for prolonged periods. [43]

Until recently, therapeutic options for these patients with chronic viral disease were extremely limited. Corticosteroid therapy alone is not useful in patients with chronic hepatitis B. [44] Interferon therapy showed some promise when used alone, [45] [46] but a regimen of prednisone withdrawal followed by interferon shows particular promise. [47] Recent studies suggest that recombinant human alpha-interferon can improve the biochemical abnormalities associated with hepatitis C virus. [48] Furthermore, a combination of ribavirin together with alpha-2B interferon appears to be especially efficacious. [49]

Several drugs are known to cause chronic liver disease that is pathologically identical to virally induced forms of hepatitis. [19] These drugs include methyldopa [50] and isoniazid. [51] In most cases, drug-induced hepatitis resolves after drug ingestion ceases.

Autoimmune hepatitis is characterized by the presence of humoral and cellular markers of immunologic disease. Patients may have smooth muscle antibody or antinuclear antibody in their serum. Selected patients may benefit from treatment with steroids or immunosuppressants, drugs that must be considered in the anesthetic plan.

Diagnosis of metabolic causes of chronic hepatocellular disease requires specific laboratory studies. For example, serum alpha-1 antitrypsin [52] may be assayed and phenotyped by isoelectric focusing of serum proteins, whereas the genotype can be established by PCR. Diagnosis may be confirmed by the demonstration of characteristic periodic acid-Schiff- positive diastase-resistant globules adjacent to liver portal tracts. Adult patients with this disorder often have emphysema. [53]

Wilson disease is an inherited disorder characterized by copper accumulation, especially in the liver, kidneys, central nervous system, and eyes. [54] Copper deposits in the eyes seen under slit-lamp, Kayser-Fleischer rings, are pathognomonic for Wilson disease. Most patients with this disease have low serum ceruloplasmin levels and increased urinary copper levels. [55] The chelating agent, penicillamine, is first-line therapy. [56]

Cirrhosis is a syndrome characterized by severe hepatic fibrosis and nodular regeneration. Worldwide, 50 percent of cirrhosis is linked to alcohol abuse, but in some countries the rate is as high as 90 percent. All types of alcoholic beverages cause liver disease, and their tendency to do so depends only on alcohol content. Regular daily consumption in excess of 80 g of alcohol for more than 9 years is more dangerous than intermittent sprees. [57] Women are more susceptible to liver damage from alcohol than are men. Chronic active hepatitis of any cause may progress to cirrhosis.

In addition to the types of hepatitis discussed previously, other rare causes of liver disease with a propensity to progress to cirrhosis include hemochromatosis and primary biliary cirrhosis. In patients with hemochromatosis, iron accumulates in hepatic parenchymal cells. [58] Patients with cirrhosis resulting from hemochromatosis have a high rate of liver cancer. [59] Characteristically, patients with hemochromatosis have elevated serum ferritin levels and an increase in transferrin saturation, but the diagnosis is often best made by liver biopsy. [60]

Primary biliary cirrhosis, which predominantly affects women, is characterized by cholestasis progressing to hepatic fibrosis. Women with this disorder frequently have malabsorption, osteoporosis, and autoimmune diseases. [61] Serum cholesterol levels are very high, and serum is usually positive for antimitochondrial antibodies.

Cryptogenic cirrhosis (no cause found) is another rare diagnosis.

The clinical presentation of cirrhosis ranges from the asymptomatic patient with normal or nearly normal liver function to the severely decompensated patient with deep jaundice and ascites. Patients with compensated cirrhosis may be completely asymptomatic or have nonspecific symptoms such as malaise, weight loss, loss of libido, and menstrual disturbances. Physical signs, if any, may include such changes as white skin spots, paper-money skin, palmar erythema, and white nails. Clubbing and cyanosis are occasionally seen.

A high-output circulatory state is a frequent feature of advanced cirrhosis, [62] associated with arteriovenous shunting, especially in the lungs. Hepatosplenomegaly may be present. Occasionally, the left lobe of the liver is prominent (particularly in alcoholics), resulting in an easily palpable and diagnostically confusing epigastric mass. Regardless of the cause, the complications of cirrhosis are similar and protean.

Preoperative Considerations

Various complications associated with cirrhosis may require intervention before a patient undergoes anesthesia and surgery. Portal hypertension is associated with complications often refractory to medical therapy including ascites, varices, and hepatorenal syndrome. Normally, pressure in the portal vein ranges between 5 and 10 mm Hg but rises when progressive disruption of the hepatic architecture distorts the normal channels for portal blood flow. When the portal pressure exceeds 10 mm Hg, a collateral circulation develops between the high pressure portal system and neighboring low pressure splenic veins, and hence portal blood is diverted to the systemic circulation. The most clinically important portal system shunts are in the gastric and esophageal veins. These varices may rupture, resulting in gastrointestinal tract (GI) hemorrhage.

Initial management of patients with GI hemorrhage involves intravenous fluid resuscitation to correct hypovolemic

shock; however, overvigorous fluid resuscitation can cause variceal rebleeding. Simultaneously, the specific source of bleeding is sought. Although varices are common in patients with alcoholic cirrhosis, they are not the only source of bleeding, [63] and endoscopy is necessary to establish the source of hemorrhage. Thereafter, a combination of mechanical and pharmacologic interventions is used to limit the bleeding.

Vasopressin lowers portal venous pressure principally by constricting the splanchnic arteriolar bed and increasing resistance to inflow of blood to the gut. Because the drug effect is not confined to the gut vasculature, serious hemodynamic consequences, including a decrease in cardiac output and vasoconstriction of the coronary arteries, may occur. Octreotide is as effective as vasopressin at decreasing variceal bleeding, but appears to have considerably fewer adverse effects on the cardiovascular system. [64]

Balloon tamponade with a Sengstaken-Blakemore tube (SBT) has been a valuable primary therapy for controlling active variceal hemorrhage, allowing resuscitation and transport of a patient to a main center for definitive therapy. Complications that may follow balloon tamponade include airway obstruction from dislocation of the tube and pulmonary aspiration of saliva. As a result, endotracheal intubation is performed in many institutions before passage of the SBT. Fewer than half the patients who have balloon tamponade as part of therapy have their bleeding controlled in a long-term fashion. Injection of sclerosing solutions via the esophagoscope directly into varices is now the treatment of choice in the definitive management of bleeding esophageal varices and can control bleeding in up to 90 percent of cases; however, this strategy is less effective if rebleeding occurs. [65] Transjugular intrahepatic portosystemic shunt is a relatively new advance in the management of variceal hemorrhage that involves anesthesiologists perioperatively. [66] In this interventional radiologic procedure, a communication is created between the hepatic and portal veins through the hepatic parenchyma with an expandable metallic stent, and it has proved to be an attractive alternative to the more invasive portacaval shunt surgery. [67] However, even though the procedure is less demanding for the patient, the anesthesiologist must be just as vigilant because the patient is likely to be a Pugh-Child B or C with a high propensity for severe morbidity.

Ascites and generalized fluid retention are due to portal hypertension and sodium retention that occurs with cirrhosis. Ascitic fluid is in dynamic equilibrium with plasma. If massive abdominal paracentesis is performed, a marked reduction in plasma volume occurs, resulting in hypotension and oliguria unless intravenous crystalloid and colloid solutions are given simultaneously. Ascites is usually treated by sodium and water restriction and administration of diuretics. More recently therapeutic paracentesis has been used successfully. The goal of therapy for ascites is loss of no more than 0.5 kg of body weight per day because a brisker diuresis may precipitate the hepatorenal syndrome. [68] Spontaneous bacterial infection of ascitic fluid resulting in peritonitis occurs in up to 10 percent of cirrhotic patients with ascites. Hyponatremia is a common complication after treatment with proximally acting diuretics and hyperkalemia after distally acting diuretics. Thus, serum electrolytes should be checked frequently, especially in the initial stages of treatment, and any disturbances should be corrected promptly.

The onset of progressive renal failure (hepatorenal failure) is a common preterminal complication in patients with end-stage liver disease. This is the result of a severe intrarenal vasoconstriction, which is precipitated by a neurohumoral response to a sensed intravascular volume depletion (from peripheral vasodilation) and possibly to the existence of portal hypertension. If a cirrhotic patient with ascites does become intravascularly volume depleted, the hepatorenal syndrome may be precipitated; also vigorous use of very potent diuretics (e.g. Zaroxolyn) can contribute to the onset of the hepatorenal syndrome, especially in patients who have ascites that has become relatively refractory to diuretics. More diuretics in this setting induce a prerenal state. More powerful diuretics (e.g., Zaroxolyn) are even more hazardous. After the hepatorenal syndrome has been established, the kidneys are extremely sensitive to various insults including volume depletion and nephrotoxic drugs (e.g., aminoglycoside antibiotics, which are absolutely contraindicated; NSAIDs; and renal contrast). The recommended therapy is with dopamine infusions. The average duration of life after the onset of azotemia is less than 6 weeks, but death is usually attributable to a major complication of the liver disease rather than to renal decompensation. Treatable causes of renal failure, especially dehydration, should always be sought. Paracentesis of tense ascites may occasionally improve renal function in this setting.

Hepatic encephalopathy is a reversible neuropsychiatric syndrome seen in association with severe acute or chronic liver disease. Clinical features may be subtle at first, including changes in personality and dulling of the intellect. Later, progressive neurologic disturbances including incoordination, dysarthria, a flapping tremor, and increased tone with hyperreflexia may supervene. The development of hepatic encephalopathy may merely reflect a gradual worsening of the liver disease with worsening of portal systemic shunting. On the other hand, encephalopathy is often precipitated by infection, GI hemorrhage, hypokalemia, alkalosis, azotemia and constipation, or dietary excess of protein. Iatrogenic factors precipitating encephalopathy include injudicious use of sedatives (especially long-acting benzodiazepines), opiates, and diuretics. Treatment for encephalopathy focuses on reversal of precipitating factors. Lactulose and neomycin are often used to limit bacterial production of toxins that cannot be cleared by the dysfunctional liver. Flumazenil, the benzodiazepine receptor antagonist, has been shown to reverse the coma in selected patients over a prolonged period. [69]

The electroencephalography in hepatic encephalopathy typically shows bilateral slow waves that are synchronous and symmetric (delta wave activity) and are superimposed on the normal alpha rhythm. The pattern is also seen in several other metabolic encephalopathies but is not pathognomonic. Blood ammonia concentration is generally higher on average in patients with hepatic encephalopathy than in patients with chronic liver disease without encephalopathy, but this test is not specific or diagnostic.

The Child-Turcotte laboratory and clinical criteria are good predictors of operative survival [70] (Table 54-3) . These predictions were based on a surgical cohort of patients undergoing portosystemic shunts. However, these guidelines have been adopted for all types of surgical procedures in patients

TABLE 54-3 -- Laboratory and Clinical Criteria for Estimating Hepatic Reserve (Child-Turcotte Classification)

CRITERIA	CLASS A	CLASS B	CLASS C
Serum bilirubin mg/100 mL	<2.0	2.0-3.0	>3.0
Serum albumin g/100 mL	>3.5	3.0-3.5	<3.0

Ascites	None	Easily controlled	Not easily controlled
Encephalopathy	None	Minimal	Advanced
Nutrition	Excellent	Good	Poor
Prothrombin time [a] (sec > control)	1-4	4-6	>6
Surgical risk mortality rate	5%	10%	50%

[a] Pugh modification.

with cirrhosis. Subsequently Pugh et al [71] provided a predictive scoring system using the same laboratory and clinical criteria adding evaluation of the prothrombin time.

Intraoperative Considerations

Complicated alterations in drug pharmacokinetics occur in patients with chronic liver disease, making it difficult to predict, except in very general terms, the appropriate drug therapy for a particular patient. [35] Parenchymal liver disease most predictably alters metabolism of drugs with high extraction ratios (e.g., lidocaine, meperidine, and morphine) due to their exquisite sensitivity to altered hepatic blood flow. If possible, drugs that are excreted via the liver probably should be avoided or given in small doses. Most of the commonly used intravenous drugs for induction of anesthesia are metabolized by the liver, but recovery from their effects depends on redistribution rather than metabolism. This has recently been confirmed for propofol in well-compensated cirrhotic patients. [72] Also, there appears to be considerable extrahepatic metabolism of propofol, which can be appreciated during the anhepatic phase of orthotopic liver transplantation. [73] Although the plasma protein binding of thiopental is decreased in patients with cirrhosis, this effect is compensated for by a decreased capacity for thiopental metabolism by the diseased liver [74] ; therefore the total body clearance of thiopental is unaltered in cirrhosis. [74] Additionally, higher doses are needed for patients with alcoholic liver disease in whom cross-tolerance between alcohol and barbiturates may be present. [75] In adults with uncomplicated alcoholic cirrhosis, the elimination half-life after a single bolus dose of either fentanyl [76] or sufentanil [77] is unaltered. Given the fact that remifentanil is metabolized by nonspecific blood and tissue esterases, it too would appear to be a safe alternative for patients with liver disease. Large doses of nondepolarizing muscle relaxants may have prolonged duration of action in patients with cirrhosis. [78] [79] However, if the dose of vecuronium and atracurium are kept below 0.15 and 0.6 mg/kg, respectively, the kinetics and duration of action will not be altered in patients with hepatic cirrhosis. [80] [81] In theory, atracurium should offer an advantage because its metabolism is apparently independent of the liver. It is metabolized by Hoffman elimination, a nonenzymatic degradation that proceeds rapidly in serum by a pseudocholinesterase-independent ester hydrolysis (Ch. 12) . In contrast, termination of the action of succinylcholine is dependent on pseudocholinesterase, which is synthesized in the liver. Although pseudocholinesterase levels often decline in liver disease, levels are seldom low enough to significantly prolong succinylcholine-induced apnea. There is sufficient pseudocholinesterase in 1 unit of fresh frozen plasma to hydrolyze the residual succinylcholine in the plasma. The amide class of local anesthetics may also pose a problem for patients with severe liver disease; not only will its hepatic metabolism be impaired, but the associated reduction in plasma proteins (especially alpha $_1$ -glycoprotein and albumin) will expose the patient to increased total and free plasma local anesthetic concentrations.

When choosing the appropriate agent for maintenance of anesthesia, the anesthetist should consider not only the metabolism of that agent by the liver and its hepatotoxicity, but also its effect on liver blood flow. Although volatile anesthetics may be associated with hepatic dysfunction, they are not contraindicated in patients with chronic liver disease and may even be preferable in many circumstances. In one study, cirrhotic rats exposed to 1.8 percent halothane in oxygen for 3 hours showed no further deterioration of liver function. [82] Regardless of the technique chosen, higher than usual concentrations of oxygen should be used because of the likelihood of intrapulmonary shunting. In patients with hepatic encephalopathy, factors that cause further deterioration such as electrolyte disturbances, long-acting CNS depressants, and opiates should be avoided, [83] especially for short surgical procedures.

Intravascular fluid balance may be particularly difficult to manage intraoperatively, especially in patients with ascites who are subjected to laparotomy. Ascitic fluid is in dynamic equilibrium with plasma so that abdominal paracentesis will result in intravascular volume depletion. Thus, rapid rehydration with a sodium-free colloid solution should be initiated as soon as ascitic fluid is lost. Exclusive use of saline-containing crystalloid solutions tends to cause rapid reaccumulation of ascites. Each liter of ascitic fluid lost should be replaced with at least 50 mL of 25 percent albumin because 1 L of ascites contains about 10 g of protein.

In patients with GI hemorrhage, aggressive blood replacement, preferably with whole fresh blood, in which the

coagulation factors have been preserved, is the goal. In theory, citrate from blood preservatives (e.g., citrate-phosphate-dextrose solution) may not be metabolized, resulting in hypocalcemia (Ch. 46) . This probably means that ionized calcium levels should be monitored, especially during liver transplantation. If the ionized calcium levels become low, calcium chloride should be given. The bleeding diathesis of liver cell failure should be treated with fresh frozen plasma because this product contains all the procoagulants and inhibitors that are absent. The goal of therapy is to correct the protime to within 3 seconds of normal by transfusing 12 to 20 mL/kg of fresh frozen plasma. If the patient cannot tolerate excessive fluid volume, the fresh frozen plasma can be substituted with the use of prothrombin complex. Total body stores of vitamin K become depleted in malnourished states within 10 days; therefore, it is always worthwhile to administer vitamin K to patients with a bleeding diathesis from liver disease. If the platelet count falls below a threshold of 100,000/muL, enough units (10,000/muL) need to be transfused to restore the platelet count to this threshold. Abnormal bleeding time in the presence of liver disease can also be treated with diamino-8- D-arginine vasopressin. [84]

In alcoholic patients, secondary effects of alcohol on organs other than the liver must be considered in the anesthetic plan. Normal acid clearance of the esophagus in supine patients is impaired after alcohol ingestion. [85] These patients, then, deserve special attention to acid-aspiration prophylaxis. Osteoporosis is a frequent finding in alcoholics [86] [87] thus, special attention should be devoted to position and padding of exposed bony prominences. Acute alcohol ingestion has a myocardial depressant effect. [88] Chronic cardiomyopathy due to alcoholism is often accompanied by ventricular arrhythmias. Alcohol also caused impaired host immune defenses. [89] Postoperative monitoring should focus on the potential for delirium tremens, which is characterized by sympathetic hyperstimulation. [90]

CHOLESTATIC LIVER DISEASE

Cholestasis literally means "standstill of bile." The term "intrahepatic cholestasis" is used when obstruction to bile flow occurs at the level of the hepatocyte or the biliary canalicular membrane, whereas obstructive jaundice is used when impediment to bile flow is in the extrahepatic biliary tree. The histologic appearance and functional effects of cholestasis, however, are similar whatever the cause.

Extrahepatic biliary obstruction is more commonly associated with progressive severe jaundice, dark urine, and pale stools than is intrahepatic cholestasis. Pruritus is normally present. High fever and chills often herald coexisting cholangitis. Pathologic entities causing obstruction include calculus, stricture, and cancer. Weight loss suggests a neoplastic lesion, and central abdominal or back pain together with a recent onset of diabetes makes a diagnosis of pancreatic cancer very likely. Abdominal pain may be misleading; some patients with common bile duct calculi have painless jaundice, whereas some patients with hepatitis have distressing pain in the right upper quadrant.

Intrahepatic cholestasis has a number of causes. Viral hepatitis uncommonly leads to severe and prolonged jaundice with bilirubin concentrations greater than 15 mg/100

TABLE 54-4 -- Drugs Associated With Cholestasis

Pure cholestasis
7-Alpha-alkyl-substituted testosterones
Methyl testosterone
Nortestosterones (e.g., norethandrolone)
Synthetic estrogens
Ethinyl estradiol
Contraceptive pill
Mestranol
Cholestatic hepatitis
Phenothiazines
Chlorpromazine
Promazine
Trifluoperazine
Others (rarely)
Carbamazepine
Erythromycin estolate
Griseofulvin
Phenytoin
Chlorothiazide
Nitrofurantoin
Azathioprine
4
, 4-Diaminodiphenylmethane (causes Epping jaundice)
Chlorpropamide
Valium
Imipramine
Iprindole
Phenindione

mL. Pruritus is a prominent symptom. Because it may be difficult to differentiate this condition from obstructive jaundice, the investigation of all patients with cholestasis should include serologic assays for acute viral hepatitis.

A variety of drugs may also cause cholestasis (Table 54-4) . Typically, the jaundice appears early with associated pruritus but little alteration in the patient's well-being, and the cholestasis resolves after discontinuing drug use (e.g., synthetic estrogens). [91] Some drugs produce cholestasis as part of a hepatitis-like lesion due to hypersensitivity. Thus a "mixed" lesion is observed with both cholestasis and liver cell necrosis accompanied by raised levels of serum transaminase. The prognosis is usually good, although rarely patients will die from acute liver cell failure or develop secondary biliary cirrhosis.

The complications of cholestasis are proportional to the intensity and duration of the jaundice. In patients with biliary obstruction, ascending infection of the biliary tree or septic cholangitis may be life-threatening. Biliary obstruction eventually destroys liver cells and causes the irreversible structural changes of secondary biliary cirrhosis. Fibrous tissue spreads from the portal tracts and eventually true cirrhosis with nodular regeneration develops. The end results are liver cell failure and portal hypertension. Failure of bile salts to reach the intestine results in fat malabsorption and steatorrhea. In addition, the fat-soluble vitamins A, D, E, and K are not absorbed, resulting in multiple vitamin deficiencies. Disordered hemostasis with an abnormally prolonged prothrombin time may further complicate the course of these patients. Cholestyramine, used to treat pruritus, binds to bile salts and exacerbates the vitamin deficiencies. Persistent cholestasis from any cause may be associated with deposits of cholesterol in the skin (cutaneous xanthomatosis) and occasionally in bones and peripheral nerves. Patients with biliary obstruction who undergo biliary

tract surgery may develop postoperative acute oliguric renal failure. The complication may be due to nephrotoxic bile salts and pigments, endotoxin, or inflammatory mediators. [92]

The cause of cholestasis is investigated with a variety of imaging techniques including noninvasive procedures such as ultrasonic scanning and computed tomography and magnetic resonance imaging. [93] Endoscopic retrograde cholangiopancreatography has the advantage of direct visualization of pancreatic and bile ducts and duodenal loop, but the biliary tree proximal to the obstruction is not visualized. Dye may be introduced percutaneously into the intrahepatic biliary tree with a Chiba needle. Complications of this technique include biliary peritonitis, sepsis, and hemorrhage. [94] Serologic markers of viral infection may point to the cause of cholestasis; a positive antimitochondrial antibody is indicative of primary biliary cirrhosis. Primary sclerosing cholangitis is usually found in association with inflammatory bowel disease. [95]

Regardless of the cause of cholestasis, serum bilirubin levels (especially conjugated) are usually high. Alkaline phosphatase, a membrane-bound enzyme localized to the bile canalicular pole of hepatocytes is also markedly elevated, but high levels of the enzyme are not specific to cholestasis. The bone isoenzyme is important in bone turnover, and up to three times the normal adult value may be seen in adolescents during a normal growth spurt. To determine whether the enzyme is likely to be of hepatic origin, measurement of the 5
-nucleotidase is undertaken, as this tends to parallel the alkaline phosphatase levels in liver disease. The concentrations of serum transaminases are usually only moderately elevated in cholestasis but may occasionally be markedly increased, especially if there is cholangitis. The prothrombin time may be prolonged because of malabsorption of vitamin K. Correction of the prothrombin time by parenteral administration of vitamin K may help to distinguish hepatocellular failure from cholestasis.

Preoperative Considerations

Twenty-five percent of jaundiced patients who are suspected on clinical grounds of having biliary obstruction eventually are diagnosed as having hepatocellular disease. [96] These patients should not be subjected to surgery and anesthesia until the diagnosis is clear. Thus, every effort should be made to visualize the biliary tree in jaundiced patients by appropriate use of noninvasive and invasive techniques as described previously.

Intraoperative Considerations

Parenteral vitamin K should be given up to the time of surgery as vitamin K-sensitive coagulation factors (II, VII, IX, and X) are dependent for their activity on a post-translational modification consisting of gamma-glutamyl carboxylation by a vitamin K-dependent enzyme. Although the package insert recommends that Vitamin K be given subcutaneously, it has been administered in a dose of 3 to 5 mg intravenously over 20 to 30 minutes because cardiovascular collapse can occur with more rapid administration. [97] However, vitamin K is insufficient therapy in the presence of coexisting parenchymal disease. Fresh frozen plasma should be administered to those patients in whom vitamin K alone has not restored the prothrombin time to normal, with attention to serum sodium levels and intravascular volume status.

Volatile anesthetics are probably the drugs of choice because they require neither hepatic biotransformation nor elimination via the biliary system. Although isoflurane is associated with less decrease in hepatic blood flow, [34] halothane has also been used with no adverse liver consequences in a pediatric population of patients with chronic cholestasis. [98] Drugs excreted by the biliary system have a prolonged elimination half-life in patients with cholestasis. [99] Specifically, in patients with extrahepatic cholestasis and normal glomerular filtration pancuronium elimination, half-life of pancuronium is prolonged 1.6-fold. [100] Cholestatic patients have both decreased plasma clearance and increased volume of distribution for pancuronium. Therefore, this neuromuscular blocker may produce unsatisfactory relaxation after a single administration yet have a prolonged duration of action. Narcotics may induce spasm of the sphincter of Oddi, producing biliary colic in patients with cholelithiasis and difficulty with interpretation of intraoperative cholangiograms. Glucagon can be used to relieve nonmechanical spasm of the sphincter of Oddi.

Elderly, deeply jaundiced patients are more likely to develop postoperative oliguric renal failure than patients of the same age without jaundice. [101] Maintenance of a perioperative diuresis has also been stressed as an important prophylactic measure.

POSTOPERATIVE LIVER DYSFUNCTION

Reversible minor changes in liver function are common in the period immediately after operation, but the relative contributions of anesthesia and surgery cannot easily be quantitated. [102] The reduction of hepatic blood flow by both regional and general anesthesia together with the general stresses (including tissue damage and caloric deprivation) produce a mild impairment of liver function. [103] If sensitive indicators of liver function are used, abnormalities can be detected postoperatively in up to 50 percent of patients. These transient abnormalities are not associated with morphologic changes in the liver and are usually clinically insignificant. However, if jaundice becomes apparent, the serum bilirubin usually exceeds 4 mg % and a more serious derangement of liver function may be assumed. Postoperative jaundice is present in up to 20 percent of patients undergoing major surgery, and the cause should be sought. Most cases are never diagnosed because there are few pathognomonic features, and liver function often normalizes quickly without specific treatment. A pathophysiologic classification of the causes of postoperative jaundice has been devised by LaMont and Isselbacher [104] (Table 54-5) .

A common cause of postoperative jaundice is relative overproduction of bilirubin. Approximately 10 percent of aged and damaged erythrocytes in stored blood will break down within 24 hours of transfusion, releasing hemoglobin which is converted to bilirubin. Thus, for 500 mL of transfused blood, 7.5 g of hemoglobin, which is equivalent to 250 mg of bilirubin, will be released. In most circumstances, this

TABLE 54-5 -- Classification of Postoperative Jaundice [104]

1. Overproduction of bilirubin
Hemolytic anemia
Hemolysis of transfused blood
Resorption of hematomas
2. Hepatocellular damage
Postoperative intrahepatic cholestasis
Circulatory failure
Halothane and methoxyflurane
Drug-induced jaundice
Preexisting liver disease
3. Extrahepatic obstruction
Common duct stone
Bile duct injury
Postoperative pancreatitis
4. Miscellaneous
Postoperative cholecystitis
Gilbert syndrome

small increase in bilirubin is easily handled by the liver, but if larger amounts of blood are transfused in the face of mild liver impairment due to anesthesia, unconjugated and conjugated hyperbilirubinemia may result. Through a similar mechanism, resorption of extravasated blood may also contribute to postoperative jaundice in patients with severe crush injuries or in patients having extensive surgical dissection. Gilbert syndrome is present in 7 to 10 percent of otherwise normal persons. Because of reduction in hepatic uridine diphosphate glucuronyl transferase, these patients are unable to handle increases in unconjugated bilirubin such as that caused by preoperative fasting. The resulting unconjugated hyperbilirubinemia, however, quickly remits as oral feedings are resumed.

Hepatocellular damage may be drug-induced and may be produced by a variety of drugs used preoperatively. The diagnosis of drug-induced disorders of the liver is often tentative and requires careful exclusion of other causes of liver disease. The spectrum of hepatic reactions is broad, ranging from cholestasis with such drugs as phenothiazines, to hepatitis, which rarely may be seen with certain halogenated anesthetic agents. [105] Concurrent clinical and hematologic manifestations of hypersensitivity such as fever, skin rash, and eosinophilia can be useful pointers to the drug-induced liver dysfunction; but some drug reactions are indistinguishable from either extrahepatic biliary obstruction or acute viral hep-atitis. Identifying the drug responsible for liver dysfunction in a patient receiving a multitude of drugs can be difficult. Diagnostic challenge to the suspected drug is dangerous because even a small subtherapeutic dose may lead to fatal he-patic necrosis in a susceptible individual. Liver biopsy is of limited usefulness in drug-induced postoperative jaundice because the histologic findings are seldom specific.

Severe postoperative jaundice most frequently follows a prolonged and complicated operation and stormy postoperative course in which hypotension and hypoxemia have occurred, multiple blood transfusions have been given, and sepsis is present. Jaundice is usually first noted on the first or second postoperative day but may be delayed up to the tenth postoperative day. Liver function tests are characterized by high levels of conjugated bilirubin and alkaline phosphatase with near normal levels of transaminases (unless anoxic damage has occurred). It is critical that the correct diagnosis be made and, in particular, extrahepatic biliary obstruction be ruled out so that a risky and unnecessary laparotomy can be avoided. A "shock liver" syndrome can occur in patients in whom marked hypotension has persisted for some hours. A coagulopathy is generally the first indication of liver dysfunction and must be distinguished from disseminated intravascular coagulopathy in these sick patients. Laboratory studies show severe hepatocellular necrosis with peak serum transaminase levels 10-fold or more above normal. Acute liver cell failure may complicate this condition.

A milder form of this shock liver syndrome is seen in cardiac patients following procedures involving cardiopulmonary bypass. [106] The onset of jaundice is on the second or third postoperative day, and there is seldom evidence of hepatocellular necrosis. This condition is usually self-limiting and is similar in course and prognosis to benign postoperative cholestasis.

Persistent jaundice following biliary tract surgery is usually due to retained common bile duct stones and demands delineation of the biliary anatomy via endoscopic retrograde cholangiography. Iatrogenic trauma to the bile duct during surgical exploration may result in stenosis, biliary fistula, or bile peritonitis. Again, prompt

surgical repair is advocated to prevent permanent damage to the liver.

Acute postoperative cholecystitis and pancreatitis are a serious but fortunately rare cause of postoperative liver dysfunction. A mortality rate as high as 25 percent has been reported in patients with postoperative cholecystitis. [107] Acalculous cholecystitis is a serious condition that may further complicate the course of a seriously ill patient and probably results from gallbladder ischemia. High fever and right upper quadrant tenderness should make one suspect the condition. Urgent surgical removal of the gangrenous gallbladder is mandatory.

In addition to intraoperative causes of postoperative liver dysfunction, some patients may have preexisting liver disease that becomes manifest only after surgery. They may be unaware of their malady because of the lack of clinical and even laboratory manifestations. Furthermore, patients may be in a latent phase of an illness (e.g., the incubation phase of viral hepatitis) or in remission. Overt disease may be precipitated by the detrimental effects of hypotension on liver function or may occur because of the natural progression of the preexisting liver disease.

Anesthetic Considerations

Isoflurane, the least metabolized anesthetic, has not yet been associated with serious postoperative liver dysfunction, although, like sevoflurane, it does result in minor elevations in bilirubin and transaminases. [108] However, the consequence of a second hypersensitivity reaction may be so catastrophic that it is probably prudent to avoid all inhalation agents.

Multivisceral Transplantation

/das/book/view/29494766/875/603.html

INTRODUCTION

Transplantation of tissue is gaining an increasing role in modern therapeutics. Cornea, heart valves, and blood vessels are relatively immunologically inert and can therefore be transplanted with great success. Similarly, cartilage, tendon, and fascia can be used as a framework for cells of healthy native tissue. Bone marrow replacement has become routine treatment for a growing list of both soft tissue and organ malignancies. Of particular interest to anesthesiologists, transplantation of vital organs with distinct blood supplies, such as the kidneys, liver, heart, and lungs, has now evolved into the preferred therapeutic option for selected patients. Furthermore, survival of both recipients and allografts is excellent, making transplantation of many major organs a very successful therapeutic option (Table 55-1) (Table Not Available) . As a consequence, anesthesia services are needed for both organ

TABLE 55-1 -- Survival of Recipients and Allografts Following Organ Transplantation

(Not Available)

donors and recipients. Optimal care requires an understanding of the many recent advances in immunobiology, molecular and clinical pharmacology, organ preservation, and biomedical ethics that together have made organ transplantation feasible in our society.

TRANSPLANTATION IMMUNOLOGY

Organs for transplantation derived from nontwin donors of the same species are termed *allografts.* The immunologic identity of allografts is established by glycoproteins on the cells' surface, termed the major histocompatibility complex (MHC) antigens. Class I MHC antigens (subtypes A, B, and C), also called human leukocyte antigens (HLA), are located on the surface membranes of all nucleated cells. Class II MHC antigens (subtypes DR, DQ, and DP), found on activated macrophages and on T and B cells, are the primary targets for helper T cells. [1] The great diversity of alleles at the chromosomal loci encoding for these antigens accounts for the varying degrees of HLA matching observed. The major blood group antigens (ABO) are the other cell-surface markers important to clinical transplantation. If preformed isohemagglutinins against the organ donor's blood type are present, allografts derived from that donor are likely to provoke fulminant rejection.

Cellular Biology of Tissue Rejection

After transplantation of an allograft, if otherwise untreated, an immunocompetent recipient will mount an immune response to the foreign surface antigens. This response comprises proliferation of both cellular elements (T lymphocytes, macrophages, and other leukocytes) and humoral factors (immunoglobulins elaborated by B lymphocytes and complement). T lymphocytes are central to the immune response to transplanted tissue because they initiate antigen recognition and ultimately mediate allograft destruction (Fig. 55-1) (Figure Not Available) . They may be further subdivided into four categories, based on their specific cell-surface antigens, all of which participate in the response to allograft tissue: helper T cells, cytotoxic T cells, suppressor T cells, and delayed hypersensitivity T cells. [2] The steps involved in T-cell activation are partially elucidated (Fig. 55-2) ; their clinical importance stems from the potential for pharmacologic control of the immune response. In a process termed corecognition, T cells are able to recognize antigens and MHC gene products, but only in conjunction with an activated macrophage of self-type. T-cell activation, in turn, involves binding of the antigen, presented by activated macrophages, to the T-cell receptor. T-cell activation is promoted by macrophage elaboration of the cytokine, interleukin-1 (IL-1), and leads to the secretion of IL-2 by helper (CD4-surface antigen-positive) T cells. IL-2 acts as a mitogen for activated T cells that express the IL-2 receptor, including the cytotoxic ($CD8^+$) subtype, leading to a cycle of local cellular proliferation. Once the supply of antigen is exhausted, the number of cell surface IL-2 receptors decreases and proliferation ceases by negative feedback.

The humoral component of the immune response is also essential to the process of allograft rejection (Fig. 55-3) and vulnerable to suppression by drugs. In general, B lymphocytes are activated by antigens presented by macrophages. After the antigen-MHC complex binds to the receptors of T-helper cells, cytokines are produced, particularly macrophage-elaborated IL-1 and T-cell-derived IL-4. B-cell activation is followed by expression of surface receptors (IL-2, -4, -5 receptors) that promote cell division. Many cycles of cell division ensue; in the human body, the presence of IL-6 and interferon-gamma (IFN-gamma) stimulates B cells to differentiate into antibody-forming cells.

Figure 55-1 (Figure Not Available) Structure of the human T-cell receptor and its subunits. All T lymphocytes express the T-cell receptor complex (called CD3 or T3), to which foreign antigens bind to initiate the immune response. The Tialpha- and Tibeta-subunits are integral membrane proteins, joined by a disulfide bridge. They are noncovalently associated with the 25-kd gamma chain of the T3 molecule, as well as two 20-kd subunits, delta and epsilon. S--S, disulfide bridge. *(Redrawn from Firestone and Firestone [271])*

Pharmacologic Modulation of the Immune Response

Immunosuppressant drugs have been developed to control the immune response and avoid allograft rejection. Although essential drugs, serious side effects and toxicities accompany their use; thus immunosuppression is reserved only for grafts essential to life. For example, immunosuppression for most endocrine transplantation (e.g., thyroid) would be inappropriate, because substitution by medication

Figure 55-2 T-lymphocyte activation. See text for details.

Figure 55-3 B-lymphocyte activation and development. See text for details.

Figure 55-4 Chemical structures of the immunosuppressants.

is far safer. Immunosuppressants in current use are relatively nonspecific, in the sense that they inhibit lymphocyte subsets other than those directed against donor-specific alloantigens.

To minimize side effects, almost all antirejection regimens combine relatively lower doses of several of the following agents: cyclosporine, azathioprine, prednisone, FK-506 or rapamycin, and antibodies (ALG and OKT3).

Cyclosporine

Cyclosporine is a cyclic peptide molecule (Fig. 55-4) derived from a soil fungus, consisting of 11 relatively lipophilic amino acids. It became the linchpin of immunosuppression after recognition that its use promoted transplant survival rates among unrelated subjects comparable with those achieved between identical

twins. Together with azathioprine and prednisone, cyclosporine forms the ubiquitous "triple-therapy" immunosuppression regimen. Its major actions are thought to be inhibition of activated macrophages from producing IL-1, inhibition of T lymphocytes from secreting the key lymphokine IL-2, and blocking activation of helper ($CD4^+$) T cells. [3]

Cyclosporine is a potent nephrotoxin, producing interstitial renal fibrosis with tubular atrophy (Table 55-2) . Blood urea nitrogen (BUN) and creatinine levels rise as a consequence of both acute and chronic use, and most patients maintained on this agent develop systemic hypertension [4] that responds to conventional antihypertensive medications. Cyclosporine can also produce hepatocellular injury, hyperuricemia, gingival hypertrophy, hirsutism, and, at high serum levels, tremors or seizures.

Azathioprine

Azathioprine is an imidazole congener of the purine, 6-mercaptopurine (see Fig. 55-4) . Its metabolite, thioinosinic acid, competes with inosinic acid for conversion to xanthylic acid, which is essential to *de novo* purine synthesis. As a result, the production of both DNA and RNA is affected, inhibiting both T- and B-cell proliferation. [5] Production of

TABLE 55-2 -- Immunosuppressant Side Effects and Toxicities

AGENT	SIDE EFFECTS
Cyclosporine	Hypertension
	BUN, creatinine elevations (secondary to glomerulosclerosis)
	Enhanced renal sensitivity to insults
	Hepatocellular damage (transaminase elevation)
	Tremors, seizures (high doses)
Azathioprine	Profound leukopenia
	Anemia
	Thrombocytopenia
	Hepatocellular and pancreatic damage
	Diminished nondepolarizing relaxant requirement
Prednisone	Abnormal stress responses (adrenal suppression)
	Glucose intolerance
	Aseptic osteonecrosis
	Peptic ulceration
	Integumental fragility
Antilymphocyte globulin	Leukopenia
	Thrombocytopenia
	Serum sickness-like symptoms
OKT3	Serum sickness-like symptoms
	Vulnerability to cytomegalovirus sepsis

other formed elements in the bone marrow is suppressed as well, possibly leading to anemia, thrombocytopenia, and occasionally, marrow aplasia. Azathioprine has also been associated with hepatocellular and pancreatic damage, as well as alopecia and gastrointestinal (GI) upset. It has been shown to increase nondepolarizing relaxant requirements modestly by presynaptic inhibition of the motor nerve terminal. [6]

Prednisone

Prednisone is a 17-hydroxyglucocorticoid (see Fig. 55-4) with potent anti-inflammatory activity. It suppresses helper T-cell proliferation by decreasing macrophage production of IL-1. [7] Glucocorticoids also diminish IL-2 production by T cells, thus blocking clonal expansion of both helper and cytotoxic T cells. [8] In clinical practice, glucocorticoids are a vital component of both maintenance and rejection-rescue immunosuppression regimens, despite association with adrenal suppression, glucose intolerance, peptic ulceration, aseptic osteonecrosis, and integument fragility. It has not been possible to eliminate prednisone from the regimens, [9] although alternate-day administration seems sufficient. Whether it is necessary to administer "stress doses" of glucocorticoids to patients with chronic adrenal suppression is controversial. [10]

FK-506 (Tacrolimus) and Rapamycin

Tacrolimus (FK-506) (see Fig. 55-4) and rapamycin are macrolide antibiotics whose immunosuppressant properties are under investigation. Tacrolimus blocks IL production and T-cell proliferation. Like cyclosporine, these agents block lymphokine (IL) production, as well as activation and proliferation of T lymphocytes. [11] Interest in these agents derives from their relative immunospecificity and potential to be used alone, without other toxic immunosuppressants. [12] Like cyclosporine, FK-506 is nephrotoxic.

Antibodies: Antilymphocyte Globulin and OKT3

Antilymphocyte globulin (ALG) is a polyclonal IgG antibody harvested from animals immunized with human lymphoid cells. It rapidly reduces circulating T lymphocytes and seems to have sustained effects on T-cell populations by promoting formation of suppressor T cells. [13] ALG may cross-react with antigens other than those on T lymphocytes, producing marked leukopenia and thrombocytopenia. Systemic symptoms such as fever and pruritus can also result, as can frank serum sickness.

OKT is a series of murine monoclonal antibodies directed against the T3 (now called CD3) surface antigen on mature T lymphocytes. CD3 is part of the T-cell receptor macromolecular complex involved in T-cell activation following antigen recognition. OKT3 specifically binds to CD3, blocking recognition of MHC antigens on foreign cells and the subsequent immune response. [14] OKT3-bound T cells are then removed from circulation and destroyed by the reticuloendothelial system. [14] The initial dose of OKT3 is usually accompanied by mild systemic symptoms, and only rarely by pulmonary edema or aseptic meningitis. Chronic use has been associated with an unusually high incidence of cytomegalovirus (CMV) susceptibility.

Clinical Immunology of Organ Matching

In the presence of major ABO incompatibilities, renal allografts may undergo a "hyperacute" rejection marked by microvascular thrombosis and fulminant graft necrosis. [15] Kidneys from type O donors may still be transplanted into otherwise compatible nonidentical (e.g., A, B, AB) recipients, although some centers only do so when a living-related donor is available and special immunosuppression protocols are employed (including splenectomy and plasmapheresis). Hyperacute rejection is also likely if preformed cytotoxic antibodies to the donor's T cells ("antilymphocyte antibodies") are present, usually precluding transplantation. [16] Given that renal allografts can survive for days *ex vivo,* HLA matching is feasible, but its specific value is not entirely clear. For example, HLA-incompatible living-related donor transplants yield excellent results, although HLA-matched cadaver allograft survival is superior. Finally, outcome may also be reflected by the panel-reactive antibody (PRA), which cross matches recipient's sera and donor cells to detect preformed antibodies. In one study, [17] the presence of reaction against more than 50 percent of

the random test panel was associated with a greater rejection rate.

Cardiac allografts are also vulnerable to hyperacute rejection on the basis of donor-specific ABO isoagglutinins. [18] Thus ABO matching is essential before transplantation. However, the practical limit of a 4- to 6-hour tolerable donor-heart ischemic time severely restricts prospective matching according to histocompatibility antigens and PRA screens. Moreover, while there are indications that HLA mismatching may promote rejection, [19] other studies fail to correlate mismatching with rejection or survival. [20]

Hyperacute rejection has not been reported during liver transplantation despite major ABO incompatibility, [21] suggesting that the liver is not susceptible to this particular form of antibody-mediated injury. [22] Nonetheless, under these circumstances, the likelihood of rejection is elevated in both the short and long term. [15] [23] [24] By contrast, T-cell crossmatch [25] and HLA histocompatibility [26] are not highly correlated with liver allograft survival.

In summary, renal allograft distribution depends primarily on immunologic factors such as ABO and HLA histocompatibility, as well as T-cell and PRA crossmatching. Distribution of cardiac and hepatic allografts will depend less on immunologic criteria, other than ABO histocompatibility, than on size compatibility with potential recipients and overall medical urgency.

PRINCIPLES OF ORGAN PRESERVATION

Donor organs are temporarily separated from blood supply and must therefore be protected from ischemia. The biologically tolerable limit of survival *ex vivo* has been extended

by combining hypothermia (decreasing metabolism) with the use of preservative solutions (to maintain cellular integrity). These solutions contain electrolytes of specific composition, as well as chemical additives that provide ready sources of energy, are cryoprotective, or prevent vasospasm, cellular swelling, and build-up of toxic metabolites. For example, free-radical scavengers (e.g., mannitol) are added to prevent oxygen-derived free radicals from damaging key intracellular constituents after reperfusion.

Kidney Preservation

The first flushing solutions for renal preservation were isotonic, with a composition resembling intracellular fluid (e.g., potassium 115 mEq/L, sodium 10 mEq/L, chloride 15 mEq/L, bicarbonate 10 mEq/L, dihydrogen phosphate 15 mEq/L, and monohydrogen phosphate 85 mEq/L, pH 7.25). [27] This composition diminished renal cortical respiration, but other additives, including procaine, heparin, and phenoxybenzamine, were used in an attempt to prevent agonal thrombosis and/or vasospasm in cadaver kidneys. An additive-free version of Collins solution, termed modified Euro-Collins, is widely used for kidney flushing and can support kidney viability *ex vivo* for more than 48 hours. [28] Besides the electrolytes already specified, it contains magnesium sulfate 1 g/L and 5 mL/L of 50 percent glucose, resulting in a measured osmolality of 375. Hypertonic intracellular solutions have also been tried (e.g., Sacks, with >400 mOsm), [29] but without any greater success.

Liver Preservation

The liver is relatively vulnerable to ischemia, due to an intrinsically high metabolic rate and large bulk that prevent rapid uniform cooling. As a consequence, until recently, postoperative graft dysfunction due to ischemia was not uncommon. University of Wisconsin (UW), or Belzer, solution was later shown to succeed in markedly diminishing primary graft dysfunction, as well as in prolonging hypothermic liver preservation for at least 24 hours *ex vivo*, [30] [31] greatly facilitating distant procurement. Impermeants, such as lactobionate (100 mM) and raffinose (30 mM), suppress hypothermia-induced cell swelling and are believed to be the key additives. The remainder of the composition is potassium phosphate 25 mM, adenosine 5 mM, magnesium sulfate 5 mM, glutathione 3 mM, and allopurinol 1 mM, as well as insulin 100 units/L, penicillin 40 units/L, dexamethasone 8 mg/L, and hydroxyethyl starch 50 g/L. At 4°C, the pH is 7.4, and the osmolality is 320 to 330 mOsm. [30]

Heart Preservation

Cellular metabolic arrest and cooling are the bases of myocardial protection [32] ; thus techniques of cardioplegia developed shortly before the organ transplantation era facilitated distant procurement of donor hearts. Although numerous preservation regimens have been tried, conventional cardioplegia solutions have had the greatest success as reflected by lack of need for inotropic support following implantation. [33] A typical crystalloid cardioplegia solution is composed of potassium 30 mEq/L, sodium 25 mEq/L, chloride 30 mEq/L, and bicarbonate 25 mEq/L, as well as dextrose 50 g/L and mannitol 12.5 g/L, at a pH of 8.1 to 8.4. [33] The heart is relatively sensitive to ischemia, and despite some promising laboratory reports, [34] the practical ischemic limit in humans remains 4 to 6 hours. [33] [35] [36]

Lung Preservation

The lung is unique among transplanted organs because it remains exposed to the external (nonsterile) environment. Donor lungs may also be jeopardized by aspiration, contusion, massive fluid resuscitation of the donor, and exposure to nonphysiologic oxygen tensions. Ideally, the donor's history should indicate early endotracheal intubation, and absence of chest tubes, pleural disease, and tracheostomy at any time. Suitable donors should have a minimal alveolar- arterial oxygen gradient (i.e., Pa $_{O_2}$ of >400 mm Hg while breathing 100 percent O_2 , or 100 mm Hg on 40 percent O_2 /5 cm H_2 O positive end-expiratory pressure [PEEP]), as well as a clear chest radiograph and sputum examination within 2 hours of harvesting. [37] Because both heart and lungs may be harvested from the same donor, a method has been developed for cardiectomy without jeopardizing the use of the lungs. [38] At some centers, before removal, the donor is treated with a pulmonary vasodilator (e.g., prostaglandin E_1 [PGE_1]) to improve distribution of a large volume of an intracellular-type cold-crystalloid preservative solution, [39] [40] infused through the pulmonary artery. Finally, the lungs may be inflated before immersion in preservation solution and stored for transportation. With such techniques, a maximum ischemic time of 6 to 8 hours has been reported. [40]

CARE OF ORGAN DONORS

Brain-dead organ donors (Ch. 76) are the source of most viscera for transplantation in the United States. Voluntary donor programs have been established by state and federal law, supplemented in some jurisdictions by legislation requiring health-care providers to request permission for donation from a brain-dead donor's family. Organs are distributed through a nationwide organ procurement and transplantation network established under federal contract, the United Network for Organ Sharing (UNOS). UNOS also collects and reports survival statistics and has a role in public education about transplantation. [41] The overall procurement process has recently been described. [41A]

Common causes of brain death include blunt and penetrating head trauma and intracranial hemorrhage. Despite such injuries, suitable organ donors must not have suffered circulatory compromise nor septicemia during subsequent hospitalization. Other infectious processes precluding organ donation include hepatitis B, herpesvirus, tuberculosis, active toxoplasmosis, and acquired immune deficiency syndrome (AIDS). By contrast, serologic evidence of CMV infection does not preclude donation to seropositive recipients. Autoimmune disease is not usually a contraindication to donation, despite a report of idiopathic thrombocytopenia purpura transmission by liver transplantation. [42] Liver function

tests are important when screening suspected alcohol or drug abusers, and BUN and creatinine levels, as well as urinalyses, are obtained from all potential kidney donors. Heart donors are typically younger than 50 years of age, with cardiac function demonstrably normal by echocardiography. The history must also be free of angina and recent need for intracardiac injections. Cardiac arrest, mild cardiac trauma, transient hypoxemia, or the use of high doses of inotropes need not mandate exclusion, provided both echocardiographic and gross examinations indicate reasonable contractility. [43]

Living donors are the other source of organs, primarily kidneys, for transplantation. Living donors must be closely related to recipients, because only high degrees of HLA matching are associated with greater allograft survival. [44] Partial liver [45] [46] and lung [47] resections from living (parental) donors have been performed to provide reduced-size allografts for children. Size considerations place additional constraints on the organ matching process in pediatric recipients, which exacerbates shortages, yet the morbidity and mortality inherent in those donor operations have sparked considerable controversy.

Brain Death Criteria

Before the advent of heart transplantation, harvesting of kidneys could be performed following cessation of the donor's heartbeat (Ch. 76) . However, unlike kidneys, the heart is intolerant of even short intervals of warm ischemia, generating the need for a uniform definition of brain death. In 1981, a special President's Commission [48] published that definition as "irreversible cessation of all function of the entire brain, including the cortex and brain stem, determined in accordance with accepted medical standards." Although those standards continue to evolve, [49] the concept of brain death is now widely accepted by society.

Cerebral cortical infarction is indicated by the absence of consciousness as well as motor activity, either spontaneous or in response to noxious stimuli administered by an experienced neurologist (Table 55-3) . Similarly, brain-stem function

TABLE 55-3 -- Brain Death Criteria[a]

Cerebrocortical function
Unconscious
Loss of spontaneous movement

Cerebral angiography
Transcranial Doppler
Xenon-enhanced computed tomography scan
Electroencephalography

[a] Also see Ch. 76 .

is deemed absent when there is a loss of reflexes mediated by both bulbar respiratory and cranial nerve nuclei. The former is assessed by the apnea test, [50] whereby respiratory efforts are judged by serial Pa CO_2 determinations after suspending mechanical ventilation under normoxic, hemodynamically stable conditions. [51] Examples of reflexes mediated by cranial nerve nuclei include: the corneal reflex (blink normally elicited by light touch); the direct pupillary light reflex (bright light normally eliciting homolateral meiosis); the oculocephalic reflex (ocular position normally not fixed [like "doll's eyes"] upon head rotation); and the oculovestibular reflex (nystagmus accompanying ice water irrigation ["cold caloric test"] of the auditory canal). Resistance to atropine's chronotropic effects on the heart is also characteristic of brain-stem infarction. [52]

Clinical studies supporting these physical findings in accordance with current medical standards include both cerebral blood flow studies and electroencephalography (EEG). Four-vessel cerebral angiography, [53] xenon-enhanced computed tomography (CT), [54] and transcranial Doppler [55] have all been used to bolster the diagnosis of brain death. Electrical silence on the EEG is not an absolute indication of brain death, because residual activity has been observed even after cessation of cerebral blood flow, [56] and reversible drug overdose and hypothermia can both produce "flat" EEGs.

Irreversibility is fundamental to the diagnosis of brain death and is established by a lack of improvement in the physical examination or clinical studies for 12 to 24 hours. Potentially reversible factors that must be ruled out include central drug effects, postictal states, cardiovascular or metabolic instability, or hypothermia, thus emphasizing the need to understand the cause of brain death. Age can also confound this diagnosis, because the potential for infants and children to recover from neurologic insults seems less predictable than in adults. [57] Thus, only appropriately experienced pediatricians should undertake brain-death evaluation in these younger age groups. [57] [58]

Clinical Management Following Brain Death

Physiologic instability often accompanies brain death but must be controlled to maintain the viability of donor organs. Hypoxemia, hypotension, cardiac arrhythmias, and hypothermia may be either a cause or an effect of brain-stem infarction. Hypoxemia can be a consequence of excessive fluid resuscitation, gastric aspiration, pulmonary contusion, atelectasis, or pneumothorax. Treatment typically involves adjustment of the F_{IO_2}, minute ventilation, and PEEP to maintain an Sa_{O_2} of greater than 95 percent. Hypotension follows from loss of central vasomotor centers, exacerbated by diuresis from radiographic dyes or diabetes insipidus, or by hemorrhage. Judicious restoration of intravascular volume with colloid and crystalloid solutions, or infusion of vasopressin (Pitressin 0.5-15 U/h) or pressors, may be necessary. Dopamine (2-5 mug/kg/min) is preferred to phenylephrine, which diminishes splanchnic perfusion, thus jeopardizing abdominal donor organs. Hypothermia may result from hypothalamic infarction or exposure and is treated in the conventional manner. Brain death can also be accom-panied by both atrial and ventricular arrhythmias, particularly

bradyarrhythmias, as well as varying degrees of heart block. [59] These conditions are usually attributable to either myocardial contusion or ischemia, electrolyte or acid-base disturbances, hypoxia, intracranial hypertension, or vagal nucleus infarction. Bradycardia is unresponsive to atropine [52] but can be treated with infusion of a direct-acting chronotropic agent (e.g., isoproterenol).

There is no typical endocrine response to brain death. Rarely, catecholamine and cortisol levels may be markedly elevated, and insulin or thyroid hormone (T_3) levels diminished. Replacement therapy under such circumstances may be warranted. Polyuria suggests onset of diabetes insipidus; the diagnosis is confirmed by the presence of relative urine hypo-osmolarity (>300 mOsm/L) despite serum hyperosmolarity (>310 mOsm/L) and hypernatremia (>150 mEq/L). This is treated by replacement of free water losses, normalization of serum osmolarity and electrolyte values, and vasopressin infusion.

Donor Operation

In the operating room, anesthesiologists continue to implement therapies begun in the intensive care unit (ICU) to promote donor organ perfusion and oxygenation. In addition, although cortical and brain-stem function are absent, somatic and visceral reflexes may trigger deleterious physiologic responses [60] that require control. For example, reflex hypertension often accompanies surgery and must be treated to avoid damaging renal microvessels. Vasodilator infusions are adequate in this setting, in which general anesthetics are clearly unnecessary. Motor activity mediated by spinal somatic reflexes is suppressed with relaxants.

The goal of the donor procedure is to minimize warm ischemia time and surgical trauma to the harvested viscera. This is currently accomplished by regional cooling and preservation of organs *in situ,* then removal en bloc [61] (Fig. 55-5) (Figure Not Available) . Specifically, after surgical preparation of the entire anterior chest and abdomen with the patient in the supine position, both sternotomy and full-length midline abdominal incisions are performed. The liver is exposed and freed from its ligamentous attachments to the diaphragm. The abdominal aorta above the celiac artery is encircled with a ligature, while the inferior mesenteric vein is cannulated for drainage; the liver is then flushed with cold preservation solution. The donor then is heparinized systemically, followed by abdominal aortic cannulation, cross-clamping, and perfusion with cold preservative. The donor's kidneys are thus flushed of blood and cooled; once the ureters are dissected and divided, the aorta and vena cava on either side of the renal pedicles are transected, followed by en bloc nephrectomy. The common bile duct and hepatic artery are divided next, freeing the liver for removal.

At the same time that *in situ* preservation of abdominal viscera begins, a second team starts the donor cardiectomy. This approach avoids inadvertent cardiac arrest before cardiectomy, which would damage the donor organs. After pericardiotomy, the epicardial coronary arteries are grossly palpated for atherosclerotic plaques. The ascending aorta is dissected, the superior vena cava (SVC) is ligated, and the inferior vena cava (IVC) and pulmonary veins are then transected to exsanguinate the heart. Finally, cold cardioplegia is administered via the aortic root; after cardiac arrest, the aorta is cross-clamped, the great arteries divided, and the heart rinsed and examined for valvular lesions or a patent foramen ovale. It is then placed in a sterile plastic bag containing iced saline, within an insulated cooler suitable for transport. [62]

The donor operation concludes with the anesthesiologist discontinuing ventilatory and circulatory support. Although death is always certified before this procedure (and not in the operating room), it is important that donors still be treated throughout with the same respect afforded to all other patients.

PREANESTHETIC EVALUATION FOR TRANSPLANTATION: GENERAL PRINCIPLES

Organ transplantation is indicated for patients with end-stage visceral disease when medical or surgical management has failed to improve the quality of life or enhance the chances for long-term survival. General contraindications to organ transplantation (Table 55-4) include factors that rapidly lead to recurrent life-threatening illness or impede recovery. Currently, such factors include incurable malignancy, old (physiologic) age, concurrent poorly controlled systemic illness, active systemic or incurable infection, obesity with physiologic impairment, ongoing substance abuse, evidence of emotional instability, or lack of a strongly supportive social milieu. However, such criteria are undergoing continuous evolution in the light of new information. For example, diabetes mellitus was considered a contraindication to major organ transplantation, until renal allograft survival was shown to be comparable with that found in the absence of this disease. Similarly, survival of the elderly after heart transplantation is comparable with that of younger patients.

Although candidates for organ transplantation frequently are found to have abnormal physical or laboratory findings, these usually indicate secondary organ involvement (e.g., azotemia resulting from left ventricular failure). Such findings must be distinguished from concurrent primary organ failure or a systemic disease that could disqualify candidacy. Occult infection (e.g., tuberculosis) must be ruled out by skin tests and serologies; otherwise postoperative immunosuppression could lead to overwhelming septic complications. Technical factors should also be considered, particularly in patients with atypical vascular anatomy or body

TABLE 55-4 -- General Contraindications to Organ Transplantation

1. Incurable malignancy
2. Old age
3. Active systemic or incurable infection
4. Other major systemic disease
5. Morbid obesity
6. Current alcohol, drug, or tobacco abuse
7. Emotional instability
8. Unsupportive social milieu

Figure 55-5 (Figure Not Available) *In situ* perfusion technique for preservation of the donor heart and abdominal organs. Appropriate preservative solutions are infused by gravity into the ascending aorta, both the portal and systemic circulations, and the aortic root. Drainage occurs via caval transections (not shown) both above and below the diaphragm to prevent venous congestion. *(From Starzl et al [267])*

habitus or in those who have undergone multiple previous surgery. Some transfusion practices are specific to transplantation as well; for example, CMV-seronegative blood products must be available for seronegative patients if CMV sepsis is to be avoided. Likewise, leukocyte-poor blood is mandatory for transplant candidates who must be transfused prior to their transplant procedure, if HLA alloimmunization is to be avoided.

Transplantation procedures are usually performed as emergencies because of the relatively short safe ischemic times for most organs (see the earlier section on principles of organ preservation). Thus, patients will have rarely fasted for an appropriate interval and may not have received the benefits of sedating premedication prior to arrival in the operating room. Finally, the shortage of donor organs may have resulted in "wait-listing" for many months, during which interval change in the patient's medical condition is common.

KIDNEY TRANSPLANTATION

Kidneys are the most common major organ transplanted, accounting for some 9,000 to 10,000 procedures each year in the United States. Roughly 10 percent of patients otherwise dependent on dialysis receive transplants each year; the only factor limiting further growth is the supply of available donor organs. [63] This is because transplantation has now gained acceptance as the preferred option for patients with end-stage renal disease, owing to lower overall morbidity and mortality than dialysis [64] and higher survival (see Table 55-1) (Table Not Available) . [65] For example, data from UNOS demonstrate a 91 percent 1-year allograft survival rate (for living-related donor organs). [66] Longer-term survival statistics, [67] as well as those for cadaveric organs, [66] are not far behind. Other measures of outcome also support the success of kidney transplantation in adults: quality of life is clearly improved [68] while remaining cost-effective. [69] Moreover, in children, kidney

transplantation has a clear advantage in providing superior growth and development. [70] [71]

Pathophysiology of End-Stage Renal Disease and Dialysis

In adults, end-stage renal disease may be a consequence of diabetic glomerulopathy (the diagnosis in 44% of transplant recipients in one large study [72]), other glomerulonephritides (23%), polycystic kidney disease (6%), chronic pyelonephritis (5%), obstructive uropathy, Alport syndrome, or lupus nephritis. Whatever the cause, patients manifest the uremic syndrome, with inability to regulate the volume and composition of their body fluids. Untreated, this results in excessive intravascular volume, acidemia, and imbalance of key electrolytes such as potassium, phosphorus, magnesium, and calcium, leading to secondary dysfunction in other organ systems. For example, the cardiovascular complications associated with uremia may include congestive heart failure (CHF), pericarditis, hypertension, arrhythmias, and capillary fragility; pulmonary edema or pleural effusions may affect the lungs; musculoskeletal manifestations include renal osteodystrophy, generalized muscle weakness, and metastatic calcifications; nervous system involvement may encompass peripheral neuropathy and a spectrum of mental status changes ranging from lethargy to coma. Hematologic effects of uremia include anemia, platelet dysfunction, and a shifted oxyhemoglobin dissociation curve; nausea, vomiting, intestinal ileus, and GI ulceration are also found, as are certain immunologic responses (impaired cellular immunity) and effects on the integument (pruritus) (Table 55-5) (Table Not Available) . Dialysis diminishes many, but not all, of these manifestations.

Indications and Contraindications

Provided there are no general contraindications (see Table 55-4) , most patients receiving dialysis are candidates for kidney transplantation. Contraindications specific to renal transplantation include processes that are highly likely to recur in the allograft (e.g., membranoproliferative glomerulonephritis and hemolytic uremic syndrome). Diabetic nephropathy and metabolic derangements (e.g., gout, cystinosis, and oxalosis) were once included in this category, but studies have shown that such patients can derive years of benefit from renal transplantation.

Preanesthetic Considerations

Living-related kidney transplantation is an elective procedure, whereas cadaver allografts are transplanted semielectively within the kidney's tolerable ischemic interval (24-72 h). [73] In both cases, there is sufficient time for ABO and lymphocyte crossmatching and HLA tissue typing.

Dialysis often precedes transplantation to correct volume or electrolyte derangements. After dialysis, the net volume status of patients must be ascertained, as should the final hematocrit, potassium and calcium levels, and presence of any residual heparin effect. Supplementation of calcium to

TABLE 55-5 -- Pathophysiology of End-Stage Renal Disease

(Not Available)

From Firestone and Firestone [271]

more than 7 mg/dL may be needed to prevent tetanus. Uremic patients are also usually profoundly anemic, but compensatory changes promoting tissue oxygen unloading may influence the decision to transfuse. Despite impending transplantation, it is still important to protect existing vascular and other routes for dialysis. Kidney allografts, particularly those derived from cadavers, may not be functional immediately.

Most adult kidney recipients have diabetes, so the possibility of coexistent ischemic heart disease is evaluated by exercise stress testing and, if indicated, coronary angiography. [74] In this setting, diffuse coronary artery disease has not been considered a contraindication to renal transplantation, provided ventricular function is not seriously compromised and the patient is willing to assume the added risk. In such cases, appropriate invasive monitoring is warranted (e.g., systemic and pulmonary artery [PA] catheters); in all others, a central venous pressure (CVP) catheter is considered sufficient to optimize intravascular volumes and renal perfusion. Finally, functionally significant pleural or pericardial effusion may require treatment, and "stress doses" of glucocorticoids should be considered for patients with adrenal suppression from long-term steroid use.

Living donors account for 20 percent of renal allografts in the United States and 60 percent in Europe. Most donors are healthy adults, as any significant systemic disease increases the risk of general anesthesia and surgery, giving rise to ethical barriers. Living-related kidney donation has gained widespread acceptance, because the overall incidence of serious perioperative morbidity in this population is lower than 2 percent, mortality is extremely rare, [75] [76] and there is no added risk of developing renal failure or hypertension over the long term. [77] Preoperatively, donors undergo

renal arteriography and intravenous pyelography (IVP) and are screened for ABO compatibility and CMV titer. Autologous blood is also donated 2 to 4 weeks prior to the donor procedure. If older than age 45 to 50 years, donors also undergo noninvasive studies to detect occult coronary ischemia. Intravenous crystalloid infusions sometimes are initiated the night before surgery, to promote active diuresis, and shortly before nephrectomy, mannitol and furosemide are administered to achieve a minimum urine output of 1 mL/min. Heparin is administered systemically immediately prior to kidney removal, and the organ is flushed free of blood with cold preservative solution and transplanted immediately. The timing of donor and recipient procedures is coordinated so that the kidney's ischemic interval is minimized.

Induction and Maintenance of Anesthesia

General anesthesia is most commonly employed for renal transplantation, [78] [79] although the use of regional techniques has also been undertaken. [80] [81] The duration of renal transplant surgery at most centers may make regional procedures impractical. In addition, general anesthesia provides superior control of ventilation, particularly when the site of delicate surgical maneuvers is close to the diaphragm. Rapid induction of general anesthesia may be warranted in patients with diabetes with delayed gastric emptying. [82] Succinylcholine may be used for this purpose, provided the serum potassium level is normal following recent dialysis. Drugs that are highly protein bound (e.g., thiopental) should be administered in reduced dosage to patients with end-stage renal disease; further discussion of the pharmacokinetics and dynamics of drugs with concurrent renal disease is found in Chapters 8 to 13 and 53 .

Nitrous oxide is often omitted to avoid distention of the bowel, particularly in small children. Thus, opioids and benzodiazepines, along with a potent inhaled anesthetic, are usually used in combination. Muscle relaxants not primarily dependent on the kidney for elimination should be used, such as vecuronium, atracurium, cisatracurium, mivacurium, and rocuronium (Ch. 12) . Neuromuscular monitoring is still considered essential, because the response to vecuronium with end-stage renal disease can be quite variable, [83] and it is seldom clear when renal function will be restored following transplantation.

In adults, renal allografts are usually implanted retroperitoneally in the upper pelvis, through a paramedian lower abdominal incision. Revascularization occurs by anastomosis of the renal pedicle to the iliac vessels, after temporarily clamping the common iliac veins. This results in some period (usually <60 min) of lower extremity ischemia, and as a consequence, when the vascular clamps are released, both renal preservative solution and venous drainage from the legs are released into the circulation. Both are rich in potassium and acidic metabolites, and pronounced hemodynamic instability may ensue in small children. To promote renal perfusion, the arterial blood pressure is increased by bolus administration of crystalloid, reducing the depth of anesthesia, and infusion of dopamine 2 to 5 mug/kg/min. However, more recently, a prospective controlled trial failed to detect any improved kidney function or survival by a dopamine infusion. [84] Increasing attention is being given to evaluating renal blood flow intraoperatively by methods such as contrast ultrasonography with sonicated albumin microspheres. [85] Such evaluations will facilitate more objective pharmacologic interventions. Finally, ureteral implantation is performed for urinary drainage.

Postoperative Management and Complications

Emergence from anesthesia may be accompanied by pain and hypertension, which is particularly hazardous for those with diabetes and ischemic heart disease. Such deleterious responses can be blunted with antihypertensives or epidural analgesics, or both. Occasionally, atelectasis, bleeding and thrombosis of vascular anastomoses, or oliguria may also be encountered. One-third of cadaveric renal transplants show varying periods of oliguria or anuria due to acute tubular necrosis [86] ; maintenance fluids must therefore be adjusted accordingly. By contrast, immediate urine flow from living-related allografts is typical. A less common cause of anuria is hyperacute rejection, because both ABO matching and crossmatching of recipient's serum to donor lymphocytes are performed routinely.

Special Considerations in Children

Pathologic processes leading to renal transplantation in children differ from those in adults (Ch. 59) . Typically, developmental anomalies and genetic defects, both anatomic and functional (i.e., inborn errors of metabolism), lead to end-stage renal disease in children. [87] Congenital anomalies may be confined to a single organ system (e.g., reflux nephropathy) or be part of a constellation of abnormalities (e.g., Alagille syndrome, characterized by congenital heart disease, renal dysfunction, and end-stage liver disease). Living-related renal transplantation is most often performed in children; the advantages include improved short-term and long-term mortality and allograft survival. [88] [89] However, because perioperative mortality and renal rejection are more frequent in infants, [90] transplantation is avoided until early childhood. In children, medical management of end-stage renal disease has an overall high morbidity and adversely affects growth and development. [91] [92] On dialysis, eventual height and weight are diminished, [93] as is cognitive development, [94] whereas transplantation appears to prevent these complications. [95] [96] This has been used to justify the recommendation to perform renal transplantation "expectantly" in children with progressive renal insufficiency, sometimes before dialysis is absolutely required. [88]

In contrast to adults, renal allografts are usually placed intra-abdominally in pediatric patients. This allows adult-size kidneys to be used in even small children, effectively increasing the donor pool. However, relatively large allografts can sequester a large proportion of a child's blood volume and may also acutely produce hypothermia. Hypotension is avoided by rapid intravenous administration of crystalloid or colloid 250 to 500 mL/70 kg and inotropic infusions to maintain systemic blood pressure in the high-normal range.

Adult kidneys initially produce adult-size volumes of urine, so intravenous maintenance fluids must be adjusted accordingly.

Anesthesia After Kidney Transplantation

General preanesthetic considerations for all patients who have previously received a transplant include the potential for infectious and malignant complications, interactions between immunosuppressants and drugs typically used during the perioperative period (including anesthetics), and special aspects of transfusion in this population. The toxicity of immunosuppressants is another feature common to anesthesia care of post-transplant patients, already considered earlier in this chapter.

Early after transplantation, bacterial infections related to wound infection, urinary catheters, and pneumonia are most common (e.g., with *Staphylococcus aureus, Escherichia coli,* and *Streptococcus pneumoniae,* respectively). Because of the particular susceptibility to pneumonia, early extubation of the trachea following general anesthesia is highly recommended. After the first few months of immunosuppression, vulnerability to opportunistic infection increases (*Pneumocystis carinii* pneumonia, herpes zoster infection, CMV enteritis, or sepsis). If diagnosis is rapid and treatment decisive, survival of such episodes is the rule. [97] CMV is the most frequent viral pathogen, resulting from either primary infection after contaminated allograft implantation or blood transfusion in seronegative recipients or secondary to reactivated infection in a seropositive patient (Ch. 46) . Prophylactic antibiotic regimens are already available for some of these pathogens (e.g., trimethoprim-sulfamethoxazole for *Pneumocystis*[98]); others are under development.

Lymphoproliferative malignancy is more likely to develop in immunosuppressed patients than in a matched population. For example, B-cell lymphoma has a 350-fold increase in incidence after renal transplantation. Such malignancies are clinically aggressive [99] and associated with relatively high mortalities (37% over 5 years in one study [100]). Epstein-Barr virus (EBV) has been implicated in the pathogenesis, and there is evidence that immunosuppressants reduce the cytotoxicity of suppressor T cells toward autologous B cells infected with EBV. With respect to relevant post-transplant drug interactions, both cyclosporine and prednisone are metabolized by the cytochrome P-450 system in hepatocytes. Therefore, drugs that inhibit those enzymes (e.g., calcium channel blockers) may increase their serum concentrations and promote toxic side effects. [101] Other drugs (e.g., barbiturates and phenytoin) may induce the P-450 enzymes and decrease cyclosporine levels below the therapeutic range. [102] In animals, cyclosporine increases the hypnotic duration of pentobarbital, [103] but such effects are probably not pharmacodynamic in nature because inhaled anesthetic potencies are not altered. [104]

Post-transplant patients are particularly susceptible to CMV sepsis, which may arise from transfusion of seropositive cellular blood products (Ch. 46) . Thus, it is mandatory to use only CMV-negative blood in seronegative patients, although use of seropositive products rendered "safe" by depletion of leukocytes with high-efficiency filters has been supported by data. [104] Following transplantation and immunosuppression, concern regarding alloimmunization by blood transfusion is limited, making leukocyte depletion or irradiation unnecessary.

After kidney transplantation, provided the allograft is functioning sufficiently well to maintain normal BUN and creatinine values, renal excretion of drugs is comparable with that produced via normal kidneys. However, some recipients may have mild renal impairment from recurrence of diabetic or other nephropathy, or even a residual dialysis requirement. In patients with diabetes, perioperative glucose control is often complicated by the steroid component of immunosuppression regimens and/or infection, yet perioperative loss of renal allografts is unusual.

Although the principles are the same no matter which surgical procedure is performed, clinical experience in specific clinical settings, such as trauma [105] and coronary artery bypass surgery, [106] is being described. Numerous reviews of anesthetic experience and pharmacology are available for more specific details. [107] [108]

[109] [110]

/das/book/view/29494766/875/609.html

LIVER TRANSPLANTATION

Although generally supportive, medical treatment for chronic end-stage liver disease does little to prolong life or improve its quality. This is especially true after serious complications, such as coma, GI bleeding, or uremia, develop. Salvage after acute hepatic failure through medical treatment is equally discouraging, with rates ranging from 5 to 20 percent. [111] By contrast, in the cyclosporine era, the overall 1-year survival for orthotopic liver recipients is greater than 75 percent (see Table 55-1) (Table Not Available) . [66] Longer-term survival is also relatively high, [112] and the quality of life is considered markedly improved for a high proportion of transplant survivors. [112] [113] As a consequence, some 2,500 liver transplants are performed in the United States annually, representing perhaps one-half the number needed. [112] Almost all these procedures are orthotopic, in which the allograft is implanted in anatomic position following native hepatectomy. Rarely, heterotopic (sometimes called auxiliary) transplantation, in which the native liver is left in place, has been used to treat reversible hepatic failure in patients too unstable for the orthotopic operation. [114]

Pathophysiology and Management of End-Stage Liver Disease

Considering the numerous synthetic and metabolic functions of the liver (Ch. 17) , the manifestations of end-stage liver disease extend to virtually every other organ system. The central nervous system may be affected by encephalopathy ranging from mild confusion to deep coma. This may be exacerbated by electrolyte abnormalities, such as hyponatremia, and worsened by GI bleeding. In fulminant hepatic failure, encephalopathy must be distinguished from cerebral edema, which may require CT scanning. Circulation is usually hyperdynamic with reduced systemic vascular resistance and increased cardiac output, and low-normal blood pressure, despite reduced plasma volume.

Pulmonary gas exchange may be adversely affected by atelectasis from abdominal distention and pleural effusion. The hepatopulmonary syndrome is characterized by intrapulmonary shunting from arteriovenous communications, which is a generalized feature of chronic liver failure. Hypoxemia may be significant, although routine causes of gas-exchange problems are more common.

Renal dysfunction is common and results from diuretic use, intravascular volume depletion, and the hepatorenal syndrome. Azotemia from the hepatorenal syndrome, which is reversible with transplantation, must be distinguished from renal dysfunction resulting from profound hypovolemia, common with aggressive diuretic use and hemorrhage.

Endocrine manifestations include glucose intolerance, although hepatic glycogen depletion may lead to chronic hypoglycemia; coagulopathy, resulting from diminished clotting factor production (particularly I [fibrinogen], II [prothrombin], V, VII, IX, and X); thrombocytopenia from hypersplenism and from low production owing to a lack of thrombopoietin; and reduced hepatic clearance of fibrinolysins and tissue plasminogen activators.

When end-stage liver disease destroys the normal hepatic architecture, portal hypertension follows, and engorged venous collateral vessels develop in the abdominal and GI tract walls, mesentery, and retroperitoneum. Hemorrhage is common from esophageal varices, and arteriovenous communications contribute to the pathologically decreased systemic vascular resistance and intrapulmonary shunting. [115] The latter leads to intractable hypoxemia, exacerbated by pleural effusions and atelectasis. Ascites develops as a result of chronic venous hypertension, diminished albumin synthesis, and sodium and water retention from unmetabolized aldosterone and antidiuretic hormone. Treatment usually consists of diuretics, which may exacerbate electrolyte and acid-base derangements and intravascular volume depletion.

PA hypotension occurs in about 2 percent of patients who present for liver transplantation. [116] Moreover, the hepatopulmonary syndrome, consisting of hypoxemia, pulmonary vasodilation, and hepatic dysfunction, occurs in approximately 30 percent of potential transplant recipients. [116] Currently, outcome studies are being conducted to better define outcome (survival) and costs of performing liver transplantation in patients with these syndromes. [116]

Indications and Contraindications

The timing of liver transplantation is seldom based solely on objective liver function tests, because these values may not reflect disease severity and vary considerably according to the specific pathologic process. Instead, both medical and social factors are balanced against the ongoing mortality associated with nonsurgical management. [112] Ideally, the procedure takes place before the onset of frank liver failure jeopardizes recovery. Diagnoses in adult liver transplant recipients are listed in Table 55-6 (Table Not Available) .

Currently, orthotopic liver transplantation is indicated for nonmalignant end-stage liver disease that will not recur in the allograft, including chronic parenchymal processes (e.g., postnecrotic cirrhosis, Budd-Chiari syndrome, congenital hepatic or cystic fibrosis); acute liver failure (from viral or

TABLE 55-6 -- End-Stage Renal Disease in Adult Renal Transplant Recipients

(Not Available)

From Firestone and Firestone [271]

toxin-induced hepatitis, or Wilson disease); cholestatic processes (biliary atresia or cirrhosis, sclerosing cholangitis, or familial cholestasis); and certain inborn errors of metabolism (e.g., primary hyperoxaluria type 1 or familial hypercholesterolemia). [112] The transplantation option is more controversial when recurrence of disease in the allograft is a possibility, in view of the limited donor supply. For example, primary liver and bile duct cancers, as well as hepatic metastases from GI and endocrine tumors, have been treated with liver transplantation with varying durations of remission. [117] But eventual recurrence is the rule, so the procedure is now reserved for those rare cases with highly circumscribed tumors and rapidly deteriorating liver function. Otherwise, if liver function is maintained, hepatic lobectomy is the preferred approach.

By contrast, patients with cirrhosis resulting from hepatitis B virus infection, once thought to be an absolute contraindication, have had successful long-term outcomes after liver transplantation [112] despite inability to prevent infection in the allograft. Similarly, results obtained in carefully selected patients with alcoholic liver disease are comparable with those obtained in groups with other liver diseases. [118]

Other possible contraindications relate to technical aspects, for example, thrombosis of major abdominal veins, prior portosystemic shunts, or scarring from multiple prior abdominal operations. Moderately advanced age is no longer considered a contraindication, because studies have shown that 5-year survival in recipients older

than 50 years of age is similar to that of younger adults. [119]

Preanesthetic Considerations

Many derangements associated with end-stage liver disease are not correctable until after transplantation. Thus, the major emphasis should be to identify the physiologic systems most seriously compromised and to treat only those that threaten the safe induction of anesthesia. For example, defects in coagulation are usually not corrected at this point, unless there is active hemorrhage or evidence of severe coagulopathy (e.g., prothrombin time [PT] >20 s). Conversely, correction of the coagulopathy may be considered for placement of invasive lines after induction of anesthesia. However, pleural effusions that lead to hypoxemia may on rare occasions necessitate thoracentesis.

The timing of transplantation may be critical to outcome in patients with fulminant hepatic failure. Provided patients

have not become deeply comatose, salvage rates can approach 75 percent, [120] which is usually better than that achieved by medical therapy alone. Certain uncommon diseases treated by liver transplantation have additional implications for anesthesiologists. For example, in children with Crigler-Najjar syndrome (bilirubin UDP-glucuronyl transferase deficiency), drugs that interfere with bilirubin- albumin interactions (e.g., barbiturates) should be avoided. Patients with Budd-Chiari syndrome, characterized by extensive hepatic venous thrombosis, may require perioperative anticoagulation. [121]

In fulminant hepatic failure, the possibility of cerebral edema in a comatose patient needs to be considered, compared with coma from encephalopathy. Brain injury during transplantation is a real possibility in this situation, and monitoring intracranial pressure perioperatively ought to be considered (Ch. 52) .

The potential for active bleeding needs to be considered, as well as appropriate analysis of coagulation and availability of blood products. In addition to standard diagnostic measures, the thromboclastograph has been frequently touted as extremely valuable for liver transplantation. [122] Hett et al [123] have provided an excellent review of this topic. Electrolyte abnormalities, including hyperkalemia and hyponatremia from renal disease or diuretic use, are common, including degrees that would lead to cancellation of almost any other case.

Pulmonary hypertension is associated with cirrhosis in a higher incidence than found in the general population. The increased risk of surgery in the presence of pulmonary hypertension depends on the degree of abnormality, but significantly increased morbidity and mortality are likely, as indicated previously. [116] Severe pulmonary hypertension may be a contraindication to transplantation. Screening for pulmonary hypertension is difficult. Symptoms are frequently delayed until the advanced stages of the disease. Echocardiography is the preliminary study of choice, with right-heart catheterization reserved for questionable cases.

Because the level of physiologic stress of liver transplantation is extremely high, concomitant coronary artery disease needs to be ruled out (Ch. 25) . Hemochromatosis is a common cause of cirrhosis but may be missed because of secondary reasons for cirrhosis, such as hepatitis C virus infection. Because of frequent GI bleeding and transfusion, standard hematologic test results for hemochromatosis may be inconclusive. Iron overload of the myocardium can lead to significant cardiac dysfunction and can potentially increase the morbidity of liver transplantation.

Finally, either as a result of the primary disease process, or of multiple subsequent transfusions, recipients may be seropositive for one or more hepatitis viruses. The anesthesiologist must be aware of the potential for infectious contamination and take appropriate precautions on behalf of the health-care team (Ch. 84) .

Induction and Maintenance of Anesthesia

The ability to transfuse rapidly is vital to successful outcome in liver transplantation, which involves transection and reanastomosis of several major venous structures (e.g., portal vein and IVC). Typically, at least two large-bore peripheral venous cannulas are inserted prior to induction, one of which is 7.0 Fr to facilitate connection to a rapid transfusion system (see later discussion). Invasive monitoring with systemic and PA catheters is standard in most centers, because major shifts in intravascular volume are the rule, and reperfusion of the allograft can be associated with profound hypotension. [124] Both radial and femoral artery catheters are placed, in that distal arterial flow may be compromised transiently by abdominal aortic clamps during hepatic artery anastomosis. The remainder of the monitoring array is analogous to that used for any critically ill patient undergoing a major surgical procedure. Nevertheless, as sicker patients undergo liver transplantation, more sophisticated monitoring is being used by some centers to detect inadequate O_2 delivery to organs such as the brain (i.e., transcranial Doppler to determine middle cerebral artery blood flow velocity), [125] heart (i.e., continuous determination of cardiac output), [126] and gastrointestinal tract (i.e., mucosal pH). [127] In addition, transesophageal echocardiography (TEE) is increasingly used (Ch. 31) .

Ascites, active GI bleeding, or hepatic encephalopathy may result in delayed gastric emptying. Therefore, aspiration precautions are recommended, and general anesthesia should proceed by either rapid-sequence induction or, in patients with hemodynamic instability, awake endotracheal intubation. Thiopental, etomidate, propofol, and ketamine, supplemented with succinylcholine, have all been used successfully for induction of anesthesia. Plasma pseudocholinesterase levels are typically low in this patient population, but prolongation of the relaxant effect of suc cinylcholine is not of clinical significance.

Drugs that do not compromise splanchnic blood flow (e.g., opioids, isoflurane, [128] desflurane, [129] and probably others) are typically used to maintain anesthesia, except in cases of fulminant hepatic failure in which the possibility of intracranial hypertension may contraindicate use of potent inhaled anesthetics. Nitrous oxide is usually avoided due to its potential for bowel distention and increased size of venous air emboli. Liver disease profoundly affects pharmacokinetics, as a result of alterations in hepatic extraction and metabolism, extracellular fluid volumes, levels of serum albumin and alpha $_1$ -acid glycoprotein, and accumulation of bilirubin and other metabolites that displace drugs from protein-binding sites. In general, the net effect of these factors for charged nondepolarizing muscle relaxants is to increase the initial dose requirements and to prolong the duration of action. [130] [131] Newer muscle relaxants, such as cisatracurium [132] and rocuronium, [133] are little affected by liver transplantation (Ch. 12) . Any residual effect is rapidly removed by the newly transplanted liver. [133] In fact, the rate of recovery from vecuronium [134] or rocuronium [135] has been used as a predictor of hepatic allograft function. However, fentanyl and sufentanil kinetics are largely unchanged. [136] [137] Liver allografts rapidly begin to metabolize drugs, [138] but other pharmacokinetic changes (e.g., enlarged volumes of distribution) persist well into the postoperative period. The orthotopic procedure involves total replacement of the diseased native liver with a preserved cadaveric organ, in the most anatomic position possible. Surgery proceeds in three stages: the preanhepatic, anhepatic, and neohepatic (summarized in Table 55-7) .

TABLE 55-7 -- Summary of Orthotopic Liver Transplantation

STAGE	SURGICAL MANEUVERS	PHYSIOLOGIC ALTERATIONS
Preanhepatic	Dissect porta hepatis	Acute decompression of ascites
	Mobilize liver	Hemorrhage (venous collaterals)
Anhepatic	Portal venous clamp	Obstruction of venous return
	Inferior vena cava, hepatic arterial clamp	Oliguria (venous congestion)
	Venovenous bypass (adults)	Atelectasis, decreased compliance
	Retraction on diaphragm	Citrate intoxication
Neohepatic	Inferior vena cava anastomosis	Hemorrhage, coagulopathy
	Flush allograft	Hyperkalemia
	Portal venous, hepatic arterial anastomoses	Hypothermia

Biliary drainage	Metabolic acidosis

During the *preanhepatic* stage, the structures of the porta hepatis are dissected and the native liver is mobilized for removal. Hemodynamic instability is common, due to numerous factors, including acute decompression of ascites, exacerbation of chronic hypovolemia from third-space losses, hemorrhage from venous collaterals in the body wall and mesentery, citrate-induced hypocalcemia, [139] hyperkalemia from rapid transfusion and hemolysis, pericardial effusions rendered significant by hypovolemia, and diminished venous return from abdominal retraction. Hemorrhage may be exacerbated by hemodilution, fibrinolysis, [140] or clotting factor deficiency; differential diagnosis is pursued by means of conventional studies (e.g., PT, partial thromboplastin time [PTT], bleeding time, platelet count, and fibrinogen and fibrin split product levels) and/or thromboelastography. In addition, endogenous heparin-like substances can impair coagulation. [141] Moreover, reperfusion in particular involves release of plasminogen activators that can occur at all stages of liver transplantation, but especially during reperfusion. Drugs such as transexamic acid, aprotinin, and conjugated estrogen have been recommended. [142] epsilon-Aminocaproic acid (Amicar), administered by infusion started prior to incision, may help control hemorrhage secondary to fibrinolysis. At the University of Pittsburgh, a rapid infusion system designed to deliver prewarmed fluids or blood products at a rate of up to 1.5 L/min is employed routinely (Fig. 55-6) (Figure Not Available) . The device consists of reservoirs, heat exchanger, fluid-level sensors, air detectors, line pressure monitors, and filters integrated

Figure 55-6 (Figure Not Available) Schematic of the rapid infusion system developed at the University of Pittsburgh for use during liver transplantation. See text for details. *(Courtesy of John Sassano, MD, Pittsburgh, PA.)*

to minimize trauma to the formed elements of blood and prevent transfusion of air. Autotransfusion systems that salvage extravasated blood are also used, provided there is no infection or malignancy. [143]

Oliguria is common in the preanhepatic phase, and once prerenal causes are eliminated, treatment with potent loop or osmotic diuretics, as well as "renal-dose" dopamine (2 to 5 mug/kg/min) is begun. Metabolic acidosis often accompanies hemodynamic instability, particularly with absent hepatic metabolic function. If severe, an infusion of tromethamine [tris(hydroxymethyl)aminomethane] (THAM) or dichloroacetate will avoid the hyperosmolar hypernatremia associated with repeated boluses of sodium bicarbonate. The aggressiveness with which metabolic acidosis should be treated has been controversial in the literature. [144] When the native liver's blood supply (hepatic artery and portal vein) is transected, and the suprahepatic and infrahepatic IVC is occluded, the *anhepatic* stage begins. A Sengstaken-Blakemore tube may be placed temporarily if large esophageal varices are jeopardized by IVC occlusion. Venovenous bypass is often used to avoid precipitous decline in venous return and cardiac output, as well as venous engorgement in the lower body, bowel, and kidneys. [145] The venovenous circuit reroutes both portal and systemic (femoral) venous blood, extracorporeally, to the axillary vein (then SVC) at 20 to 50 percent normal systemic flow rates. Heparin-bonded tubing obviates the need for systemic anticoagulation. Although venous bypass clearly helps preserve renal function, it has been associated with air and thromboembolism, [146] can prolong the procedure and contribute to heat loss, [147] and does not clearly improve overall morbidity and mortality. [148]

Native hepatectomy and allograft implantation require vigorous retraction near the right hemidiaphragm, resulting in atelectasis, hypoventilation, and diminished respiratory compliance. PEEP and augmentation of inspiratory pressure may compensate to some extent. In patients with pulmonary hypertension, sudden cardiovascular depression is more likely. Gillis et al [149] even used manual compression of the abdominal aorta to increase arterial pressure and coronary perfusion in this situation. Citrate intoxication from rapid transfusion is common during this stage, owing to the absence of the liver's metabolic functions. Rapid transfusion of blood products, especially fresh frozen plasma, which contains the largest amount of citrate, may overwhelm the metabolic activity of the diseased liver. During the anhepatic stage, the complete absence of any metabolism of citrate necessitates the administration of calcium to prevent profound hypocalcemia. Hypotension, which is common during liver transplantation, may be significantly exacerbated by hypocalcemia. Thus, calcium must be supplemented to maintain the ionized level at more than 1.0 mM. Both calcium chloride and gluconate will suffice, even in the absence of the liver. Hyperkalemia, from rapid transfusion, can still be treated in the conventional manner, with glucose and insulin infusion, but metabolic acids, notably lactate, remain uncleared during the anhepatic stage. Even clonidine administration has been recommended to improve fluid requirements and hemodynamic variables. [150]

The *neohepatic,* or postreperfusion, stage begins with reanastomoses of the hepatic major vessels. Prior to unclamping, the allograft is flushed of preservative solution, air, and debris, using portal venous blood. Nonetheless, final removal of the vascular clamps can still be associated with release of a large load of potassium and metabolic acids into the circulation. Hypotension, arrhythmias, and cardiac arrest may follow; inotropic support may be needed to treat myocardial depression from putative cardioactive mediators [151] or venous air embolism. [152] Perhaps the excessive use of antifibrinolytic drugs could contribute to the occurrence of thromboembolism. [153] "Reperfusion syndrome" may cause significant hypotension. The incidence may be 30 to 50 percent. Hypotension occurs within minutes after unclamping the portal vein. Hemodynamically, it is characterized by systemic vascular resistance. Right heart dysfunction has also been described during initial reperfusion. Suggested mediators of reperfusion syndrome include kallikrein-bradykinin syndrome, endotoxin, nitric acid, and prostaglandins. Various predictive approaches (e.g., hemodynamic response to clamping of the IVC, [154] drugs to accelerate graft recovery [155] and avoidance or cardiovascular depressant anesthetics [156] have been recommended with varying degrees of success. Increases in end-tidal nitrogen are useful to distinguish the latter mechanism. Cardiovascular collapse may also be due to pulmonary thromboembolism during reperfusion. [157] [158] [159] With return of allograft function, both metabolic and hemodynamic stability are gradually restored. Urine output typically improves, even in patients with prior hepatorenal syndrome, [150] and inotrope requirements diminish. Clotting variables gradually return to normal, by a combination of specific replacement therapy and production by the allograft. The procedure is completed by biliary reconstruction, either by direct bile "duct-to-duct" anastomosis or by a Roux-en-Y choledochojejunostomy.

Postoperative Management and Complications

Primary nonfunction of liver allografts is rare since the introduction of the UW solution for preservation. [160] Recovery from primary nonfunction has been reported, but more typically, retransplantation is necessary. [161] Provided allograft function is sustained, metabolic acids including lactate continue to be metabolized and systemic alkalosis may result. Postoperative respiratory complications are common, due to nosocomial pneumonia, diaphragmatic injury, adult respiratory distress syndrome (ARDS) from massive transfusion, and nutritional deficiencies. Thus, pulmonary toilet regimens are of paramount importance. Triple immunosuppression (i.e., cyclosporine, azathioprine, prednisone) is begun immediately in the ICU, yet early rejection episodes are common. Rescue with extra steroid boluses or antibodies (ALG or OKT3) is almost always effective. Other perioperative complications include vascular or biliary leaks, hepatic artery or portal vein thrombosis (particularly in small children), or abdominal abscesses. Longer-term complications include recurrence of hepatitis B or neoplasms, [162] opportunistic infection, and the development of a lymphoproliferative malignancy.

Most patients remain intubated and mechanically ventilated in the ICU. Recently, interest in "fast tracking" liver transplant patients has increased efforts at early tracheal intubation. Provided patients are hemodynamically stable, pulmonary gas exchange and mechanics are good, bleeding

and coagulopathy are controlled, and the graft appears to be functioning well, possibly 20 percent of patients may be tracheally extubated immediately at the end of surgery. At two major institutions, major reductions in cost without change in outcome were a result of "fast track" approaches to early tracheal extubation. [163]

Special Considerations in Children

One-fifth of all liver transplants are performed in children, mostly younger than 5 years of age (Ch. 59) . [164] Overall 1-year survival for the orthotopic procedure in children is comparable to that in adults (i.e., 70-75%), but results are not nearly as good in younger (<3-year-old) and smaller (<12-kg) patients (45-50% 1-year survival). [164] [165] Biliary atresia accounts for a high proportion of preoperative diagnoses, followed by inborn errors of metabolism (alpha $_1$ - anti-trypsin deficiency, glycogen storage disease, Wilson disease, tyrosinemia), and syndromes characterized in part by biliary obstruction (e.g., Alagille and Byler syndromes). Children with biliary atresia have usually undergone a prior decompression procedure (e.g., Kasai choledochojejunostomy), which may complicate both transplant surgery and subsequent biliary reconstruction. Venovenous bypass is limited to patients weighing more than 20 kg, so that oliguria and intestinal complications from lower-body venous engorgement are more common in small children. As with kidney transplantation, oversized liver allografts may lead to blood volume sequestration, profound

hyperkalemia after reperfusion, and hypothermia. Peritoneal lavage with warm saline will effectively prevent the last complication.

The limited supply of suitably sized donor organs has led to the development of techniques to transplant part of a liver. Reduced-size ("split") liver allografts enable one donor liver to be used for multiple patients. The method carries with it a significantly higher complication rate, including hemorrhage, [166] organ necrosis, and diminished recipient survival, [165] so it is usually reserved for the desperately ill. In a variation on this theme, living-related (partial) liver donation has been advocated in view of the nearly 50 percent mortality of children waiting for a donor liver. However, there is significant potential for donor morbidity, and considering the relatively reduced survival noted for reduced-size liver recipients, few centers offer this option. Poorer survival among younger and smaller children probably relates to the use of these reduced-sized allografts and to a far greater incidence of hepatic artery thrombosis. [167]

Anesthesia After Liver Transplantation

The potential for infectious and malignant complications in the post-transplant setting, interactions between immunosuppressants and drugs typically used in the perioperative period, toxicity of immunosuppressants, and special aspects of transfusion in organ transplant recipients have already been considered in detail earlier in this chapter.

Liver disease affects pharmacokinetics, and despite a well-functioning allograft, some changes (e.g., enlarged volume of distribution) persist well into the postoperative period whereas others (e.g., hepatic metabolism) return to normal. [168] Early in the postoperative period, the most common reasons liver recipients return to the operating room include exploratory laparotomy for biliary leak or abscess drainage, or open liver biopsy. Ileus or abdominal distention would mandate rapid sequence induction for general anesthesia. Coagulation studies have usually normalized, so regional anesthesia is also a reasonable option. Later, biliary reconstruction procedures are most common.

Conclusion

Liver transplantation is now a major therapeutic approach to patients with liver disease. As our success and skills increase, sicker patients with more severe liver disease are qualifying as recipients, further challenging our perioperative anesthetic skills. [169]

HEART TRANSPLANTATION

After exponential growth in the mid-1980s, the annual number of heart transplants worldwide has leveled out at 3,000 cases (Ch. 49) . The limited supply of donor organs prevents further growth, although it has been estimated that each year in the United States alone, some 15,000 additional patients with end-stage heart disease could benefit from transplantation. [170] The orthotopic procedure accounts for most transplant cases; heterotopic transplants comprise a small minority. [171] The addition of cyclosporine to immunosuppression regimens after heart transplantation dramatically improved overall survival worldwide from 40 percent [172] to 80 percent at 1 year and almost 70 percent at 5 years. [171] Individual experienced transplant centers have reported survivals as high as 90 percent at 4 years (see Table 55-1) (Table Not Available) . [172] Importantly, quality of life is also enhanced after heart transplantation. [173]

Pathophysiology and Management of End-Stage Heart Disease

There are both acquired and congenital causes of end-stage heart disease. In the former category, ischemic and valvular heart disease, and primary (viral or idiopathic) cardiomyopathy are the leading causes. Whatever the cause, a varying period of physiologic compensation is inevitably followed by CHF. The onset of this symptom is ominous and is associated with a less than 50 percent 5-year survival. [174]

The initial compensation for left ventricular failure is an increase in left ventricular end-diastolic volume, [175] which restores stroke volume but increases left atrial pressure, thus leading to pulmonary venous congestion. Later compensations include elevated catecholamine [176] and renin production, resulting in salt and water retention. With progression of disease, ejection fraction falls, and CHF becomes refractory to drug therapy. Most patients are minimally ambulatory at this point and may require inotropic, vasodilator, or mechanical (e.g., intra-aortic balloon or ventricular assist device) circulatory support. Low cardiac output may secondarily compromise function in other organs

---

(e.g., prerenal azotemia), until the coronary bed itself is inadequately perfused, leading to cardiogenic shock and fatal cardiac arrest. Patients may be evaluated for heart transplantation at any of these stages, even when morbidly ill. Yet overall survival remains high, even in those who require mechanical circulatory support as a bridge to transplantation. [177] [178]

Indications and Contraindications

Heart transplantation is indicated when New York Heart Association class IV (NYHA IV) status ("severely compromised") and prognosis ("guarded despite therapy") persist despite maximal medical therapy. Candidates are typically middle-aged men with left ventricular ejection fractions of less than 20 percent because of ischemic cardiomyopathy. Patients with idiopathic and viral cardiomyopathy comprise the next biggest group, and the remainder have systemic diseases (e.g., amyloidosis) or congenital intracardiac defects. In the latter, either long-standing cyanosis or myocardial hypertrophy leads to end-stage heart disease. [179]

Aside from the general contraindications applicable to any major organ transplant (see Table 55-4) , there are few specific to the orthotopic heart procedure. For example, advanced age is no longer considered a major barrier, because many older patients have now undergone heart transplantation without disproportionate morbidity. The same is true for patients with diabetes, particularly since the demonstration that even insulin-dependent patients can be immunosuppressed successfully without the aid of steroids. [180] Even cancer is no longer absolute grounds for exclusion, as long-term cures for certain malignancies (e.g., Hodgkin lymphoma) become routine. In contrast, irreversible pulmonary hypertension remains an absolute contraindication to orthotopic heart transplantation, because the right ventricle of a normal donor heart will rapidly decompensate in the face of high, fixed pulmonary vascular resistance (PVR). [181] The maximum level of pulmonary hypertension deemed acceptable is 6 to 8 Wood units (480-640 dyn/s/cm ^{5}), or a transpulmonary gradient (mean pulmonary artery [PA] pressure minus mean pulmonary capillary wedge pressure) of 10 to 15 mm Hg. Beyond such levels, heterotopic heart transplantation alone or in a combined heart-lung procedure is the remaining option.

Preanesthetic Considerations

End-stage heart disease with low cardiac output may lead to secondary dysfunction in other organ systems. For example, the lungs may be affected by pulmonary venous congestion, interstitial edema, pleural effusions, and atelectasis; there may be prerenal azotemia and oliguria; the liver may be enlarged from chronic passive congestion and the abdomen distended from ascites; and the sensorium clouded from inadequate perfusion and hypoxemia. Preoperative evaluation of acceptable candidates must lead to the conclusion that all such effects will be reversible when cardiac output is restored.

Heart transplant candidates are usually maintained on a multidrug regimen of oral or intravenous inotropes (e.g., digoxin, dobutamine), vasodilators (e.g., captopril, amrinone), diuretics, and antiarrhythmics. Because patients with dilated cardiomyopathy are apt to form intracardiac thrombi, they may be given an anticoagulant (e.g., warfarin) as well. Bacterial pneumonia is common early after heart transplantation, [182] so administration of appropriate broad-spectrum prophylactic antibiotics, as well as use of bacterial filters on breathing circuits, seems reasonable. However, it has not been found necessary to sterilize tracheal intubation equipment.

Induction and Maintenance of Anesthesia

Patients with ischemic or congenital cardiomyopathy may have undergone previous cardiac surgery and are likely to require additional time for invasive monitoring placement and surgical preparation for cardiopulmonary bypass. Such factors must be taken into account by both the surgical and anesthesia teams, if unnecessary prolongation of donor organ ischemia time is to be avoided.

Despite considerable apprehension built up over many months or longer, patients frequently arrive in the operating room without the benefit of sedating premedication. However, because residual cardiac performance critically depends on elevated endogenous catecholamines, only modest doses of conventional sedatives or analgesics are appropriate. At the University of Pittsburgh, the essential hemodynamic monitoring regimen consists of femoral or radial, and PA catheters, as well as TEE. PA catheters are inserted via the right internal jugular vein, which does little to jeopardize access for future endomyocardial biopsies. Positioning such catheters in this setting can be complicated by cardiac dilation (promoting intraventricular coiling), tricuspid regurgitation, atrial fibrillation, severe orthopnea (necessitating a semisitting position), and congenital vascular anomaly. Once positioned, a long sterile sheath is used because the catheter is pulled back to "CVP position" prior to bicaval cannulation.

Considering the short notice for these procedures, most patients may have recently eaten and thus require rapid induction. Various techniques have been described, [183] [184] [185] [186] [187] [188] [189] all compatible with the pathophysiology of end-stage heart disease. For example, a combination of etomidate 0.3 mg/kg with fentanyl 10 mug/kg and succinylcholine 1.5 mg/kg IV will rapidly produce acceptable intubating conditions without cardiovascular depression. [189] Anesthesia can then be

maintained with supplemental fentanyl (35-75 mug/kg total) with scopolamine (0.3 mg), or with a benzodiazepine as tolerated. Following intubation, azathioprine infusion is begun, and the cardiac chambers examined by TEE for the presence of thrombus (Ch. 31) . TEE is also particularly useful for visualizing intracavitary volumes, because the ventricles may be extremely noncompliant in end-stage heart disease, and filling pressures seldom accurately reflect volumes. At this juncture, hypotension may stem from even small changes in preload or afterload but will almost always respond to appropriate adjustments.

After bicaval and aortic cannulation, cardiopulmonary bypass is initiated. Patients with markedly expanded blood volumes benefit from hemoconcentration on bypass, and mannitol or furosemide may be necessary to maintain urine flow.

Cardiac manipulation is kept to a minimum if thrombus was demonstrated by TEE. As the donor organ arrives, the aorta is cross-clamped and the native heart excised, leaving an atrial cuff containing the caval and pulmonary venous orifices and long remnants of the aorta and PA. The back wall of the allograft is trimmed to facilitate anastomosis with the recipient's atrial remnant. The anterior wall of the allograft is most vulnerable to warming, particularly during posterior anastomoses, which may contribute to right ventricular failure later. As the aorta and PA are resewn, the heart is filled with cold saline to displace the air, and after mechanical deairing maneuvers, cross-clamp removal marks the end of the ischemic interval. Immediately prior to release of the aortic cross-clamp, to modulate the possibility of "hyperacute" immune response, methylprednisolone (500 mg IV) is administered.

After cross-clamp release, slow junctional rhythms or AV nodal dysfunction is relatively common. An infusion of either isoproterenol or another catecholamine with positive chronotropic effects is begun to support heart rate. Most of these arrhythmias spontaneously resolve, but some persist postoperatively, even in the absence of rejection. Ultimately, 5 percent of recipients require implantation of a permanent pacemaker. Immediately prior to weaning from cardiopulmonary bypass, the posterior anastomosis is rechecked because leaks in this area are difficult to repair without extracorporeal support. After final deairing, the SVC cannula is removed, the PA catheter is advanced, and the serum ionized calcium restored to normal. If heart rate persists at less than 70 beats/min, epicardial electrodes are placed and pacing begun.

Many transplant centers routinely use inotropic infusions to wean from cardiopulmonary bypass, because cardiac performance is often mildly compromised immediately following heart transplantation. Despite early reports of exaggerated effects, [190] responses to catecholamines are qualitatively similar to those in other cardiac surgical patients. Transient pulmonary vasospasm can occur during weaning, even in patients with previously normal PA pressures, producing life-threatening right heart failure. PGE_1 at infusion rates of 0.025 to 0.2 mug/kg/min can effectively unload the right heart, [191] although simultaneous norepinephrine or phenylephrine infusion may be necessary to support the systemic circulation. Pulmonary vasospasm usually resolves within the first few hours postoperatively, [192] [193] although rarely, mechanical right ventricular assist has been required for varying periods. [194]

Postoperative Management and Complications

In the ICU, short-term management goals include cardiovascular support, as well as rapid and accurate diagnosis of infection and rejection. [182] Excessive mediastinal bleeding and coagulopathy are often seen in patients who have previously undergone a cardiac surgical procedure and are treated in a conventional manner. At most transplant centers, heart recipients are treated with triple immunosuppression [171] and possibly, OKT3. Fever and pulmonary infiltrates are frequently encountered and their sources aggressively sought. Bacterial pneumonias with typical nosocomial organisms are common; opportunistic infection with CMV, *Pneumocystis,* or *Legionella* may occur somewhat later. [195] Bradyarrhythmias and/or atrioventricular (AV) block can appear in the early postoperative course, requiring temporary pacing. Persistently low cardiac output may result from rejection or from reperfusion injury; endomyocardial biopsy will definitively distinguish between these possibilities. If hemodynamic stability is maintained, evidence of mild kidney or liver compromise present prior to transplantation will gradually disappear. If, however, the allograft functions poorly, organs with preoperative impairment may rapidly decompensate.

Heterotopic Heart Transplantation

Heterotopic heart transplantation, reserved for patients with pulmonary hypertension who are ineligible for orthotopic heart transplantation, is becoming increasing rare in an era of mechanical circulatory support. The procedure begins with median sternotomy, followed by the creation of a right pleuropericardial flap. After cannulation and initiation of cardiopulmonary bypass, the native myocardium is protected with cardioplegic arrest, and the allograft is placed in the right hemithorax anterior to the lung. The donor and recipient (SVC) Fig. 55-7) (Figure Not Available) and right atria (RA) are incised and sutured together, and the donor's aorta is sutured end-to-side to the recipient's ascending aorta. The donor and recipient PA are then connected by means of a Dacron graft. After cross-clamp release, weaning from cardiopulmonary bypass proceeds in a reasonably conventional manner. Short-term postoperative management and complications are similar to those discussed for orthotopic transplant recipients.

Special Considerations in Children

Congenital heart disease recently overtook dilated cardiomyopathy as the major indication for heart transplantation

Figure 55-7 (Figure Not Available) Anatomy of heterotopic heart transplantation. See text for abbreviations. *(From Cooper and Lanza [268])*

in children; thus, most recipients are younger than 5 years of age (Ch. 50) . [196] In contrast to older children and adults, overall mortality for young children is higher (76 versus 81% 1-year survival, respectively). [196] In children, cardiac-related deaths are more common, owing to complex vascular anatomy, previous cardiac surgery, and elevated PVR. In infants, it is often difficult to accurately quantify the fixed component of PVR, thus perioperative acute right heart failure is more common than in adults.

In newborns, heart transplantation is indicated for hypoplastic left heart syndrome and aortic atresia. If reconstruction of the aortic arch is required, profound hypothermia and circulatory arrest are usually necessary. Positional or size discrepancies of the great vessels are further sources of complications in this population, suggesting why overall 1-year survival after heart transplantation for neonates is only 66 percent. Rejection contributes relatively little to this figure, because the neonatal immune system seems relatively tolerant of foreign antigens. [197] [198]

Anesthesia Following Heart Transplantation

Cardiac allograft recipients return to the operating room months and even years following transplantation. [199] [200] [201] [202] [203] [204] [205] [206] Overall, one-fourth or more of these patients require general surgical consultation within 2 years of transplantation. [207] [208] [209] [210] Immunocompromise may account for the need for procedures such as incision and drainage of an abscess or laparotomy for diverticulitis; steroid dependence could explain the occurrence of perforated viscus; but a relatively high incidence of cholecystectomy is unexplained. [207] Orthopedic procedures are also common, secondary to the joint complications of long-term steroid use. [211]

This is a physiologically unique population, because the cardiac allograft is denervated following transection of the cardiac plexus located on the surface of the aorta and main PA. In contrast to canine hearts that readily reinnervate after transplantation, [212] human myocardial specimens obtained up to 12 years following transplantation fail to reveal evidence of abundant reinnervation. [213] [214] Most studies of transplanted heart rate responses to exercise and respiratory stimuli in humans also support that autonomic efferent denervation is permanent. [214] [215] [216] [217] However, one report that patients with allograft coronary atherosclerosis may perceive angina pectoris [218] demonstrates that afferent reinnervation may occur in a small minority of patients. Other studies suggest the possibility of some return of efferent function as well. [219] [220]

Despite denervation, in the absence of rejection, resting stroke volume and contractility of cardiac allografts are either normal [221] or only subtly reduced. [222] However, with demands for increased cardiac output (e.g., during exercise), the denervated allograft's performance is demonstrably different (Fig. 55-8) (Figure Not Available) . In contrast to the normal heart, in which rapid increases in cardiac output are mediated by elevation in heart rate, the denervated heart can respond only by increasing stroke volume, not heart rate. Recipients are thus "preload dependent" and must have adequate central volume to meet the demands of stress and of anesthetic

techniques that redistribute vascular volume to the periphery.

Eventually, the denervated heart can increase its rate. However, the maximum achievable pulse rate develops more slowly than in controls, and the return to baseline is slower as well. [223] The period of delay in increases in heart rate corresponds to the time required for secretion and circulation of adrenal catecholamines, whereas the delay in return to baseline is probably related to the absence of vagal input.

With the midatrial orthotopic surgical technique, transplant recipients retain remnants of the native atria, and their electrocardiograms (ECG) may contain both donor and native P waves. Because the sinus node is normally under the continual influence of autonomic (vagal) nerves, [224] the rate of the transplanted atria general exceeds that of the native atria. [225] With parasympathetic activation (e.g., accompanying laryngoscopy or drug effects), the native atrial rate may decrease but the donor atrial rate remains unchanged, because vagal input to the allograft is lacking. In contrast, sympathetic stimulation (from hypoxemia, pain) can still increase the donor heart's sinus rate (via circulating catecholamines). In contrast to effects at the sinoatrial (SA) node, denervation generally has little effect on AV conduction time [225] [226] or ventricular conduction. Another key physiologic finding in denervated patients is an accelerated form of atherosclerosis, such that by the third postoperative year, there is a 30 percent incidence of multivessel coronary disease [227] (Fig. 55-9) (Figure Not Available) . This is characterized by focal concentric narrowings of epicardial coronary lumina [228] that may arise from areas of immune-mediated endothelial damage. Such lesions are often amenable to angioplasty or surgical bypass, and prophylactic drug therapy may even have a role in prevention. [229] Nonetheless, at present, coronary disease

Figure 55-8 (Figure Not Available) Schematic of the physiologic responses to exercise before (left) and after (right) cardiac denervation. *(From Kent and Cooper, [265] copyright 1974 Massachusetts Medical Society. All rights reserved.)*

Figure 55-9 (Figure Not Available) Cumulative incidence of occlusive coronary artery disease in cardiac allograft recipients. A population of 427 adult recipients was evaluated by angiogram over 7 years. *(Adapted from Uretsky et al [270])*

still limits the useful life of most allografts. Despite a report documenting the ability to perceive angina pectoris in a small group of these patients, [218] afferent innervation seems to be lacking in most, rendering episodes of myocardial ischemia silent. Thus, diagnostic ECG monitoring is essential throughout the perioperative period, and paroxysmal dyspnea may be the only indication of ischemia. The effects of cardioactive drugs may also be altered by denervation. Clearly, drugs that usually act indirectly, via autonomic fibers, will fail to produce their classic effects after heart transplantation. For example, atropine and pancuronium will not increase heart rate. By contrast, drugs that act directly on myocardium or cardiac conduction tissue will manifest their usual effects; for example, isoproterenol will increase both contractility and heart rate, whereas propranolol will have the opposite effects. However, neostigmine, once thought to act only indirectly, has been shown to have direct postsynaptic effects producing bradycardia. [230] Similarly, digoxin, which has mixed direct-indirect actions, [231] can act only directly after transplantation. In such circumstances, an intravenous bolus of digoxin will fail to alter either the functional or effective refractory periods of the AV node, [232] instead of significantly increasing the refractory period. Thus, the acute chronotropic effects of digoxin are vagotonic and depend on intact autonomic innervation. Norepinephrine's effects are also altered by denervation; infusions at conventional doses are accompanied by more pronounced chronotropic effects than usual. This is probably because the direct-adrenergic receptor-mediated effects on the sinus node are no longer masked by vagal reflexes. The effects of alpha $_1$ -adrenergic agonists are also persistently blunted [233] in this population, most likely because of peripheral desensitization to the effects of chronically elevated catecholamine levels.

LUNG TRANSPLANTATION

End-stage pulmonary disease resulting from destruction of the pulmonary parenchyma or vasculature is a leading cause of mortality and morbidity among adults. Several transplantation operations have been devised to treat end-stage pulmonary disease, each with particular conceptual or practical advantages. These include the heart-lung, en bloc double lung, single lung, and bilateral sequential lung procedures. Outcome data have shown that when cardiac performance is preserved, isolated lung transplantation is reasonably safe and can benefit carefully selected subgroups (see Table 55-1) (Table Not Available) . [234] [235] For example, at one specialized center, actuarial survival was 90 percent at 1 year after single lung transplantation [234] and 82 percent after the bilateral sequential operation. Exercise tolerance, gas exchange, and PA pressures have all been noted to improve significantly following lung transplant surgery. [234] [236]

Pathophysiology of End-Stage Pulmonary Disease

End-stage parenchymal lung diseases are either obstructive, restrictive, or infectious in nature (Chs. 48 and 72) . Briefly, *obstructive diseases* are characterized by elevated airway resistance, diminished expiratory flow rates, severe ventilation-perfusion mismatching, and pronounced air trapping. The most common cause is smoking-induced emphysema, but others include asthma and several comparatively rare congenital disorders. Among these, alpha $_1$ - antitrypsin deficiency is associated with severe bullous emphysema in the fourth or fifth decade of life. With *restrictive diseases,* interstitial fibrosis results in a loss of lung elasticity and compliance. Most fibrotic diseases are idiopathic in nature but may also be caused by an immune process or inhalation injury. Interstitial lung pathology may affect pulmonary blood vessels as well, so pulmonary hypertension is a frequent concomitant finding. Functionally, diseases in this category are associated with diminished lung volumes and diffusion capacity, but with preserved airflow rates. Respiratory muscle strength is usually excellent, because the work of breathing is chronically increased. Cystic fibrosis (CF) and bronchiectasis are the common *infectious* causes. CF occurs in 0.2 percent of live births in the United States and produces mucous plugging of peripheral airways, pneumonia, chronic bronchitis, and bronchiectasis. Smoking and environmental exposures may also lead to bronchiectasis. End-stage *pulmonary vascular diseases* may arise from diffuse arteriovenous malformations, congenital heart disease with Eisenmenger syndrome, or, primary pulmonary hypertension (PPH). PPH is a relatively rare disease of unknown origin, characterized by a marked increase in PVR from hyperplasia of the muscular PA and fibrosis of small arterioles.

Indications and Contraindications

With all end-stage pulmonary diseases, the general indications for transplantation are progressive exercise intolerance, increasing oxygen requirements and carbon dioxide retention, or right heart failure. Recurrent need for phlebotomy and increasing physical and social debilitation are other factors favoring transplantation. The rate of functional deterioration and ability of the right ventricle to tolerate progression of pulmonary hypertension will determine the timing of surgery. Specific contraindications to isolated lung transplantation relate to processes that would impede recovery, including neuromuscular disease or long-standing ventilator

dependence, severe chest deformity or pleural disease (complicating the surgical procedure), advanced right ventricular failure, or glucocorticoid dependence (complicating the healing of airway anastomoses).

The choice of lung transplant procedure is based on the consequences of leaving the native lung *in situ.* For example, if infection or severe bullous emphysema is present in the contralateral lung, single lung transplantation is not an option. Infection would inevitably cross contaminate a healthy allograft, and bullous disease could lead to gross ventilation-perfusion mismatching and compression of the allograft. Instead, double lung transplantation is chosen for such cases. Similarly, double lung transplantation may also lead to better functional outcomes in the treatment of end-stage pulmonary hypertension. [234] [236] The relative rate of perioperative complications is the other major factor influencing the choice of procedure. For example, single lung transplantation is feasible without cardiopulmonary bypass and seldom complicated by coagulopathy. In contrast, en bloc double lung transplantation mandates extracorporeal circulation with extensive mediastinal dissection and full systemic heparinization--both risk factors for developing a postoperative bleeding diathesis. Single lung transplantation has the added advantage of using bronchial anastomoses, which heal with fewer complications than do the tracheal suture lines inherent in the en bloc double lung procedure. Bilateral sequential lung transplantation, a recently introduced alternative, combines advantages by employing bibronchial anastomoses while (usually) avoiding cardiopulmonary bypass.

Preanesthetic Considerations

Preanesthetic considerations for single and double lung transplantation have been reviewed. [237] [238] [239] [240] Briefly, size matching is facilitated by comparing the vertical and transverse radiologic chest dimensions of donor and recipient. Organs are also matched on the basis of ABO compatibility; because the value of histocompatibility is still unknown and the tolerable ischemic time for the lungs is relatively short (6-8 h), HLA matching is only done retrospectively. Monitoring both systemic and PA pressure is clearly vital during lung transplant procedures, although dyspnea and pulmonary hypertension may complicate PA catheter insertion prior to induction. Pulmonary catheters should be inserted through a long sterile sleeve to facilitate withdrawal during PA anastomoses and subsequent repositioning.

Induction and Maintenance of Anesthesia

Preoperative pulmonary function and right heart catheterization studies, ventilation-perfusion scans, and arterial blood gas values are useful to predict difficulties likely to be encountered during and after induction. For example, elevated PA pressures may indicate a likelihood that cardiopulmonary bypass will be necessary, because right ventricular failure can suddenly result when either one lung ventilation or pulmonary artery ligation is begun. Air trapping and diminished expiratory flow rates may exacerbate hypercapnia and lead to hemodynamic instability during mask ventilation and after tracheal intubation. With borderline arterial blood gas values, "pump standby" is prudent even when single lung transplantation is contemplated. [241]

Single lung transplantation involves pneumonectomy and implantation of a new lung. If the native lungs are equally impaired and pleural scarring is absent, the left lung is chosen for relative technical simplicity: the native right pulmonary veins are less accessible than those on the left; the left hemithorax can more easily accommodate a somewhat oversized donor lung; the recipient's left bronchus is also longer. Most surgeons prefer that the dissected lung be collapsed; both double lumen endobronchial tubes and bronchial blockers have been used for this purpose. Advantages of endobronchial tubes include: easier switching of the ventilated lung, ability to suction the nonventilated lung, ability to apply continuous positive airway pressure (CPAP) to the nonventilated lung, and an option for postoperative independent lung ventilation. Left-sided endobronchial tubes are recommended for both right and left single lung transplants, as well as for the bilateral sequential operation, as the right upper lobe bronchial orifice is relatively close to the origin of the mainstem bronchus and is easily occluded.

Drugs that do not release histamine or depress the myocardium (e.g., etomidate, vecuronium) are preferred for induction of anesthesia by rapid sequence technique (Chs. 9 , 10 , and 12) . Nitrous oxide is avoided in patients with elevated PVR, when 100 percent O_2 is required to maintain acceptable arterial saturation, or with

bullous disease. Both high-dose opioids and potent inhaled anesthetics, supplemented by long-acting relaxants, have been used successfully to maintain anesthesia. After lateral thoracotomy positioning, with the onset of one lung ventilation, acute deterioration in gas exchange and/or hemodynamics is the rule. Strategies for improving oxygenation under these circumstances include: use of PEEP in the dependent lung (provided bullous disease or emphysema is absent), CPAP or high-frequency ventilation in the nondependent lung, or ligation of the (nondependent) PA. If PA pressures provoke right heart failure, vasodilators and/or inotropes may improve hemodynamics, but gas exchange can worsen. If so, one lung ventilation should be abandoned. Similarly, if hemodynamics or systemic arterial saturations deteriorate with PA clamping, cardiopulmonary bypass may be necessary.

Immediately prior to implantation, the donor hilar structures are trimmed to match the size of the recipient bronchus, branch PA, and atrial cuff containing the pulmonary venous orifices. While the allograft is kept scrupulously cold, the atrial, PA, and bronchial anastomoses are completed in sequence. The ischemic interval ends with the removal of vascular clamps but, until ventilation is restored, systemic arterial saturation remains depressed. The allograft is then reinflated, sometimes with the aid of a flexible bronchoscope, and a pedicle of vascularized omentum may be used to wrap the anastomosis to promote healing. [242] [243] Alternatively, a "telescoping" bronchial anastomosis may be used. After restoration of the supine position, the endobronchial tube is either exchanged for a standard endotracheal type, or, with emphysema, retained for independent lung ventilation postoperatively.

In patients with CF or PPH, double lung transplantation is the rule. An en bloc operation is performed with the patient

Figure 55-10 Patient positioning for "clamshell" incision (bilateral anterior thoracotomies with transverse sternotomy) used during bilateral sequential lung transplantation. The patient's arms are padded and suspended from an ether screen.

supine, and either median sternotomy or the "clamshell" incision (Fig. 55-10) may be employed. Cardiopulmonary bypass is mandatory, because both lungs are replaced at once, and cardioplegic arrest is used to accomplish anastomosis of the left atrial cuff containing all four pulmonary venous orifices. The airway is transected at the level of the trachea, so a standard endotracheal tube is appropriate. The extensive retrocardiac dissection often leads to cardiac denervation [244] and postoperative bleeding is difficult to control. Bilateral sequential lung transplantation is used to treat the same spectrum of patients as the en bloc procedure, but it obviates the need for cardiopulmonary bypass, mediastinal dissection, and tracheal anastomosis. Its major disadvantage is that serial implantation prolongs the ischemic time for the second allograft. Access to the hilar structures also requires the "clamshell" transverse sternotomy.

Postoperative Management and Complications

Aside from acute, intensive respiratory support, the great challenge of postoperative management is differentiating between lung infection and rejection, usually by means of transbronchial biopsy obtained by flexible bronchoscopy [245] or occasionally, by open lung biopsy. Early respiratory insufficiency is usually due to reperfusion injury, characterized by large alveolar-arterial O_2 gradients, poor pulmonary compliance, and parenchymal infiltrates despite low cardiac filling pressures. Mechanical ventilation with PEEP is essential, but inflation pressures are kept to a minimum in consideration of the new airway anastomoses. Similarly, F_{IO_2} is maintained at the lowest levels compatible with acceptable systemic oxygen saturations. After single lung transplantation for emphysema, the endobronchial tube is kept in place to facilitate independent ("split") lung ventilation. This technique can be used to avoid overinflation of the native lung, shifting of the mediastinum, and gross ventilation-perfusion mismatching. [246]

Along with their exposure to the external environment, other factors increasing the susceptibility of transplanted lungs to infection include lymphatic disruption, poor mucociliary function, and the presence of suture lines across the airway. In the first postoperative month, nosocomial gram-negative bacteria are the most frequent causes of pneumonia. [247] Thereafter, CMV pneumonitis becomes more common, particularly if organs from a CMV-seropositive donor are used in a CMV-seronegative recipient.

Hemorrhage most frequently occurs after en bloc double lung transplantation, particularly in patients with pleural disease or Eisenmenger syndrome. The vagus, phrenic, and recurrent laryngeal nerves are jeopardized during lung transplantation, and injury will complicate the process of weaning from mechanical ventilation. Tracheal anastomotic leaks often lead to fatal mediastinitis. By contrast, bronchial fistulas lead to strictures that are treated by silicone stents and repeated dilation. Long-term complications include bronchiolitis obliterans, a pathologic condition characterized by luminal destruction of small respiratory bronchioles, [248] and opportunistic lung infections with organisms such as *Candida albicans* and *P. carinii.*

Special Considerations in Children

In children with severe developmental anomalies of the lung (including congenital diaphragmatic hernia with pulmonary hypoplasia) and with cystadenomatous malformations, isolated lung transplantation may offer the only chance for survival (Chs. 50 and 59) . The scarcity of suitable donor organs has led to instances of living-related lung donation, but the success of this approach is not yet fully evaluated. Rarely, heart-lung transplantation may be indicated during childhood for PPH, CF, or Eisenmenger syndrome. [249] [250]

Heart-Lung Transplantation

Heart-lung transplantation is indicated for patients with end-stage lung disease complicated by irreversible right heart failure (cor pulmonale) or end-stage congenital heart disease with secondary pulmonary vascular destruction (Eisenmenger syndrome). Specific pathologic diagnoses in recipients have included PPH, emphysema, multiple pulmonary emboli, CF, and fibrotic and granulomatous diseases of the lung. The donor blocs consist of the entire heart and lungs, including a tracheal segment long enough to facilitate anastomosis. Distal procurement is made possible by flushing the harvested bloc with modified Euro-Collins or UW solution, to which PGE_1 or other pulmonary vasodilators may be added. Because both the heart and lungs must meet the criteria for acceptability, suitable donor blocs are in extremely short supply. Monitoring and induction strategies are similar to those for heart transplantation, but pulmonary hypertension and air trapping are additional factors that may lead to hemodynamic instability. Difficulty when securing the airway during induction can exacerbate hypercarbia or hypoxia and elevate PVR. Under such circumstances, bidirectional

intracardiac shunts may become predominantly right to left and lead to profound hypoxemia. Such shunts may also lead to paradoxic air emboli, so that bubbles in intravenous tubing must be scrupulously avoided. Chronically cyanotic patients are also frequently severely polycythemic (hematocrit >60%) and may manifest clotting derangements and focal central nervous system deficits. Under these circumstances, phlebotomy and hemodilution are beneficial. Large endotracheal tubes are preferred in all recipients to facilitate therapeutic bronchoscopies both intraoperatively and postoperatively.

Prior to cardiopulmonary bypass, surgical dissections may be complicated by extensive pleural adhesions or prior cardiac or thoracic surgery. After the patient receives extracorporeal support, en bloc implantation is readily accomplished by sequential tracheal, right atrial, and aortic anastomoses provided the donor organs are a reasonable size match. Tracheal anastomosis generally involves some technique to prevent dehiscence, for example, wrapping the suture line with vascularized omentum. During this phase of the procedure, the phrenic, vagus, and recurrent laryngeal nerves are particularly vulnerable to injury during both dissection and topical cooling. Reexpansion of the donor lungs may require bronchoscopy to relieve mechanical obstruction by secretions, and occasionally, bronchodilators will be useful to treat bronchospasm. [251] Owing to the extensive mediastinal and/or pleural dissection, and the presence of elaborate vascular collaterals, the early post-bypass period is often complicated by hemorrhage leading to coagulopathy. Pulmonary compliance and gas exchange may deteriorate during this period, owing to intraparenchymal hemorrhage or inadequate preservation, and the use of PEEP and diuretics is often required.

Postoperatively, rejection episodes (characterized by infiltrates, fever, and deteriorating gas exchange), are relatively common. Pulmonary allografts may suffer rejection without significant abnormalities in endomyocardial specimens, [252] so low cardiac output is not necessarily a symptom of rejection. Bacterial pneumonia, which is very common during this phase, may present with the same clinical picture as rejection. Thus bronchoalveolar lavage, or transbronchial biopsy, may be

necessary for definitive diagnosis. The most dreaded complication of heart-lung transplantation is tracheal dehiscence, which can lead to fatal mediastinitis. Nutritional support, prophylactic antibiotics, and careful endotracheal cuff positioning may help prevent this complication. Eventually, most survivors develop bronchiolitis obliterans, as in other lung transplant populations (see previous discussion).

Indications for heart-lung transplantation are diminishing as experience with isolated lung transplantation accumulates. The latter operation will suffice in most cases, when performed *before* right ventricular failure becomes irreversible, or in concert with intracardiac repair of simple congenital defects.

Nonpulmonary Surgery in Lung Transplant and Heart-Lung Transplant Patients

Transplanted lungs can be infected or in the process of being rejected. Clearly, evaluation of this problem is essential. In addition, these patients lack a cough reflex below the tracheal anastomosis, which places prime importance on protecting the airway. Otherwise common anesthetic principles for managing a very sick patient should prevail. Several groups have reviewed their experience and the literature in this area. [253] [254] [255] [256]

OTHER ORGAN TRANSPLANTATION PROCEDURES

In view of the considerable patient populations who stand to benefit, there is considerable interest in transplantation of the pancreas and small intestine. However, these are extremely fragile viscera, and optimal preservation regimens and implantation procedures are currently being defined.

Pancreatic Transplantation

In the United States each year, there are as many as 20,000 new cases of type I (insulin-dependent, juvenile onset) diabetes mellitus. The disease arises from an inflammatory process that destroys pancreatic beta cells. The resulting microangiopathy is among the leading causes of renal failure and blindness. Pancreatic transplantation has been viewed as a potential cure since the 1960s, and by 1989, the annual rate of such procedures reported to an international registry was 554. [257] The reported operative mortality is low (<1%), 1-year survival high (>90%), and insulin independence achieved in 50 to 70 percent of cases at 1 year. [258] In many of the cases described, patients received pancreas allografts at kidney transplantation, to prevent recurrence of diabetic nephropathy, [259] as well as some of the other microvascular complications.

Considering the side effects of immunosuppression, pancreas transplantation is currently reserved for only the patients with the most brittle forms of diabetes who have rapidly progressive complications. Whole organ transplantation is accomplished using the "bladder drainage" technique, [260] involving extraperitoneal placement and exocrine drainage via duodenocystostomy. This technique allows allograft exocrine function to be closely monitored (via urine pH and amylase), which in turn deteriorates during episodes of rejection. Postoperatively, assiduous control of serum glucose by insulin infusion is recommended, which then becomes superfluous with commencement of oral feeding.

Pancreatic islet transplantation, in which only the required cell type is introduced, has recently undergone clinical trials. [261] In this procedure, which does not require surgical intervention, the islets are isolated by cell-separation techniques and then infused into the portal vein. In some cases, islet cells have become fully functional over several weeks and restored insulin independence [261] ; in others, insulin requirement has been diminished but not eliminated.

Multivisceral Transplantation

Replacement of multiple digestive organs simultaneously, termed "cluster operation," was introduced to treat two diseases: locally confined GI tumors and short-gut syndrome. [262]

With short-gut syndrome from any cause, parenteral feeding may lead to liver failure and subsequent need for en bloc replacement of the liver, pancreas, stomach, duodenum, and jejunum. In children, multivisceral transplantation has been performed, with some success, for short-gut syndrome resulting from necrotizing enterocolitis or midgut volvulus. [263]

In adults, hepatomas and cholangiocarcinomas, as well as proximal GI or pancreatic carcinomas, have been treated by cluster operation after upper abdominal exenteration. Although experience is still limited, 1-year survivals have been on the order of 70 percent (with sarcomas or GI-derived endocrine tumors) or 44 percent (primary liver cancer). [264] By contrast, without surgery, the prognoses for patients with these cancers is considerably worse, and even partial resections combined with chemotherapy or radiation offer little improvement in overall survival. Anesthetic management of cluster surgery has been reviewed. [265] Briefly, the types and doses of previous chemotherapy should be ascertained, because some agents may have long-lasting toxic effects on the heart or kidneys. Hormone-secreting tumors producing "carcinoid crises" can be suppressed with ketanserin, a serotonin antagonist; octreotide acetate, a somatostatin analogue; or by arterial embolization. The management issues during surgery resemble those for liver transplantation alone, namely, massive transfusion, coagulopathy, hypothermia, and electrolyte or acid-base abnormalities. Postoperative complications include a high incidence of rejection, particularly of the small bowel, sepsis from loss of the intestinal barrier, and graft-versus-host disease (GVHD). The likelihood of GVHD is roughly proportional to the length of intestine transplanted, probably reflecting the quantity of lymphoid tissue contained in the wall of this organ. [266]

Chapter 56 - Anesthesia for Laparoscopic Surgery

Jean L. Joris

INTRODUCTION

Surgical procedures have been improved to reduce trauma to the patient, morbidity, mortality, and hospital stay, with consequent reductions in health-care costs. The development of better equipment and facilities, along with increased knowledge and understanding of anatomy and pathology, have allowed the development of endoscopy for diagnostic and operative procedures. Starting in the early 1970s, various pathologic gynecologic conditions have been diagnosed and treated using laparoscopy. This endoscopic approach was extended to cholecystectomy in the late 1980s. Since the introduction of the first laparoscopic cholecystectomy procedures, laparoscopy has expanded impressively both in scope and volume. It quickly became apparent that laparoscopy results in multiple benefits compared with open procedures, [1] [2] [3] and is characterized by better maintenance of homeostasis. Overenthusiasm ensued, which explains the effort to use the laparoscopic approach for other surgical procedures, not only in gastrointestinal (colonic, gastric, splenic, hepatic surgery) but also in gynecologic (hysterectomy) and urologic (nephrectomy) surgery.

The pneumoperitoneum and the patient positions required for laparoscopy induce pathophysiologic changes that complicate anesthetic management. The duration of some operative laparoscopies, the risk of unsuspected visceral injury, and the difficulty in evaluating the amount of blood loss are other factors that make anesthesia for laparoscopy a potentially high-risk procedure.

Although laparoscopy was introduced early in the 20th century [4] and developed in the 1970s for gynecologic procedures, the recent extension of laparoscopy to gastrointestinal surgery has created new interest and considerations for the anesthetic management of patients having laparoscopy. Several elements explain this growing interest. Young, healthy women are the largest group of patients undergoing gynecologic laparoscopy, during which minor or modest cardiorespiratory changes are of little concern. For instance, before the systematic use of capnometry, unsuspected hypercapnia frequently developed but was well tolerated by most of these young patients. With the development of laparoscopy for gastrointestinal surgery, we now must care for older patients who are more likely to have known or undiagnosed diseases. Furthermore, because of the multiple benefits reported after laparoscopy, the laparoscopic approach tends to be readily proposed for ill patients.

An understanding of the pathophysiologic consequences of increased intra-abdominal pressure is important for the anesthesiologist who must ideally prevent or, when prevention is not possible, adequately respond to these changes, but also evaluate and prepare the patient preoperatively in light of these disturbances. Therefore, the pathophysiologic changes and the complications of laparoscopy are first reviewed. Then the postoperative period is considered, with examination of the benefits of laparoscopy, as well as certain specific postoperative problems (pain, nausea). Finally, practical consequences for the anesthetic management of laparoscopy are presented. Many animal and human studies of the consequences of lap-aroscopy have been published since the early 1970s. Since much higher intra-abdominal pressures (>20 mm Hg) were previously used, and because of potential species differences, we have focused this review, when possible, on recent human literature (after 1990) using low intra-abdominal pressure (<15 mm Hg) and modern anesthesia techniques.

VENTILATORY AND RESPIRATORY CHANGES DURING LAPAROSCOPY

Intraperitoneal insufflation of CO_2, the current routine technique to create pneumoperitoneum for laparoscopy, results in ventilatory and respiratory changes and can cause four principal respiratory complications: CO_2-subcutaneous emphysema, pneumothorax, endobronchial intubation, and gas embolism.

Ventilatory Changes

Pneumoperitoneum decreases thoracopulmonary compliance. Compliance was reduced by 30 to 50 percent in healthy, [5] [6] [7] [8] [9] [10] [11] obese, [12] and American Society of Anesthesiologists (ASA) III-IV patients [13]; but the shape of the pressure-volume loop does not change (Fig. 56-1). Once the pneumoperitoneum is created and kept constant, compliance is affected neither by subsequent patient tilting, [14] [15] nor by increasing the minute ventilation required to avoid intraoperative hypercapnia. Therefore, on-line compliance and pressure-volume loop monitoring are helpful in diagnosing complications resulting in increased inspiratory airway pressure, such as bronchospasm, changes in muscle relaxation, endobronchial intubation, and pneumothorax. [16] Reduction in functional residual capacity due to elevation of the diaphragm [17] and changes in the distribution of pulmonary ventilation and perfusion secondary to increased airway pressure can be expected. However, increasing intraabdominal pressure to 14 mm Hg with the patient in a 10- to 20-degree head-up or head-down position does not signi-ficantly modify either physiologic dead space or shunt in patients without cardiovascular problems. [18] [19] [20] [21]

Increase in $Paco_2$

During uneventful CO_2-pneumoperitoneum, Pa_{CO_2} progressively increases to reach a plateau 15 to 30 minutes after the beginning of CO_2 insufflation in patients under controlled mechanical ventilation during gynecologic laparoscopy

Figure 56-1 Change in total respiratory compliance during pneumoperitoneum for laparoscopic cholecystectomy. The intra-abdominal pressure was 14 mm Hg, and the head-up tilt 10 degrees. Illustration of the airway pressure (Paw) versus volume (V) curves and data were obtained from the screen of a Datex Ultima. A, before insufflation; B, 30 min after insufflation; TV (mL), tidal volume; Ppeak (cm H_2O), peak airway pressure; Pplat (cm H_2O), plateau airway pressure; C (mL/cm H_2O), total respiratory compliance; $P_{ET}CO_2$ (mm Hg), end-tidal P_{CO_2}.

in the Trendelenburg position, [22] [23] or laparoscopic cholecystectomy in head-up position (Fig. 56-2). [24] [25] Therefore, any significant increase in Pa_{CO_2} after this period requires a search for a cause either independent of or related to CO_2 insufflation, such as CO_2-subcutaneous emphysema (see later). The increase in Pa_{CO_2} depends on the intra-abdominal pressure. [26] [27] During laparoscopy with local anesthesia, Pa_{CO_2} remains unchanged but minute ventilation significantly increases. Hyperventilation is achieved by increasing respiratory rate rather than tidal volume. [28] [29] However, during general anesthesia with spontaneous breathing, the compensatory hyperventilation is insufficient to avoid hypercapnia because of anesthetic-induced ventilatory depression and increased work of breathing secondary to the decreased thoracopulmonary compliance. [30] [31] Because it takes 15 to 30 minutes for Pa_{CO_2} to plateau, anesthetic techniques using spontaneous breathing should be limited to short procedures at low intra-abdominal pressures. [32] [33]

Capnography and pulse oximetry provide reliable monitoring of Pa_{CO_2} and arterial oxygen saturation in healthy patients and in the absence of acute intraoperative disturbances (see Fig. 56-2). [20] [24] [25] [34] Although mean Pa_{CO_2} - $P_{ET}CO_2$ (Deltaa-$_{ET}CO_2$) gradients do not change significantly during peritoneal insufflation of CO_2, individual patient data regularly show an increase of this difference during pneumoperitoneum. However, two other reports recommend that "end-tidal P_{CO_2} ($P_{ET}CO_2$) monitoring should be used as an estimate of Pa_{CO_2} with caution." [35] [36] Wahba and Mamazza found negative Deltaa-$_{ET}CO_2$ in 5 of 28 patients. [36] Pa_{CO_2} and Deltaa-$_{ET}CO_2$ increase more in ASA II-III patients than ASA I patients (Fig. 56-3). [37] Preoperative pulmonary function tests (demonstrating forced expiratory volumes less than 70 percent of predicted values and diffusion defects), but neither age nor duration of surgery, are identified as risk factors for developing intraoperative hypercapnia and acidosis. [38]

Figure 56-2 Ventilatory changes (pH, Pa_{CO_2}, $P_{ET}CO_2$) during CO_2 pneumoperitoneum for laparoscopic cholecystectomy (13 ASA I and II patients). Minute ventilation was kept constant at 100 $mL/kg^{-1}/min^{-1}$ with a respiratory rate of 12 per minute during the study. Intra-abdominal pressure was 14 mm Hg. Data are mean ± SEM.* $P < .05$ as compared with time 0.

Figure 56-3 Ventilatory changes as a function of patient physical status. Pa_{CO_2} and $P_{ET}CO_2$ were measured before and during CO_2 insufflation. Patients were grouped according to ASA classification: group 1 (-
-), ASA I (n = 20); group 2 (-
-), ASA II-III (n = 10). *(Data from Wittgen et al [37])*

These results were confirmed in a canine model of chronic obstructive pulmonary disease (COPD). [39] These data, therefore, highlight the lack of correlation between Pa_{CO_2} and $P_{ET}CO_2$ in sick patients, particularly those with impaired CO_2 excretion capacity, and in otherwise healthy patients with acute cardiopulmonary disturbances. Consequently, arterial blood sampling is recommended when hypercapnia is clinically suspected, even in the absence of abnormal $P_{ET}CO_2$. Postoperative intra-abdominal CO_2 retention results in increased respiratory rate and $P_{ET}CO_2$ of patients breathing spontaneously after laparoscopic cholecystectomy as compared with open cholecystectomy. [40]

During CO_2 pneumoperitoneum, the increase of Pa_{CO_2} may be multifactorial: absorption of CO_2 from the peritoneal cavity, impairment of pulmonary ventilation and perfusion by mechanical factors such as abdominal distention, patient position, and volume-controlled mechanical ventilation, as well as depression of ventilation by premedicant and anesthetic agents in the case of spontaneous breathing (Table 56-1). The observation of an increase in Pa_{CO_2}, when CO_2, but not nitrous oxide (N_2O) or helium, was used as the insufflating gas, suggests that the main mechanism of the increased Pa_{CO_2} during CO_2-pneumoperitoneum is absorption of CO_2 rather than the mechanical ventilatory repercussions of increased intra-abdominal pressure. [41] [42] [43] [44] [45] Accordingly, direct measurement of CO_2 elimination (V_{CO_2}) using a metabolic monitor, combined with investigation of gas exchange showed a 20 to 30 percent increase of V_{CO_2} without significant changes in physiologic dead space in healthy patients undergoing pelvic laparoscopy (intraabdominal pressure: 12-14 mm Hg) in head-down position, [18] [23] [46] or laparoscopic cholecystectomy in head-up position. [23] [47] [48] [49] [50] Furthermore, the time courses of the increase in V_{CO_2} and Pa_{CO_2} are superposable. The absorption of a gas from the peritoneal

cavity depends on its diffusibility, the absorption area, and the perfusion of the walls of that cavity. Because CO_2 diffusibility is high, absorption of large quantities of CO_2 into the blood, and consequently marked increases in Pa CO_2, would be expected to occur. The limited rise of Pa CO_2 actually observed can be explained by the capacity of the body to store CO_2, [51] and by impaired local perfusion due to increased intra-abdominal pressure. [27] [31] Accordingly, during desufflation, CO_2 accumulated in collapsed

TABLE 56-1 -- Causes of Increased Pa CO_2 During Laparoscopy

1. Absorption of CO_2 from the peritoneal cavity
2. V A/Q mismatch: increased physiologic dead space
   - Abdominal distention
   - Position of the patient (steep tilt)
   - Controlled mechanical ventilation
   - Reduced cardiac output

   These mechanisms are accentuated in sick patients (obese, ASA II-III, ...)
3. Increased metabolism (insufficient plane of anesthesia)
4. Depression of ventilation by anesthetics (spontaneous breathing)
5. Accidental events:
   - CO_2 emphysema (subcutaneous or body cavities)
   - Capnothorax
   - CO_2 embolism
   - (Selective bronchial intubation)

peritoneal capillary vessels reaches the systemic circulation, leading to a transient increase in V CO_2. [47] [48]

Respiratory changes during the laparoscopic procedure might also contribute to increasing CO_2 tension. Mismatching of ventilation and pulmonary perfusion can result from the position of the patient, [22] [29] [52] and the increased airway pressures associated with abdominal distention. [29] [31] [53] Lister et al [27] investigated the relationship between V CO_2 and intraperitoneal CO_2 insufflation pressure in pigs. They observed that for intra-abdominal pressure (IAP) up to 10 mm Hg, increased V CO_2 accounts for the increased Pa CO_2. At higher IAP, the continued rise of Pa CO_2 without a corresponding increase in V CO_2 results from an enlargement of respiratory dead space, as reflected by a widening of the Deltaa- $ET CO_2$ gradient. [27] Therefore, if controlled ventilation is not adjusted in response to the increased dead space, alveolar ventilation will decrease and Pa CO_2 will rise. Whereas in healthy patients, absorption of CO_2 from the abdominal cavity represents the main (or the only) mechanism responsible for increased Pa CO_2, in patients with cardiorespiratory problems ventilatory changes also contribute significantly to increasing Pa CO_2. [13] [37] As far as Pa O_2 and intrapulmonary shunt are concerned, they do not change significantly during laparoscopy. [19] [22] [25] [26] [37] [41]

Increases in Pa CO_2 and the ensuing arterial and tissue acidosis may cause dysfunction in several organs. However, current trends are more permissive with regard to hypercapnia than 20 years ago. In the treatment of certain situations, such as acute respiratory distress syndrome (ARDS) and status asthmaticus, marked hypercapnia is even accepted. [54] Although increased Pa CO_2 may be well tolerated by young, otherwise healthy patients, the extent to which hypercapnia is acceptable has not been determined and probably varies according to the patient's physical status. Therefore, it is wise to maintain Pa CO_2 within physiologic ranges by adjusting controlled mechanical ventilation. Except in special circumstances, such as CO_2 -subcutaneous emphysema, correction of increased Pa CO_2 can be easily achieved by a 10 to 25 percent increase in alveolar ventilation.

Respiratory Complications

CO_2 -Subcutaneous Emphysema

CO_2 -subcutaneous emphysema can develop as a complication of accidental extraperitoneal insufflation, [55] but can also be considered as an unavoidable side effect of certain laparoscopic surgical procedures that require intentional extraperitoneal insufflation, such as inguinal hernia repair and pelvic lymphadenectomy (Fig. 56-4). Finally, during laparoscopic fundoplication for hiatal hernia repair, the opening of the peritoneum overlying the diaphragmatic hiatus allows passage of CO_2 under pressure through the mediastinum to the cervicocephalic region. In these three circumstances, V CO_2 and consequently Pa CO_2 and P $ET CO_2$ increase. [22] [48] [49] Therefore, any increase in P $ET CO_2$ occurring after P $ET CO_2$ has plateaued should suggest this complication. The increase in V CO_2 may be such that prevention of hypercapnia by adjustment of ventilation becomes almost impossible. In this case, laparoscopy must be temporarily interrupted to allow CO_2 elimination and can be resumed after correction of hypercapnia using a lower insufflation pressure. Indeed, CO_2 pressure determines the extent of the emphysema and the magnitude of CO_2 absorption. Accordingly, when the preperitoneal space is dissected for inguinal hernia repair by insufflation of a subcutaneous balloon and maintained using low CO_2 pressures (10 mm Hg), the increase in P $ET CO_2$ is

Figure 56-4 Diagnosis of respiratory complications during laparoscopy. *(Data from Wahba et al [16])*

similar to that observed during CO_2 -pneumoperitoneum. [56] CO_2 -subcutaneous emphysema will readily resolve once insufflation has ceased. Therefore, CO_2 -subcutaneous emphysema, even cervical, does not counterindicate tracheal extubation at the end of surgery. [57] We recommend keeping the patient under controlled mechanical ventilation until hypercapnia is corrected, particularly in COPD patients, to avoid excessive increases in work of breathing.

Pneumothorax, Pneumomediastinum, Pneumopericardium

Movement of gas during the creation of a pneumoperitoneum can produce pneumomediastinum, [58] unilateral and bilateral pneumothorax, [59] [60] [61] and pneumopericardium. [62] [63] Embryonic remnants constitute potential channels of communication between the peritoneal cavity and the pleural and pericardial sacs, which can open when intraperitoneal pressure increases. [60] Defects in the diaphragm or weak points in the aortic and esophageal hiatus may allow gas passage into the thorax. Pneumothorax may also develop secondary to pleural tears during laparoscopic surgical procedures at the level of the gastroesophageal junction (fundoplication for hiatal hernia). Whereas opening of peritoneopleural ducts results mainly in right-sided pneumothorax (in the same way that ascites or peritoneal dialysis may be associated with right-sided pleural effusions [64]) pneumothorax during fundoplication is more frequently located on the left. Finally, because of the increased alveolar inflation secondary to increased minute ventilation during pneumoperitoneum, preexisting pulmonary bullae can rupture leading to pneumothorax.

These complications are potentially serious and may lead to respiratory and hemodynamic disturbances. Capnothorax (CO_2 -pneumothorax) reduces thoracopulmonary compliance and consequently airway pressures increase. V CO_2, Pa CO_2, and subsequently P $ET CO_2$ also increase. [65] In effect, not only is the absorption surface of CO_2 increased, but the absorption from the pleural cavity is greater than from the peritoneal cavity. [31] In case of pneumothorax secondary to

alveolar rupture, $P_{ET}CO_2$ does not increase, but instead decreases due to decreased cardiac output. Hemodynamic changes and capillary oxygen desaturation are not constant, but tension pneumothorax with cardiorespiratory compromise can occur. The observation by the laparoscopist of abnormal motion of one hemidiaphragm is also helpful for the diagnosis. Diagnosis must be confirmed by auscultation of the chest and roentgenography. It should be noted that cervical and upper thoracic subcutaneous emphysema can develop without pneumothorax.

When pneumothorax is caused by highly diffusible gas such as N_2O or CO_2 without associated pulmonary trauma, spontaneous resolution of the pneumothorax occurs within 30 to 60 minutes after exsufflation. [60] Therefore, when capnothorax develops during laparoscopy, we provide the following guidelines [65] :

1. Stop N_2O administration.
2. Adjust ventilator settings to correct hypoxemia.
3. Apply positive end-expiratory pressure (PEEP).
4. Reduce IAP as much as possible.
5. Maintain close communication with the surgeon.
6. Avoid thoracocentesis unless necessary, as pneumothorax will spontaneously resolve after exsufflation.

In case of pneumothorax secondary to rupture of preexisting bullae, PEEP must not be applied and thoracocentesis is mandatory.

Endobronchial Intubation

The cephalad displacement of the diaphragm during pneumoperitoneum also results in cephalad movement of the carina, potentially leading to endobronchial intubation (Ch. 39). [66] Cases of endobronchial intubation associated with laparoscopy are now reported during gynecologic laparoscopy in the head-down position, [67] as well as during laparoscopic cholecystectomy, despite the head-up position. [68] [69] [70] This complication results in a decrease in Sp_{O_2} associated with an increase in plateau airway pressure.

Gas Embolism

Although rare, gas embolism (Ch. 52) is the most feared and dangerous complication of laparoscopy [71] and may occur more frequently when laparoscopy is associated with hysteroscopy. [72] [73] Intravascular injection of gas may follow direct needle or trocar placement into a vessel, or it may occur as a consequence of gas insufflation into an abdominal organ. This complication develops principally during the induction of pneumoperitoneum, [74] [75] [76] [77] particularly in patients with previous abdominal surgery. [78] Therefore, peritoneal insufflation with CO_2 must be started slowly (i.e., at a rate not greater than 1 L/min). Indeed, early recognition and treatment of gas embolism reduce the size of the embolism and thus the severity of its effects and sequelae. [79] Gas embolism may also occur later during surgery. [72] [73] [80] [81] [82] CO_2 is used most frequently for laparoscopy because it is more soluble in blood than either air, oxygen, or even N_2O. The capacity for CO_2 carriage of the blood is high due to bicarbonate buffering and combination with hemoglobin and plasma proteins. [51] Rapid elimination also increases the margin of safety in case of intravenous injection of CO_2 . All these characteristics explain the rapid reversal of the clinical signs of CO_2 embolism with treatment. Consequently, the lethal dose of embolized CO_2 is approximately five times greater than that of air. [79]

The pathophysiology of gas embolism is also determined by the size of the bubbles and the rate of intravenous entry of the gas. [83] [84] During neurosurgery, the slow entrainment of small bubbles of air is more likely to result in air entrapment in the pulmonary vessels, whereas during laparoscopy, the rapid insufflation of gas under high pressure probably causes a "gas lock" in the vena cava and right atrium [75] ; obstruction to venous return with a fall in cardiac output or even circulatory collapse will result. Acute right ventricular hypertension may open the foramen ovale, which is patent in 20 to 30 percent of the population, [85] allowing paradoxic gas embolization of the cerebral and coronary beds. [72] [86] Paradoxic embolism, however, may occur without patent

foramen ovale. [87] [88] V_A/Q mismatching develops with increases in physiologic dead space and hypoxemia. CO_2 embolism does not produce bronchoconstriction or the changes in pulmonary compliance that accompany air embolism. [89] Increased airway pressure, however, has been reported during CO_2 embolism. [72]

The diagnosis of gas embolism depends on the detection of gas emboli in the right side of the heart or on recognition of the physiologic changes secondary to embolization. Early events, occurring with 0.5 mL/kg of air or less, include changes in Doppler sounds and increased mean pulmonary artery pressure when these monitors are used. When the size of the embolus increases (2 mL/kg of air), tachycardia, cardiac arrhythmias, hypotension, increased central venous pressure, alteration in heart tones (millwheel murmur), cyanosis, and electrocardiographic changes of right heart strain can develop; all these changes are rarely consistently positive. [90] Pulmonary edema can also be an early sign of gas embolism. [86] [91] Although transesophageal echocardiography, [83] esophageal [92] or precordial Doppler probes, [93] or pulmonary artery catheters [94] are the most sensitive means of detecting small quantities of gas before physiologic changes, the low incidence of gas embolism during laparoscopy precludes the routine use of such invasive or expensive monitors. [95] [96] Whereas pulse oximetry is helpful in recognizing hypoxemia, capnometry and capnography are more valuable in providing early diagnosis of gas embolism and determining the extent of the embolism. $P_{ET}CO_2$ decreases in the case of embolism due to the fall in cardiac output and the enlargement of the physiologic dead space. Consequently, Deltaa-$_{ET}CO_2$ will increase. Interestingly, CO_2 embolization may cause a biphasic change in $P_{ET}CO_2$. The decrease in $P_{ET}CO_2$ is preceded by an initial increase secondary to pulmonary excretion of the CO_2 , which has been absorbed into the blood. [72] [75] [84] Aspiration of gas or foamy blood from a central venous line will definitively establish the diagnosis. Routine preoperative insertion of a central venous line, however, does not appear justified for these procedures. [75]

Treatment of CO_2 embolism consists of immediate cessation of insufflation and release of pneumoperitoneum. The patient is placed in steep head-down and left lateral decubitus (Durant) position. The amount of gas that will advance through the right heart to the pulmonary circulation is less if the patient is in this position, as the buoyant foam will be displaced laterally and caudally away from the right ventricular outflow tract. [75] Discontinuing N_2O will allow ventilation with 100 percent O_2 to correct hypoxemia, and reduce the size of the gas embolus and its consequences. [84] Hyperventilation increases CO_2 excretion and is made necessary by the enlargement of the physiologic dead space. If these simple measures are not effective, a central venous or pulmonary artery catheter may be introduced for aspiration of the gas. Cardiopulmonary resuscitation must be initiated if necessary. External cardiac massage may be helpful in fragmenting CO_2 emboli into small bubbles. The high solubility of CO_2 in blood, resulting in rapid absorption from the blood stream, accounts for the rapid reversal of the clinical signs of CO_2 embolism with treatment. [75] [77] [95] CO_2 embolism, however, may be fatal. [71] [73] Cardiopulmonary bypass has been used successfully to treat massive CO_2 embolism. [72] Hyperbaric oxygen treatment should be strongly considered if cerebral gas embolism is suspected. [86]

Finally, air emboli have been reported during operative endoscopy using the Nd:YAG laser. [81] [97] [98] [99] The Nd:YAG laser is used with an artificial sapphire scalpel, which is protected from laser-induced thermal damage by cooling with a continuous flow of air, CO_2 , or N_2 . Inadvertent penetration of the sapphire tip into an abdominal viscus can result in air embolism. The anesthesiologist, therefore, should be aware of this possibility.

Risk of Aspiration

Patients undergoing laparoscopy might be considered to be at risk of developing the acid aspiration syndrome. [100] [101] However, the increased intra-abdominal pressure results in changes of the lower esophageal sphincter, which allow maintenance of the pressure gradient across the gastro-esophageal junction, and which might therefore reduce the risk of regurgitation. [102] [103] Furthermore, the head-down position should help to prevent any regurgitated fluid from entering the airway.

/das/book/view/29494766/875/617.html

HEMODYNAMIC PROBLEMS DURING LAPAROSCOPY

Hemodynamic changes observed during laparoscopy result from the combined effects of pneumoperitoneum, patient position, anesthesia, and hypercapnia secondary to the absorbed CO_2 . In addition to these pathophysiologic changes, reflex increases of vagal tone and arrhythmias can also develop.

Hemodynamic Repercussions of Pneumoperitoneum in Healthy Patients

Peritoneal insufflation to IAPs higher than 10 mm Hg induces significant alterations of hemodynamics. [104] [105] [106] These disturbances are characterized by decreases of cardiac output, elevations of arterial pressure, and increases of systemic and pulmonary vascular resistances. Heart rate either remains unchanged or increases only slightly. The decrease in cardiac output is proportional to the increase in IAP. [26] [107] Cardiac output has also been reported to be increased [30] [108] or unchanged during pneumoperitoneum. [109] [110] [111] These discrepancies might be due to differences in rates of CO_2 insufflation, IAP, steepness of patient tilt, time intervals between insufflation and collection of data, and techniques used to assess hemodynamics. However, recent studies have shown a fall of cardiac output (10 to 30 percent) during peritoneal insufflation whether the patient was placed in the head-down, [112] [113] [114] or head-up position. [114] [115] [116] These adverse hemodynamic effects of pneumoperitoneum have been confirmed by studies using pulmonary artery catheterization, [114] [115] thoracic electrical bioimpedance, [113] [116] esophageal echo-Doppler, [117] and transesophageal echocardiography. [118] [119] Normal intraoperative values of $Sv^{-}{}_{O_2}$ and lactate concentrations suggest that changes in cardiac output occurring

Figure 56-5 Schematic representation of the different mechanisms leading to decreased cardiac output during pneumoperitoneum for laparoscopy.

during pneumoperitoneum are well tolerated by healthy patients. [19] Cardiac output, which decreases shortly after the beginning of peritoneal insufflation, subsequently increases, probably as a result of surgical stress. Therefore, hemodynamic degradation occurs mainly at the beginning of peritoneal insufflation.

The mechanism of the decrease of cardiac output is probably multifactorial (Fig. 56-5) . A decrease in venous return is observed after a transient increase in venous return seen at low IAPs (<10 mm Hg). [26] [107] [120] [121] Indeed, increased IAP results in caval compression, [122] pooling of blood in the legs, [123] and an increase in venous resistance. [121] The decline in venous return, which parallels the decrease in cardiac output, [26] [107] is confirmed by a reduction in left ventricular end-diastolic volume measured using transesophageal echocardiography. [119] Cardiac filling pressures, however, rise during peritoneal insufflation. [22] [26] [114] [115] The paradoxic increase of these pressures can be explained by the increased intrathoracic pressure associated with pneumoperitoneum. [26] [124] [125] Therefore, right atrial pressure and pulmonary artery occlusion pressure can no longer be considered to be reliable indices of cardiac filling pressures during pneumoperitoneum. The fact that atrial natriuretic peptide concentrations remain low despite increased pulmonary capillary occlusion pressure during pneumoperitoneum further suggests that abdominal insufflation interferes with venous return. [114] The reduction in venous return and cardiac output can be attenuated by increasing circulating volume before the pneumoperitoneum (Fig. 56-6) . [121] [126] Increased filling pressures can be achieved by fluid loading and/or tilting the patient to a slight head-down position before peritoneal insufflation.

Although inotropism is difficult to assess, [118] the ejection fraction of the left ventricle assessed by echocardiography does not appear to decrease significantly when IAP increases to 15 mm Hg. [119] [127] On the other hand, all studies reported to date describe an increase in systemic vascular resistance during pneumoperitoneum. This increase in afterload cannot be considered simply to be a reflex sympathetic response to decreased cardiac output. [115] Indeed, systemic vascular resistance also increased in studies in which no decrease in cardiac output was reported. [110] [127] Whereas the normal heart tolerates increases in afterload under physiologic conditions, the changes in afterload produced by pneumoperitoneum can result in deleterious effects in patients with cardiac diseases and may lead to further decreases in cardiac output. [128] The increase in systemic vascular resistance is affected by patient position. Whereas the Trendelenburg position attenuates this increase, the head-up position aggravates it. [110] [111] [114] [129] Therefore, the patient's circulating volume affects not only changes in venous return, but also changes in afterload. The increase in systemic vascular resistance can be corrected by administra-tion of vasodilating anesthetic agents (isoflurane) [115] or direct vasodilating drugs, such as nitroglycerin [130] or nicardipine. [131]

The increase in systemic vascular resistance is considered to be mediated by mechanical as well as neurohumoral factors. [104] [113] [115] Indeed, the return of hemodynamic variables to baseline is gradual and takes several minutes, suggesting the involvement of neurohumoral factor(s). [22] [104] [113] [128] Catecholamines, the renin-angiotensin system, and especially vasopressin are all released during pneumoperitoneum and may contribute to increasing afterload. [114] [116] [125] [132] [133] [134] [135]

Figure 56-6 Changes in cardiac index and systemic vascular resistance during laparoscopy in two groups of patients. Group 1 (control; filled bar): pneumoperitoneum was induced with patients in 10-degree head-up position. Group 2 (volume loaded; empty bar): patients received 500 mL lactated Ringer's solution before anesthesia induction and were insufflated in the supine position. N = 10 in each group, data are mean ± SEM.

However, only the time course of vasopressin release parallels that of systemic vascular resistance. [116] [134] Increases in plasma vasopressin concentrations have been correlated with changes in intrathoracic pressure and transmural right atrial pressure. [125] Mechanical stimulation of peritoneal receptors also results in increased vasopressin release, [136] systemic vascular resistance, and arterial pressure. [137] However, whether increasing IAP to 14 mm Hg is sufficient to stimulate these receptors is unknown. The increase in systemic vascular resistance also explains why the arterial pressure increases, whereas the cardiac output falls. [104] [105] Use of $alpha_2$ -adrenergic agonists such as clonidine or dexmedetomidine significantly reduces both hemodynamic changes and anesthetic requirements. [134] [138] [139] [140]

Effect of Pneumoperitoneum on Regional Hemodynamics

Increased IAP and the head-up position result in lower limb venous stasis. [123] [141] [142] Femoral vein blood flow decreases progressively with increasing IAP and no adaptation to the reduced femoral venous outflow occurs, even during prolonged procedures. [142] These changes may predispose to the development of thromboembolic complications. Although cases of thromboembolism have been reported in the literature, their actual incidence does not seem to be increased by

laparoscopy. [143] [144]

The effect of CO_2 -pneumoperitoneum on renal function has also been investigated. [145] [146] [147] [148] Urine output, renal plasma flow, and glomerular filtration rate decrease to less than 50 percent of baseline values during laparoscopic cholecystectomy and are significantly lower than those during open cholecystectomy. [145] Urine output significantly increases after desufflation.

Controversy persists with regard to the effect of CO_2 -pneumoperitoneum on splanchnic blood flow. A significant reduction was reported in both animals [146] [149] [150] and humans. [151] However, others have not noted any significant changes. [152] [153] [154] [155] Blobner et al, [153] comparing CO_2 - and air-pneumoperitoneum in pigs, observed a reduction in splanchnic blood flow during air-, but not CO_2 -pneumoperitoneum. They suggest that the direct splanchnic vasodilating effect of CO_2 may counteract the mechanical effect of increased IAP. The rarity of reports of mesenteric ischemia following laparoscopy [156] [157] suggests that the effects of pneumoperitoneum on the splanchnic circulation are not clinically significant.

Cerebral blood flow velocity increases during CO_2 -pneumoperitoneum in response to the increased Pa_{CO_2} . [158] When normocarbia is maintained, pneumoperitoneum combined with the head-down position does not induce harmful changes in intracranial dynamics. [159] Intracranial pres- sure nevertheless rises during CO_2 -pneumoperitoneum, independently of changes in Pa_{CO_2} , in pigs with either preoperative induced intracranial hypertension or normal intracranial pressure, [160] [161] as well as in children with ventriculoperitoneal shunts. [162] Intraocular pressure is not affected by pneumoperitoneum in women with no preexisting eye disease. [163] In an animal model of glaucoma, pneumoperitoneum only slightly increases intraocular pressure. [164]

Hemodynamic Repercussions of Pneumoperitoneum in High-Risk Cardiac Patients

The demonstration of significant hemodynamic changes during pneumoperitoneum raises the question of tolerance of these changes by cardiac patients (Chs. 22 and 25) . In patients with mild to severe cardiac disease, the pattern of change in mean arterial pressure, cardiac output, and systemic vascular resistance is qualitatively similar to that in healthy patients. [128] [130] [165] [166] [167] [168] Quantitatively, these changes appear to be more marked. In a initial study including ASA III-IV patients, $Sv^{-}{}_{O_2}$ decreased in 50 percent of patients despite preoperative hemodynamic optimization using a pulmonary artery catheter. [165] Patients who experienced the most severe hemodynamic changes with inadequate O_2 delivery were patients with low preoperative cardiac output and central venous pressure, and high mean arterial pressure

and systemic vascular resistance (i.e., a profile suggesting depleted intravascular volume). The authors suggest preoperative preload augmentation to offset the hemodynamic effect of pneumoperitoneum. Intravenous nitroglycerin, nicardipine, or dobutamine has been used to manage the hemodynamic changes induced by increased IAP in selected patients with heart disease. [130] [131] [167] Nitroglycerin was chosen to correct the reduction in cardiac output associated with increased pulmonary capillary occlusion pressures and systemic vascular resistance. The administration of nicardipine may be more appropriate than that of nitroglycerin. As mentioned previously, right atrial and pulmonary capillary occlusion pressures are not reliable indices of cardiac filling pressure during pneumoperitoneum. Increased afterload is a major contributor to the altered hemodynamics seen during pneumoperitoneum in cardiac patients. Nicardipine acts selectively on arterial resistance vessels and does not compromise venous return. [169] Finally, this drug is beneficial in case of congestive heart failure. [170] [171] Because normalization of hemodynamic variables does not occur for at least 1 hour postoperatively in certain patients, [56] [128] [168] congestive heart failure can develop in the early postoperative period. Dhoste et al [172] did not observe impaired hemodynamics in elderly ASA III patients, but used low intraperitoneal pressure (10 mm Hg) and slow insufflation rates (1 L/min). Interestingly, the hemodynamic consequences of pneumoperitoneum are minor in heart transplant recipients with good ventricular function. [173] [174] Finally, we have successfully managed laparoscopic adrenalectomy in eight patients with pheochromocytoma using a continuous infusion of nicardipine. [175]

Cardiac Arrhythmias During Laparoscopy

Arrhythmias during laparoscopy may have several causes (Ch. 32).

Attention has been focused on hypercapnia developing during peritoneal insufflation of CO_2 in patients under anesthesia with spontaneous breathing. [176] [177] However, the responsibility of the raised Pa_{CO_2} for the arrhythmias occurring during laparoscopy was questioned. [31] Indeed, arrhythmias are not correlated with Pa_{CO_2} and may develop early during insufflation, when high Pa_{CO_2} is unlikely. [31]

Reflex increases of vagal tone may result from sudden stretching of the peritoneum. Bradycardia, cardiac arrhythmias, and even asystole can develop. Vagal stimulation will be accentuated if the level of anesthesia is too superficial or if the patient is taking beta-blocking drugs. Electrocoagulation of the fallopian tubes can stimulate a vagal reaction. [80] These events are easily and quickly reversible. Treatment consists of interruption of insufflation, atropine administration, and deepening of anesthesia after recovery of heart rate.

Cardiac irregularities most often occur early during insufflation, when pathophysiologic hemodynamic changes are the most intense. [31] [115] For this reason, arrhythmias may also reflect intolerance of these hemodynamic disturbances in patients with known or latent cardiac disease.

Finally, gas embolism can also result in cardiac arrhythmias.

PROBLEMS RELATED TO PATIENT POSITION

Patient positioning (Ch. 26) depends on the site of surgery; whereas head-down tilt is used for pelvic and inframesocolic surgery, the head-up position is preferred for supramesocolic surgery. In addition, the patient is often placed in the lithotomy position. These positions may be responsible for, or contribute to, the development of pathophysiologic changes or injury during laparoscopy. The steepness of the tilt requested directly affects the magnitude of these changes.

Cardiovascular Effects

In normotensive subjects, the head-down position results in an increase in central venous pressure and cardiac output. In fact, the baroreceptor reflex response to increased hydrostatic pressure consists of systemic vasodilation and bradycardia, which stabilizes the cardiovascular status. [178] Although these different reflexes may be impaired during general anesthesia, the hemodynamic changes induced by this position during laparoscopy remain insignificant. [110] [113] [114] [129] However, central blood volume and pressure changes are greater in patients with coronary artery disease, particularly with poor ventricular function, leading to potentially deleterious increased myocardial oxygen demand. [52] The Trendelenburg position may also affect the cerebral circulation, particularly in case of low intracranial compliance, [161] and result in elevation of the intraocular venous pressure (which can worsen acute glaucoma). [164] Although the intravascular pressure increases in the upper torso, the head-down position decreases transmural pressures in the pelvic viscera, reducing blood loss, but increasing the risk of gas embolism. [52]

As concerns the head-up position, a decrease in cardiac output and mean arterial pressure is observed secondary to the reduction in venous return. [110] [114] [115] [129] This decrease in cardiac output compounds the hemodynamic changes induced by pneumoperitoneum. The steeper the tilt, the greater the fall in cardiac output.

Venous stasis in the legs occurs during the head-up position and may be aggravated by the lithotomy position with knees flexed. [52] Because pneumoperitoneum further increases blood pooling in the legs, [123] [141] [142] any additional factor contributing to circulatory dysfunction should be avoided. The legs must be freely supported and not tightly strapped, and pressure on the popliteal space must be prevented.

Respiratory Changes

The head-down position facilitates the development of atelectasis. Steep head-down tilt results in decreased functional residual capacity, total lung volume, and pulmonary compliance. It should be noted that these changes are more marked in obese, elderly, or debilitated patients. In healthy patients no major changes are seen. [52] The head-up position is usually considered to be more favorable to respiration. [52] [179] Changes in patient position during laparoscopy

induce only minimal alterations in gas exchange [22] [25] [25] [28] [29] and thoracopulmonary compliance. [14] [15]

Nerve Injury

Nerve compression is a potential complication during the head-down position. Overextension of the arm must be avoided. Shoulder braces should be used with great caution and must not impinge on the brachial plexus. Lower extremity neuropathies (peroneal neuropathy, meralgia paresthetica, femoral neuropathy) have been reported after laparoscopy. [180] [181] The common peroneal nerve is particularly vulnerable and must be protected when the patient is placed in the lithotomy position. Prolonged lithotomy position, such as required for some operative laparoscopies, can result in lower extremity compartment syndrome. [182] [183]

POSTOPERATIVE BENEFITS AND CONSEQUENCES OF LAPAROSCOPY

Implicit in the decision to use the laparoscopic approach is the assumption that the intraoperative consequences of pneumoperitoneum described in the previous sections are counterbalanced by multiple postoperative benefits. In contrast to laparotomy, improved and more rapid recovery, reduced postoperative fatigue, [184] [185] and a heightened feeling of well-being are commonly reported and reflect better maintenance of homeostasis. [3] [185]

Stress Response

In patients undergoing cholecystectomy, the laparoscopic approach allows for a reduction of the acute phase reaction seen after open cholecystectomy. Plasma concentrations of C-reactive protein and interleukin-6, which reflect the extent of tissue damage, are significantly lower after laparoscopy as compared with laparotomy. [3] [185] [186] [187] [188] The metabolic response (hyperglycemia, leucocytosis) is also reduced after laparoscopy. As a consequence, nitrogen balance and immune function might be better preserved. [189] [190] [191] [192] Laparoscopy avoids prolonged exposure and manipulation of the intestines and decreases the need for peritoneal incision and trauma. Consequently, postoperative ileus and fasting, duration of intravenous infusion, and hospital stay are significantly reduced after laparos-copy. [186] [192] [193] [194] [2] [3] The economic implications of these factors are self-evident and beneficial. [195] [196] [197]

Surprisingly, whereas laparoscopy allows for a reduction of surgical trauma, the endocrine response to laparoscopic and open cholecystectomy does not differ significantly; plasma concentrations of cortisol and catecholamines, [3] [185] [198] [199] urinary concentrations of cortisol and catecholamine metabolites, [186] and anesthetic requirements [3] are similar after both procedures. Combined general and epidural anesthesia for laparoscopic cholecystectomy does not result in a decreased stress response compared with general anesthesia alone. [198] Several hypotheses might be invoked to explain these observations. Pain and discomfort secondary to peritoneal stretching, hemodynamic disturbances, and ventilatory changes induced by pneumoperitoneum might contribute to the stress response of laparoscopy. Whereas parietal afference, which is markedly reduced by laparoscopy, appears to be an important stimulus for postoperative hyperglycemia, visceral nociception, less affected by laparoscopy, might contribute more to the adrenocortical stimulation. [185] The intraoperative stress response, however, can be reduced by preoperative administration of alpha$_2$ -agonists. [134] [138] [139] [140]

Postoperative Pain

Surgical trauma contributes to pain and pulmonary dysfunction. Laparoscopy allows a significant reduction in postoperative pain and analgesic consumption (Ch. 69) . [3] [186] [198] [200] [201] [202] [203] [204] [205] [206] Nevertheless, pain intensity may be significant. [207] [208] The nature of pain varies depending on the surgical technique; after laparotomy, patients complain more of parietal pain (abdominal wall), whereas after laparoscopic cholecystectomy, patients report visceral pain (biliary colic [cholecystectomy], pelvic spasm [tubal ligation]), and shoulder-tip pain resulting from diaphragmatic irritation). [3] [208] Neck and shoulder pain is reported by 80 percent of patients at 24 hours, and by as many as 50 percent at 48 hours. [209] CO_2 insufflation induces more discomfort than use of N_2O as insufflating gas. [210] Different treatments have been proposed to provide pain relief. Topical anesthesia [211] [212] or infiltration of the fallopian tubes decreases postoperative pain and analgesic consumption after laparoscopic sterilization. [213] Intraperitoneal administration of local anesthetic (80 mL of 0.5% lidocaine or 0.125% bupivacaine with epinephrine) in the right subdiaphragmatic area reduces shoulder pain and analgesic requirements after minor gynecologic laparoscopy, [214] [215] but not after laparoscopic cholecystectomy. [208] [216] [217] [218] Residual CO_2 -pneumoperitoneum contributes to postoperative pain. Careful evacuation of residual CO_2 after desufflation was also shown to be effective. [219] [220] [221] Thoracic epidural analgesia significantly decreases postoperative pain, but only during the first 24 hours. [198] The performance of bilateral rectus sheath block for diagnostic laparoscopy leads to the same benefits. [222] Preoperative administration of nonsteroidal anti-inflammatory drugs (NSAID) decreases pain and opiate consumption after gynecologic laparoscopy [223] [224] [225] [226] and laparoscopic cholecystectomy. [227] [228] However, others have failed to demonstrate any significant effect of preoperative NSAID on pain after laparoscopic sterilization more severe than after diagnostic gynecologic laparoscopy. [229] [230] [231] [232] Preoperative multimodal analgesia is also effective in reducing postoperative pain. [233] [234]

Pulmonary Dysfunction

Upper abdominal surgery results in postoperative changes in pulmonary function. Respiratory dysfunction is less severe and recovery is quicker after laparos-copy. [3] [104] [198] [200] [201] [235] [236] [237] [238] Diaphragmatic function remains, nevertheless, significantly impaired after laparoscopy. [239] [240] [241] [242] Thoracic epidural analgesia does not improve lung function after laparoscopic cholecystectomy. [198]

Greater reductions in expiratory volumes and slower recovery of pulmonary function after laparoscopy are reported in older, [243] obese, [204] [244] smokers, and patients with COPD [244] than in healthy patients. Postoperative pulmonary function of these patients, however, is improved after laparoscopy as compared with laparotomy. [204] [244] Post-operative pulmonary function is less impaired after gynecologic laparoscopy than after upper abdominal laparoscopic surgery. [245]

Postoperative Nausea and Vomiting

Laparoscopy also carries a high incidence of minor postoperative sequelae (Ch. 65) , which can persist more than 48 hours, and which can significantly delay discharge of outpatients. [209] In addition to postoperative pain of various types, the most frequent complaints are headache, sore throat (in case of endotracheal intubation), and, more particularly, nausea and vomiting. Postoperative nausea and vomiting is one of the main complaints after laparoscopy (in 40 to 75% of patients), [209] [246] [247] [248] [249] [250] and the most important factor determining the length of stay after ambulatory anesthesia. [251] Whereas intraoperative opioids increase the incidence of nausea and vomiting, [252] [253] propofol anesthesia can markedly reduce the high incidence of these side effects. [247] [251] The effect of N_2O on the incidence of nausea is still controversial. [254] [255] [256] [257] [258] [259] Drainage of gastric contents also reduces nausea and vomiting. [260] Intraoperative administration of droperidol and more recently the use of ondansetron appear to be helpful in the prevention and treatment of these side effects. [261] [262] [263] [264] [265] Transdermal scopolamine reduces nausea and vomiting after outpatient laparoscopy. [248] Finally, analgesic techniques that allow reductions of opioid consumption can contribute to decreasing these symptoms. [212] [266]

ALTERNATIVES TO CO_2 -PNEUMOPERITONEUM

New approaches are currently under investigation to reduce pathophysiologic consequences of CO_2 -pneumoperitoneum.

Inert Gases

Insufflation of inert gas (helium, argon) instead of CO_2 avoids the increase in Pa_{CO_2} secondary to absorption. Consequently, hyperventilation is not required. [42] [43] [44] [45] [267] On the other hand, the ventilatory consequences of the increased IAP persist. The hemodynamic changes produced by pneumoperitoneum using inert gas are similar to those observed with CO_2 . However, the use of these gases accentuates the decrease in cardiac output, whereas the increase in arterial pressure is attenuated. [44] [45] [268] Therefore, peritoneal insufflation of CO_2 , even in the absence of hypercapnia, apparently stimulates the cardiovascular system and subsequently partially corrects the hemodynamic repercussions due to increased IAP. [104] Unfortunately, the low blood solubility of the inert gases raises the issue of safety in the event of gas embolism. [269] [270]

Gasless Laparoscopy

Another alternative is gasless laparoscopy. The peritoneal cavity is expanded using abdominal wall lift obtained with a fan retractor. This technique avoids the hemodynamic and respiratory repercussions of increased IAP as well as the consequences of the use of CO_2 . [271] [272] [273] [274] [275] Renal and splanchnic perfusion is not altered. [148] [151] [276] Postoperative pain, nausea, and vomiting are reduced after cholecystectomy, [271] but not after gynecologic laparoscopy. [277] [278] Port-site metastases following laparoscopic surgery for cancer are also reduced after gasless laparoscopy. [279] [280] This technique, therefore, is appealing for patients with severe cardiac or pulmonary disease. However, gasless laparoscopy compromises surgical exposure and increases technical difficulty. [273] [277] [278] Combining abdominal wall lifting with low pressure CO_2 -pneumoperitoneum (5 mm Hg) might improve surgical conditions.

LAPAROSCOPY DURING PREGNANCY AND IN CHILDREN

The most common nonobstetric surgical procedures during pregnancy are appendectomy and cholecystectomy, both amenable to laparoscopic surgery (Chs. 57 and 59) . Laparoscopy during pregnancy raises several concerns. Abdominal surgery increases the risk of miscarriage or premature labor. However, all the reports in the literature of laparoscopy carried out between 4 and 32 weeks of estimated gestational age have resulted in uncomplicated pregnancies. [281] Another concern is the risk of damaging the gravid uterus. This can be avoided by alternative entry sites for the Verres needle and trocars. The effects of increased IAP and hypercarbia on the human fetus were also investigated. CO_2 -pneumoperitoneum induced significant fetal acidosis. Fetal heart rate and arterial pressure increased, but these changes were minimal. [282] All these alterations resulted from hypercarbia, and not from increased IAP, as N_2O-pneumoperitoneum did not affect blood-gas values, heart rate, or blood pressure. After desufflation, all variables quickly returned to normal. [282] Provided maternal Pa CO_2 is maintained at normal levels, fetal placental perfusion pressure and blood flow, pH, and blood gas tensions were unaffected by insufflation or desufflation. [283] Recommendations for safe laparoscopy in pregnant patients are the following [281] :

1. Operation should occur during the second trimester, ideally before the 23rd week of pregnancy, to minimize the risk of preterm labor and to maintain adequate intra-abdominal working room.
2. Tocolytics are beneficial to arrest preterm labor, but their prophylactic use is debatable.
3. Open laparoscopy should be used for abdominal access to avoid damaging the uterus.
4. Fetal monitoring may be performed using transvaginal ultrasonography.
5. Mechanical ventilation must be adjusted to maintain a physiologic maternal alkalosis.

Gasless laparoscopy is an alternative to avoid the potential side effects of CO_2 -pneumoperitoneum, and can sometimes be managed using epidural anesthesia. [284] [285]

2014

Laparoscopy is now frequently performed in infants and children. However, only few data concerning the hemodynamic and ventilatory tolerance of pneumoperitoneum by children are available. The hemodynamic changes observed in piglets are similar to those reported in adults. [286] [287] [288] In this animal model, Pa CO_2 increases and plateaus within 15 minutes as a result of CO_2 absorption from the peritoneal cavity. This absorption may be more intense and faster in infants than in adults because the peritoneal surface area referred to body weight is greater in infants. [287] [289] Accordingly, in young swine, intraperitoneal CO_2 insufflation produces marked acidemia, hypercapnia, and decreased oxygenation. [286] However, during brief laparoscopy (less than 15 minutes), peak airway pressure and $P_{ET}CO_2$ rise only slightly; no increase in ventilation is required. [290] Good cardiorespiratory tolerance of laparoscopic fundoplication has been reported in children, provided that hypovolemia is prevented. [291] Controversy concerning the use of laparoscopy for appendectomy, the most frequent indication for laparoscopy in children, persists. In a recent randomized study, laparoscopy did not improve analgesia or postoperative recovery after appendectomy. [292]

COMPLICATIONS OF LAPAROSCOPY

With the development of more sophisticated endoscopic operations, it is important to consider the risks and benefits of laparoscopy. Whereas the benefits of the laparoscopic approach are well documented, knowledge of the incidence of complications is more imprecise and is frequently based on retrospective studies.

The experience of gynecologic laparoscopists extends over a relatively long time and, as a result, large surveys are available. [293] [294] [295] [296] Mortality rates have varied from 1 per 10,000 to 1 per 100,000 cases. The number of serious complications requiring laparotomy was 2 to 10 per 1,000 cases. Intestinal injuries accounted for 30 to 50 percent of these, and remained undiagnosed during laparoscopy in half of the cases. Vascular complications also accounted for 30 to 50 percent. Burns were responsible for 15 to 20 percent of the reported complications. Whereas the death rate decreased, the complication rate was noted to be slightly higher in the most recent surveys, probably because of the increased complexity of the laparoscopies performed over the last few years.

Although the introduction of laparoscopic cholecystectomy is relatively recent (1989), large surveys are already available. [196] [297] [298] [299] [300] The overall mortality rate is approximately 0.1 to 1 per 1,000 cases. Conversion to laparotomy was necessary in approximately 1 percent of patients. Bowel perforation occurred in about 2 per 1,000 cases, common bile duct injury in 2 to 6 per 1,000 cases, and significant hemorrhage in 2 to 9 per 1,000 cases. Laparoscopic cholecystectomy was accompanied by a greater frequency of minor operative complications, whereas open cholecystectomy had a higher rate of minor general complications. A learning curve was demonstrated for laparoscopic cholecystectomy; experience was associated with decreased operative times and rates of minor or moderate complications. Some of these complications might be prevented by open laparoscopy. [301]

Whereas large vessel injury (aorta, inferior vena cava, iliac vessels) obviously caused emergency situations, retroperitoneal hematoma can develop insidiously and result in significant blood loss without major intraperitoneal effusion, leading to delayed diagnosis. During gynecologic laparoscopy, complications occur more frequently during the creation of pneumoperitoneum and the introduction of trocars, whereas during gastrointestinal surgery they are more closely related to the surgical procedure itself. [196] [302] [303] Injuries provoked by the Verres needle are usually less severe than those by trocars and may even remain undiagnosed. Unrecognized gastrointestinal tract injury and subhepatic abscess formation can lead to potentially lethal septic complications. [304] Although all these events are surgery related, the anesthesiologist must be aware of both the complications and timing of their occurrence. He or she must be ready to respond promptly and adequately to these mishaps and to help the surgeon diagnose a complication.

ANESTHESIA FOR LAPAROSCOPY

Preoperative Evaluation of the Patient and Premedication

Without regard to surgical contraindications, absolute contraindications to laparoscopy and pneumoperitoneum are rare, and certain still require characterization (Ch. 23) . Pneumoperitoneum is undesirable in patients with increased intracranial pressure (tumor, hydrocephalus, head trauma), hypovolemia, ventricular peritoneal shunt, [162] and peritoneojugular shunt. Pneumoperitoneum, however, can be performed safely in patients with these shunts, provided the shunt has been clamped before peritoneal insufflation. [305] In case of glaucoma, the effects on intraocular pressure do not seem to be clinically significant, but deserve further confirmation. Gasless laparoscopy may be a safe alternative to laparoscopy with pneumoperitoneum for all these cases.

In patients with heart disease, cardiac function should be evaluated in light of the hemodynamic changes induced by pneumoperitoneum and patient position, particularly in case of compromised ventricular function (Table 56-2) . Over the last 4 years, patients with progressively more severe cardiac disease have safely undergone laparoscopy because of the improved knowledge of the cardiovascular repercussions of laparoscopy. Patients with severe congestive heart failure and terminal valvular insufficiency are certainly more prone to develop cardiac complications than patients with ischemic cardiac disease during laparoscopy. Whether laparoscopy is more dangerous than laparotomy in these patients has not yet been explored directly, but deserves careful consideration. For these patients, the postoperative benefits of laparoscopy must be balanced against the intraoperative risks when the choice of laparoscopy versus laparotomy is discussed (Table 56-3) . Gasless laparoscopy may represent an alternative for these patients.

Because of the side effects of increased IAP on renal function, patients with renal failure deserve special care to optimize hemodynamics during pneumoperitoneum, and the concomitant use of nephrotoxic drugs should be avoided.

TABLE 56-2 -- Management of Patients With Cardiac Disease for Laparoscopy

Preoperative evaluation: echocardiography
If left ventricular ejection fraction <30%
Intraoperative monitoring
Intra-arterial line
Pulmonary artery catheter
Transesophageal echocardiography?
Continuous ST segment analysis?
Gasless laparoscopy?
Laparotomy?
Intraoperative management
Slow insufflation
Low intra-abdominal pressure
Hemodynamic optimization before pneumoperitoneum (preload augmentation)
Patient tilt after insufflation
Anesthesia: isoflurane vasodilating drugs (nicardipine, nitroglycerin) cardiotonic agents
Experienced surgeon
Postoperative care
Slow recovery from anesthesia (benefit of clonidine)

In patients with respiratory disease, laparoscopy appears preferable to laparotomy because of reduced postoperative respiratory dysfunction. This positive effect counterbalances the risk of pneumothorax during pneumoperitoneum and the risk of inadequate gas exchange secondary to V_A/Q mismatching.

Because of venous stasis in the legs during laparoscopy, prophylaxis of deep vein thrombosis should be initiated before surgery, as for laparotomy.

Premedication should be adapted to the duration of the laparoscopy and to the necessity for quick recovery in the outpatient setting. Preoperative administration of NSAIDs may be helpful in reducing postoperative pain and opiate requirements. Finally, preoperative clonidine and dexmedetomidine decrease the intraoperative stress response and improve hemodynamic stability. [134] [138] [139] [140]

Patient Positioning and Monitoring for Laparoscopy

Patients must be positioned (Ch. 26) with great care to prevent nerve injuries; padding should protect from nerve compression, and shoulder braces, if needed, should be placed overlying the coracoid process. Patient tilt should be reduced as much as possible and should not exceed 15 to 20 degrees. Tilting must be slow and progressive to avoid sudden hemodynamic and respiratory changes. The position of the endotracheal tube must be checked after any change in patient position. Induction and release of the pneumoperitoneum must be smooth and progressive. Mask ventilation before intubation can inflate the stomach with gas, which must be aspirated before trocar placement to avoid gastric perforation, particularly for supramesocolic laparoscopy. The bladder should be emptied before pelvic laparoscopy or prolonged procedures.

During laparoscopy, arterial blood pressure, heart rate, electrocardiogram, capnometry, and pulse oximetry must be continuously monitored. Although this level of

monitoring is valuable for detection of cardiac arrhythmias, gas embolism, CO_2-subcutaneous emphysema, and pneumothorax, it provides only indirect evidence of the hemodynamic changes induced by the pneumoperitoneum. Although more invasive

hemodynamic monitoring may be necessary in patients with cardiac diseases, increased intrathoracic pressure complicates the interpretation of measured central venous and pulmonary artery pressures. Transesophageal echocardiography might be more helpful in patients with severe cardiac disease (see Table 56-2) . $P_{ET}CO_2$ and Sp_{O_2} reliably reflect Pa_{CO_2} and Sa_{O_2} . However, we must keep in mind that the Deltaa-$_{ET}CO_2$ may vary from patient to patient, and during the course of laparoscopy in the same patient. $P_{ET}CO_2$ must be monitored carefully to avoid hypercapnia and to detect gas embolism. Because Deltaa-$_{ET}CO_2$ may increase more in patients with cardiac and pulmonary diseases, cannulation of a radial artery is helpful to allow direct measurement of Pa_{CO_2} from an arterial blood sample.

Anesthetic Techniques

General, local, and regional anesthesia have been used successfully and safely for laparoscopy.

General Anesthesia

General anesthesia with endotracheal intubation and controlled ventilation is certainly the safest technique and, therefore, is recommended for inpatients and for long laparoscopic procedures. During pneumoperitoneum, controlled ventilation must be adjusted to maintain $P_{ET}CO_2$ at approximately 35 mm Hg. In our experience, this requires no more than a 15 to 25 percent increase of minute ventilation, except when CO_2-subcutaneous emphysema develops. Increase of respiratory rate rather than of tidal volume might be preferable in patients with COPD, and in patients with a history of spontaneous pneumothorax or bullous emphysema to avoid increased alveolar inflation and reduce the risk of pneumothorax. Anesthetic agents that directly depress the heart should be avoided in patients with compromised cardiac function in favor of anesthetics with vasodilating properties such as isoflurane (see Table 56-2) . [115] Infusion of vasodilating agents, such as nicardipine, reduces the hemodynamic repercussions of pneumoperitoneum and might facilitate management of cardiac patients. [131] Nitrous oxide has been suspected to affect oocyte function. The success rate of *in vitro* fertilization, however, is not decreased by use of N_2O. [306] The contribution of N_2O to nausea and vomiting is still controversial. [254] [257] [258] There is apparently no clinical advantage to omitting nitrous oxide. [307] Whereas N_2O does not seem to be contraindicated for laparoscopic cholecystectomy, [259] omission of N_2O improves surgical conditions for intestinal and colonic surgery. The choice of anesthetic technique does not seem to play a major role in patient outcome. [307] [308] [309] Propofol, nevertheless, results in fewer postoperative side effects. [247] [310] [311] [312] Propofol anesthesia for laparoscopic pronuclear stage transfer, however, is associated with lower clinical and ongoing pregnancy rates compared with isoflurane. [313] IAP should be monitored, kept as low as possible to reduce hemodynamic and respiratory changes, and not allowed to exceed 20 mm Hg. Increases in IAP can be avoided by ensuring a deep plane of anesthesia. Whether profound muscle relaxation is necessary for lap-aroscopy is not clear. [314] [315] Because of the potential for reflex increases of vagal tone during laparoscopy, atropine should be administered before the induction of anesthesia, or should be available for injection if necessary.

The laryngeal mask airway results in less sore throat and might be proposed as an alternative to endotracheal intubation, [316] [317] [318] [319] [320] even if this device does not protect the airway from aspiration of gastric contents. [318] [321] Indeed, it allows controlled ventilation and accurate monitoring of $P_{ET}CO_2$. However, decreased thoracopulmonary compliance during pneumoperitoneum frequently results in airway pressures exceeding 20 cm H_2O. Because the laryngeal mask airway cannot guarantee an airway seal above this pressure, its use for controlled ventilation should be limited to healthy, thin patients.

General anesthesia in patients breathing spontaneously without intubation can be performed safely and avoids tracheal irritation as well as administration of muscle relaxant. [320] [322] However, a report from the Centers for Disease Control revealed that almost one third of deaths associated with laparoscopic procedures were related to anesthetic complications during general anesthesia without intuba-tion. [323] This anesthetic technique should thus be restricted to short procedures performed using low IAP and small degrees of tilt. [33] In these cases, the laryngeal mask airway might improve the safety of anesthesia for laparoscopy in patients breathing spontaneously [316] [320] [324] and is therefore recommended.

Local and Regional Anesthesia

Local anesthesia offers several advantages: quicker recovery, decreased postoperative nausea and vomiting, early diagnosis of complications, and fewer hemodynamic changes. [325] [326] [327] Sequelae of general anesthesia such as sore throat, muscle pain, and airway trauma can be avoided. However, this anesthetic approach requires precise and gentle surgical technique, and may result in increased patient anxiety, pain, and discomfort during the manipulation of pelvic and abdominal organs. For these reasons, local anesthesia is routinely supplemented with intravenous sedation. The combined effect of pneumoperitoneum and sedation can lead to hypoventilation and arterial oxygen desaturation. [328] Success with local anesthesia requires a relaxed and cooperative patient, a supportive operating room staff, and a skilled surgeon. IAP should be as low as possible to reduce pain and ventilatory disturbances. Although laparoscopic tubal ligation might be a good

indication for local anesthesia, multiple constraints explain the lack of enthusiasm of gynecologic laparoscopists for this anesthetic technique. [58] Any other laparoscopic procedure that requires multiple puncture sites, considerable organ manipulation, steep tilt, and voluminous pneumoperitoneum makes spontaneous breathing difficult for the patient, results in discomfort, and must not be managed with local anesthesia. [58]

Regional anesthesia, including epidural and spinal techniques, combined with the head-down position, can be used for gynecologic laparoscopy without major impairment of ventilation. [29] [329] The metabolic response is reduced by regional anesthesia. [330] Globally, epidural and local anesthesia share the same benefits and disadvantages. [56] [329] [331] Regional anesthesia has the advantages of reducing the need

---

for sedatives and narcotics, produces better muscle relaxation and can be proposed for laparoscopic procedures other than sterilization. Shoulder-tip pain secondary to diaphragmatic irritation and discomfort secondary to abdominal distention are incompletely alleviated using epidural anesthesia alone. [331] [332] Extensive sensory block (T4-L5) is necessary for surgical laparoscopy and may also lead to discomfort. The epidural administration of opiates and/or clonidine might help to provide adequate analgesia. [331] The hemodynamic effects of pneumoperitoneum under epidural anesthesia have not been studied. Although sympathetic block might facilitate the development of vagal reflexes, vasodilation and the avoidance of positive pressure ventilation might reduce the cardiovascular changes described during pneumoperitoneum. Once again, patient cooperation, an experienced and skilled laparoscopist, reduced IAP, and tilt are necessary to guarantee the success of epidural anesthesia, which should be avoided for long procedures. Regional anesthesia can provide adequate relief of pain and discomfort in case of gasless laparoscopy, thus avoiding most of the side effects of CO_2 -pneumoperitoneum. [285] [333] [334] Also see chapters 42 and 43 .

Recovery and Postoperative Monitoring

Hemodynamic monitoring should be continued in the postanesthesia care unit (Ch. 68) . Indeed, hemodynamic changes induced by the pneumoperitoneum, and more particularly the increased systemic vascular resistance, outlast the release of the pneumoperitoneum. The hyperdynamic state developing after laparoscopy could conceivably lead to a precarious hemodynamic situation in patients with cardiac disease. [128] [168]

Despite the reduction in postoperative pulmonary dysfunction, Pa_{O_2} still decreases after laparoscopic cholecystectomy. [3] [200] [237] Furthermore, increased O_2 demand is observed after laparoscopy. [19] Although laparoscopy tends to be considered a minor surgical procedure, O_2 should be administered postoperatively, even to healthy patients. [335] During the early postoperative period, respiratory rate and $P_{ET}CO_2$ of patients breathing spontaneously are higher after lap-aroscopy as compared with open surgery. [40]

Finally, prevention and treatment of nausea, vomiting, and pain are important, particularly after outpatient laparoscopic procedures. This issue has been addressed previously.

SUMMARY

Laparoscopy results in multiple postoperative benefits including less trauma, less pain, less pulmonary dysfunction, quicker recovery, and shorter hospital stay. These advantages are regularly emphasized and explain the increasing success of laparoscopy, which is now proposed for many surgical procedures. Intraoperative cardiorespiratory changes occur during pneumoperitoneum. Pa co_2 increases due to CO_2 absorption from the peritoneal cavity. In compromised patients, cardiorespiratory disturbances aggravate this increase in Pa co_2 . Hemodynamic changes are accentuated in high-risk cardiac patients. Improved knowledge of the pathophysiologic hemodynamic changes in healthy patients allows for successful anesthetic management of cardiac patients, by optimizing preload before pneumoperitoneum and through judicious use of vasodilating agents. Alternative insufflating gases (He, Ar, N_2O) do not seem to reduce the hemodynamic changes. Gasless laparoscopy may be more helpful, but unfortunately increases technical difficulty. The incidence of complications has now been reported in several large surveys and compares favorably to that of open surgery. The death rate during operative laparoscopy is approximately 0.1 to 1 per 1,000 cases; the incidence of both hemorrhagic complications and visceral injury is 2 to 5 per 1,000 cases. Whereas no anesthetic technique has proved to be clinically superior to any other, general anesthesia with controlled ventilation seems to be the safest technique for operative laparoscopy. Improved knowledge of the intraoperative repercussions of laparoscopy permits safe management of patients with more and more severe cardiorespiratory disease, who may subsequently benefit from the multiple postoperative advantages offered by this approach.

Chapter 57 - Anesthesia for Obstetrics [*]

Beth Glosten

INTRODUCTION

Important issues when anesthetizing the pregnant woman for labor, vaginal delivery, or cesarean delivery include the physiologic changes of pregnancy, the direct and indirect effects of anesthetics on the fetus and neonate, and the benefits and risks of various anesthetic techniques to the mother. In choosing appropriate anesthetic techniques, the anesthetist must consider any medical or obstetric complications, obstetric requirements, the patient's wishes, and the anesthesiologist's judgment.

PHYSIOLOGIC CHANGES IN THE MOTHER DURING PREGNANCY

Respiratory Changes

The most notable change in maternal lung capacities and volumes occurs in functional residual capacity, which decreases 15 to 20 percent by term (Table 57-1) . [1] [2] [3] [4] [5] Vital capacity remains essentially unchanged throughout pregnancy. The transverse and anteroposterior diameter of the chest increases to compensate for the elevation of the diaphragm from the gravid uterus. The diaphragm moves freely at term; however, as pregnancy progresses, abdominal breathing decreases in favor of thoracic breathing. Measurements of closing volume confirm that in the supine position, one-third of parturients have airway closure during normal tidal ventilation [4] [6] and are therefore at risk for developing atelectasis and an increased oxygen alveolar-arterial gradient. [7] Flow-volume loops, timed forced expiratory volume, and other indicators of respiratory flow during pregnancy do not differ much from their counterparts in nonpregnant women. [3] [5] In addition, diffusing capacity decreases only slightly. [5]

Oxygen uptake increases about 20 percent during pregnancy, owing to increased maternal metabolism and work of breathing and fetal metabolism. [8] [9] Minute ventilation at term is increased about 50 percent, [1] mostly as a result of increased tidal volume, with only a slight increase in respiratory rate. As a result of increased alveolar ventilation at term, arterial carbon dioxide pressure usually decreases to about 32 mm Hg, but arterial pH remains normal because of a compensatory decrease in serum bicarbonate (from 26 to 22 mEq/L) (see Table 57-1 ; Fig. 57-1) (Figure Not Available) . Partial pressure of arterial oxygen is slightly increased from the increased minute ventilation. The oxyhemoglobin dissociation curve shifts to the right during normal pregnancy (increased P50) (Table 57-2) (Table Not Available) , [10] allowing a greater volume of oxygen to be unloaded to the tissues (fetus) at a given arterial oxygen pressure.

This chapter is dedicated to the memory of Sol M. Shnider, who was the senior author of this chapter in all previous editions.

**See Appendix 1, Practice Guidelines for Obstetrical Anesthesia*

TABLE 57-1 -- Maternal Respiratory Changes at Term

VARIABLE	AVERAGE CHANGE
Volumes and capacities	
Total lung capacity	0 to -5%
Inspiratory lung capacity	+5%
Functional residual capacity	-20%
Expiratory reserve volume	-20%
Residual volume	-20%
Vital capacity	No change
Closing volume	No change
Mechanics	
Minute ventilation	+50%
Alveolar ventilation	+70%
Tidal volume	+40%
Respiratory rate	+15%
Dead space	No change
Airway resistance	-36%
Total pulmonary resistance	-50%
Total compliance	-30%
Lung compliance (alone)	No change
Chest-wall compliance (alone)	-45%
FEV_1	No change
Diffusing capacity	-5%
Blood gases	
Arterial P_{CO_2}	-10 mm Hg
Serum bicarbonate	-4 mEq/L
Arterial pH	No change
Arterial P_{O_2}	+10 mm Hg
Oxygen consumption	+20%

During labor, particularly in the late first stage and second stage, the pain from episodic uterine contractions produces corresponding increases in maternal minute ventilation (as much as 300% over that of nonpregnant women) and oxygen consumption. Maternal hypocarbia (arterial carbon dioxide pressure = 20 mm Hg or less), and alkalemia (pH 7.55) results. Hypocarbia can lead to hypoventilation between uterine contractions, resulting in intermittent hypoxemia (particularly in obese patients or those who have received par- enteral opioids) (Fig. 57-2) . Epidural analgesia eliminates these pain-induced increases in oxygen consumption and

Figure 57-1 (Figure Not Available) Progressive changes of alveolar carbon dioxide tensions, pH, alkali reserve throughout pregnancy. *(From Bonica [424])*

TABLE 57-2 -- P50 Values of Nonpregnant, Pregnant, and Preeclamptic Subjects

(Not Available)

From Kambam et al [10]

minute ventilation and the accompanying hyperventilation-hypoventilation cycle (see Fig. 57-2) . [11]

The respiratory and pulmonary changes of pregnancy have notable clinical effects. First, reduced oxygen stores (low functional residual capacity) and increased oxygen consumption lead to pregnant patients' having a much greater and more rapid decline in partial pressure of arterial oxygen when rendered apneic as compared with nonpregnant women. [12] This rapid development of hypoxia can be avoided by administering 100 percent oxygen before induction of anesthesia. In addition, these changes increase the rate at which inhalation anesthesia is induced.

During pregnancy, capillary engorgement of the mucosa occurs throughout the respiratory tract, potentially causing edema in the nasopharynx, oropharynx, larynx, and trachea. Therefore, manipulation of the upper airway requires extreme care. Suctioning of the oropharynx, insertion of airways, and laryngoscopy may cause further edema and bleeding. Because the area of false cords may be swollen, a small, cuffed endotracheal tube (6.5-7.0 mm) is recommended for use when the trachea is intubated. Repeated attempts at laryngoscopy during management of a difficult airway must be minimized to prevent obstructing airway edema.

Cardiovascular Changes

The cardiovascular system is progressively stressed during pregnancy and parturition (Table 57-3 , Figs. 57-3 (Figure Not Available) and 57-4) (Figure Not Available) . Many of the changes appear during the first trimester of pregnancy (increase in cardiac output of 22% and decrease in systemic vascular resistance [SVR] by 30% at 8 weeks' gestation). [13] The changes continue into the second and early third trimester of pregnancy, when cardiac output increases to approximately 30 to 40 percent above nonpregnant values. [14] [15] The increase in cardiac output during pregnancy is primarily a result of an increase in stroke volume (by about 30%), with a more modest increase in heart rate (10-15 beats per minute [bpm]) [13] noted. Arterial blood pressure does not change during normal pregnancy because of a decrease in peripheral vascular resistance. Early reports suggested that cardiac output decreased markedly during the third trimester. These reports, however, studied gravid patients in the supine position.

Figure 57-2 Cyclical changes in maternal transcutaneous (tc) P_{O_2} as a result of hypoventilation between uterine contractions. Epidural analgesia eliminates the decreases in maternal P_{O_2} . *(Modified from Peabody [425])*

Lees and associates [14] [16] and Ueland et al [17] showed that this marked decrease in cardiac output occurring after 28 weeks of pregnancy in subjects in the supine position was caused by obstruction of the inferior vena cava by the gravid uterus. Decreased venous return and reduced cardiac output were not seen in subjects in the lateral position, which eliminates this obstruction.

Maternal blood volume increases markedly during pregnancy (Fig. 57-5) (Figure Not Available) . [18] [19] Near term, blood volume has increased approximately 35 to 40 percent, (i.e., by more than 1,000 mL). Plasma volume increases from 40 mL/kg before pregnancy to 70 mL/kg during late pregnancy, and red blood cell volume increases from 25 to 30 mL/kg. The latter increases at a slower rate than the former, accounting for the relative anemia of pregnancy. Although the dilutional anemia of pregnancy decreases the oxygen-carrying capacity of the blood, several factors compensate for this, including an increase in maternal partial pressure of arterial oxygen (see Table 57-1) , a decrease in blood viscosity, an increase in cardiac output, and a rightward shift in the maternal oxyhemoglobin dissociation curve (see Table 57-2) (Table Not Available) . [10] As a result, transport of oxygen to important organs increases during pregnancy.

The increased blood volume and cardiac output may produce changes in the cardiac examination of the pregnant patient. Auscultation may reveal a wide, loud split first sound and a soft systolic ejection murmur caused by increased blood flow and vasodilation. [20] The position of the heart is usually altered by the elevated diaphragm at term gestation. This displaces the point of maximum impulse to the left and changes the axis of the heart on the electrocardiogram to the left. [20] The electrocardiogram may show minor, nonspecific ST-, T-, and Q-wave changes and benign arrythmias. [20] These normal findings should be differentiated from those indicating heart disease. Signs of significant heart disease in the pregnant woman include true cardiac enlargement, severe arrhythmias, systolic murmur greater than grade 3, or significant diastolic murmur.

TABLE 57-3 -- Hemodynamic Changes in Pregnancy

	NONPREGNANT	PREGNANT	CHANGE (%)
Cardiac output (L/min)	4.3±0.9	6.2±1.0	+43
Heart rate (beats/min)	71.0±10.0	83.0±10.0	+17
Stroke volume (mL)	73.4±9.0	88.3±11.0	+18
Left ventricle change rate (dD/dt), systole	6.7	9.3	+28
Myocardial thickness, end-diastolic (cm)	4.67	4.86	+4
Systemic vascular resistance ($dyne^2/cm/s^{-5}$)	1530±520	1210±266	-21
Pulmonary vascular resistance ($dyne^2/cm/s^{-5}$)	119±47	78±22	-34
Colloid oncotic pressure (mm Hg)	20.8±1	18.0±1.5	-14
Colloid oncotic pressure/Pulmonary capillary wedge pressure gradient (mm Hg)	14.5±2.5	10.5±2.7	-28

D, diameter; t, time

Data from Robson et al [416] and Clark et al [419]

Figure 57-3 (Figure Not Available) Maternal cardiovascular changes during pregnancy and labor from studies on patients in the lateral and supine positions. *(From Mangano [426])*

Figure 57-4 (Figure Not Available) Effects of uterine contractions on cardiac output, stroke volume, and heart rate during labor. Values represent percent increases from control measurements in late pregnancy. *(From Mangano [426])*

The pain and apprehension of labor adds to cardiac work during pregnancy and increases stroke volume and cardiac output by 45 percent over prelabor values. [21] [22] Blood pressure increases during painful labor. Additional stresses are imposed by uterine contractions, which cause, in effect, an autotransfusion. With each uterine contraction, blood from the body of the uterus is pushed into the central circulation, and blood volume and cardiac output increase by 10 to 25 percent. [22] [23] After delivery, the same autotransfusion occurs. In addition to an increase in central blood volume, obstruction of the vena cava is relieved. As a result, there is a marked increase (up to 80% of prelabor values) in stroke volume and cardiac output immediately postpartum. Patients with limited cardiac reserve may experience cardiac

failure at this time.

Despite the increase in blood volume and cardiac output, the parturient at term is susceptible to hypotension when supine. When the patient is supine, the gravid uterus partially or completely compresses the aorta and inferior vena cava, leading to decreased venous return, decreased cardiac output, hypotension, and reduced uterine blood flow (Figs. 57-6 (Figure Not Available) , 57-7 (Figure Not Available) , and 57-8) (Figure Not Available) . [24] [25] [26] [27] [28] Up to 10 percent of pregnant patients near term develop signs of shock (hypotension, pallor, sweating, nausea, vomiting, changes in cerebration) when they assume this position. Compensatory mechanisms include increased sympathetic tone and collateral routes (paravertebral veins to azygos vein) to improve venous return during obstruction of the vena cava. Caval compression also increases uterine venous back pressure, which further decreases uterine blood flow. Compression of the aorta is not associated with maternal symptoms but does cause arterial hypotension in the lower extremities and uterine arteries, which can further decrease uterine blood flow and impair uteroplacental perfusion. [29]

The anesthesiologist must recognize the importance of the aortocaval compression syndrome and the potential for its adverse effects to be exaggerated by anesthesia. Drugs causing vasodilation, such as potent inhaled agents, and particularly anesthetic techniques causing sympathetic blockade (subarachnoid or epidural anesthesia) exacerbate decreased

Figure 57-5 (Figure Not Available) Percent of increase in the volume of plasma, red blood cells (RBC), and total blood during pregnancy, labor, and the puerperium. *(From Bonica [424])*

Figure 57-6 (Figure Not Available) Venogram in the supine position just before cesarean section. (A) Dye has been injected into both femoral veins but does not reach the inferior vena cava, traversing instead the paravertebral veins. (B) Same patient just after cesarean section. The dye now easily reaches the inferior vena cava. *(From Kerr et al [27])*

Figure 57-7 (Figure Not Available) Schematic of lateral angiograms obtained from two women lying in the supine position. In the nonpregnant woman (left), there is a clear gap between the vertebral column and the aorta. Note the uniform width of the aorta. In the pregnant patient near term (right) the aorta is clearly displaced in the dorsal direction, encroaching on the shadow of the spine. The aorta is narrowed at the level of the lumbar lordosis. *(From Bieniarz et al [427])*

Figure 57-8 (Figure Not Available) Serial hemodynamic studies in a patient who exhibited supine hypotension. After the patient had lain supine for 6 minutes, a profound fall in arterial pressure and heart rate was seen. *(From Kerr [26])*

venous return to the heart when the vena cava is obstructed. Aortocaval compression must be prevented. Displacement of the uterus off the great vessels can be accomplished by manually displacing the uterus to the left. During labor, the patient should be positioned either on her side or with a left tilt. During delivery, the operating or delivery table can be tilted laterally to the left, or a small pillow or foam rubber wedge can be used to elevate the patient's right buttock and back about 10 to 15 cm.

The pregnant woman at term is in a hypercoagulable state owing to increases in factors VII, VIII, X, and plasma fibrinogen. [30] Estimates of blood loss at delivery vary but may be around 500 mL for an uncomplicated vaginal delivery. Blood loss during cesarean delivery varies widely, with 500 to 1400 mL being reported. [31] [32]

Hepatic Changes

Levels of alkaline phosphatase, serum transaminases, lactic dehydrogenase, and cholesterol increase slightly during pregnancy and labor. [33] Serum bilirubin levels and hepatic blood flow do not change. Total protein concentration and the albumin-to-globulin ratio decrease. Although plasma cholinesterase activity is reduced during pregnancy and in the immediate postpartum period, [34] moderate doses of succinylcholine and chloroprocaine are usually metabolized easily. [35] [36]

Gastrointestinal Changes

During pregnancy, the secretion of gastric acid increases, possibly owing to markedly elevated levels of the hormone gastrin, which is produced by the placenta. [37] During late pregnancy, gastric emptying is slowed as a result of displacement of the pylorus by the enlarged uterus. Pain, anxiety, and use of opioid analgesia during labor contribute to impaired gastric emptying. When ultrasound was used to examine gastric contents after a test meal, no solid food was detected in healthy nonpregnant volunteers or in pregnant patients not in labor 4 hours after ingestion. However, in pregnant patients in labor, solid food was found in 41 percent of those who had not eaten for 8 to 24 hours before the ultrasound examination. [38] Intragastric pressure is increased during pregnancy, and lower esophageal sphincter pressure is decreased during pregnancy. [39] All these changes increase the risk of regurgitation and aspiration during either general anesthesia or impaired consciousness from any other cause. It remains controversial as to what point in gestation these gastrointestinal changes dictate institution of measures to prevent aspiration pneumonitis during administration of general anesthesia and how long these changes persist in the postpartum period. [40] That aspiration pneumonitis is a greater problem in pregnant versus nonpregnant women is supported by a survey of aspiration pneumonitis in gynecologic and obstetric patients in Norway. This study revealed an incidence of 4 of 3,600 (0.11%) in cesarean section patients

(all four cases received general anesthesia; two were complicated by difficulties with airway management) compared with 0.01 to 0.04 percent in gynecologic patients. [41]

Central Nervous System Changes

Pregnancy reduces anesthetic requirements both during regional and general anesthesia. During spinal or epidural anesthesia, less local anesthetic is required to produce a given level of anesthesia. This reduced anesthetic requirement was thought to be due to the mechanical effects of increased intra-abdominal pressure, causing epidural venous engorgement and a reduction of both the epidural and the subarachnoid spaces. However, Fagraeus et al [42] showed that reduced local anesthetic requirements are seen in early pregnancy (8-12 weeks) before the mechanical effects of the gravid uterus are present. Datta et al [43] compared the effects of bupivacaine on nerve conduction in the isolated vagus nerve from pregnant and nonpregnant rabbits. The onset of block was significantly faster in nerves from pregnant animals. This study indicates that during pregnancy, either nerve fibers have increased sensitivity to local anesthetics or there is enhanced diffusion of the local anesthetic to the membrane receptor site.

Animal studies demonstrate that the requirement for inhaled anesthetics is decreased by up to 40 percent during pregnancy (Table 57-4) (Table Not Available) . [44] Reduced minimum alveolar concentration (MAC) has also been demonstrated in humans during early pregnancy (10-12 weeks' gestation) [45] and in the immediate (24-36 hours) postpartum period. [46] The sedative effects of increased levels of progesterone was proposed as a mechanism, and rabbits given exogenous progesterone show a reduced halothane MAC. [47] However, studies of halothane MAC in nonpregnant, pregnant, and lactating rats showed no correlation between decreased MAC and progesterone levels. [48] Another mechanism for the decrease in MAC during pregnancy was suggested by Gintzler, [49] who found that in pregnant rats there is a progressive increase in pain tolerance, which can be abolished by long-term administration of an opioid antagonist. An increased tolerance to visceral pain conferred by pregnancy in rats is also reversed with naloxone. [50] Thus, a pregnancy-induced activation of the endorphin system is likely a major contributor to the decreased anesthetic requirement observed during pregnancy.

Renal Changes

Renal plasma flow and glomerular filtration rate increase rapidly during pregnancy, reflecting changes in cardiac output. During the third trimester, they slowly return toward normal. Creatinine clearance usually increases, and therefore the upper limits of normal for blood urea nitrogen and serum creatinine are lower in the pregnant

woman.

/das/book/view/29494766/875/629.html

UTERINE BLOOD FLOW

Uterine blood flow in the parturient at term is approximately 700 mL/min and is determined by the following relationship:

There is no autoregulation of uterine blood flow; the vessels are maximally dilated during pregnancy. As such, in the absence of aortic compression, uterine arterial pressure directly reflects maternal blood pressure and cardiac output. Uterine blood flow decreases during maternal hypotension (sympathetic block, hypovolemia, hemorrhage, compression of the inferior vena cava), in circumstances in which uterine venous pressure is increased (compression of the inferior vena cava, abruptio placentae), and with increases in uterine vascular resistance (maternal hypertensive disorders, alpha-agonists, uterine hypercontractility).

Obstetric anesthesia may affect uterine blood flow by changing the perfusion pressure (i.e., by altering the uterine arterial or venous pressure) or by changing uterine vascular resistance, either directly through changes in vascular tone or indirectly by altering uterine contractions or uterine muscle tone. For example, hypotension associated with a sympathetic block or deep general anesthesia decreases perfusion pressure and reduces uterine blood flow in animals. Vasopressors with pure alpha-adrenergic action (e.g., phenylephrine) increase uterine vascular resistance and also decrease uterine blood flow (Fig. 57-9) (Figure Not Available) . Conditions that increase the frequency or duration of uterine contractions (e.g., an overdose of oxytocin or abruptio placentae) also decrease uterine blood flow.

TABLE 57-4 -- MAC Presented as Percent End-Tidal Anesthetic Concentration (Mean ± SE)

(Not Available)

From Palahniuk et al] [44]

Figure 57-9 (Figure Not Available) Mean changes in uterine blood flow at equal elevations of mean arterial blood pressure following administration of ephedrine (0.25, 0.5, 1.0, and 2.0 mg/kg), mephentermine (0.25, 0.5, 1.0, and 2.0 mg/kg), methoxamine (0.025, 0.05, 0.1, and 0.2 mg/kg) and metaraminol (0.025, 0.05, 0.1, and 0.2 mg/kg) to pregnant sheep. Uterine blood flow was not adversely affected by doses of ephedrine which increased maternal blood pressure by up to 50%. *(From Ralston et al* [52] *)*

Ephedrine is the vasopressor of choice for the treatment of hypotension during obstetric anesthesia. Both animal data [51] [52] [53] [54] [55] (see Fig. 57-9 (Figure Not Available) 57-10) (Figure Not Available) and years of clinical use [56] support its beneficial effects of increasing maternal blood pressure, cardiac output, uterine blood flow, and fetal status when used to treat hypotension. The uterine vessels of pregnant sheep do not have the constriction response to ephedrine seen in nonpregnant animals. [55] [57] Thus, when maternal blood pressure and cardiac output is restored with ephedrine therapy, uterine blood flow increases (see Fig. 57-10) (Figure Not Available) . In patients in whom the tachycardic effects of ephedrine should be avoided (e.g., mitral stenosis), it is reassuring that phenylephrine (80- to 100-mug increments) has been used successfully in well-hydrated, healthy cesarean section patients to correct maternal blood pressure during regional anesthesia without adverse effects on neonatal outcome. [58] [59]

PLACENTAL TRANSFER OF ANESTHETICS

Medications administered to the mother enter the fetal circulation primarily by passive diffusion. The Fick law of diffusion determines the rate of transfer across the placenta, which is represented by

where Q/t is the rate of diffusion, K is the diffusion constant of the drug, A is the membrane surface area, Cm is the maternal

Figure 57-10 (Figure Not Available) Changes in maternal and fetal sheep arterial pH following maternal spinal hypotension and subsequent correction with ephe-drine. Numbers identify the eight different maternal-fetal sheep preparations. *(From Shnider et al [51])*

---

drug concentration, Cf is the fetal drug concentration, and D is the membrane thickness.

Passive diffusion is the primary means of placental transfer of drugs. As such, the maternal-fetal concentration gradient, the uterine and umbilical blood flow, and the various factors that determine the diffusion constant of the drug are important in determining fetal exposure to maternally administered anesthetics. Factors producing a high diffusion constant (i.e., rapid diffusion) include low molecular weight (<500 d), low protein binding, high lipid solubility, and low degree of ionization. Almost all drugs used to produce anesthesia, analgesia, or sedation have a molecular weight of less than 500 d, are partially not ionized at physiologic pH, have a relatively high lipid solubility, and are incompletely protein bound in maternal blood and rapidly cross the placenta. Neuromuscular blocking drugs, because of their low lipid solubility and high degree of ionization, are not transferred across the placenta in clinically significant amounts. Factors tending to increase maternal drug concentration are high total doses, use of slowly metabolized drugs, low protein binding, and administration of drugs into highly vascular areas. Once the drug crosses the placenta, fetal pH and protein binding [60] affect the drug disposition. Circumstances of fetal acidosis and low pH favor "trapping" of potentially ionized drugs (e.g., local anesthetics) in the fetal circulation. [61]

The fetal circulation is unique in several ways and greatly modifies drug distribution (Fig. 57-11) (Figure Not Available) . Drugs cross the placenta and enter the fetal circulation via the umbilical vein.

Figure 57-11 (Figure Not Available) Diagram of the fetal circulation. Numbers indicate mean percent oxygen saturation. *(From Born et al [430])*

Umbilical venous blood returning from the placenta either perfuses the liver (40-60%) or bypasses the liver via the ductus venosus. [62] Hepatic drug uptake in the fetus may protect against the occurrence of high drug levels in the fetal heart and central nervous system (CNS). [63] [64] Dilution of umbilical venous blood in the fetal right atrium and shunting of blood across the foramen ovale and ductus arteriosus also modify fetal drug distribution.

Hepatic enzyme activity in the fetus is generally less than that in adults. However, liver microsomes of human fetuses have significant levels of cytochrome P-450 and nicotinamide adenine dinucleotide phosphate-cytochrome C reductase as early as week 14 of gestation. [65] [66] This enzyme activity, even though less than that in adults, suggests that even the premature human fetus has the capacity to metabolize numerous drugs, including most local anesthetics.

EVALUATION OF THE FETUS

The anesthesiologist should include an assessment of the fetus in the preanesthetic evaluation of the parturient. Understanding the means of assessing fetal well-being available to obstetricians also promotes communication in circumstances of emergency delivery for fetal concerns.

Fetal heart rate (FHR) monitoring [67] is commonly used to assess fetal well-being. It is monitored externally with ultrasound or internally with a fetal scalp electrode. Assessing FHR is helpful in confirming fetal well-being (i.e., a normal FHR tracing is consistent with a well-oxygenated fetus) but is an imperfect method to reliably identify fetal asphyxia (an abnormal tracing may reflect conditions other than fetal asphyxia). [68] Under normal conditions, FHR represents a balance of parasympathetic and sympathetic input. A normal FHR is 120 to 160 bpm. An increase in FHR may indicate fetal asphyxia, maternal fever, or drug effects (e.g., ephedrine and terbutaline). A decrease in FHR, particularly if sudden and severe, may represent fetal hypoxia. FHR beat-to-beat variability is an important component of FHR assessment. Normal short-term variability is seen as beat-to-beat FHR differences of two to three beats. This is superimposed on a pattern of long-term variability of five to 20 beats. Normal FHR variability is consistent with a well-oxygenated fetal CNS. FHR variability is decreased from maternally administered opioids or sedatives and fetal sleep. Reduced FHR variability also occurs in fetal hypoxia and acidosis.

The FHR can have periodic patterns related to uterine contractions (measured with a tocodynamometer or an intrauterine pressure catheter placed through the vagina into the uterine cavity). [67] Early decelerations occur with, and mirror, a uterine contraction. The rate rarely drops below 110 bpm. This type of deceleration is thought to represent a vagal reflex in response to fetal head compression and is typically seen during the second stage of labor. Late FHR decelerations begin 20 seconds or more after the onset of a uterine contraction and are worrisome because they represent uteroplacental insufficiency. Late decelerations with normal FHR variability are thought to be due to hypoxia-induced increased vagal discharge. Late decelerations with absent FHR variability are concerning because it is believed that these reflect direct hypoxia-induced myocardial depression.

Variable FHR decelerations are variable in configuration and relationship to uterine contractions and likely represent periodic compression of the umbilical cord. They classically begin with an acceleration in heart rate, followed by a bradycardia, and then return of FHR to normal after the contraction ceases. If persistent through labor, these repetitive variable decelerations can lead to fetal asphyxia and loss of FHR variability.

A nonstress test is used to document fetal well-being during pregnancy. It involves monitoring FHR for 20 minutes and checking for the presence of normal short-term and long-term variability and the absence of decelerations. A contraction stress test similarly evaluates FHR patterns with the added stress of periodic uterine contractions (usually stimulated with an intravenous (IV) infusion of oxytocin). The fetal biophysical profile has been developed to assess fetal well-being. The FHR pattern as well as fetal breathing movements, fetal body movements, fetal tone, and amount of amniotic fluid measured by ultrasound examination are assessed. [69] During labor, fetal scalp capillary blood can be sampled to measure fetal pH. Fetal capillary blood pH has been shown to correlate well with fetal umbilical blood gas values. [70] A fetal scalp blood pH of less than 7.20 indicates significant asphyxia and usually dictates urgent delivery. A value between 7.20 to 7.24 is intermediate and indicates the need for close monitoring and perhaps repeat sampling. A value of greater than 7.24 is reassuring. A positive response (an increase of FHR by 15 bpm lasting 10 seconds) to the less invasive "fetal scalp stimulation test" (tactile stimulation of the fetal scalp) has been shown to correlate with a fetal scalp pH of greater than 7.20. [68]

When abnormal FHR patterns are recognized, means to improve the uterine environment include giving supplemental oxygen to the mother, avoiding aortocaval compression, treating anesthetic (or otherwise)-induced hypotension, altering maternal position (adopting the full lateral or knee-chest position), decreasing uterine activity (discontinuing oxytocin and/or administering terbutaline, 0.25 mg subcutaneously), and/or instituting an amnioinfusion to relieve umbilical cord compression.

NORMAL PROGRESS OF LABOR

"Labor" is the term used to describe the physiologic process by which the products of conception are expelled from the uterus through the vagina. Normal labor requires

Figure 57-12 (Figure Not Available) Composite of the average dilation curve for nulliparous labor based on analysis of the data derived from the patterns traced by a large, nearly consecutive series of gravidas. The first stage is divided into a relatively flat latent phase and rapidly progressive active phase. The active phase has three identifiable component parts--an acceleration phase, a linear phase of maximum slope, and a deceleration phase. *(Modified by Friedman, [428] from Friedman [429])*

uterine contractions and progressive cervical dilation (Fig. 57-12) (Figure Not Available) . Traditionally, labor has been divided into three stages: the first stage extends from the start of regular uterine contractions causing effacement (thinning) and dilation of the cervix until complete cervical dilation, the second stage proceeds from the end of the first stage until delivery of the fetus, and the third stage extends from delivery of the baby until the placenta and membranes are expelled.

At the start of labor, contractions are infrequent and of low intensity. During active labor, uterine contractions occur about every 3 minutes, have a duration of about 1 minute, and achieve an intrauterine pressure of 50 to 70 mm Hg before returning to a resting uterine tone of 10 mm Hg.

Abnormal progress of labor can be classified as follows: slow latent phase, active phase arrest, slow-slope active phase, slow descent, and arrest of descent. Diagnostic features for abnormal progress of labor are listed in Table 57-5 . During the active phase or second stage of labor, cephalopelvic disproportion, malposition, and malpresentation are the most common causes of prolongation. Controversy exists regarding the potential impact of regional analgesic techniques utilized during labor on uterine activity and progress of labor. Retrospective studies assessing the impact

TABLE 57-5 -- Diagnostic Features of Prolonged Labor

FEATURE	NULLIPARAS	MULTIPARAS
Slow latent phase	>20 h	>14 h
Slow-slope active phase	>1.2 cm/h	>1.5 cm/h
Active phase arrest	No cervical dilation for 2 h	
Slow descent of fetus	<1 cm/h	<2 cm/h
Arrest of descent	No descent for 1 h	
	SECOND STAGE	
Nulliparous	More than 2 h without regional analgesia	
	More than 3 h with regional analgesia	
Multiparous	More than 1 h without regional analgesia	
	More than 2 h with regional analgesia	

of regional analgesia on the course of labor and delivery (length and mode of delivery) are difficult to interpret because of selection bias. That is, women with a prolonged, painful labor are more likely to request regional analgesia than women with faster labors. Pain has been suggested as a factor predicting long labor and need for operative vaginal or cesarean delivery. [71] Few prospective, randomized studies of analgesic technique on labor outcome are published, and the results are variable. [72] [73] [74] [75] Although not consistently proved to be important, reasonable principles to follow to minimize any potential effect of obstetric analgesia on outcome of labor and delivery include avoiding maternal hypotension and excessively high or dense blocks with motor impairment. The role of "early" institution of regional analgesia (e.g, at 3-5 cm of cervical dilation) on the outcome of labor (including duration of the first stage of labor and need for cesarean delivery) is also controversial, with some studies indicating an adverse effect of early analgesia and other studies not demonstrating an effect. [75] [76] [77]

ANESTHESIA FOR VAGINAL DELIVERY

Pain Pathways

During the first stage of labor, pain is due primarily to uterine contractions that cause stretching and thinning of the uterine cervix. Pain impulses travel via visceral afferent fibers accompanying the sympathetic nerves and enter the spinal cord at the T10, T11, T12, and L1 spinal segments. This pain is generally poorly localized and described as dull or cramping. In late first stage and in the second stage, stretching of the perineum produces additional pain, more somatic in nature, described as well localized and sharp. These impulses travel via the pudendal nerves from the S2, S3, and S4 spinal segments.

The amount of pain experienced by a woman during labor and delivery can be influenced by many factors, including participation in childbirth preparation classes, parity, and use of oxytocin. A variety of analgesic techniques are available.

Psychologic Techniques

A number of psychologic techniques have been used to assist women with the pain of labor, including hypnosis and psychoprophylaxis. The psychoprophylactic method of Lamaze [78] is the most popular form of psychologic analgesia. This technique relies on positive conditioning and patient education to decrease fear and anxiety regarding the process of childbirth. The patient is taught to focus on a specific object or location away from herself, concentrate on release of muscle tension, maintain a learned breathing rhythm, and listen to reassuring words from her coach. The increased concentration required by these activities distracts from, or inhibits, the painful sensations associated with uterine contractions. Preparation usually begins 6 weeks before delivery and includes instruction in the normal anatomy and physiology of pregnancy, labor, and delivery.

Using the McGill Pain Questionnaire, Melzack and colleagues [79] [80] measured the intensity of labor pain in parturients with and without prepared childbirth training. Those who had received prepared childbirth training had lower pain scores than those who had received no such training (Fig. 57-13) (Figure Not Available) . However, the differences in pain scores were relatively small. Scott and Rose [81] found that although mothers prepared in Lamaze required less analgesia, neonatal outcome in such patients was indistinguishable from that of mothers not prepared in Lamaze. Nevertheless, preparation for the event of childbirth is probably of benefit to almost all women and, regardless of the type of anesthesia used, can make the experience more pleasant. [82]

Acupuncture [83] [84] and transcutaneous electrical nerve stimulation [85] [86] [87] have also been evaluated with varied success.

Systemic Medication

Systemic medications, likely because of their ease of administration, are the most commonly used method to assist women with pain management during labor (Table 57-6) . [88]

Sedatives

Sedative-tranquilizers (Chs. 8 . and 9) may be used, either alone or in combination with an opioid, during the early first stage of labor to promote rest. The use of short-acting or medium-acting barbiturates, such as secobarbital, is no longer popular. The principal objection to the use of barbiturates is their antianalgesic effects in the mother and the prolonged depressant effects on the neonate. [89] Even with small doses that result in no clinical depression ascertainable by the Apgar score, the newborn's attention span may be decreased for 2 to 4 days. [90] The primary indication for the use of barbiturates is as a sedative-hypnotic during the early latent phase of labor when delivery is not anticipated for 12 to 24 hours. The phenothiazine derivatives promethazine and propiomazine seem to be equally effective in relieving anxiety, reducing opioid requirements, and controlling emesis during early labor. [91] Differences among these drugs are relatively minor. Hydroxyzine (Vistaril), although chemically unrelated to the phenothiazines, has similar ataractic properties. [92]

Benzodiazepines are used uncommonly in obstetrics but can be used in small doses for sedation and/or anxiolysis during very early labor or before cesarean delivery. Diazepam has been most extensively studied; it crosses the placenta rapidly, and maternal and fetal blood levels are approximately

TABLE 57-6 -- Analgesia for Labor and Delivery, a Survey of Practice in the United States, 1981 Versus 1992

ANALGESIC TECHNIQUE	1981	1992
None, psychologic techniques	35%	19%
Parenteral opioids	47%	52%
Lumbar epidural	15%	34%
Spinal	0%	4%
Paracervical block	5%	4%

Data from Hawkins et al [88]

equal within minutes of an IV dose. [93] Although the neonate is capable of metabolizing small doses of diazepam, when the total maternal dosage during labor exceeds 30 mg, the drug and its active metabolite persist in pharmacologically active concentrations for at least a week in the neonate. [94] The principal adverse effects of large doses of diazepam are hypotonia, lethargy, decreased feeding, and hypothermia. [94] [95] [96] In small doses, diazepam produces minimal effects on the fetus and neonate, although reduced beat-to-beat variability may be noted on the FHR tracing. [96] [97] Midazolam is a water-soluble benzodiazepine with a rapid onset and a short duration of action. It is most often used for sedation during cesarean delivery (after delivery of the newborn). Rapid IV administration may produce deep sedation and amnesia, [98] and if it is used, it should be administered slowly in increments of 0.5 to 1.0 mg or less with careful observation of the mother. When midazolam (0.3 mg/kg) was used for induction of general anesthesia, more adverse neonatal effects (problems with general body tone and body temperature) were noted when compared with thiopental (4 mg/kg). [99]

Opioids

The most commonly used opioids (Ch. 10) . for labor analgesia include meperidine, morphine, fentanyl, nalbuphine, and butorphanol. No opioid can produce completely effective analgesia for labor and delivery without causing side effects that include some degree of maternal respiratory depression, sedation, and obtundation of reflexes. Therefore, opioids are used to reduce rather than completely eliminate pain. Opioids are most often administered via intermittent intramuscular (IM) or IV injection. Clinical reports describe successful use of patient controlled analgesia to administer opioids (meperidine, nalbuphine, fentanyl) [100] [101] [102] [103] during labor.

Meperidine

Meperidine is a commonly used opioid in obstetrics. The usual IM dose is 50 to 100 mg and the IV dose is 25 to 50 mg. The peak analgesic effect occurs 40 to 50 minutes after IM administration and 5 to 10 minutes after IV administration. The duration of action is 3 to 4 hours. Meperidine used for labor analgesia can produce dose-dependent neonatal depression, [104] as evidenced by prolonged time to sustained respiration, decreased Apgar scores, [89] and abnormal results from neurobehavioral examination. [105] [106] These effects are related to the dose and to the time interval between drug administration in the mother and delivery of the infant. Infants born within 1 hour or more than 4 hours after IM administration of 50 to 100 mg of meperidine to the mother are no more depressed than neonates not receiving meperidine (Fig. 57-14) . [89] Fetal exposure to meperidine is highest 2 to 3 hours after administration of the drug to the mother (Fig. 57-15) (Figure Not Available) . [106] The prolonged changes in neonatal neurobehavior examinations after *in utero* exposure to meperidine are attributed to the prolonged presence of the meperidine metabolite normeperidine in the neonatal circulation. [107] [108]

Figure 57-14 Correlation of the time of administration of meperidine and neonatal depression (defined as Apgar score of 0 to 6). *(From Shnider and Moya [85])*

Figure 57-15 (Figure Not Available) Following maternal administration of meperidine (50 mg IV) during labor, meperidine excretion was measured in the neonate's urine for the first 3 days. The relationship between the drug-delivery interval and the urinary excretion of meperidine by the neonate is shown. For each bar, the mean, standard error, and number or infants are given. Infants whose mothers received meperidine 1 to 2 and 2 to 3 hours prior to delivery excreted more meperidine. *(From Kuhnert et al [431])*

Fentanyl

The usual doses of fentanyl used during labor are 50 to 100 mug IM and 25 to 50 mug IV. After IV administration, the peak effect occurs within 3 to 5 minutes, and the duration is 30 to 60 minutes. Placental transfer is rapid. [109] [110] A dose of 1 mug/kg administered IV to the mother within 15 minutes of cesarean delivery did not produce adverse effects on umbilical cord blood gases or neonatal Apgar scores or neurobehavioral scores. [110] It was concluded that fentanyl might be a useful adjuvant for either regional or general anesthesia for cesarean delivery. Use of fentanyl for intrapartum labor analgesia has also been studied. [101] [111] Temporary analgesia and mild sedation were apparent after administration of 50 or 100 mug. A transient decrease in FHR variability was noted after fentanyl administration. Regardless of the maternal dose (average, 140 ± 42 mug; range, 50-600 mug), newborn drug levels were low and always less than maternal levels. No adverse effects of *in utero* exposure to fentanyl was noted on neonatal examination. [111]

Morphine

The peak analgesic effect of morphine occurs 1 to 2 hours after IM administration and 20 minutes after IV administration. The duration of action is 4 to 6 hours. In equianalgesic doses, morphine produces more respiratory depression of the newborn than does meperidine (Fig. 57-16) (Figure Not Available) . [112] Because of the delayed onset and the prolonged duration of action of morphine in the mother and the greater sensitivity of the newborn's respiratory center to morphine, meperidine and fentanyl have replaced it as obstetric analgesics during active labor. Morphine is usually reserved for use in very early labor.

Butorphanol and Nalbuphine

Butorphanol and nalbuphine are two synthetic agonist-antagonist narcotic analgesics. In nonpregnant patients, analgesic doses of butorphanol (2 mg) and nalbuphine (10 mg) produce respiratory depression equivalent to that caused by 10 mg of morphine. Although larger doses of morphine produce more respiratory depression, larger doses of butorphanol and nalbuphine do not. [113] [114] However, larger doses of these drugs may produce maternal dizziness and somnolence and adverse neonatal neurobehavioral effects. [115] Even with the usual clinical doses, both of these drugs are rapidly transferred across the placenta and have produced sinusoidal FHR patterns. [116] [117] (This heart rate abnormality, which is associated with high-output cardiac failure in the fetus, appears to be benign when it results from medication and does not in itself signify fetal compromise.) The few studies that have been performed with these drugs in obstetrics have not shown significant advantages over other opioids. [103] [118] [119] [120] [121]

Ketamine

Dissociative or amnesia-producing drugs, such as ketamine (Ch. 9) . and scopolamine, are used infrequently during labor. In obstetrics, low-dose IV ketamine (10-25 mg, or 0.25-mg/kg increments) can be used in lieu of inhaled agents to produce analgesia (which can be useful during operative

Figure 57-16 (Figure Not Available) Effect of equianalgesic doses of morphine and meperidine on the CO_2 response curve in the newborn. The standard error of the mean is indicated by the rectangles above each point. *(From Way et al [112])*

vaginal delivery or cesarean delivery). [122] Care must be used to avoid loss of maternal protective reflexes during IV analgesia provided by ketamine.

Inhaled Analgesia

Use of inhaled anesthetics (other than nitrous oxide) for labor analgesia is rare. Methoxyflurane was used in the past to assist with the pain of labor. Now, use of inhalational analgesia is limited but might be used, for example, during operative vaginal delivery. Proper administration of inhaled analgesia in this context requires administration of potent inhaled agents by mask in low concentrations to prevent loss of consciousness and protective airway reflexes. The anesthesiologist must remain in verbal contact with the patient and provide continuous reassurance and encouragement. The major risk of inhaled analgesia is accidental anesthetic overdose with resulting loss of protective reflexes. Vomiting or silent regurgitation may then occur, resulting in aspiration pneumonitis, obstruction, and asphyxia.

Nitrous oxide can be administered for analgesia during labor. It is usually combined by use of a blender apparatus with 50 percent oxygen. These portable machines should be equipped with scavenging devices that reduce the occupational exposure to nitrous oxide for labor room personnel. Reliable analgesia with 50 percent nitrous oxide has not been demonstrated. [123] [124]

Regional Anesthesia

Regional analgesic techniques (Ch. 42) are the most effective means of providing analgesia for labor and vaginal delivery, and their use for analgesia in the United States has increased in the past decade (see Table 57-6) . [88] Regional blocks provide pain relief while allowing the parturient to be awake and able to participate in the labor and delivery process. Epidural analgesia has been shown to reduce levels of catecholamines in the maternal circulation, [125] which may be beneficial to the fetus. [126] Compared with parenteral or inhalational analgesic techniques, regional anesthesia is unlikely to produce drug-induced depression in the fetus or mother. The most common regional anesthetic techniques are lumbar epidural, caudal, and spinal blocks. Paracervical, pudendal, and local perineal infiltration are techniques

usually administered by the obstetrician. Each technique has a specific application and can be used to block some or all of the nerves carrying the pain impulses.

Patient Preparation

Before administering a regional block, an IV infusion should be started, and equipment for resuscitation and treating complications must be immediately available. These include an oxygen delivery system, airways, laryngoscope, endotracheal tubes, suctioning apparatus, thiopental or diazepam for treatment of convulsions, ephedrine for treatment of hypotension, and naloxone for treatment of opioid-induced respiratory depression. A preanesthetic evaluation of the patient, an understanding of the obstetric plan, and an understanding of the fetal status should be performed before a regional block or other anesthetic is administered. Although this is sometimes difficult during the pain of labor, informed consent for the procedure must be obtained. Appropriate monitors (at our institution, maternal blood pressure, electrocardiogram, and FHR are monitored while a regional block is performed) must be in place. Before the block is given, approximately 500 mL of IV balanced saline solution should be infused to decrease the incidence of hypotension from anesthetic-induced sympathetic block.

Lumbar Epidural Analgesia

Lumbar epidural analgesia is the most common regional block performed for labor analgesia. Usually, the block is placed once the patient is in established labor. If augmentation with oxytocin is anticipated, the block can be started earlier. Continuous epidural analgesia provides the ability to

administer analgesics for the duration of labor, with the dose adjusted for desired effect. Low doses of local anesthetics or opioids are often sufficient during the first part of labor to provide an effective T10 to L1 segmental block. As labor progresses, anesthetic dose may need to be increased to cover the increased pain of the late first and second stages of labor and the distribution of the pudendal nerve (S2-S4). The benefits of epidural analgesia include effective pain relief, reduction in maternal catecholamines, and a means to provide surgical anesthesia should that be necessary. There are few absolute contraindications for epidural (spinal or caudal) analgesia; these include patient refusal, infection at the site of needle placement, overt maternal coagulopathy, and maternal hemodynamic instability. Other conditions (e.g., preexisting neurologic disease, prior back surgery, isolated coagulation abnormalities, some cardiac disease) must be considered on a case-by-case basis, with the particular nature of the patient's problem and the risks and benefits of available analgesic techniques being weighed.

The Epidural Test Dose in Obstetrics

Placement of catheters for epidural use may be complicated by IV or subarachnoid placement of the catheter. Initially, aspiration can help identify possible IV or subarachnoid placement of the catheter. Because a negative aspiration does not always ensure against an intravascular or subarachnoid injection, the catheter position must be verified by injecting a test dose. The function of a test dose is to allow recognition of accidental subarachnoid or intravascular catheter location, without causing harm. Injection of a small dose (e.g., 45 mg of lidocaine, 7.5 mg of bupivacaine) can be used to detect subarachnoid injection; evidence of anesthetic block (including sacral analgesia) and possibly leg weakness should be present after 3 to 5 minutes. [127] [128]

Controversy surrounds the best means to detect accidental IV placement of an epidural catheter in obstetric patients. If injected into a blood vessel, epinephrine, 15 mug (i.e., 3 mL of a 1:200,000 solution), has been shown to rapidly produce a transient increase in heart rate of 20 to 30 beats/min in volunteers and surgical patients. [129] However, in the laboring patient, maternal heart rate variability stemming from the pain of uterine contractions may confuse interpretation of the heart rate response after injection of an epinephrine test dose. Further, the pregnant patient may respond less reliably to 15 mug of epinephrine. Leighton et al [130] administered IV either 15 mug of epinephrine or saline to laboring women. When surgical criteria (an increase in heart rate of 25 bpm within 2 minutes of injection) were applied, only five of ten parturients were identified as having received epinephrine. When alternative criteria were applied (an increase in heart rate of >10 bpm over the maximum heart rate observed during the 2 minutes before injection), nine of ten patients had a "positive" response. Another concern with epinephrine is its potential adverse effect on uterine blood flow. Animal data reveal that IV injection of 15 mug epinephrine transiently reduces uterine blood flow. [131] Further, a hypertensive patient may have an exaggerated response to IV epinephrine. Means to improve the reliability of epinephrine include injecting the test dose between uterine contractions when maternal heart rate is stable, repeating test doses when the response is equivocal, and considering only rapid, sudden increases in heart rate to be positive. [132] However, the lack of specificity, sensitivity, and potential adverse effects have led many to avoid this test dose in obstetrics.

Injection of subconvulsant doses of local anesthetics (e.g., 100 mg of lidocaine [133] or chloroprocaine) have also been suggested for use as a test for IV catheter placement. Detection of IV placement relies solely on the subjective responses (tinnitus, perioral numbness) by the mother, which may be unreliable in the anxious or previously medicated parturient. Use of catecholamines other than epinephrine that produce increases in maternal heart rate without adverse effects on uterine blood flow (e.g., isoproterenol, 5 mug [134]) have also been studied, but data from humans are limited. [135] [136] Others have described the injection of 1 to 2 mL of air into the epidural catheter and listening for evidence of IV air with a Doppler monitoring device placed over the maternal precordium. [137] [138]

The safe practice of administering epidural analgesia involves catheter aspiration, testing for possible IV placement (recognizing the limitations of the available tests), testing for possible subarachnoid placement, and injecting the total dose of anesthetic in small increments (
5 mL) while waiting 30 to 60 seconds between injections and constantly observing the patient for evidence of local anesthetic toxicity.

Epidural Agents for Labor and Delivery

The agent or agents used for epidural analgesia must provide effective analgesia and be safe for the mother, fetus, and neonate. When used for labor and vaginal delivery, the agent should produce minimal maternal skeletal muscle relaxation, thereby permitting normal flexion and internal rotation of the fetal head and normal maternal expulsive efforts during the second stage of labor. Epidural opioids, local anesthetics, and their combination are used for labor analgesia.

Epidural Opioids for Labor

Epidural morphine was the first epidural opioid evaluated for labor analgesia. Unfortunately, it has a very long onset time (30-60 minutes), and even with generous doses (7.5 mg), it provides only mediocre pain relief and is often ineffective during the late first and second stages of labor (Fig. 57-17) . [139] Epidural meperidine, 100 mg, provides consistently good analgesia that lasts for about 2.5 hours. [140] Epidural fentanyl, 100 to 200 mug, quickly provides analgesia (5-10 minutes) that lasts 1 to 2 hours with few side effects. [141] In some patients, these doses had to be repeated as often as three times; however, umbilical artery fentanyl levels are low, and in one study, one of 38 neonates was treated for presumed opioid-related depression. [141] Epidural sufentanil, 5 to 50 mug, following a test dose of 45 mg of lidocaine and 15 mug of epinephrine has been reported to provide significant dose-related analgesia for labor. [142] The lower doses, 5 to 15 mug, providedapproximately 1 hour of pain relief, and the larger doses, 40 mug and 50 mug, resulted in a 2-hour analgesic period. Certainly, there is a concern of accidental IV or

Figure 57-17 Pain relief during labor following intrathecal or epidural morphine compared with epidural bupivacaine. *(*Data from Abboud et al [216] ; **data from Hughes et al [139])*

subarachnoid injection of such large doses of sufentanil. Interestingly, epidural administration of 10 mug of sufentanil failed to provide analgesia in patients who did not receive any local anesthetic as a test dose. [143] For meperidine and fentanyl, lower doses (25 mg of meperidine, [144] 80 mug of fentanyl [144]) are effective if combined with a small dose of local anesthetic.

It is not clear what should be considered the maximal total dose of epidural opioid that can be given before birth without affecting the clinical condition of the neonate. Some believe that 30 mug of sufentanil should not be exceeded, [145] although there are data to suggest that 50 mug is safe. [142] One observational study reported decreased neurologic and adaptive capacity scores in neonates whose mothers had received more than 200 mug of fentanyl during labor. [146] Because data clarifying the maximum dose are scarce, if epidural opioids become ineffective for labor analgesia, it makes sense to consider changing to a different epidural analgesic rather

than giving several doses of an opioid.

Epidural Local Anesthetics

Epidural local (Ch. 13) anesthetics are the most commonly used epidural analgesics for labor and delivery. The anesthetics used include bupivacaine, lidocaine, 2-chloroprocaine, and more recently, ropivacaine.

Bupivacaine.

Bupivacaine is the most commonly used local anesthetic for labor analgesia. Its relatively long duration of action and apparent lack of tachyphylaxis [147] are attractive features. Bupivacaine is highly protein bound, and placental passage is low (the umbilical venous:maternal venous concentration ratio is about 0.3). [148] Further, bupivacaine is effective in low concentrations (0.125% alone, or as low as 0.04% when combined with opioid [149]) for early labor. Somewhat higher concentrations (0.25% alone or 0.125% with opioid) may be necessary in late labor. Use of low concentrations minimizes motor block. The 0.5 percent concentration is reserved for use during cesarean delivery.

A concern with the use of bupivacaine is its cardiotoxicity. Bupivacaine-induced seizures from accidental intravascular injection have been associated with cardiac arrests resulting in difficult resuscitation or death. [150] Although these arrests occurred in patients given either 0.5 percent or 0.75 percent bupivacaine, in the early 1980s, the U.S. Food and Drug Administration proscribed the use of the 0.75 percent in obstetrics. (It is important to underscore that cardiac arrests have occurred with concentrations less than 0.75 percent--the total dose and subsequent serum level of bupivacaine determine whether a toxic reaction occurs, not the concentration of the solution. It is, however, easier to give a large dose quickly with the higher concentration.) Animal studies have revealed that bupivacaine appears to be more cardiotoxic than lidocaine. [151] [152] [153] [154] [155] The most likely mechanism for such cardiotoxicity relates to the action of bupivacaine on cardiac sodium channels and the physicochemical properties of bupivacaine. Both lidocaine and bupivacaine block the sodium channels of nerve and heart, an effect that slows or stops conduction. Blockade of cardiac sodium channels by lidocaine appears to be well tolerated by the heart; in fact, the drug is commonly used as an antiarrhythmic agent. When electrophysiologic differences between lidocaine and bupivacaine were compared, lidocaine was found to enter the sodium channel quickly and to leave quickly; bupivacaine was found to be a "fast-in, slow-out" agent. [155] Avid protein binding, particularly at low pH, contributes to this feature and contributes to the difficulties in resuscitating patients in cardiac arrest from bupivacaine toxicity. In addition, the higher lipid solubility of bupivacaine (compared with that of lidocaine) allows the drug to enter the cell more easily. [156]

Most of the reported cases of bupivacaine cardiotoxicity have involved obstetric patients. The reason for the increased

---

incidence and the poor outcome of cardiotoxic reactions to bupivacaine in pregnancy is not clear. It may reflect the more frequent use of bupivacaine for obstetric epidural block or the fact that it is easier to accidentally puncture a dilated epidural vein during parturition. In addition, physiologic changes during pregnancy (low functional residual capacity, high oxygen consumption, and aortocaval compression) make the parturient more difficult to resuscitate than the nonpregnant patient. [157] The hypoxia and acidosis that would be expected to occur rapidly in the pregnant patient contribute to bupivacaine cardiotoxicity. [158] [159] [160] Further animal data suggest that reduced protein binding and higher free bupivacaine levels in pregnancy [161] [162] and progesterone-enhanced bupivacaine (but not lidocaine) cardiac toxicity [163] may contribute to the problem during pregnancy. It is encouraging that an apparent reduction in regional anesthetic-related maternal mortality has been noted since 1984, [164] despite the increased use of regional blocks for labor and cesarean delivery. Perhaps, at least in part, this is a result of the clinical practice of routine testing of epidural catheters for IV or subarachnoid placement and avoiding large bolus injections of local anesthetic.

Lidocaine.

Lidocaine, a local anesthetic commonly used in the operating room, is very popular in obstetrics, particularly for cesarean delivery (1.5-2.0% solutions). For labor, concentrations of 0.75 to 1.0 percent have been used but may not be as effective as bupivacaine. [165] Umbilical venous:maternal venous concentrations are approximately 0.8. [166] [167] However, in 1974, Scanlon et al [168] reported that when used for maternal epidural analgesia during labor, lidocaine compromised neonatal neurobehavioral function. Numerous subsequent studies [169] [170] have either failed to corroborate these findings or found changes so minimal as to be clinically insignificant.

2-Chloroprocaine.

2-Chloroprocaine is an ester-type local anesthetic with a rapid onset and a brief duration of action. Because of its rapid hydrolysis by maternal plasma cholinesterase (the half-life of chloroprocaine in maternal blood is 21 seconds), very little drug crosses the placenta. [171] [172] A disadvantage of 2-chloroprocaine is its apparent antagonism of subsequently injected epidural opioids [173] and bupivacaine. [174] [175] It is particularly useful to rapidly extend a labor epidural block for operative vaginal (2-3% solutions) or cesarean (3% solution) delivery.

In the past, 2-chloroprocaine was thought to be neurotoxic because of reports of arachnoiditis following accidental subarachnoid injection. [176] [177] [178] [179] Subsequent investigations traced the cause of arachnoiditis to the low pH of the anesthetic solution to which sodium bisulfite, an antioxidant, had been added to stabilize the formulation. [176] [180] [181] Replacement of bisulfite by disodium ethylenediaminetetraacetic acid (EDTA) has removed the apparent associated danger of arachnoiditis and exchanged it for the less serious side effect of backache, which tends to accompany large doses (>30 mL) of this formulation. [182]

Ropivacaine.

Ropivacaine is a newer amide local anesthetic similar in structure, potency, and pharmacodynamics to bupivacaine. In animal studies, ropivacaine appears to have a cardiotoxicity that is intermediate between those of lidocaine and bupivacaine. [151] [183] [184] Unlike with bupivacaine, progesterone does not appear to enhance its cardiotoxicity. [185] In pregnant sheep, a more rapid clearance of ropivacaine than that of bupivacaine after IV administration led to a larger dose (but not serum concentration) required to produced toxicity. [186] These findings suggest that there may be a greater margin of safety in pregnant patients with ropivacaine than with bupivacaine, if accidentally injected IV.

Clinical reports find ropivacaine very similar to bupivacaine for labor analgesia. Solutions of either ropivacaine or bupivacaine, 0.25 percent, given as a bolus, followed by an infusion of the same concentration, provided equivalent analgesia. [187] Similarly, 0.125 percent solutions of ropivacaine or bupivacaine delivered comparable analgesia when administered via patient-controlled epidural analgesia. [188] Although an *in vitro* study suggested reduced blockade of motor fibers with ropivacaine compared with bupivacaine, [189] studies in laboring patients have yet to confirm this potential advantage. [187] [188]

Epinephrine as an Adjuvant to Local Anesthetics.

Many investigators recommend that epinephrine be added to local anesthetics to decrease systemic absorption, provide a longer duration of action, and intensify the motor block. Reports of studies questioning whether added epinephrine decreases systemic absorption of epidurally injected local anesthetics in the obstetric patient have been variable. [190] [191] [192] [193] [194] In epidural anesthesia for vaginal delivery, the addition of epinephrine, except for the test dose, is unnecessary because of the small amounts of drug used and the lack of need for motor block. Although the beta-sympathomimetic effects of systemically absorbed epinephrine may produce a transient decrease in uterine contractility, [195] the significance of this finding is unclear. Enhanced analgesia, however, is a potential advantage. [196] For cesarean delivery, in which larger doses of local anesthetic are used and more profound motor block is desired, many favor the addition of epinephrine 1:200,000 to the local anesthetic solution.

Epidural Opioids plus Local Anesthetics

Combining epidural local anesthetics with opioids has become a common practice in obstetric analgesia for labor and delivery. The rationale is that these agents work at two distinct sites--the local anesthetic at the nerve axon and the opioid at the spinal cord receptor--to eliminate pain via a combined and possibly synergistic mechanism. The use of a combination of local anesthetic plus an opioid reduces the total amount of local anesthetic required to produce effective analgesia, and

therefore less motor block occurs, which parturients appreciate.

Mixtures of epidural fentanyl or sufentanil with bupivacaine are commonly used during labor to initiate and maintain analgesia. [145] [149] [175] [197] [198] [199] [200] [201] [202] [203] [204] [205] [206] Addition of 50 mug of fentanyl or 10 mug of sufentanil to 0.04 to 0.25 percent bupivacaine in a 10 mL bolus produces a more rapid onset of more complete labor analgesia than does bupivacaine alone. When continuous infusions are administered after the initial bolus,

TABLE 57-7 -- Suggested Techniques for Lumbar Epidural Anesthesia for Labor and Vaginal Delivery

1. Place epidural catheter in usual manner after maternal informed consent, hydration, and placement of appropriate monitors.
2. Use test dose to rule out accidental intravascular or subarachnoid injection (e.g., 3 mL of lidocaine 1.5% with epinephrine 1:200,000).
3. Initial block--options:
   a. Bupivacaine 0.125-0.25%, lidocaine 1%, or 2-chloroprocaine 2% (8-15 mL)
   b. Sufentanil 10-15 mug in 10 mL of saline
   c. Bupivacaine 0.0625-0.125% + fentanyl 50 mug or sufentanil 10 mug
4. Subsequent analgesia--options:
   a. Intermittent--repeat as above, as necessary, to maintain maternal comfort
   b. Continuous infusions: 8-15 mL/h
      1. Bupivacaine 0.04-0.125% + fentanyl 1-2 mug/mL or sufentanil 0.1-0.3 mug/mL
      2. Bupivacaine 0.125% without opiate
   c. Patient-controlled epidural analgesia (above continuous-infusion drug regimens; background infusion: 4-6 mL/h; option for patient-administered doses: 3-4 mL every 10-20 min) [204] [211] [212] [213]
5. Blood pressure is monitored every 1-2 min for the first 10 min after initial injection of local anesthetic, then every 5-15 min during the infusion and until the block wears off.
6. Careful nursing supervision is mandatory.
7. Patient should be maintained in the lateral position throughout labor to prevent aortocaval compression. Patient should turn from side to side every hour to avoid a one-sided block.
8. Sensory level, adequacy of anesthesia, and motor block should be checked regularly.
9. Adjust infusion rate up or down, depending on dermatome level. Increase concentration of local anesthetic if block is not adequately dense.
10. Diminishing analgesia may indicate intravascular migration. A repeat test dose should be administered before any bolus injections.
11. Development of motor block may indicate subarachnoid migration. Catheter location should be verified by aspiration, careful sensorimotor examination, and if necessary, cautious administration of test dose.
12. If perineal anesthesia is required, administer 10 to 20 mL of local anesthetic, e.g., the bupivacaine infusate, or for denser anesthesia, lidocaine 1.5-2% or chloroprocaine 2-3%.

very low concentrations of bupivacaine (0.04-0.125%) may be combined with fentanyl, 1 to 2.5 mug/mL, or sufentanil, 0.1 to 0.3 mug/mL, at a rate of 8 to 15 mL/h to achieve excellent labor analgesia for the first and often the second stage of labor. One study found the analgesia conferred by an infusion of 0.0625 percent bupivacaine with 2.5 mug/mL of fentanyl at 12 mL/h to be equivalent to that from 0.0625 percent bupivacaine with 0.25 mug/mL of sufentanil. [207] The most significant advantage of combining these opioids with bupivacaine is the lack of motor blockade, [202] which may promote spontaneous vaginal delivery. [145] [203] There appear to be no adverse neonatal effects [198] or loss of beat-to-beat FHR variability when this technique is used. [200]

Suggested drug regimens for initiating lumbar epidural anesthesia for labor and vaginal delivery are presented in Table 57-7 . While an epidural block is being established, the mother should be kept on her side or positioned with left uterine displacement to prevent supine hypotension. Arterial blood pressure should be monitored every 1 to 2 minutes for the first 10 to 20 minutes after injection of local anesthetic until the block is established and stable. During the first 20 minutes after the initial dose and after any additional doses, the patient should be observed continuously and not be left unattended. The FHR and uterine contractions should be continuously monitored electronically before and after an epidural block is instituted. If the initial anesthetic injection does not result in satisfactory analgesia, the anesthesiologist assesses whether or not the epidural catheter is properly situated in the epidural space. If not, the catheter is replaced. If the block is too low or asymmetric, additional volume can be given. Some also advocate withdrawing the epidural catheter 1 cm or so and positioning the patient with the unblocked side dependent to assist with achieving a bilateral block. If labor is progressing rapidly, a more potent analgesic solution may be necessary.

Continuous-Infusion Lumbar Epidural Analgesia

Continuous infusion of low concentrations of local anesthetic into the epidural space provides a continuous stable anesthetic level, thereby avoiding the fluctuations in pain relief found with intermittent epidural injections during labor, and results in improved patient satisfaction. [208] [209] [210] Other potential benefits include less maternal hypotensive episodes from fluctuating levels of sympathetic block and a less labor-intensive anesthetic because there is no need for the time-consuming repeat test doses or the necessary close monitoring of the patient for the first 20 minutes after a reinjection. Because of the dilute local anesthetic solutions used, motor block can be limited. To safely achieve optimum analgesia and patient satisfaction, the anesthesiologist should examine and interview the patient frequently. At these times, the anesthesiologist can make necessary adjustments in the rate of infusion or the concentration of local anesthetic and can note any signs of intravascular or subarachnoid migration of the catheter. Between visits, the patient must be closely supervised by trained nurses. The technique is outlined in Table 57-7 .

The potential complications of this technique are intravascular or subarachnoid migration of the catheter during the infusion or epidural infusion rates that are too high. If the epidural catheter migrates into a blood vessel, the only side effect would probably be loss of analgesia. Significant systemic toxicity is avoided because of the very low rate of infusion of local anesthetic. If the epidural catheter accidentally punctures the dura mater, the onset of motor block from the resulting spinal analgesia would be slow and easily diagnosed. If the infusion rate is too high, the slowly ascending sensory level should be easily recognized.

Another form of continuous-infusion epidural analgesia is

patient-controlled epidural analgesia. [204] [211] [212] [213] [214] [215] After the epidural block is established, a slow rate of infusion is set, with the option for the patient to self-administer a small top-up dose as needed (see Table 57-7) . This form of analgesia requires that the patient understands that she has control over her analgesia. With analgesia being equivalent, one study found overall patient satisfaction with patient-controlled epidural analgesia to be higher than traditional continuous-infusion techniques. [214]

Caudal Analgesia

A caudal block is administered only after labor is well established. Caudal blocks are performed in patients positioned either on their sides or prone with a bolster under the thighs. With the coccyx used as a landmark for the midline, the sacral cornua and the sacrococcygeal ligament are palpated. Once the needle is placed in the canal, the surgical drapes are removed, and a rectal examination is performed to exclude the possibility of accidental puncture of the fetal presenting part and

subsequent anesthetic intoxication of the fetus. [216] After drapes and gloves are replaced, the caudal catheter is introduced through the needle. After aspiration, test doses of local anesthetics (as described for epidural anesthesia) are given. The volume necessary to provide a T10 block varies from 10 to 20 mL.

Lumbar epidural anesthesia is preferable to caudal anesthesia in labor for several reasons: (1) segmental T10-L1 dermatome levels can be achieved in early labor when sacral anesthesia is not required; (2) less drug is needed during labor; (3) pelvic muscles retain their tone, and rotation of the fetal head is more easily accomplished; and (4) despite the increased risk of dural puncture, placement of the lumbar epidural needle is often technically easier for the anesthesiologist and less painful for the patient than caudal anesthesia. Caudal anesthesia administered just before delivery has advantages over lumbar epidural anesthesia in that the onset of perineal anesthesia and muscle relaxation is more rapid. A "double-catheter" technique has been described in which a lumbar epidural catheter is placed for use during the first stage of labor, and a caudal catheter is placed for use during the second stage and delivery. This technique can be used in patients with cardiac disease in whom it is desired to avoid the high anesthetic (and sympathetic) block height that sometimes accompanies attempts to provide complete perineal analgesia with a lumbar epidural catheter.

Spinal Opioid Analgesia

Intrathecal injection of very small doses of opioids (Ch. 69) can produce effective labor analgesia without the usual systemic effects of opioids and without the motor block and sympathectomy that often accompany the use of epidural and spinal local anesthetics. Techniques using opioids alone during labor may be particularly useful in patients who wish to ambulate during early labor or in those with cardiac disease who require analgesia that is adequate to prevent the potentially dangerous increases in heart rate and cardiac output associated with painful labor and in whom anesthesia-related decreases in SVR and cardiac output would not be tolerated (e.g., aortic stenosis and pulmonary hypertension).

Morphine was the first intrathecal opioid studied for the relief of labor pain. Large doses were used initially (0.5-2.0 mg). [217] [218] Although intrathecal morphine provides good analgesia during the first stage of labor for many patients (see Fig. 57-17) , it is often inadequate for the second stage of labor. [218] The latency of analgesia with morphine is long (40-60 minutes), and the side effects, nausea (>50%) and pruritus (80%), are common. [218] Pruritus can be treated with diphenhydramine, nalbuphine, or naloxone. [219] Other side effects include urinary retention, drowsiness, dizziness, and potential respiratory depression. Subsequently, use of a smaller dose of morphine (0.25 mg) combined with fentanyl (25 mug) was reported [220] and found to provide a rapid onset (about 5 minutes) of reasonably good analgesia for the first stage of labor, but side effects remained problematic. Key to the successful use of intrathecal morphine for labor analgesia are recognizing and treating side effects and managing inadequate analgesia. Although respiratory depression is a rare side effect of intrathecal morphine, sedation and drowsiness can occur if women receive systemic analgesics in addition to intrathecal morphine. [221] The side effect profile of intrathecal morphine has led many to abandon its use in laboring patients, but it may be of benefit in patients with significant medical problems in whom it is desired to avoid the effects of epidural local anesthetics. [222] [223]

Sufentanil (10 mug) is commonly administered as an initial analgesic for labor. It has a rapid onset of action which lasts 60 to 180 minutes. Fentanyl (10-25 mug) alone also provides a rapid onset of analgesia lasting 30 to 120 minutes. [224] Fentanyl is used less often than sufentanil because of its shorter duration of action and a clinical impression that sufentanil provides better analgesia. [224] Sufentanil has a faster onset time than epidural bupivacaine (Fig. 57-18) (Figure Not Available) . [225] The addition of a small dose of bupivacaine (2.5 mg) to intrathecal sufentanil has been proposed to improve and increase the duration of the analgesia afforded by sufentanil alone [226] and has been described as being particularly helpful in patients in advanced labor. [227]

There are, however, notable side effects from intrathecal sufentanil. Pruritus is a frequent side effect (>80%). [224] [225] Hypotension (defined as a decrease in systolic blood pressure to <90 mm Hg) has also been reported following intrathecal sufentanil analgesia for labor. [226] Hypotheses to explain this hypotension include (1) a reduction in stress response as a result of analgesia and (2) sympathetic block from a local anesthetic effect of the opioid. Although sensory levels have been measured following intrathecal sufentanil [228] and may at times be quite high, [229] one study found no evidence of sympathetic block following intrathecal sufentanil, [230] suggesting that the observed changes in blood pressure are a result of reduced catecholamine levels and analgesia. Changes in the FHR have also been reported to occur within 40 minutes of injection of intrathecal sufentanil in 14 to 18 percent of patients. [228] [231] The cause of the FHR changes is unknown, but the incidence is similar to that following epidural bupivacaine. [231] Uterine hyperactivity following analgesia has been suggested. [232] It is prudent to monitor maternal blood pressure, uterine contractions, and FHR after intrathecal sufentanil injection. Finally, although rare (estimated incidence, 0.021%), [233] respiratory depression

Figure 57-18 (Figure Not Available) Visual analog pain scores after injection of intrathecal sufentanil (squares) or epidural bupivacaine (circles). Intrathecal sufentanil was injected at -2 minutes. Time 0 is the beginning of the injection of epidural bupivacaine (the times differ because a CSE technique was used for both groups of patients--the epidural bupivacaine patients received intrathecal saline, and the intrathecal sufentanil patients received epidural saline). Each point represents the median ± 25th and 75th percentiles of 25 patients. All time points beyond baseline differ from their respective baseline values. Intrathecal sufentanil provided a more rapid onset of analgesia, even allowing for the different injection times. * $P < .05$ versus sufentanil. *(From D'Angelo et al [225])*

and/or arrest have been reported following the use of intrathecal sufentanil. [234] [235] Proposed risk factors for respiratory depression include large dose (15 mug), repeat doses, and prior administration of parenteral opioids. Patients must be carefully observed for this side effect.

Intrathecal meperidine offers unique features for laboring patients. Intrathecal meperidine has local anesthetic effects, and large doses (60 mg) have been used for surgical anesthesia. Doses of 10 to 20 mg have been used for labor analgesia and have been reported to be particularly effective in patients in advanced labor. [236]

Combined Spinal-Epidural Analgesia

Intrathecal opioids can be administered as a single injection, through a continuous spinal catheter (e.g., an epidural catheter placed via an epidural needle--this technique may be feasible if attempted epidural placement proved difficult and was complicated by dural puncture), or by a combined spinal-epidural (CSE) technique. The CSE technique involves identifying the epidural space with an epidural needle, placing a long spinal needle through the epidural needle, confirming cerebrospinal fluid (CSF) flow, injecting the intrathecal drug, withdrawing the spinal needle, and then placing an epidural catheter to be used later in labor. When the epidural catheter is dosed for labor analgesia, the usual precautions (aspirating, administering a test dose, fractionating the total local anesthetic dose) must be followed. Less epidural local anesthetic may be required for effective analgesia in patients who have received intrathecal opioids, perhaps from an additive or synergistic effect of the previously injected opioid or from leak of the local anesthetic across the dura into the subarachnoid space. [237] [238]

Spinal Anesthesia for Vaginal Delivery

Spinal anesthesia of the sacral nerve roots, often called saddle block, is administered immediately before delivery. A small dose of hyperbaric local anesthetic (e.g., bupivacaine, 5 mg, or lidocaine, 15-20 mg), is injected into the subarachnoid space while the patient is in the sitting position to accomplish sacral anesthesia. More commonly, however, anesthetic distribution to a T10-S5 dermatome level is desired and can be accomplished with slightly larger doses of hyperbaric bupivacaine (6-8 mg) or lidocaine (30-50 mg). Care must be taken not to administer the drug just before or during a uterine contraction lest the accompanying Valsalva maneuver result in an excessively high anesthetic level.

Complications of Regional Analgesia

The most significant complications of regional anesthesia are severe hypotension, convulsions induced by local anesthetics, total spinal anesthesia with resulting respiratory arrest, nerve injury, and headache secondary to dural puncture.

Hypotension

Hypotension remains the most common side effect of major conduction anesthesia for vaginal or cesarean delivery. The incidence and the severity of hypotension depend on the dermatome level of the block, the position of the parturient, the physical status of the parturient, and the prophylactic measures taken to avoid hypotension. Such measures include administration of IV fluids before the block, left uterine displacement, and administration of ephedrine. [239] [240] [241] [242] It is most common after induction of spinal anesthesia for cesarean delivery but can certainly occur in the laboring patient. After administration of any regional block, vigilant monitoring of maternal blood pressure and symptoms (dizziness, shortness of breath, nausea) must be carried out. The FHR must also be evaluated so that any adverse effects on the fetus can be recognized. Hypotension in the obstetric patient can be defined as a systolic blood pressure of less than 90 mm Hg, or a decline

of 20 to 30 percent from baseline. Treatment of hypotension involves ensuring proper maternal position with the uterus displaced off the vena cava, administration of oxygen to the mother, infusion of IV fluids, use of head-down tilt, and administration of ephedrine, 5 to 10 mg IV. If recognized and treated promptly, transient maternal hypotension does not usually cause maternal or neonatal morbidity. [56] [243] [244]

Convulsions Induced by Local Anesthetic

Central nervous system toxicity occurs when the level of local anesthetic in arterial blood (and brain tissue) exceeds a critical level. High blood levels result from accidental intravascular injection, accumulation of local anesthetic after repeated injections, and rapid systemic absorption of local anesthetic from a highly vascular area. Accidental intravascular injection may occur with any regional anesthetic technique, including paracervical and pudendal blocks.

The elimination half-life of amide local anesthetics is 2 to 3 hours. Therefore, systemic accumulation of such anesthetics to near-toxic levels may occur when large doses are given repeatedly or frequently. During properly conducted regional anesthesia, however, the blood level of local anesthetics that occurs as a result of absorption rarely causes symptomatic toxicity, but there is large individual variability, particularly with lidocaine. [245] The risk of systemic accumulation can be minimized by use of the smallest quantity of drug necessary to achieve the desired anesthetic effect and by use of agents that are rapidly metabolized and intrinsically less toxic, such as chloroprocaine.

By talking to the patient frequently and by constantly observing her physical condition and vital signs, the physician not only can recognize incipient toxic reactions but may also mitigate their potential for serious effects as well. Systemic toxicity is usually heralded by sedation and slurred speech, and oxygen is administered. Administering thiopental, 50 to 75 mg, or a benzodiazepine may help prevent a convulsion. Should a seizure occur, the airway is maintained and the patient is ventilated with 100 percent oxygen. Succinylcholine both terminates the skeletal muscle activity (the source of metabolic acidosis after a seizure) and facilitates ventilation and intubation. [246] The maternal circulation is supported with IV fluids and vasopressors as needed. As soon as possible, the condition of the fetus should be assessed and, if necessary, the subsequent course of delivery altered appropriately. Prompt maternal resuscitation usually restores uterine blood flow and fetal oxygenation and permits fetal excretion of local anesthetic to the mother via the placenta.

Treatment of Cardiac Arrest

Cardiac arrest from IV injection of bupivacaine should be treated with external cardiac massage; defibrillation, if necessary; bretylium [247] ; and repeated doses of epinephrine. If the arrest occurs before delivery, all efforts should be made to rapidly deliver the fetus. Not only does this move the fetus to a healthier environment, but it also facilitates maternal resuscitation by relieving aortocaval compression. [157] Maternal blood gases are checked frequently, and any acidosis is corrected. [158] In one case report, cardiopulmonary bypass was used in a nonpregnant patient to support the circulation, minimize metabolic acidosis, and enhance clearance of the bupivacaine from the circulation. [248]

Total Spinal Anesthesia

Total spinal anesthesia usually occurs from an excessive spreading of local anesthetic administered intrathecally. It can occur during intended spinal anesthesia, even when appropriate doses are used. It can also occur if a presumed epidural catheter migrates into the subarachnoid space. [249] A high block can also result from subdural injection of anesthetics. [250] [251] [252] Characteristics of a subdural block include a relatively rapid onset of a high sensory level, sacral sparing, a patchy block, and an incomplete or absent motor block. Although total spinal anesthesia occurs infrequently, the patient must be monitored for it carefully after institution of an epidural or spinal block; severe hypotension and hypoxia from respiratory embarrassment occur quickly, with adverse maternal and fetal effects. Treatment consists of establishing an airway and ventilating with oxygen. Endotracheal intubation should be performed as soon as possible to protect the airway from aspiration. The Trendelenburg position and left uterine displacement should be used to increase venous return to the heart. Fluids and ephedrine should be administered as necessary to maintain blood pressure at a normal level. If accidental injection of a large volume of local anesthetic into the subarachnoid space is suspected, aspiration of the CSF should be considered.

Nerve Injury

Direct nerve injury from spinal or epidural needles and catheters is extremely rare. Pressure on the cord or spinal roots by a needle point produces excruciating pain, and the needle would be withdrawn immediately. Other potential neurologic complications, also very rare, include epidural hematoma; infections, such as epidural and caudal abscess and meningitis; and chemical contamination of the subarachnoid or epidural space. The few instances of reported epidural hematoma associated with regional blocks have occurred mainly in older patients who had defective coagulation capabilities.

In obstetrics, nerve injury in the mother is usually not related to anesthesia but either to compression of the lumbosacral trunk (Fig. 57-19) (Figure Not Available) between the head of the fetus and the sacrum or stretching or compression injuries of the femoral, lateral femoral cutaneous, or peroneal nerves when the patient is in the lithotomy position (Fig. 57-20) (Figure Not Available) . Recovery from these injuries may require 12 to 16 weeks.

Headache After Dural Puncture

Headaches secondary to puncture of the dura mater are caused by leakage of CSF through a patent hole in the dura. Loss of the cerebral CSF "cushion" results in traction on sensitive structures (blood vessels) within the cranium. CSF leak and incidence of headache are related to the size of the needle used (lower with smaller-gauge needles), [253] the number of dural punctures, the patient age, the type of spinal needle (cutting versus noncutting or pencil point), [253] [254] [255] and the direction of the needle bevel (lower with the bevel of a cutting-type needle placed parallel to the dural fibers). [253] [256] [257] About 80 percent of parturients experience a headache after puncture with a 16-gauge epidural needle [256] (i.e., when the dura is accidentally punctured during an attempted epidural block), and about 1 to 4 percent have a significant headache when a 24- to 26-gauge

Figure 57-19 (Figure Not Available) Relationship of the lumbosacral cord to the pelvis and the psoas major muscle. *(From Cole [433])*

Figure 57-20 (Figure Not Available) Common peroneal nerve compressed between lithotomy stirrup and neck of fibula. This can be avoided by padding or having the legs hang away from the stirrup supports. *(From Britt and Gordon [434])*

pencil-point spinal needle is used. [258] [259] Diagnosis is made from clinical history; classically, a postdural puncture headache is postural (worse on standing). Conservative therapy consists of bed rest, analgesics, hydration, and wearing of a tight abdominal binder, which increases epidural pressure and decreases the amount of leaking CSF. Caffeine, perhaps via cerebral vasoconstriction, has also been suggested as therapy for postdural puncture headache. [260] [261]

A blood patch epidural with autologous blood may be performed in patients having severe headaches following dural puncture. Under a rigidly aseptic technique, approximately 10 to 20 mL of blood is withdrawn and immediately placed into the epidural space at the site of the dural rent. If the site of the dural rent is uncertain because of the presence of multiple puncture sites, the lowermost interspace should be used because of the cephalad spread of solutions in the epidural space. [262] The success rate for this procedure is about 90 to 95 percent. [263] [264] Follow-up evaluation has indicated that the epidural blood patch is without serious complication. [265] Although backache is the most common complication, it is seldom severe or incapacitating. The administration of a prophylactic blood patch after accidental dural puncture is controversial. Loeser et al [266] reported a high failure rate for epidural blood patches performed less than 24 hours after dural puncture, but others have found that 15 to 20 mL of autologous blood injected through an epidural catheter after delivery was highly effective in avoiding a subsequent headache. [267] [268] Infusion of epidural saline (10-15 mL/h for 24 hours) after the dural puncture may also limit postdural puncture headache. [269]

Other Blocks in Obstetrics

Paracervical Block

Paracervical block is a relatively simple procedure sometimes used by obstetricians to provide analgesia during labor. Local anesthetic is injected in the submucosa of the fornix of the vagina lateral to the cervix (Fig. 57-21) (Figure Not Available) . The Frankenhauser ganglion, which contains all the visceral sensory nerve fibers from the uterus, cervix, and upper vagina, is anesthetized, but the somatosensory fibers from the perineum are not blocked. Thus, this technique is effective only during the first stage of labor. The major disadvantage of paracervical block anesthesia is the relatively high incidence (8-39%) [270] of fetal bradycardia that occurs after the block. This bradycardia is associated with fetal acidosis, decreased oxygenation,

---

Figure 57-21 (Figure Not Available) Diagram of paracervical area in relation to uteroplacental circulation. From this figure it can be appreciated that the local anesthetic is deposited close to the uterine artery where vasoconstriction or rapid uptake could occur. *(From Asling et al [432])*

and increased likelihood of neonatal depression. Bradycardia usually develops within 2 to 10 minutes of the block and lasts from 3 to 30 minutes. Bradycardia may be related to decreased uterine blood flow, caused by constriction of the uterine artery from closely applied local anesthetics, [271] or it may be related to high levels of local anesthetics absorbed into the fetal circulation (see Fig. 57-21) (Figure Not Available) . [272]

Pudendal Block

Pudendal block and local perineal infiltration anesthesia are usually administered just before delivery and are most commonly performed by the obstetrician through the vagina. During the block, the patient is in the lithotomy position. To give a pudendal block, the physician palpates the ischial spine, places a needle guide under the spine, and introduces a 20-gauge needle through the guide until the point rests on the vaginal mucosa. The needle is advanced approximately ½ inch and pierces the sacrospinous ligament. After negative aspiration, 10 mL of local anesthetic (e.g., 1% lidocaine or mepivacaine and 2% 2-chloroprocaine) is injected. The technique is then repeated on the other side.

General Anesthesia

General anesthesia is rarely needed for vaginal delivery but might be used for emergent operative (forceps or vacuum extraction) vaginal delivery if regional techniques are contraindicated and if other analgesics have proved to be inadequate. General anesthesia can also be used if profound uterine relaxation is needed for intrauterine manipulations for internal podalic version, complete breech extraction, manual removal of the placenta, or replacement of an inverted uterus. The potent inhaled anesthetics isoflurane, enflurane, and halothane cause dose-dependent uterine muscle relaxation and can be used therapeutically. After rapidsequence induction and endotracheal intubation, oxygen and inhaled agent are administered in doses high enough to provide uterine muscle relaxation, while maternal hemodynamics are carefully monitored. As soon as the desired effect is reached and the intrauterine manipulation is complete, the inhaled agent is discontinued to allow the uterus to contract after delivery and to stop bleeding. Uterine muscle relaxation can also apparently be accomplished with IV injection of small (50-100 mug) incremental doses of nitroglycerin. [273] [274] [275] This technique is particularly useful when effective analgesia exists (e.g., with a regional block or IV opioids) because it avoids the need to induce general anesthesia.

ANESTHESIA FOR CESAREAN SECTION

The choice of anesthesia for cesarean section depends on the reason for the operation, the degree of urgency, and the desires of the patient. The anesthesiologist must choose the method that is believed to be safest and most comfortable for the mother and least depressant to the newborn and that provides the optimal working conditions for the obstetrician. Survey data from 1992 from the United States reveal that more than 84 percent of cesarean deliveries are performed with regional anesthesia (spinal, 40%; epidural, 44%; general, 17%). [88] This represents a change since 1981 (spinal, 34%; epidural, 21%; general, 41%). [88]

Regional Anesthesia

Advantages to regional anesthesia include an awake mother, minimal newborn depression, and avoidance of the risks of general anesthesia. These advantages of regional anesthesia (and the risk of general anesthesia) are recognized not only by anesthesiologists but also by the American College of Obstetricians and Gynecologists. In the 1992 Committee Opinion publication "Anesthesia for Emergency Deliveries," [276] the risks of failed intubation and aspiration pneumonitis are recognized as serious complications of general anesthesia. Goals to promote the use of regional anesthesia and minimize the need for general anesthesia are stated and include (1) anesthetic consultation for patients in whom emergency induction of general anesthesia would be particularly hazardous, (2) establishment of IV access and placement and testing of an epidural catheter early in labor in patients at risk for cesarean delivery, and (3) recognition that cesarean delivery for a nonreassuring fetal status does not necessarily preclude the use of regional anesthesia.

Spinal Anesthesia

Advantages of spinal anesthesia include its simplicity, small drug dose, low failure rate (about 3% [277]) and rapid onset.

Figure 57-22 (Figure Not Available) The relationship between height and weight and maximum cephalad spread of block after intrathecal injection of 12 mg hyperbaric bupivacaine to 50 term parturients undergoing cesarean delivery. Symbols: circle, one patient; square, two patients; triangle, three patients; diamond, four patients. There was no predictable relationship between patient height or weight on the extent of spinal block. *(From Norris [435])*

Disadvantages include a higher incidence of hypotension and a finite duration of anesthesia.

Use of hyperbaric bupivacaine limits the significance of the finite duration of spinal anesthesia because its duration (1.5-2 hours) is suitable for the majority of cases. However, the block level with single-shot spinal anesthesia is not predictable. When giving all parturients a set dose (12 mg) of hyperbaric bupivacaine for cesarean delivery, Norris [278] found that anesthetic block levels ranged from T7 to C8. Patient height, weight, or body mass index did not correlate with block height (Fig. 57-22) (Figure Not Available) . On average, increasing the dose of spinal anesthetic increases block height, [279] but the range of block heights is still great. Flexibility limitations of spinal anesthesia can be overcome by use of a continuous spinal anesthetic technique. Continuous spinal anesthesia (using an epidural catheter threaded into the subarachnoid space via an epidural needle) is an option if the initial block attempt was difficult and/or complicated by dural puncture and has been described in a patient with severe kyphoscoliosis [280] and in morbidly obese parturients. [281]

Hypotension occurs more often during spinal (45- 100%) [59] [241] [282] than epidural anesthesia (15-44%). [169] [283] The varied percentage of hypotension in different studies probably stems from varied definitions of hypotension and regimens of prehydration, as well as factors that are difficult to control (completeness of left uterine displacement and preoperative volume status). As previously described, treatment strategies for hypotension include ensuring left uterine displacement, using head-down tilt, administering IV fluids, and administering ephedrine boluses or infusion. [284] [285] Phenylephrine has also been studied for use during cesarean delivery and has been found to be safe and effective in normal parturients. [58] [59] The impact on the fetus of maternal hypotension during spinal anesthesia is controversial. Some have reported decreased umbilical arterial pH in fetuses born of mothers receiving spinal anesthesia compared with those receiving epidural anesthesia for cesarean delivery. [286] [287] Others have not found differences in umbilical cord acid/base status with these two anesthetics. [288] Most studies do not find important differences in newborn vigor or neurologic and adaptive capacity scores with the two anesthetic techniques. [286] [287] [288] The potential impact of hypotension on the fetus must be appreciated.

Analgesia during spinal anesthesia has been reported to be improved when 0.2 mg of epinephrine, [289] 0.2 mg of morphine, [290] epinephrine 0.2 mg plus morphine 0.2 mg, [290] 10 mug of fentanyl, [291] [292] [293] or 10 mug of sufentanil [294] are added to hyperbaric bupivacaine or lidocaine. The addition of opioids to spinal bupivacaine also improves the duration of analgesia after surgery. A suggested technique of spinal anesthesia for cesarean delivery appears in Table 57-8 .

Epidural Anesthesia

Flexibility is probably why epidural anesthesia is used more often than spinal anesthesia for cesarean delivery. [88] Patients with an epidural catheter in place for labor can have the block extended to provide suitable anesthesia for cesarean delivery. An epidural catheter should be placed early and tested for function in patients at risk for cesarean delivery, such as obese parturients. [295] Flexibility for the duration of anesthesia for surgery and control of block height are other advantages of epidural anesthesia.

TABLE 57-8 -- Suggested Technique for Regional Anesthesia for Cesarean Section

1. Administer a nonparticulate oral antacid within 1 h of anesthetic induction.
2. Transport the patient to the operating room in the lateral position. Monitor maternal blood pressure, heart rate, and oxygen saturation throughout surgery. Monitor the FHR during induction of anesthesia, if possible.
3. Administer rapidly 1,000-2,000 mL of dextrose-free balanced salt solution IV. Administer supplemental oxygen to the mother via face mask or nasal prongs.
4. Before starting the block, check resuscitation equipment and drugs: (1) oxygen delivery system in the anesthesia machine; (2) airways; (3) laryngoscope; (4) endotracheal tubes; (5) thiopental or diazepam for possible convulsions; (6) ephedrine for hypotension; and (7) suction apparatus.
5. Administer block.

SPINAL ANESTHESIA

Use smallest needle possible and/or needle with noncutting point (Sprotte, Whitacre, or Gertie Marx).

LOCAL ANESTHETIC OPTIONS:

i. 7-10 mg of hyperbaric tetracaine (tetracaine 1% and equal volumes of 10% dextrose in water)

ii. 60-75 mg of lidocaine (1.2-1.5 mL of lidocaine 5% in 7.5% dextrose in water)

iii. 12-15 mg of bupivacaine (1.6-2.0 mL of bupivacaine 0.75% in 8.25% dextrose in water)

ADDITIVES:

i. Epinephrine, 0.2 mg

ii. Sufentanil, 10 mug

iii. Fentanyl, 10 mug

iv. Morphine 0.1-0.25 mg

v. Fentanyl and morphine in above doses

EPIDURAL ANESTHESIA

Epidural catheter is placed by use of usual technique and tested for possible intravascular or subarachnoid location.

LOCAL ANESTHETIC OPTIONS:

(15-30 mL total dose given in 5-mL increments)

i. 1.5-2.0% lidocaine

ii. 0.5% bupivacaine

iii. 3.0% chloroprocaine

iv. 0.5% ropivacaine

v. Epinephrine may be added to a maximum concentration of 1:200,000.

OPIOID OPTIONS:

i. Fentanyl, 50-100 mug, or sufentanil, 10-20 mug, may be added to above local anesthetics to enhance intraoperative analgesia.

ii. Morphine (3-5 mg) may be administered through the epidural catheter following delivery.

6. Position patient with left uterine displacement and slight (10-degree) Trendelenburg tilt.

7. Monitor arterial blood pressure every minute until birth of the baby, then every 5 min for duration of block.

8. If systolic blood pressure falls by 30% or below 90 mm Hg, ensure left uterine displacement and increase IV infusion rate. If blood pressure is still not restored, administer 5-15 mg of ephedrine IV; repeat if necessary.

9. Treat anxiety and incomplete or "spotty" anesthesia with one or more of the following agents:

a. 0.25-1.0 mg of midazolam IV

b. 0.5-1 mug/kg of fentanyl IV

c. 40-50% nitrous oxide

d. 0.25 mg/kg of ketamine IV

e. 10-20 mL of 0.5% lidocaine intraperitoneally

10. If analgesia is inadequate, proceed to general anesthesia with endotracheal intubation.

11. Postoperative analgesia can be provided with intrathecal or epidural morphine [420] or patient-controlled analgesia. [421] [422] A system for detecting side effects, including excessive sedation and/or respiratory depression, should be in place if intrathecal or epidural morphine is used. [423]

It is notable that despite some decrease in blood pressure during the induction of a surgical level of epidural anesthesia, remarkable stability in maternal cardiac output has been reported. [286] There are maternal conditions that favor the less rapid onset of sympathetic blockade of epidural anesthesia, such as severe hypertension and preeclampsia. [296] With only moderate prehydration (500-750 mL of crystalloid) and a slow onset of anesthetic block, remarkable hemodynamic stability can be maintained. Similarly, patients with mitral or aortic stenosis have been given epidural anesthesia (induced slowly) with appropriate cardiovascular monitoring guiding treatment of hemodynamic perturbations. [297] [298] [299]

The commonly used drugs for epidural anesthesia for cesarean delivery include 2 percent lidocaine ± epinephrine, 1:200,000; 3 percent 2-chloroprocaine; 0.5 percent bupivacaine; and 0.5 percent ropivacaine. Usually, 15 to 30 mL of local anesthetic is required. As such, the possibility of local anesthetic toxicity must be recognized. IV placement of the epidural catheter must be identified, and any epidural local anesthetic must be injected in incremental doses. 2-Chloroprocaine, because of its rapid onset and rapid metabolism, is a good choice for urgent/emergent surgery. Otherwise, lidocaine, which has a longer duration of action and less interference with epidural opioids, is often used. Bupivacaine and ropivacaine have similar characteristics, with a slower onset time and longer duration than lidocaine.

Intraoperative analgesia with lidocaine epidural anesthesia is improved in some patients if fentanyl, 50 to 100

---

mug, [300] [301] or sufentanil, 10 to 20 mug, [302] is added to the local anesthetic. With either spinal or epidural anesthesia, patients undergoing cesarean delivery are most comfortable when regional block height is at least T4. [303] A suggested technique for epidural anesthesia for cesarean delivery appears in Table 57-8 .

CSE Anesthesia

Perhaps the advantages of spinal anesthesia (rapid onset of a dense block) and the advantages of epidural anesthesia (prolonged intraoperative anesthesia and postoperative analgesia) can be obtained with a CSE block. A low or standard dose of local anesthetic is first administered intrathecally, then an epidural catheter is placed. The initial spinal anesthetic can be extended (in height or duration) with epidural local anesthetic. Rawal et al [304] reported improved anesthesia with CSE versus epidural bupivacaine alone. Thoren et al [305] reported CSE to be similar to spinal anesthesia alone. Potential problems of the CSE technique include the inability to "test" the epidural catheter for proper location and the enhanced spread of previously injected spinal drug following the epidural injection. [306]

General Anesthesia

General anesthesia may be necessary for management of cesarean delivery in the obstetric patient in circumstances of severe fetal compromise, maternal hemorrhage or overt coagulopathy, or patient preference. General anesthesia has the advantages of rapid induction, less associated hypotension and cardiovascular instability, and better control of the airway and ventilation. Management of anesthesia for cesarean section is outlined in Table 57-9 . Potential problems during general anesthesia include pulmonary aspiration of gastric contents, failed intubation, maternal hyperventilation, neonatal depression, maternal awareness, and uterine atony.

TABLE 57-9 -- Suggested Technique for General Anesthesia for Cesarean Section

1. Administer a nonparticulate oral antacid within 1 h of induction. A histamine $_2$ blocker and/or metoclopramide can also be given.
2. Position the patient with left uterine displacement. Maternal monitoring includes at least blood pressure, ECG, pulse oximetry, capnography.
3. Preoxygenate with high flow rates of oxygen (>6 L/min).
4. When the surgeon is ready to begin, an assistant applies and maintains cricoid pressure until position of endotracheal tube is verified and trachea is sealed by inflated cuff.
5. Administer 4-5 mg/kg of thiopental and 1.5 mg/kg of succinylcholine, wait approximately 60 s, then intubate trachea.
6. Administer 50% nitrous oxide in oxygen plus either halothane 0.5%, isoflurane 0.75%, or enflurane 1%. Use muscle relaxant as necessary.
7. Avoid maternal hyperventilation.
8. After the umbilical cord is clamped, deepen anesthesia with nitrous oxide, opioid, or benzodiazepine; the halogenated hydrocarbon may be continued in low doses.
9. Extubate when the patient is awake.

Prevention of Pulmonary Aspiration of Gastric Contents

Aspiration of gastric contents during general anesthesia is a major cause of maternal morbidity and mortality. Routine administration of clear antacid, such as sodium citrate, before induction significantly raises gastric pH. [307] [308] However, use of antacids does not diminish the risk of aspiration of particulate matter. Preanesthetic administration of a histamine$_2$ -receptor antagonist, such as ranitidine, [309] [310] has been suggested to decrease gastric acidity and volume; an interval of several hours after oral administration [310] and at least 30 minutes after IV administration are needed for the agent to be effective. [309] Metoclopramide is an antiemetic that increases stomach emptying and raises gastroesophageal sphincter tone. [311] Its efficacy and safety for aspiration prophylaxis in obstetrics have not been fully elucidated. [312] [313] Because of its possible beneficial effects on gastroesophageal sphincter tone and gastric volume, it might be useful in obese parturients or in those who have recently eaten. No adverse fetal or neonatal effects have been described. [312] [313]

A rapid-sequence induction of anesthesia is used for cesarean delivery to minimize the chance of regurgitation before endotracheal intubation. Preoxygenation (either 3-5 minutes of tidal ventilation or four vital capacity breaths) [314] must occur before induction to prevent hypoxia during the apnea before intubation. Positive-pressure ventilation should be avoided, and cricoid pressure should be (Sellick maneuver) used to occlude the esophagus and prevent passive regurgitation. [315] Finally, the patient should be extubated only after she is fully awake and after protective laryngeal reflexes have been restored.

Failed Endotracheal Intubation

A report of anesthesia-related maternal mortality (1979-1990) found that most (106/129; 82%) maternal deaths during anesthesia occur during cesarean delivery. [164] Further, 67 (52%) occurred during general anesthesia, and airway problems accounted for 73 percent of general anesthesia-related deaths. Other reports have found the inability to secure an airway to be a leading cause of anesthesia-related maternal mortality (Ch. 39) . [316] [317] [318] Difficulties with endotracheal intubation occur more commonly in obstetric patients than in general surgical patients. [319] [320] Although maternal deaths resulting from complications of regional anesthesia have decreased over the past decade, the number of deaths resulting from general anesthesia has remained fairly constant. [164] Factors that may contribute to the risk of death during general anesthesia include inadequate time for a thorough airway evaluation, unpredicted airway edema, emergency situations, inadequate skill, and inadequate assessment of proper endotracheal tube position.

Rocke et al [321] looked at factors that were assessed preoperatively that were associated with difficult intubation in 1500 parturients undergoing cesarean delivery with general anesthesia. Mallampati [320] [322] [323] airway classification, short neck, receding mandible, and protruding maxillary incisors emerged as important factors predicting a difficult or failed

Figure 57-23 (Figure Not Available) The probability of experiencing a difficult intubation (defined as either a very difficult intubation requiring mask ventilation, intubating stylet, or different laryngoscope, or the inability to pass a tracheal tube after several attempts or unrecognized esophageal intubation) for the combination of risk factors: Mallampati class I, II, III, or IV, short neck (SN), protruding maxillary incisors (PI), or receding mandible (RM). Data were obtained from 1500 patients undergoing cesarean delivery with general anesthesia. Values in parentheses are the observed incidences of risk factor combinations in the series. *(From Rocke et al [321])*

intubation. However, other airway measures were not assessed, such as mouth opening and atlanto-occipital joint mobility. From their data, an estimated prediction of difficult intubation was calculated from various combinations of these factors (Fig. 57-23) (Figure Not Available) .

Although it is useful to have an index of suspicion about airway problems, airway difficulties may not always be predicted from the preoperative examination. Therefore, a failed intubation drill should be rehearsed by all those providing obstetric anesthesia. The following principles are offered

1. Perform as thorough an airway examination as possible given the clinical circumstances. When a patient has a known or predicted difficult airway, inform the obstetricians that rapid induction of general anesthesia could jeopardize the health of the mother and that you will require time to perform either an awake intubation or a regional anesthetic.
2. Have equipment available (either in the operating room or in a known place that an assistant could quickly find) to help manage the difficult airway. This might include a variety of laryngoscope blades, several sizes of endotracheal tubes, laryngeal mask airway, Combitube, fiberoptic bronchoscope, and a means of transtracheal jet ventilation. Use familiar equipment.
3. If a difficult airway is encountered, call for help and obtain difficult intubation equipment. Inform all operating room personnel and obstetricians of your situation. Prior education of operating room personnel and obstetrics staff helps them assist you.
4. Hypoxia occurs quickly during management of a difficult airway of the parturient. Monitor oxygen saturation during induction of general anesthesia and airway manipulation. Institute mask ventilation if oxygen saturation decreases.
5. Maintain cricoid pressure during induction and attempts at intubation unless cricoid pressure is contributing to difficulties with airway management.
6. Avoid multiple attempts at laryngoscopy. This only contributes to airway edema and increased difficulty oxygenating by mask. Do something different with each attempt at laryngoscopy--do not repeat unsuccessful techniques. Patients die from hypoxia, not the absence of an endotracheal tube.
7. Avoid repeated doses of succinylcholine. Optimize success on the first attempt at intubation by waiting for the onset of complete paralysis before performing laryngoscopy. If intubation is unsuccessful, allow the patient to resume spontaneous ventilation--this helps preserve maternal oxygenation.
8. In nonemergent circumstances, the patient should be awakened, and the surgery should be performed under either regional anesthesia or general anesthesia after the airway is secured with the patient awake. [324]
9. In emergency situations (e.g., severe fetal compromise), make an honest assessment about your ability to oxygenate the mother. This is the priority. If you are able to oxygenate the mother, assess whether or not you can adequately

ventilate and anesthetize the mother. Is maintaining anesthesia by mask a reasonable option? After delivery, the patient may be easier to support (functional residual capacity increases, aortocaval compression is released). An anesthetic technique utilizing spontaneous ventilation, 100 percent oxygen, low-dose inhaled anesthetic, and intermittent IV ketamine or other IV analgesic has been suggested for this situation.

10. In emergent situations in which mask ventilation is difficult or impossible, the priority is still maternal oxygenation. The laryngeal mask airway, although not protecting against aspiration, may be helpful in this circumstance to maintain a patent airway and has been described during the management of the difficult airway in obstetric patients. [325] [326] With the patient breathing spontaneously, the laryngeal mask airway can be used to administer inhaled anesthetics. Further, the laryngeal mask airway provides a conduit to potentially guide placement of a fiberoptic bronchoscope followed by an endotracheal tube. The Combitube, a tube with separate esophageal and tracheal lumens, could also be used to maintain the maternal airway. If oxygenation is not adequate with these techniques, move on to transtracheal jet ventilation or a surgical airway (tracheostomy). [327]

11. Use a method of detecting exhaled carbon dioxide to ensure proper placement of the endotracheal tube.

A diagram of suggested management principles appears in Figure 57-24 .

Adverse Effects of Hyperventilation

Maternal hyperventilation (arterial carbon dioxide pressure < 20 mm Hg) during general anesthesia may be harmful to the unborn fetus. Uterine blood flow is reduced during the institution of positive-pressure ventilation, and hyperventilation causes a leftward shift in the maternal oxygen-hemoglobin dissociation curve and decreases oxygen

Figure 57-24 An algorithm for management of a difficult intubation in the obstetric patient. Means to oxygenate the mother include mask ventilation, laryngeal mask airway, Combitube, transtracheal jet ventilation, or tracheostomy. Alternative anesthetic techniques include regional anesthesia, general anesthesia following awake intubation, or local anesthesia.

availability to the fetus. [328] Hypocarbia may also cause decreased umbilical blood flow from vasoconstriction. [329]

Neonatal Depression

The general anesthetics (nitrous oxide and volatile anesthetics) used for cesarean delivery cross the placenta and can cause neonatal depression (Ch. 58) . Neonatal depression is limited if the time from induction of anesthesia to delivery is less than 10 minutes. [330] Therefore, the duration of anesthesia before delivery should be as brief as possible. This can be accomplished by delaying induction of anesthesia until the patient is prepared and draped and the obstetrician is ready to start. However, although prolonged exposure reduces Apgar scores, the acid/base status of the newborn is not affected provided that maternal hypoxia, excessive hyperventilation, aortocaval compression, and hypotension are avoided and the uterine incision to delivery interval is less than 3 minutes. [331] Retrospective studies associate neonatal depression with the use of general anesthesia; however, these reports are flawed by selection bias. Neonates born of mothers receiving general anesthesia may be more depressed and acidotic and require increased resuscitation not because of general anesthesia per se but because of the reason that general anesthesia was chosen (e.g., severe fetal compromise, maternal hemorrhage). [332] [333] Comparisons of neonatal outcome after elective cesarean delivery with either general or epidural anesthesia do not show important differences in neonatal outcome. [288] [334]

Drugs Used for Induction of Anesthesia

Thiopental

Thiopental is the most commonly used induction agent in obstetrics. Clinical data, in which Apgar scores were used to assess newborn vigor, suggest that the neonate is not depressed following maternal administration of bolus doses of 4 to 7 mg/kg of thiopental [335] [336] to induce general anesthesia. Because thiopental crosses the placenta rapidly, delivery is not possible before the drug is transferred to the fetus (Fig. 57-25) (Figure Not Available) . [63] [335] Fetal brain concentrations of thiopental are limited because blood from the placenta first passes through the liver; most of the thiopental is either cleared by the liver or diluted by blood from the lower extremities and the viscera. [63]

Ketamine

Ketamine is an induction agent that is often used in the asthmatic or potentially hypovolemic patient. Ketamine crosses the placenta rapidly but does not produce neonatal depression unless it is used in doses above 1 to 1.5 mg/kg. [337] [338] At higher doses (>2 mg/kg), neonatal depression has been reported. [339] Because of its sympathomimetic effects, it is usually avoided in patients with hypertension. It has varied effects on uterine contraction frequency, with studies showing an increase postpartum and in early gestation [340] [341] and another study showing no effect at term. [341]

Figure 57-25 (Figure Not Available) The level of thiopental in maternal vein, umbilical vein, and umbilical artery after injection of a single dose of 4 mg/kg for induction of anesthesia. Note the rapid decay of the maternal venous blood level and the rapid transfer to the fetus. *(From Kosaka et al [335])*

Propofol

Propofol has been evaluated for use both as an induction agent and as a maintenance anesthetic during cesarean delivery. For induction, use of 2.0 to 2.5 mg/kg of propofol is not different than thiopental, 4 to 5 mg/kg, in terms of newborn vigor but is associated with less maternal hypertension. [342] [343] [344] [345] [346] Placental transfer of propofol appears to be similar to that of thiopental. Animal studies suggest that an induction dose of propofol does not adversely effect uterine blood flow and placental gas exchange. [347]

Etomidate

Etomidate has also been studied for use in the obstetric patient. When compared with thiopental, 3 to 4 mg/kg, etomidate, 0.3 mg/kg, is associated with a greater hypertensive response to laryngoscopy and intubation. Neonatal outcomes are equivalent. [348] This agent is perhaps best suited for clinical circumstances of maternal hypovolemia or when the myocardial depressant effects of thiopental should be avoided.

Muscle Relaxants

Succinylcholine, pancuronium, atracurium, and vecuronium do not cross the placenta in clinically significant amounts and may be used safely during cesarean section. [349] [350] [351] At this time, no nondepolarizing muscle relaxant matches the rapid onset of succinylcholine. Preliminary studies of rocuronium (0.6 mg/kg) with thiopental (6 mg/kg) or ketamine (1.5 mg/kg) in obstetric patients reveals a favorable profile (onset time, about 1.5 minutes; duration, 30-45 minutes). [352] [353]

Maintenance of Anesthesia

Anesthetic maintenance before delivery must balance neonatal vigor with adequate maternal anesthesia. To ensure adequate fetal oxygenation, an F_{IO_2} of at least 50 percent before delivery is recommended. However, 50 percent nitrous oxide alone does not provide adequate maternal anesthesia. Crawford [354] reported a high incidence (26%) of awareness during surgery if anesthesia was maintained with only 50 percent nitrous oxide and oxygen before delivery. Adding a low dose of potent inhaled agent (e.g., 0.5% halothane, 0.75% isoflurane, 1.0% enflurane) to 50 percent nitrous oxide limits maternal recall without increasing newborn depression. [330] A survey of 3,000 patients who received such a general anesthetic for cesarean delivery reported an overall rate of recall of 0.9 percent and a 6.1 percent rate of dreaming. [355] Clinical trials have also found sevoflurane (1.0% end tidal [ET]) to be equivalent to isoflurane (0.5% ET) [356] and desflurane (3.0% ET) to be equivalent to enflurane (0.6% ET). [357] Halothane, isoflurane, and enflurane decrease uterine contractility and tone in a dose-related fashion. [358] This feature can be advantageous if uterine relaxation is needed during cesarean delivery with general anesthesia. However, after delivery of the fetus, uterine muscle contraction is necessary to stop uterine bleeding. High doses of the volatile anesthetics could contribute to bleeding by inhibiting uterine muscle contraction. However, the uterus contracts in response to oxytocin, provided less than 0.8 to 1.0 MAC of volatile agent is administered. [359]

After delivery of the fetus, nitrous oxide concentrations can be increased as appropriate, and IV opioids or benzodiazepines can be administered in order to maintain adequate maternal anesthesia. Continued use of low doses of inhaled agent can also be used.

ANESTHESIA FOR COMPLICATED OBSTETRICS

Emergency Cesarean Delivery

Sudden, unexpected complications occurring during late pregnancy or labor that adversely affect the mother or fetus may necessitate an immediate emergency cesarean delivery. Such complications include massive bleeding, prolapsed umbilical cord, or concerns about fetal status. When the mother or fetus is in immediate jeopardy, general anesthesia is usually selected, but under some circumstances, extension of an existing epidural or administration of a subarachnoid block may be appropriate.

When concerns about the fetus lead to cesarean delivery, the anesthesiologist should help institute measures to improve the uterine environment. If the worrisome fetal condition persists, choice of anesthetic for cesarean delivery must weigh the urgency of the situation against the risk of a specific anesthetic to the mother. Marx et al [360] reported fetal outcome after cesarean delivery for "fetal distress" (defined as severe heart rate abnormalities and a capillary blood pH < 7.20 or decreasing steadily) depending on anesthetic management (general anesthesia [*n* = 71], spinal anesthesia [*n* = 33], or extension of an existing epidural block [*n* = 22]). There were no differences between the groups with regard to fetal biochemical data, but the use of general anesthesia was associated with lower Apgar scores at 1 minute. When faced with providing anesthesia for emergency cesarean delivery, the anesthesiologist communicates with the obstetrician. Choice of anesthetic technique for emergency cesarean delivery for fetal concerns must consider fetal status (estimated degree of acidosis and time before delivery should be accomplished) and condition of the mother (volume status, airway examination).

Preeclampsia and Eclampsia

Preeclampsia, a disease unique to the parturient, complicates 7 to 10 percent of all pregnancies. Preeclampsia is categorized as mild or severe (Table 57-10) . Preeclampsia and other hypertensive disorders are a leading cause of maternal mortality. Causes of maternal death include cerebral vascular accidents, pulmonary edema, and hepatic necrosis/rupture. Obstetric management involves medical management of the disease symptoms; the timing of delivery considers the maternal condition (worsening of disease) and fetal issues (prematurity, intrauterine growth retardation). The disease is cured by delivery.

Pathophysiology

The cause of preeclampsia remains unknown. A proposed theory suggests that an abnormality in placentation results in reduced trophoblastic perfusion. This causes the release of some substance that is cytotoxic to endothelial cells. [361] Endothelial cell damage triggers vasoconstriction (hypertension), platelet activation, and prostacyclin/thromboxane imbalance. [362] The hypertension contributes to ongoing endothelial cell damage. [363] Endothelial cell damage disrupts capillary integrity, resulting in edema. Although classically preeclampsia has been defined as the triad of hypertension, proteinuria, and edema occurring after 20 weeks' gestation, it is clear from consideration of the pathophysiology that preeclampsia is a multisystem disease. Virtually all organ systems can be affected. Anesthetic management of preeclamptic patients starts with an assessment of how the disease affects a particular patient.

Manifestations

Preeclampsia is a state of generalized vasoconstriction and hypoperfusion. Despite retention of sodium and water and generalized edema, the intravascular volume is usually decreased. The cardiac effects of preeclampsia are diverse and reflect the severity of the disease. [296] A spectrum exists from hypertension from a high cardiac output state with a low SVR to relatively low cardiac output with hypertension from a high SVR. Appreciating where a given patient lies on this spectrum helps the anesthesiologist choose appropriate antihypertensive therapy. The high cardiac output state typically exists in younger patients early in the course of the disease. Conversely, an older patient with chronic hypertension

TABLE 57-10 -- Classification of Preeclampsia and Eclampsia

MILD PREECLAMPSIA
Blood pressure >140/90 mm Hg or >30/15 mm Hg increase from baseline
Generalized edema
Proteinuria >300 mg/L (1-2+ dipstick)
SEVERE PREECLAMPSIA
Blood pressure >160/110 mm Hg
Proteinuria >5 g/24 h
Cerebral involvement (headache, visual disturbances)
Oliguria
Increased serum creatinine level
Pulmonary edema
Epigastric pain, right upper quadrant abdominal pain, evidence of hepatic injury (HELLP)
Thrombocytopenia or disseminated intravascular coagulation
ECLAMPSIA
Preeclampsia progressing to seizures

usually has a higher SVR. Patients with high SVR hypertension may experience the largest blood pressure changes with the induction of regional anesthesia. Extra vigilance is required because the fetus of a patient with long-standing hypertension is most vulnerable to changes in maternal cardiac output.

Pulmonary edema may complicate preeclampsia (prevalence, 2-3%). [364] Pulmonary edema can be from cardiac failure, altered capillary permeability, altered hydrostaticoncotic forces, [365] or some combination. [366] Patients at risk for pulmonary edema are those with concomitant medical problems (diabetes, chronic

hypertension) and older maternal age. [364]

Central hemodynamic monitoring has been advocated to assist the management of severe preeclamptic patients, particularly if the disease is complicated by pulmonary edema. Candidates might include patients with pulmonary edema before delivery, patients with severe chronic hypertension who are at risk for cardiac failure, and patients with refractory oliguria who are unlikely to deliver soon. Monitoring central venous pressure or pulmonary artery pressure depends on the clinical situation and the monitoring capabilities. Although a low central venous pressure value is helpful to determine a patient's intravascular volume, a midrange or high value may not be helpful. Data suggest that at these values, correlation with pulmonary capillary wedge pressure is poor. [367]

Uteroplacental perfusion is impaired in the preeclamptic patient, particularly if the patient has underlying chronic hypertension. The placenta may have areas of infarction that limit oxygen delivery to the fetus and cause intrauterine growth retardation. Placental changes contribute to the excess perinatal mortality observed in pregnancies complicated by hypertension. [368] Renal biopsies of patients with preeclampsia demonstrate glomerular endotheliosis and fibrin deposition. Proteinuria is a hallmark of the disease. Renal blood flow and glomerular filtration rate are reduced during preeclampsia, and the normal creatinine of pregnancy (0.4-0.6 mg/dL) may be elevated, as may serum uric acid level. Although acute renal failure is not a common complication of preeclampsia (1%), oliguria may occur in the severely preeclamptic patient and may reflect intravascular volume depletion, poor cardiac output from myocardial failure, or renal artery spasm. Hepatocellular damage, or HELLP (*h*emolysis, *e*levated *l*iver enzymes, *l*ow *p*latelets) syndrome may present as right upper quadrant pain, elevated liver enzymes, and reduced coagulation factors. Rarely, hepatic rupture complicates preeclampsia. Liver function should be evaluated in patients with abdominal pain.

The normal hematocrit value of pregnant patients is 33 to 34 percent, but preeclamptic patients may have higher hematocrit values (39-40%) because of hemoconcentration. Preeclampsia can be complicated by coagulation problems, the most common being thrombocytopenia. Although disseminated intravascular coagulation can occur, it is rare and usually accompanies the HELLP syndrome. Patients with severe preeclampsia are more likely to have thrombocytopenia. [369] Other abnormalities in coagulation tests were unlikely in the absence of thrombocytopenia. Thrombocytopenia can be progressive, not resolving until 2 to 3 days after delivery. [370] Kelton et al [371] suggested that not only are platelet counts low in patients with preeclampsia but also platelet function may be abnormal. This conclusion was based on a comparison of bleeding times as a function of platelet count in preeclamptic and normal pregnant patients. However, the importance of this finding is unclear because the bleeding time is not necessarily a reliable predictor of abnormal bleeding. The exact platelet count value associated with a negligible risk of abnormal bleeding and epidural hematoma formation remains unknown. Regional anesthesia has been used in patients with unknown thrombocytopenia without problems. [372] The decision to place an epidural block should consider several aspects of a preeclamptic patient's disease. First, what is the patient's presentation? Some patients present with a rapid onset of severe disease with rapid organ function deterioration. Severe thrombocytopenia may occur rapidly in these patients and precludes neuraxial block. Serial platelet counts help assess the patient's course. Second, is there evidence of other coagulation disorders? Finally, the decision to perform any procedure must always weigh risks and benefits of available anesthetic techniques.

The CNS shows increased irritability in preeclampsia that may progress to eclamptic seizures. Early CNS symptoms include headache and visual disturbances. The exact cause of eclamptic seizures is unknown, but vasospasm, hypertensive encephalopathy, and cerebral edema are proposed mechanisms. Should eclamptic seizures occur, maternal oxygenation and proper positioning with left uterine displacement should be ensured. The patient should receive IV magnesium. If the seizure is prolonged or if the patient is unable to control her airway, intubation may be necessary, although this is not usually the case. The fetus may develop bradycardia from the maternal metabolic acidosis resulting from the seizure. The fetus is monitored, and while in utero resuscitation is probably best, if the fetus does not recover from the effects of the seizure, urgent delivery may be necessary.

Pharmacologic Therapy

Pharmacologic therapy of preeclampsia includes blood pressure control and seizure prophylaxis. Parenteral labetalol or hydralazine may be used to control blood pressure. Seizure prophylaxis is accomplished with magnesium therapy. [373] It is usually given IV (4-g load over 15 minutes, followed by a continuous infusion of 1-3 g/h). Therapeutic levels of magnesium are 4 to 6 mEq/L (Table 57-11) . levels

TABLE 57-11 -- Effects of Increasing Plasma Magnesium Levels

OBSERVED CONDITION	mEq/L
Normal plasma level	1.5-2.0
Therapeutic range	4.0-6.0
ECG changes (P-Q interval prolonged, QRS complex widened)	5.0-10
Loss of deep tendon reflexes	10
Sinoatrial and atrioventricular block	15
Respiratory paralysis	15
Cardiac arrest	25

must be monitored closely in a patient with renal dysfunction. Magnesium toxicity is treated with IV calcium. During administration of the bolus dose in preeclamptic patients, magnesium sulfate causes a fall in blood pressure and an increase in cardiac output via a decrease in SVR. [374] At the neuromuscular junction, magnesium sulfate decreases the amount of acetylcholine liberated, diminishes the sensitivity of the endplate to acetylcholine, and depresses the excitability of the muscle membrane. Thus, the pharmacodynamics of muscle relaxants is affected. Animal studies reveal an increased sensitivity to both depolarizing and nondepolarizing muscle relaxants in the presence of magnesium sulfate. [375] However, although one clinical report revealed that the clinical effect of succinylcholine was not altered by magnesium sulfate, [376] the duration of action of vecuronium was prolonged. [376] It is advisable to monitor neuromuscular function during general anesthesia in patients receiving magnesium sulfate therapy. In addition, a small dose of nondepolarizing muscle relaxant (pretreatment) should not be given in order to prevent fasciculations from succinylcholine.

Anesthetic Issues

Anesthetic management of the preeclamptic patient must first include a careful preanesthetic visit in which the manifestations of the disease in the patient is evaluated. Some have raised concerns about the use of regional anesthesia in preeclamptic patients because sympathetic block and maternal hypotension may further compromise uteroplacental circulation. There are also concerns about maternal pulmonary and/or cerebral edema from excessive IV fluid administration [366] in the face of low plasma oncotic pressure. [365] Other investigators have found epidural analgesia to be a valuable technique for the laboring preeclamptic patient. [377] [378] Effective analgesia reduces maternal catecholamines and blood pressure changes as a result of the pain of labor. [125] [379] In addition, provided that hypotension is avoided, epidural analgesia can improve intervillous blood flow. [380] [381] Regional anesthesia can safely be administered to preeclamptic patients and in fact may be beneficial, provided that the pathophysiology of the disease is understood. Blood pressure should be monitored carefully, and any decrease in blood pressure should be treated aggressively to prevent reductions in uterine blood flow. The FHR should be continuously monitored. Only a modest amount of IV fluid as prehydration (e.g., 200-500 mL) should be administered. Anesthesia is induced slowly to allow administration of small boluses of IV fluids or ephedrine to maintain a stable blood pressure. Preeclamptic patients tend to be more sensitive to vasopressors; therefore, only small doses of ephedrine are usually needed. Intrathecal or epidural opioids can also be used in these patients.

In the choice of anesthetic technique for cesarean delivery, maternal physiology and degree of urgency must be considered. Epidural anesthesia is a good anesthetic for cesarean delivery. [378] Modest IV hydration can be administered (about 500-1000 mL of crystalloid) during a slow induction of surgical anesthesia. Any change in maternal blood pressure is treated as previously described. The FHR is monitored continuously while the block is established. Slowly establishing the anesthetic (and sympathetic) block can enable remarkable hemodynamic stability. Although the use of spinal anesthesia for cesarean delivery in preeclamptic patients has been described, [382] the anesthesiologist should be aware of rapid hemodynamic changes with induction.

General anesthesia may be necessary in preeclamptic patients because of overt coagulation problems, maternal hemorrhage, or worrisome fetal status. A concern associated with the use of general anesthesia is the possibility of airway edema complicating intubation. Another problem with induction of general anesthesia in the preeclamptic patient is exaggerated hypertension during laryngoscopy and intubation. [383] Strategies to minimize extreme increases in blood pressure with intubation

include administration of labetalol [384] or small doses of fentanyl before induction and use of a generous dose of thiopental (ketamine should be avoided). Hypertension after intubation can be treated with transient administration of a high dose of volatile anesthetic. IV infusions of nitroprusside, [385] trimethaphan, [386] and nitroglycerin [387] [388] have also been used in this situation (with direct arterial pressure monitoring).

The postpartum preeclamptic patient should be monitored for evidence of uterine atony (magnesium sulfate may contribute to uterine bleeding). The anesthesiologist should be aware that patients with underlying chronic hypertension or diabetes are at risk for developing pulmonary edema in the postpartum period.

Abnormal Fetal Presentation

The usual fetal presentation during vaginal delivery is cephalic in the occiput anterior position. Occasionally, the fetal head is in the occiput posterior presentation. This is a more difficult presentation to deliver vaginally; forceps rotation to the occiput anterior position or forceps assisted delivery may be necessary. Pain, particularly back pain, may be greater when the fetus is in the occiput posterior presentation. Effective regional analgesia can be helpful for these patients.

Breech presentation of the fetus means that the fetal buttocks or lower extremities are the presenting parts. Breech presentation occurs more commonly in the premature fetus. [389] The obstetrician may try to change the fetal position from breech to cephalic presentation by externally manipulating the fetus in the uterus (external cephalic version). If attempted version is not successful, the obstetrician may opt for cesarean delivery of a breech fetus. Vaginal delivery of a term breech fetus may also be attempted. The anesthesiologist should be aware that prolapse of the umbilical cord is more common with breech presentations and may necessitate emergent cesarean delivery. For labor, adequate analgesia, particularly during the second stage, is very helpful. Lumbar epidural analgesia can be titrated to the desired effect to promote perineal relaxation and maternal cooperation during delivery. Rarely, contraction of the lower uterine segment traps the fetal head, precluding vaginal delivery and necessitating rapid uterine muscle relaxation.

Prematurity

Preterm delivery occurs in up to 10 percent of all births and is defined as delivery at 36 weeks of gestation or less.

Prematurity is the major cause of neonatal mortality. [390] These infants are at risk for respiratory distress syndrome and CNS complications from intracranial hemorrhage. To prevent premature delivery, various tocolytic agents are employed when preterm labor occurs. The anesthesiologist should be aware of the maternal and fetal side effects of these tocolytic agents. [391]

Magnesium sulfate reduces uterine contractility and may be the first-line tocolytic employed to stop premature contractions. [392] Serum magnesium levels are maintained between 4.0 and 6.0 mEq/L.

beta-Adrenergic agonists (ritodrine and terbutaline) may be used for tocolysis. Direct stimulation of the beta-adrenergic receptors present in uterine smooth muscle leads to increased intracellular cyclic adenosine monophosphate and uterine muscle relaxation. These drugs have significant side effects. Most women experience tachycardia (either from a direct $beta_1$ effect or in response to $beta_2$ -mediated vasodilation). Hyperglycemia and hypokalemia may also complicate beta-adrenergic agonist therapy. Chest pain and pulmonary edema can also occur. [393] [394] Patients receiving beta-adrenergic agonists are at risk for fluid overload and cardiogenic pulmonary edema as a result of stimulated antidiuretic hormone activity. [395] Further, preterm labor is often precipitated by an infectious process that predisposes to increased capillary permeability and noncardiogenic pulmonary edema. Risk factors for pulmonary edema from beta-adrenergic agonists include anemia, preexisting cardiac disease, multiple gestation, excessive hydration, tachycardia, prolonged tocolytic therapy, and associated infection (e.g., chorioamnionitis).

The anesthesiologist may be required to administer an anesthetic for labor and delivery to a patient who has recently been treated with tocolytic drugs. The respiratory status of patients receiving beta-adrenergic agonist therapy should be closely assessed. Drugs that could exaggerate tachycardia (atropine, pancuronium) should be avoided. Because halothane can sensitize the myocardium to exogenous catecholamines, it may predispose the patient to dysrhythmias and should be avoided. Hydration before regional anesthesia should be modest. If patients receiving magnesium sulfate require general anesthesia, careful neuromuscular blockade monitoring is required, as previously discussed. In addition, uterine atony may occur after delivery.

If vaginal delivery of the preterm fetus is anticipated, effective epidural analgesia provides the advantages of perineal analgesia to facilitate a gentle delivery, perhaps assisted with outlet forceps. If the fetus is in the breech presentation, cesarean delivery is likely because the breech is smaller than the head of the preterm infant, and entrapment of the fetal head behind an incompletely dilated cervix could occur during attempted vaginal delivery. Anesthesia for cesarean delivery considers the usual issues, with epidural, spinal, or general anesthesia being appropriate. The anesthesiologist should be aware that the preterm fetus is particularly susceptible to maternally administered drugs because of immature enzyme systems available for drug metabolism, poorly developed blood-brain barrier, less protein available for drug binding, and competition for drug binding sites from increased levels of bilirubin. After delivery, the preterm infant may require aggressive resuscitation, and appropriate personnel should be available. Anticipated problems include birth asphyxia, respiratory distress, hypoglycemia, and temperature instability.

Multiple Gestations

Important anesthetic considerations of multiple gestations is the high likelihood of prematurity, abnormal presentation (either breech or transverse lie), and need for operative delivery. The anesthesiologist should be aware that the large gravid uterus may be difficult to displace off the inferior vena cava and that hypotension is likely during the induction of regional anesthesia. Further, uterine atony is possible after delivery. Depending on the fetal presentations, twins may be delivered vaginally. During labor and anticipated vaginal delivery, epidural analgesia is useful because it can be titrated to desired effect. After delivery of the first twin, the presentation and status of the second twin can change quickly, possibly necessitating emergent cesarean delivery. Uterine muscle relaxation may be requested to promote gentle cesarean delivery of fetuses in abnormal presentations.

Obstetric Hemorrhage

Obstetric hemorrhage is classified according to timing: antepartum or postpartum. Although most patients tolerate the normal blood loss associated with either vaginal or cesarean delivery, occasionally, blood loss is excessive. Obstetric hemorrhage is an important cause of maternal mortality. [396]

Antepartum Hemorrhage

Antepartum hemorrhage complicates about 4 percent of pregnancies. Important causes include placenta previa, abruptio placentae, and uterine rupture.

Placenta Previa

Placenta previa exists when the placenta lies over the uterine cervix in front of the fetal presenting part (Fig. 57-26) (Figure Not Available) . The diagnosis is suspected from the clinical picture of painless vaginal bleeding and is confirmed by ultrasonography. Vaginal examinations are avoided, and delivery is via cesarean section. Tocolytic therapy may be instituted when premature uterine contractions trigger bleeding. If the gestation is term, delivery may need to proceed urgently. Anesthetic management depends on the degree of urgency and the maternal and fetal status. Regional anesthesia is appropriate for elective surgery, but general anesthesia is appropriate when surgery is prompted by maternal hemorrhage. Excessive bleeding can also occur during surgery because delivery may require cutting through the placenta, and the placental implantation site in the lower segment of the uterus may not contract well after delivery.

Abruptio Placentae

Abruptio placentae is bleeding behind the placenta, causing partial separation (Fig. 57-27) (Figure Not Available) . Both mother and fetus

---

Figure 57-26 (Figure Not Available) Types of placenta previa. (A) Low implantation of the placenta. (B) Partial placenta previa. (C) Total placenta previa. *(From Bonica and Johnson [436])*

Figure 57-27 (Figure Not Available) Abruptio placentae. (A) Internal or concealed hemorrhage. (B) External hemorrhage. (C) Complete placental separation and prolapse. *(From Bonica and Johnson [436])*

can be adversely affected: the mother from acute blood loss and coagulopathy from disseminated intravascular coagulation, and the fetus from reduced uterine blood flow and loss of functional placenta. A large abruption can result in fetal demise. Risk factors for abruptio placentae include chronic hypertension, abdominal trauma, cocaine use, advanced maternal age, multiparity, and history of prior abruption. [397] Abruptio placentae typically presents with painful, frequent uterine contractions and vaginal bleeding. The amount of maternal blood loss can be significant and may not be reflected by the amount of vaginal bleeding because blood can be sequestered behind the placenta. About 10 percent of cases of abruptio placentae are complicated by disseminated intravascular coagulation. Management of patients with abruptio placentae depends on the severity of the abruption and the maternal and fetal condition. A small abruption may trigger labor, which may continue to vaginal delivery if the status of the mother and the fetus is stable. A more significant abruption may lead to emergent cesarean delivery because of maternal and/or fetal instability. The anesthesiologist should be aware that uterine atony can occur because blood extravasated into the myometrium may preclude normal uterine contraction after delivery.

Uterine Rupture

Uterine rupture is a less common (0.4%) but potentially devastating cause of obstetric hemorrhage. It may occur in a previously scarred uterus (particularly after a classical [vertical] uterine incision) or may result from uterine manipulation (forceps, uterine curettage), trauma, or overaggressive

use of IV oxytocin. Other risk factors are uterine anomalies, tumors, and placenta percreta (invasion of the placenta through the uterine wall). Uterine rupture is different than uterine scar dehiscence. Uterine scar dehiscence is a defect in the uterine wall at the site of a previous incision (usually low transverse) that does not result in obstetric hemorrhage. It is reported to occur in about 0.7 percent of patients undergoing vaginal birth after prior cesarean. [398] Uterine rupture is reported to occur in 0.6 to 0.8 percent of vaginal birth-after-cesarean patients. [398] [399] Rupture of an unscarred uterus can result in massive maternal hemorrhage. Symptoms can be nonspecific and include maternal hemodynamic instability, fetal bradycardia, vaginal bleeding, and loss of function of uterine pressure monitors. Treatment requires emergent laparotomy and may require obstetric hysterectomy. [400]

Postpartum Hemorrhage

Postpartum hemorrhage complicates about 10 percent of deliveries and is defined as a blood loss of greater than 500 mL. Important causes include uterine atony, retained placenta, placenta accreta, birth trauma, and uterine inversion.

Uterine Atony

Uterine atony is the most common cause of postpartum hemorrhage. Contraction of the uterine muscle is necessary to stop uterine bleeding after delivery of the placenta. Ineffective uterine muscle contraction leads to hemorrhage. Risk factors for uterine atony include prolonged labor, overdistended uterus (e.g., with twin gestation), grand multiparity, and use of drugs known to decrease uterine muscle contraction (halogenated inhaled anesthetics, beta-adrenergic agonists, and magnesium sulfate). Treatment includes volume resuscitation and administering uterotonic medications. Such medications include oxytocin, carboprost tromethamine, and ergot preparations. Oxytocin is often routinely given as a dilute infusion (20 U/L of IV fluid) after delivery to promote uterine contraction. Bolus doses are avoided because hypotension can result. [391] Carboprost-tromethamine (Hemabate) is the 15-methyl analogue of prostaglandin $F_{2\ alpha}$ and is a potent uterotonic medication given IM (250 mug). Side effects include nausea, vomiting, diarrhea, and bronchoconstriction. [401] The ergot derivatives ergonovine maleate and methylergonovine maleate are effective uterotonic medications. The usual dose is 0.2 mg IM. Hypertension is an important side effect that results from the drug's alpha-adrenergic activity. These medications should be avoided in patients with hypertension or intracranial vascular disease and in those who have recently received vasopressors.

Retained Placenta

Retained placenta exists when all or part of the placenta fails to deliver spontaneously within 1 hour of birth. Hemorrhage results from failure of the uterus to contract where the placenta is adherent. Treatment involves placental removal either manually or via curettage. Anesthetic management involves volume resuscitation, provision of adequate analgesia (with epidural or spinal anesthesia if maternal volume status allows, IV or inhalational analgesia, or general anesthesia), and if necessary, assisting with uterine muscle relaxation to allow uterine manipulation and delivery of the placenta (with halogenated anesthetics administered via an endotracheal tube, or IV nitroglycerin, 50- to 100-mug bolus doses. [402])

Placenta Accreta

Placenta accreta, increta, or percreta (Fig. 57-28) (Figure Not Available) involves invasion of the placenta through the endometrium, into the myometrium, and through the myometrium, respectively. Risk factors include previous uterine surgery or trauma. [403] Normal placental delivery is often precluded and results in hemorrhage perhaps necessitating obstetric hysterectomy. [404] Placenta accreta occurs in about 0.04 percent of pregnancies, but the risk increases markedly in patients with placenta previa (5%) and increases even more dramatically in patients with placenta previa with prior cesarean delivery (24% after one prior cesarean, 40-60% after three to four prior cesareans). [403] The anesthesiologist should be aware of this potential problem when caring for a patient with placenta previa undergoing repeat cesarean delivery and should be prepared to manage massive hemorrhage.

Birth Trauma

Cervical and vaginal lacerations can result in persistent vaginal bleeding postpartum. The anesthesiologist is needed

Figure 57-28 (Figure Not Available) Classification of placenta accreta based on degree of pen-etration of the myometrium. Placenta accreta: adherence of the placenta to the myometrium; placenta increta: invasion of the myometrium; placenta percreta: the placenta erodes through the myometrium to involve the serosa of the uterus and even the surrounding structures. *(From Kamani et al [437])*

to provide the necessary analgesia or anesthesia to allow the obstetrician to visualize and repair the injury. The anesthesiologist should be aware that the amount of blood loss from such lacerations is difficult to assess and is often underestimated.

Uterine Inversion

Uterine inversion is a rare cause of postpartum hemorrhage in which the uterine fundus actually inverts through the cervix into the vagina, precluding uterine contraction. [405] Predisposing factors include retained placenta, prolonged labor, and precipitous labor. Management involves correction of the inversion and may require uterine muscle relaxation. [275] [406]

ANESTHESIA FOR SURGERY DURING PREGNANCY

Pregnant women undergoing surgery require special attention in their anesthetic management if injury to the fetus is to be avoided. Goals include maternal safety, avoidance of teratogenic drugs, avoidance of intrauterine fetal asphyxia, and prevention of preterm labor. Many of the physiologic changes of pregnancy are due to hormonal influence and may occur early in pregnancy. Significant changes in minute ventilation, functional residual capacity, cardiac output, and anesthetic requirements occur during the second and third trimesters. Similarly, the hypotensive syndrome associated with the supine position begins to manifest itself early in the third trimester and may lead to decreases in cardiac output, blood pressure, and uterine blood flow.

Most commonly used anesthetic and sedative drugs are teratogenic in some animal species. The applicability of many of these animal studies to human subjects is not clear. Studies in humans have shown an association between increased risk of congenital anomalies and ingestion of minor tranquilizers, such as diazepam (Valium). [407] However, a direct link between the anomaly and the specific drug is difficult to confirm because of confounding issues (including the reason for taking the medication).

Long-term exposure to trace amounts of anesthetic gases or vapors had been suggested as having an adverse effect on reproductive outcome (including spontaneous abortion). However, a review of 14 studies from 1967 to 1982 concluded that no adverse effect of anesthetic gases on reproductive outcome could be accepted on the basis of the retrospective inquiries because of important methodologic problems, including unclear outcomes, poor survey response rates, selection bias, recall bias, and lack of control of confounding variables. [408]

All surveys of women who have received anesthesia for operations during pregnancy have failed to indict any anesthetic as a teratogen. [409] [410] [411] [412] [413] [414] However, in all studies to date, the number of pregnant women receiving an anesthetic for an operative procedure is, in fact, likely too small to state categorically that anesthetics are not teratogenic.

In a large survey, Mazze and Kallen [414] combined data from three Swedish health care registries for the years 1973 to 1981. Adverse outcomes examined were (1) congenital

Figure 57-29 (Figure Not Available) Total number of observed and expected adverse outcomes among women having nonobstetric operations during pregnancy. Incidence of infants with birth weights under 1,500 g and of infants born alive and dying within 168 hours of birth were significantly increased ($P < .05$) in the surgical patients. *(From Mazze and Kallen [414])*

anomalies, (2) stillborn infants, (3) infants dead at 168 hours, and (4) infants with very low and low birth weights. There were 5,405 operations in the population of 720,000 pregnant women (operation rate, 0.75%). Of these, 2,252 operations were performed in the first trimester, and 65 percent received general anesthetics, almost all of which included nitrous oxide. The results are summarized in Figure 57-29 (Figure Not Available) . The incidences of congenital malformations and stillbirths were not increased in the offspring of women undergoing operations. However, the incidences of very low and low-birth-weight infants were increased, as a result of both prematurity and intrauterine growth retardation. The incidence of infants born alive but dying within 168 hours was increased. No specific types of anesthesia or operation were associated with increased incidences of adverse reproductive outcomes.

Some reports have suggested that anesthesia and surgery during pregnancy are associated with the onset of preterm labor. [410] No one agent or technique has been associated with a higher incidence of premature delivery. However, the halogenated anesthetics decrease uterine contractility; if uterine manipulation is anticipated, the use of these agents would theoretically be more likely to minimize the possibility of preterm labor. Alternatively, tocolytic drugs can be given in conjunction with the anesthetic for surgery.

During the anesthetic visit before surgery during pregnancy, great effort should be made to allay maternal anxiety and apprehension. The lack of documented teratogenicity can be presented. The patient should understand that the likelihood of first-trimester miscarriage increases from 5.1 percent without surgery to 8 percent with surgery, [411] and the incidence of premature delivery increases from 5.13 percent without surgery to 7.47 percent with surgery. [414] Although it is clear that there is significant risk to the fetus when an operation is performed during pregnancy, it is not clear whether the hazard is due to the surgery, the pathology for which the surgery was necessary, or the anesthetic.

Elective surgery should be deferred until after delivery when the physiologic changes of pregnancy have returned toward normal. Women of child-bearing age who are scheduled for elective surgery should be carefully queried regarding the possibility of pregnancy. Urgent surgery (i.e., operations that are essential but can be delayed without

Figure 57-30 (Figure Not Available) Effect of electrically induced stress (30-60 seconds) on maternal arterial blood pressure, plasma norepinephrine levels, and uterine blood flow in sheep. All values subsequent to control are given as mean percentage change with standard error. *(From Shnider et al [415])*

increasing the risk of permanent disability) should be deferred until the second or third trimester. Despite the lack of proof that particular drugs should be avoided, we consider it prudent to minimize or eliminate fetal exposure to drugs during the vulnerable first trimester.

Emergency surgery (i.e., operations that cannot be delayed without increasing the risk of maternal morbidity or mortality) may be necessary at any time during pregnancy. The minimal drug exposure conferred by regional anesthesia (particularly spinal anesthesia) makes these techniques theoretically preferable; however, general anesthesia should not be withheld if it will accomplish the best surgical conditions. If general anesthesia is necessary during the first trimester, there is no proof that any well-conducted technique is superior to any other. Adequate oxygenation and avoidance of hyperventilation are mandatory. During pregnancy, patients may be at increased risk of aspiration, and the usual safeguards to prevent aspiration pneumonitis should be observed. Aortocaval compression during the second and third trimesters should be prevented by avoiding the supine position. Ideally, continuous FHR monitoring during surgery should be employed if possible after the middle of the second trimester. This may provide an indication of abnormalities in maternal ventilation or uterine perfusion. Uterine activity should be monitored continuously with an external tocodynamometer during the postoperative period to detect the onset of preterm labor.

/das/book/view/29494766/875/637.html

SUMMARY

A number of anesthetic techniques are safe and effective for facilitating labor, vaginal delivery, and cesarean delivery or for assisting with the management of obstetric complications. The various techniques of obstetric analgesia or anesthesia each has advantages and risks for the mother and the fetus. Whatever the choice of anesthetic, skillful administration and observance of the issues discussed in this chapter is paramount to a safe anesthetic for mother, fetus, and neonate.

In some circumstances, avoidance or inadequate use of analgesia in the name of safety carries its own hazards, in that maternal stress may be left untreated. In pregnant sheep, stress results in maternal hypertension and increased plasma norepinephrine, which is associated with a decrease in uterine blood flow (Fig. 57-30) (Figure Not Available) . [415] In pregnant Rhesus monkeys, psychologic stress results in fetal bradycardia and asphyxia, whereas alleviation of stress with a barbiturate causes an immediate and significant improvement in heart rate and oxygenation. [416] [417] Such studies support the view that skillful anesthesia, coupled with reassurance and emotional support of the parturient, may make birth less stressful not only for the mother but also for the fetus.

Chapter 58 - Resuscitation of the Newborn

George A. Gregory

INTRODUCTION

Profound changes occur in the cardiovascular and respiratory systems at birth. Failure to make these changes may lead to death or central nervous system (CNS) injury. Because of these problems, newborn resuscitation is intensive care of the most complicated type. This chapter discusses the causes and effects of cardiorespiratory insufficiency at birth and discusses currently practiced techniques of resuscitation.

PERINATAL STRESS

During the 1970s, the concept of stress-free birth evolved but was shown to be potentially harmful to patients. Late-term fetuses and neonates are capable of producing large quantities of catecholamines, which help them prepare for birth, adapt to extrauterine life, and cope with hypoxia. Animals who are deprived of a catecholamine surge at birth are less likely to survive hypoxia than those who have a catecholamine surge. Catecholamines initiate clearance of liquid from the lungs before birth, and this improves lung compliance after birth. Catecholamines also release surface-active material (SAM) from alveolar type II cells. During asphyxia, catecholamines maintain cardiac output and redistribute blood flow from the periphery to the heart, brain, and adrenal gland. They also increase arterial blood pressure and slow heart rate, which reduces myocardial oxygen consumption. [1] Catecholamines also are required for breakdown of stored fuels. [2] Infants delivered by cesarean section without maternal labor have lower blood glucose concentrations than those born after labor. Furthermore, blood flow to peripheral organs is higher after vaginal delivery and is related to plasma catecholamine concentrations. Neonates with elevated catecholamine concentrations have higher Apgar scores than those with low concentrations. Thus, stress appears to be an important part of the transition from intra- to extrauterine life.

PERINATAL CARDIORESPIRATORY PHYSIOLOGY

The fetal lung arises from the foregut at 24 days' gestation. By 20 weeks, the airways are lined with cuboidal epithelium and pulmonary capillaries are present. By 26 to 28 weeks, the capillaries are closely approximated to the developing terminal airways. Between 30 and 32 weeks' gestation, the cuboidal epithelium has flattened and thinned, [3] a process that is accelerated by administering steroids to the mother. [4] By 20 weeks' gestation, SAM is present within the alveolar lining cells, [5] and by 28 to 32 weeks' gestation, it is present within the lumen of the airways. Significant amounts of SAM do not appear in terminal airways until 34 to 38 weeks' gestation unless its production and release are stimulated by stress or steroids. At birth, the onset of respiration further increases the concentration of SAM in alveoli. [6] Administration of SAM (calf, human, or artificial) decreases the incidence of hyaline membrane disease and the

Figure 58-1 (Figure Not Available) Intrathoracic pressures during delivery. Note the increased intrathoracic pressure when the mouth and head have been delivered. *(From Gregory [97])*

incidence of serious cardiopulmonary complications in neonates. [7] Administration of these compounds has become a routine part of resuscitation of premature neonates.

At term the fetal lung contains approximately 90 mL (30 mL/kg) of an ultrafiltrate of plasma. About 50 to 150 mL/kg/day [8] [9] of this fluid is produced by the lung and expelled into the mouth, where the fluid is either swallowed or released into the amniotic fluid. Normally, there is no amniotic fluid in lung fluid. If the depth of fetal breathing increases (e.g., during stress), however, amniotic fluid is drawn into the lung. Amniotic fluid in the lung is indicated by the presence of squamous cells and other debris in the lungs of infants in whom gasping occurred *in utero.*[9] Approximately two-thirds of the fluid is expelled from the lungs of a term neonate when the vagina and muscles of the pelvic floor squeeze the fetal chest during the birth process [9] (Fig. 58-1) (Figure Not Available) . The remaining fluid is removed by capillaries, lymphatics, and breathing. Small, preterm neonates, those born rapidly, and those born by cesarean section fail to get this "vaginal squeeze." As a result, these neonates have excess lung water at birth and have more difficulty sustaining respiration than babies whose chests are squeezed effectively during the birth process. Retention of lung fluid results in transient tachypnea of the newborn. [10] Clearance of water from the lung is initiated by labor. Animals born by cesarean section following a period of labor have similar amounts of lung water as animals born vaginally. However, those born by cesarean section without previous labor have increased amounts of lung water. [11] [12]

Neonates normally breathe by 30 seconds of age and sustain respiration by the time they are 90 seconds old. During birth, outward recoil of the compressed chest helps fill the lungs with air. Stimulation of the respiratory centers by mild acidosis, hypercarbia, hypoxia, pain, cold, touch, noise, and clamping of the umbilical cord initiates and sustains rhythmic respiration. [13] [14] Severe acidosis, hypoxia, CNS damage, and maternal drugs (narcotics, barbiturates, local anesthetics, magnesium, alcohol) depress breathing. A few minutes after birth the respiratory rate is 40 to 60 breaths per minute. This rapid respiratory rate removes the increased carbon dioxide produced by the high metabolic rate and helps maintain a normal functional residual capacity.

The circulation of the fetus is in parallel; that of the adult is in series [15] [16] (Fig. 58-2) (Figure Not Available) . The right ventricle ejects two-thirds of the combined ventricular output and the left ventricle ejects one-third. [17] This disparity in output between the two ventricles of fetuses occurs because fetuses have intracardiac and extracardiac shunts, namely, the foramen ovale and ductus arteriosus. Blood returning from the placenta is well oxygenated. As a function of the anatomy, the inferior vena cava and foramen ovale allow oxygenated placental blood to enter into the left atrium. Poorly oxygenated blood from the superior vena cava is directed into the right ventricle and into the pulmonary artery. Of blood entering the pulmonary artery, 95 percent is shunted through the ductus arteriosus into the descending aorta. [16]

The pulmonary vascular resistance (PVR), which is elevated *in utero,* decreases dramatically in response to lung expansion, breathing, increased pH, and the increase in alveolar oxygen tension that occurs at birth. [18] [19] PVR also decreases in the first 5 minutes to 24 hours of life owing to recruitment and dilation of small arteries. During the next few weeks, PVR continues to decrease owing to reduced amounts of arterial muscle. [20] Neonates born by cesarean section have higher pulmonary artery pressures and resistances than those delivered vaginally. [21] Hypoxia, acidosis, hypovolemia, hypoventilation, atelectasis, and cold increase PVR. [18] [22] The combination of hypoxia and acidosis increases PVR more than either hypoxemia or acidosis alone.

The decrease in PVR at birth reduces pulmonary artery pressure and increases pulmonary blood flow. Systemic vascular resistance and left atrial pressure increase, preventing right-to-left shunting of blood through the ductus arteriosus. In fact, left-to-right shunting of blood often occurs. The increased pulmonary blood flow increases the volume of blood returning to the left atrium, which raises left atrial pressure above right atrial pressure and closes the foramen ovale. Closure of the foramen ovale prevents right-to-left shunting of blood through this structure. Anatomic closure of the foramen ovale may not occur for months, if ever. Consequently, if right atrial pressure exceeds left atrial pressure (e.g., in pneumonia, acidosis, or hypoxia) right-to-left shunting of blood will again occur.

The ductus arteriosus of animals born at term gestation closes in response to oxygen, acetylcholine, parasympathetic

Figure 58-2 (Figure Not Available) Diagram of the fetal circulation. The numbers within the circles are percentages of the combined ventricular output. *(From Rudolph and Heymann, [16] with permission from the Annual Review of Physiology, Volume 36, copyright 1974, by Annual Reviews)*

nerve stimulation, and prostaglandins. [23] [24] [25] [26] [27] A Pa O_2 of 60 to 100 mm Hg constricts the ductus arteriosus of term lambs, but a Pa O_2 of 300 to 500 mm Hg fails to constrict the ductus arteriosus of preterm animals. [23] Functionally, the ductus arteriosus closes when the pulmonary arterial pressure is less than systemic arterial pressure. Anatomically, the ductus arteriosus of term neonates may not close completely until the neonate is 10 to 14 days of age. It may take several months for the ductus arteriosus of preterm neonates to close. The parallel circulation of the fetus can be reestablished in term neonates if they become hypoxic, cold, or acidotic during the first 2 weeks of life. It can be reestablished in preterm neonates during the first several weeks of extrauterine life.

/das/book/view/29494766/875/643.html

ASPHYXIA

Asphyxia (decreased Pa O_2 , increased Pa CO_2 and decreased pHa) occurs when gas exchange by the placenta (fetus) and by the lung (neonate) is inadequate. Large quantities of metabolic acids are produced, which are partially buffered by bicarbonate. [28] *In utero,* asphyxia is caused by maternal hypoxia, decreased placental-umbilical blood flow, and fetal heart failure. Maternal hypoxia is caused by maternal cyanotic congenital heart disease, congestive heart failure, or respiratory failure. Asphyxia, caused by maternal hypotension, catecholamine secretion, abruptio placentae, or placental disease (fibrosis, calcification, infarction, infections) reduces placental-umbilical blood flow.

Physiologic Effects

During fetal asphyxia, the Pa O_2 decreases from its normal value of 25 to 40 mm Hg to less than 5 mm Hg in about 2 minutes (Fig. 58-3) (Figure Not Available) . As a result of the severe hypoxia, anaerobic metabolism occurs. The Pa CO_2 rises rapidly. The pH quickly decreases to less than 7.0 because of the combined metabolic and respiratory acidosis. In as little as 5 minutes, the pH may be less than 6.90, the Pa CO_2 greater than 100 mm Hg, and the Pa O_2 unmeasurable. [15] [25] Some of the metabolic acidosis may be due to reduced uptake of lactate by the liver rather than to increased lactate production. [2]

Cardiac output is normal early in the course of asphyxia, but its distribution is altered. [30] [31] [32] Blood flow to the liver, kidney, gut, skin, and muscle is reduced, whereas blood flow to heart, brain, adrenal glands, and placenta is maintained constant or increased. This redistribution of blood flow helps maintain oxygenation and nutrition of the brain and heart, even though the oxygen content of arterial blood is very low. Oxygen extraction by tissues is greatly increased. [33] In part, the function of hypoxemic hearts is maintained by the metabolism of myocardial glycogen and by the metabolism of lactic acid. [34] When these sources of energy fail, as they eventually do, the myocardium fails, and the arterial blood pressure and cardiac output decrease. The myocardium usually fails when the pH is 7.0 or less. If the heart rate decreases to less than 100 beats/min during asphyxia, cardiac output decreases significantly. Central venous pressure rises during asphyxia because the systemic capacitance vessels constrict and increase the central blood volume and

Figure 58-3 (Figure Not Available) The response of newborn monkeys to asphyxia. *(From Dawes [15])*

because the failing myocardium cannot eject the increased volume of blood. Fetuses and newborns may survive severe hypoxia because they have large quantities of endogenous opiates in their blood. [35] These substances, which increase during hypoxia, [36] may reduce oxygen consumption. A normal response to catecholamines is also important for survival from asphyxia (see earlier). Initial systemic circulatory adaptations to hypoxia are mediated on a reflex basis. [37] Normal responses to asphyxia include increased plasma adrenocorticotropic hormone, glucocorticoids, catecholamines, atrial natriuretic factor, renin, arginine vasopressin, and decreased insulin concentrations. [38] [39] Arginine vasopressin causes hypertension, bradycardia, and redistribution of systemic blood flow. [40] Glycogenolysis maintains blood glucose concentrations. [2]

Intrapartum asphyxia can cause either hypervolemia or hypovolemia. [41] Asphyxia during labor usually causes hypervolemia unless (1) umbilical cord compression obstructs the umbilical vein more than it obstructs the umbilical arteries (e.g., cord around the neck, cord compression by the after-coming head during a breech delivery), (2) hemorrhage occurs from the fetoplacental unit (e.g., abruptio placentae, transection of the placenta during cesarean section), (3) maternal hypotension occurs (e.g., shock, trauma, anesthesia), or (4) asphyxia occurs during the latter part of labor and delivery.

ASSESSMENT OF THE FETUS AT BIRTH

The Apgar score, if done properly, is a simple, useful *guide* to neonatal well-being and resuscitation [42] [43] (Table 58-1) . *It is only a guide.* The 1-minute score correlates well with both acidosis and survival. [44] The 5-minute score may be predictive of neurologic outcome. [45] [46] To be of value, each variable encompassed by the score must be evaluated at both 1 and 5 minutes. The Apgar scores of neonates born to women who smoke cigarettes are lower than those of neonates whose mothers do not smoke. [47] The clinician should be well aware that some neonates have relatively normal Apgar scores at 1 and 5 minutes but may be very acidotic. These neonates often have peripheral vasoconstriction and pallor despite relatively normal heart rates and arterial blood pressures.

Heart Rate

The heart rate of normal neonates is 120 to 160 beats/min. Although most neonates tolerate heart rates up to 220 beats/min with little detrimental effect, heart rates below 100 beats/min are often poorly tolerated because they reduce cardiac output and tissue perfusion. Unfortunately, bradycardia is common in asphyxiated neonates. On occasion, bradycardia is associated with congenital heart disease, congenital heart block, and congestive heart failure. Prenatal

TABLE 58-1 -- The Apgar Scoring System[a]

SIGN	SCORE		
	0	**1**	**2**
Heart rate	Absent	Less than 100/min	More than 100/min
Respiratory effort	Absent	Slow, irregular	Good, crying
Color	Blue, pale	Body pink, extremities blue (acrocyanosis)	Completely pink
Reflex irritability (response to insertion of a nasal catheter)	Absent	Grimace	Cough, sneeze
Muscle tone	Limp	Some flexion of extremities	Active motion

[a] Each variable is evaluated individually and scored from 0 to 2 in an infant at both 1 and 5 minutes of age. The total score at each time period is the sum of the scores of the individual variables. A total score of 10 is perfect.

electrocardiogram and echocardiogram allow diagnosis of these problems before birth. If they occur, one must be prepared to treat the bradycardia if there is evidence that the arterial blood pressure and tissue perfusion are compromised (lactic acidosis).

Respiratory Effort

Breathing usually begins by 30 seconds of age and is sustained by 90 seconds of age. Within a few minutes after birth, the respiratory rate of normal neonates is between 30 and 60 breaths/min. There is no pause between inspiration and expiration, which helps to develop and maintain a normal functional residual capacity (FRC). At these rates, the time constants of the lung are too short for the FRC to be exhaled. Apnea and bradypnea prolong exhalation, which reduces FRC and causes hypoxia. Apnea and bradypnea occur with severe acidosis, asphyxia, maternal drugs, infections (meningitis, septicemia, pneumonia), and CNS damage. Tachypnea (>60 breaths/min) occurs with hypoxemia, hypovolemia, acidosis (metabolic and respiratory), CNS hemorrhage, pulmonary gas leaks, pulmonary disease (hyaline membrane disease, aspiration syndromes, infections), pulmonary edema, and maternal drugs (narcotics, alcohol, magnesium, barbiturates).

Muscle Tone

Most neonates, including those who are preterm, are active at birth and move all extremities in response to stimuli. Asphyxia, maternal drugs, CNS damage, amyotonia congenita, and myasthenia gravis decrease muscle tone. Flexion contractures and absent joint creases are signs of CNS damage that occurred *in utero.*

Reflex Irritability

Normal neonates move when an extremity is flicked and grimace or cry when a catheter is inserted into a nostril. Failure to respond occurs with hypoxia, acidosis, sedation by maternal drugs, CNS injury, and congenital muscle disease.

Color

Essentially all neonates have a blue-tinged cast to their skin at the moment of birth. By the time they are 60 seconds old, most neonates are entirely pink, except for their hands and feet, which remain blue (central cyanosis). If central cyanosis persists beyond 90 seconds of age, asphyxia, low cardiac output, pulmonary edema, methemoglobinemia, polycythemia, congenital heart disease, arrhythmias, and pulmonary disorders (respiratory distress, airway obstruction, hypoplastic lungs, diaphragmatic hernia) should be considered, especially when the infant remains cyanotic despite oxygen and controlled ventilation.

Neonates who are pale at birth are often asphyxiated, hypovolemic, acidotic, or anemic or have congenital heart disease (usually left-sided obstructive disease). Neonates whose skin is entirely pink within 2 minutes of birth may be intoxicated with alcohol or magnesium, or they may be alkalotic (pH >7.50). Rubrous neonates are usually polycythemic.

/das/book/view/29494766/875/645.html

RESUSCITATION EQUIPMENT

To ensure that resuscitation proceeds without difficulty, the whereabouts and function of all resuscitation equipment must be known by all delivery room personnel. Before each birth, the equipment should be checked and calibrated to be sure it is functioning properly.

The resuscitation bed should tilt to permit the neonate's head to be positioned below the level of the body. This promotes drainage of lung fluid and reduces the likelihood of aspiration of gastric contents. A servocontrolled infrared heater should be used to maintain the neonate's axillary temperature between 36 and 37°C. A suction device should be included, and the person doing the resuscitation should be able to vary the suction pressure. A second suction device may be required to continuously drain a pneumothorax. The suction pressure should not exceed 100 mm Hg. The resuscitation area should have a bright light with a small focal spot to illuminate catheter insertion sites.

The equipment required for tracheal intubation includes 0 and 00 straight laryngoscope blades; a pencil-type laryngoscope handle; a 2.5-, a 3.0-, and a 3.5-mm Magill-type endotracheal tube; and a suction catheter that easily fits through each size endotracheal tube. Cole tubes reduce the likelihood of an endobronchial intubation but can damage the larynx if enough pressure is applied to force the large portion of the tube into the trachea. [48]

The ventilation system used for resuscitation must permit a positive end-expiratory pressure (PEEP) and ventilatory rates of at least 150 breaths/min to be maintained. The system should not include one-way valves because they often stick in the closed position, especially when high gas flows and respiratory rates are used. If the valve sticks, the patient may develop a pneumothorax. The modified Jackson-Rees or Ayres system shown in Figure 58-4 (Figure Not Available) works well for neonatal resuscitation. It permits controlled ventilation at rapid respiratory rates and maintenance of PEEP. It also has a "pop-off" to reduce the likelihood of creating a pneumothorax. This ventilation system has no valves. The use of Ambu bags may be less effective because the valves can stick closed, it is more difficult to deliver 100 percent oxygen, and it is not possible to maintain a PEEP with these devices. The latter is important when resuscitating neonates who have atelectasis.

As in any intensive care situation, blood gas and pH measurements are mandatory, and the results of these tests must be available within 10 minutes of drawing the blood sample. Insertion of umbilical artery catheters that contain a Pa O_2 electrode or oxygen saturation probe allows Pa O_2 [49] and oxygen saturation [50] to be measured continuously during resuscitation. These catheters (Fig. 58-5) (Figure Not Available) also permit simultaneous measurement of arterial pressure and constant infusion of maintenance fluids. (Oxygen saturation can be measured immediately after birth with a pulse oximeter applied to a hand or foot.)

Because the response time of these catheters is 10 to 15 seconds, the effectiveness of resuscitation efforts in improving oxygenation can be readily ascertained (Fig. 58-6) . Although

Figure 58-4 (Figure Not Available) A modified Ayres T-piece that allows positive end-expiratory pressure and has a "pop-off" to reduce the likelihood of a pneumothorax. *(Modified from Gregory et al, [98] copyright 1971 Massachusetts Medical Society. All rights reserved.)*

Figure 58-5 (Figure Not Available) The oximetric system for measuring arterial oxygen saturation continuously. The catheter contains fiberoptics that transmit light to and from blood passing the catheter tip. *(From Wilkinson [96])*

the level of oxygenation can also be measured transcutaneously, these electrodes take 15 minutes to stabilize after being applied to the skin. Furthermore, the values only correlate with Pa O_2 when the blood pressure is normal and the body temperature is above 35.5°C. [51] Oxygen saturation can also be measured by applying a pulse oximeter probe to the palm of the hand. [52] These devices give good estimates of oxygen saturation when stable, but may give falsely low oxygen saturations with rapid decreases in saturation. [53]

Needle electrodes inserted under the skin provide continuous ECGs and heart rate values. Two pressure transducers are required to measure arterial and central venous pressures. Monitors used in neonatal intensive care units are adequate for use during resuscitation.

PROCEDURE

Someone other than the obstetrician should evaluate and resuscitate the neonate. If intrauterine asphyxia is known to exist or is strongly suspected (Table 58-2) , at least two additional people are required to resuscitate the neonate, one to control ventilation and the other to insert an umbilical artery catheter and correct acid-base and blood-volume abnormalities. A plan for the resuscitation of each neonate should be developed and understood by everyone in the delivery room before the neonate's birth.

Initial Evaluation

The neonate should be observed closely during delivery. As the head is delivered, the mouth and nose are suctioned with a bulb syringe. The neonate is held at the level of the introitus and dried with a towel to stimulate crying and reduce evaporative heat loss. Once breathing is established and the umbilical cord has stopped pulsating, the cord is cut and the neonate taken to the resuscitation table. Holding the neonate below the introitus increases blood volume and

Figure 58-6 The relationship among ventilation, oxygen saturation, Pa $_{O_2}$, and inspired oxygen concentration (F $_{IO_2}$) during neonatal resuscitation.

causes polycythemia. [54] Raising the neonate above the level of the introitus or clamping the umbilical cord early decreases blood volume. [55]

Stripping blood from the umbilical cord to the neonate increases blood volume, [56] respiratory rate, [57] lung water, [58] pulmonary artery pressure, and Pa $_{CO_2}$. [59] Lung compliance, FRC, [60] and Pa $_{O_2}$ [60] decrease. Figure 58-7 (Figure Not Available) shows the effects of early and late cord clamping on placental blood volume. The larger the placental volume, the smaller the neonate's blood volume. Early cord clamping can deprive neonates of up to 30 mL of blood/kg body weight. [55]

If the neonate is flaccid, pale, limp, and/or cyanotic, the umbilical cord should be clamped and cut and the neonate handed off to be resuscitated. It should be remembered that the neonate is probably hypovolemic because the umbilical cord was clamped early.

The neonate should be placed in a radiantly heated resuscitation bed with the head slightly lower than the body, and

Figure 58-7 (Figure Not Available) The effects of early and late cord clamping on placental blood volume. *(From Ogata [55])*

the airway should be cleared of secretions and blood by gently suctioning the mouth and nose with a bulb syringe. In my experience, prolonged suctioning can cause vomiting and arrhythmias, the most common of which is bradycardia, but ventricular arrhythmias occur in 10 to 20 percent of those who are suctioned vigorously while hypoxic.

If the respiratory pattern and color are normal, nothing more needs to be done except to dry the neonate with a towel and quickly insert a suction catheter into the posterior pharynx through each nostril to rule out choanal atresia. The same catheter is then passed through the mouth into the stomach to rule out esophageal atresia and small bowel atresia (see later) and to empty the stomach of its contents. Bilateral choanal atresia may be lethal because the airway will be totally obstructed when the mouth is closed. When the mouth is open, the neonate is pink; when the mouth is closed, the neonate continues to make breathing efforts, but there is no gas movement into or out of the lung. To alleviate the airway obstruction, an oral airway or an endotracheal tube should be inserted. The neonate should be seen by a knowledgeable ear, nose, and throat surgeon, and the bony obstruction should be relieved surgically. The 1-minute Apgar score can be used to guide resuscitation, but it is only a guide. One should not wait until 1 minute has passed before initiating resuscitation. The 5-minute Apgar score may have some predictive value for neurologic outcome.

Apgar Score

Score 8 to 10

Apgar scores of 8 to 10 are achieved by 90 percent of all neonates. Nothing is required except nasal and oral suctioning, drying of the skin, and maintenance of normal body temperature. A careful reevaluation of the neonate's condition should occur at 5 minutes of age because some neonates hypoventilate when stimulation ceases. When stable,

TABLE 58-2 -- Disorders Frequently Associated With Asphyxia at Birth

Maternal conditions
Elderly primigravida (>35 years of age)
Diabetes
Hypertension
Toxemia
Maternal treatment with any of the following:
Glucocorticoids
Diuretics
Antimetabolites
Reserpine, lithium

- Magnesium
- Ethyl alcohol
- beta-Adrenergic drugs (to stop premature labor)

Abnormal estriol levels

Anemia (hemoglobin level less than 10 g/100 mL)

Blood type or group isoimmunization

Previous birth of child with a hereditary disease

Current maternal infection or infection during pregnancy with rubella, herpes simplex, or syphilis

Abruptio placentae

Placenta previa

Antepartum hemorrhage

History of previous infant with jaundice, thrombocytopenia, cardio respiratory distress, or congenital anomalies

Narcotic, barbiturate, tranquilizer, or psychedelic drugs

Ethyl alcohol intoxication

History of previous neonatal death

- Prolonged rupture of membranes

Conditions of labor and delivery

- Forceps delivery other than low elective
- Vacuum extraction delivery
- Breech presentation and delivery or other abnormal presentation
- Cesarean section
- Prolonged labor
- Prolapsed umbilical cord
- Cephalopelvic disproportion
- Maternal hypotension
- Sedative or analgesic drugs given intravenously within 1 hour of delivery or intramuscularly within 2 hours of delivery

Fetal conditions

- Multiple births
- Polyhydramnios
- Meconium-stained amniotic fluid
- Abnormal heart rate or rhythm
- Acidosis (fetal scalp capillary blood)
- Decreased rate of growth (uterine size)
- Premature delivery
- Amniotic fluid surfactant test negative or intermediate within 24 hours of delivery

Neonatal conditions

- Birth asphyxia
- Birth weight (inappropriate for gestational age)
- Meconium-staining of the skin, nails, or umbilical cord
- Signs of cardiorespiratory distress

---

the neonate should be wrapped in a warm blanket and handed to the parents.

Score 5 to 7

Neonates with Apgar scores of 5 to 7 have suffered mild asphyxia just before birth. They usually respond to vigorous stimulation and to oxygen blown over the face. If they are slow to respond and to become pink, they should be ventilated with 80 to 100 percent oxygen via bag and mask. By 5 minutes of age, patients with Apgar scores of 5 to 7 at 1 minute are usually well. At 2 minutes of age, Pa o_2 is usually 50 to 70 mm Hg, Pa co_2 is 40 to 50 mm Hg, and pHa is about 7.15. The base deficit is approximately 12 mEq/L. By 10 minutes of age, the pHa will increase to 7.30 and Pa co_2 will decrease to below 40 mm Hg. The base deficit usually returns to normal (-3.0 to +3.0 mEq/L).

Score 3 to 4

Neonates with Apgar scores of 3 to 4 are moderately depressed at birth. They are usually cyanotic and have poor respiratory efforts, but they usually respond to bag and mask ventilation by breathing and becoming pink. If they have not breathed spontaneously, ventilating the lungs with a bag and mask may be difficult because the airway resistance exceeds that of the esophagus. If so, gas preferentially enters and distends the esophagus, stomach, and gut, which may interfere with ventilation and cause vomiting and regurgitation. Decompressing the stomach makes it easier to ventilate the lungs. If the neonate has not breathed or is breathing ineffectively, an endotracheal tube should be inserted before ventilating the lungs. Umbilical artery and vein blood should be obtained from a double-clamped segment of umbilical cord to measure blood gases and pH. The blood gases are frequently abnormal: a Pa o_2 below 20 mm Hg, Pa co_2 above 60 mm Hg, pHa below 7.15. If the pH and base deficit are unchanged or worse on a sample of blood obtained from a radial or temporal artery, an umbilical artery catheter should be inserted and, if necessary, sodium bicarbonate should be administered (see later).

Score 0 to 2

Neonates with Apgar scores of 0 to 2 are severely asphyxiated and require immediate resuscitation. It is *not* appropriate to stand around and wait to see what the patient will do. The patient's condition will get worse. Get on with the resuscitation! What follows is a discussion of resuscitation of neonates with Apgar scores of 0 to 2.

/das/book/view/29494766/875/647.html

PULMONARY RESUSCITATION

For pulmonary resuscitation, the trachea should be intubated immediately and positive-pressure ventilation should be begun at a rate of 30 to 60 breaths/min. Every fifth breath should be held for 2 to 3 seconds to expand atelectatic lung and to help remove lung fluid. A PEEP of 1 to 3 mm Hg should be maintained. Care must be taken *not* to use excessive pressures to ventilate the lungs of neonates in the delivery room. Recent evidence demonstrates that as few as six large breaths at birth markedly increases the amount of lung injury seen in premature lambs 30 minutes to several hours later and that the response to surfactant is significantly diminished in those ventilated with large breaths. [61]

Tracheal Intubation

The neonate's larynx is located four to six vertebrae more cephalad than the larynx of adults and consequently is more anterior than that of adults. Extension at the head places the larynx in an even more anterior position and makes tracheal

---

Figure 58-8 (Figure Not Available) Laryngoscopy of the newborn infant. See text for details. *(From Gregory [100])*

intubation more difficult. Therefore, the head should be placed in a neutral or "sniffing" position during bag-and-mask ventilation and during tracheal intubation. The laryngoscope should be held with the thumb and index finger and the chin grasped with the ring and middle fingers of the left hand. This "welds" the head and hand into a single unit and reduces the likelihood of pharyngeal lacerations occurring if the neonate's head moves. To improve the view of the larynx, pressure should be applied over the hyoid bone with the small finger of the left hand (Fig. 58-8) (Figure Not Available) . This maneuver moves the larynx posteriorly and exposes the vocal cords. An appropriate-size endotracheal tube should be inserted and the tip of the tube placed 1 to 2 cm below the vocal cords, depending on the size of the neonate. (The appropriate-size endotracheal tube is one that permits a small amount of gas to leak from between the endotracheal tube and trachea when a pressure of 15 to 25 cm H_2O is generated. This usually means a 2.5-mm [internal diameter] tube for neonates weighing less than 1.5 kg, a 3.0-mm tube for those between 1.5 and 2.5 kg, and a 3.5-mm tube for those weighing more than 2.5 kg.)

Adequacy of Ventilation

Adequacy of ventilation is best determined by physical examination and analysis of arterial blood gases. Both sides of the chest should rise equally and simultaneously with inspiration. If one side of the chest rises before the other, the tip of the endotracheal tube may be in a mainstem bronchus, or there may be a pneumothorax or congenital anomaly of the lung. Listening to the breath sounds may be misleading. Because the chest is small, breath sounds are well transmitted within the thorax. Thus, the breath sounds may be normal, even though the neonate has a pneumothorax or congenital anomaly of the lung. A difference in breath sounds between the two sides of the chest should raise suspicion that an endobronchial intubation, a pneumothorax, atelectasis, or a congenital anomaly of the lung is present. Breath sounds are usually heard over the stomach, but these are not as loud as the breath sounds heard over the chest. If they are as loud, it should be determined whether an esophageal intubation has occurred or whether the neonate has a tracheoesophageal fistula. If ventilation is adequate, the neonate will become pink, initiate rhythmic breathing, and have a normal heart rate. Normal blood gases will eventually be restored.

Most asphyxiated neonates do not have lung disease. Therefore, they seldom require more than 25 cm H_2O peak pressure to expand their lungs, even for the first few breaths. Excessive airway pressures cause pulmonary gas leaks and may cause lung injury. [61] Neonates whose lungs are stiff (erythroblastosis fetalis, congenital anomalies of the lung, pulmonary edema, severe meconium aspiration, diaphragmatic hernia) often require much higher inspiratory pressures to ventilate their lungs. If so, they are likely to develop pulmonary gas leaks. To reduce this likelihood, the lungs should first be ventilated with inspiratory pressures of 15 to 20 cm H_2O and rates of 150 to 200 breaths/min. If this low-pressure (low-volume), high-rate ventilation does not improve the blood gases, higher pressures and volumes should be used. One should remember that failure to use adequate pressures (volumes) during controlled ventilation may make hypoxemia worse and lead to CNS damage or even death. However, excessive pressures can be equally problematic. If a pulmonary gas leak occurs and interferes with oxygenation, carbon dioxide removal, or circulation, the gas should be drained with a thoracostomy tube. Pneumopericardia or pneumomediastina seldom requires drainage.

The effects of ventilation should be monitored closely. If the Pa_{O_2} is greater than 80 mm Hg or the oxygen saturation exceeds 94 percent, the inspired oxygen concentration should be reduced in 5 to 10 percent steps until the Pa_{O_2} is between 50 and 80 mm Hg or the oxygen saturation is between 87 and 94 percent. It is especially important to maintain oxygenation within this range when resuscitating neonates of 34 weeks' gestation or less, because they can develop retinopathy of prematurity (retrolental fibroplasia). [62] [63] Although it is not clear what level of Pa_{O_2} (or oxygen saturation) causes retrolental fibroplasia, we know that it can occur in premature neonates with a Pa_{O_2} of about 150 mm Hg for 2 to 4 hours. Furthermore, repeated increases in Pa_{O_2} to these levels may be as dangerous as a constant Pa_{O_2} of 150 mm Hg. The neonate's heart rate should be continuously monitored during endotracheal intubation because arrhythmias are common during this procedure, especially if the neonate is hypoxic at the time of tracheal intubation.

Routine Tracheal Suctioning

In certain situations, the trachea should be suctioned before ventilation of the lungs. These situations include meconium staining of the amniotic fluid or major vaginal bleeding. We found that most meconium is in major airways at birth and that suctioning of the airway after birth removes the majority of this material from the lungs. [64] Meconium aspiration is rare in appropriate-for-gestational age neonates who weigh less than 2,000 g at birth. Meconium aspiration has been reviewed elsewhere. [65]

About 10 percent of pregnant women have meconium staining of their amniotic fluid, and 60 percent of neonates born to mothers with meconium-stained amniotic fluid have meconium in their tracheas at birth. [66] If the airway is not suctioned before or shortly after the onset of breathing,

---

meconium in the airways will move into the alveoli and small airways with the onset of ventilation. About 15 percent of meconium-stained neonates develop respiratory difficulties during the first few days of life, and 10 percent develop a pneumothorax or pneumomediastinum on chest roentgenogram. Most intrathoracic gas leaks are small and cause only tachypnea. However, some large pneumothoraces cause collapse of the cardiovascular system and death if they are unrecognized and untreated.

Because of the seriousness of these complications, "pea soup" or particulate meconium should be removed from the lung before breathing is established to improve

the survival of neonates with meconium aspiration. [67] (Thin, watery meconium does not require suctioning.) Meconium is best removed from the lung by inserting an endotracheal tube, applying a suction device especially designed for this purpose, and sucking on the endotracheal tube as it is withdrawn from the trachea. [68] The laryngoscope should be left in place as the endotracheal tube is removed. If meconium is retrieved from the airway, the endotracheal tube should be quickly reinserted and the airway suctioned again. The lungs should then be gently ventilated with oxygen. The absence of meconium in the mouth and posterior pharynx does not preclude the presence of meconium in the trachea. [66] In one study, 13 percent of neonates had meconium in the trachea but none in the mouth or pharynx. [66] The heart rate should be continuously monitored during laryngoscopy and suctioning and 100 percent oxygen blown over the neonate's face. Suctioning the stomach will remove meconium that might be regurgitated and aspirated later. Chest physical therapy and postural drainage should be done every 30 minutes for 2 hours and hourly thereafter for the next 6 hours to help remove residual meconium from the lung. All neonates born following meconium aspiration should be observed for 24 hours because they can develop persistent fetal circulation (PFC) syndrome, [69] the major cause of death following meconium aspiration. When PFC occurs, blood is shunted right-to-left across the ductus arteriosus and foramen ovale. Little blood perfuses the lung. Of these neonates, 50 percent die during the first few days of life. Recently, extracorporeal membrane oxygenation (ECMO) has been used successfully to treat patients with severe hypoxia from meconium aspiration. [70] [71] Several days are required for pulmonary hypertension to abate and for ECMO to be no longer required. The long-term outcome of children who had meconium aspiration at birth is very good. Unless they had asphyxia in the perinatal period, they are intellectually intact. They also have normal pulmonary function at 6 to 11 years of age. [72] [73]

Other Causes of Respiratory Failure

There are other causes of respiratory failure besides those just described. These must be ruled out if the response to resuscitation is not immediate.

Pneumothorax

Pneumothorax occurs in 1 percent of all vaginal deliveries, in 10 percent of meconium-stained neonates, [66] and in 2 to 3 percent of neonates who require mechanical ventilation in the delivery room. To detect a pneumothorax, the chest should be carefully examined. The hemithorax containing free air is usually hyperexpanded and moves poorly with ventilation. The point of maximum cardiac impulse is shifted toward the chest that does not have a pneumothorax. The heart tones may be muffled.

If a pneumothorax is suspected, a small, high-intensity, cold light should be shone onto the skin of the chest. [74] If a pneumothorax is present, the involved chest will glow. A 22-gauge, relatively blunt needle should be inserted into the second intercostal space in the midclavicular line. The needle should be occluded with a closed stopcock. A "pop" is felt when the needle enters the pleural cavity. Fixing the needle at skin level with a hemostat reduces the likelihood of the needle advancing too far into the chest and accidently damaging the lung. If gas is found in the pleural space, as much gas as possible should be removed with a syringe while a thoracostomy tube is being inserted. The thoracostomy tube should be connected to underwater drainage.

Congenital Anomalies

Congenital anomalies of the airway are relatively common. Choanal atresia is discussed in the section on initial evaluation. Micrognathia (Pierre Robin syndrome) and relative macroglossia cause inspiratory obstruction. If an oral airway can be inserted, the problem is usually temporarily solved. If an oral airway cannot be inserted, a large (10 French) nasogastric tube should be inserted through the nose and the tip of the catheter placed in the stomach. This maneuver prevents the tongue from making a tight seal with the pharyngeal wall, which prevents the neonate from developing large negative pressures in the pharynx and "sucking" the tongue into the pharynx. Grasping the tongue with a towel clip and pulling outward is seldom effective and may cause harm. However, in a life-threatening situation, this maneuver should be tried. The tips of the towel clip should be placed in the sides of the tongue, not in the middle. Neonates with micrognathia should be nursed in the prone position to let the tongue fall forward. It is seldom necessary to do a tracheotomy; however, it is occasionally necessary to intubate the trachea. It is also possible to insert a #1 laryngeal mask; this often provides a good airway. [75] However, the connecting tube is a large deadspace and may significantly increase the Pa CO_2 .

Congenital anomalies of the larynx, such as webs, atresia, and vocal cord paralysis or fusion, are uncommon but when present cause stridor and respiratory distress. On occasion, it may be necessary to force a small endotracheal tube through these lesions. Subglottic stenosis, subglottic webs, and subglottic hemangiomas are also uncommon, but they too cause severe airway obstruction.

Esophageal Atresia and Tracheoesophageal Fistulas

Esophageal atresia and tracheoesophageal fistulas occur in 1 in 2,400 to 4,500 births. Respiratory distress occurs if the neonate aspirates gastric secretions or esophageal pouch

secretions, or if the stomach and gut distend with air and limit movement of the diaphragm. Controlled ventilation may distend the gut further and should be avoided unless it is absolutely necessary. If it is necessary to ventilate the lungs, the tip of the endotracheal tube should first be advanced beyond the fistula. Breath sounds heard over the stomach will diminish in intensity at this time. After ensuring that both lungs are being ventilated equally (i.e., equal chest movement and breath sounds), the endotracheal tube is firmly fixed in place. A sump-type catheter should be placed into the esophageal pouch and the catheter connected to suction to prevent accumulation of secretions in the pouch. The neonate should be nursed in the reverse Trendelenburg position to reduce the likelihood of aspirating the contents of the stomach and pouch.

Diaphragmatic Hernia

Diaphragmatic hernia occurs in 1 in 2,000 births. If the hernia is large, gut fills the involved chest cavity (usually the left) and causes hypoplasia of both lungs. [76] The ipsilateral lung is about 10 to 20 percent of its normal size, and the contralateral lung is about 60 to 70 percent of normal. Because the gut is in the chest cavity, the abdomen is scaphoid. (The abdomen of normal neonates is protuberant.) The breath sounds of the affected chest may or may not be decreased. Acidosis and hypoxia are usually present because of the hypoplastic lungs and because of right-to-left shunting of blood through the patent ductus arteriosus. In addition, many of these patients have pulmonary hypertension. The Pa O_2 of temporal artery or right radial artery blood (which is preductal) is higher than the Pa O_2 of blood from the descending aorta. [77]

The trachea should be intubated and the lungs ventilated rapidly (60-150 times per minute) with small breaths. No attempt should be made to expand the hypoplastic lung, as this may cause a pneumothorax on the side of the "good" lung. Neonates with diaphragmatic hernias are usually hypovolemic and require expansion of their intravascular volume with whole blood or plasma. Overhydration should be avoided because it causes pulmonary edema and makes the Pa O_2 and Pa CO_2 worse. Correction of the acidosis (both respiratory and metabolic) reduces PVR and improves pulmonary blood flow; reduced pulmonary blood flow is the usual cause of death. Hyperventilation (Pa CO_2 20-25 mm Hg) often increases pulmonary blood flow and improves blood gases, [78] but it may reduce cerebral blood flow, especially if the baby is hypotensive.

Recently, ECMO has been used to treat pulmonary hypertension associated with diaphragmatic hernia. [79] The success of this therapy has resulted in the survival of many neonates who otherwise would have died. Nevertheless, the mortality of neonates with a diaphragmatic hernia is still nearly 50 percent.

Administration of Surfactant

Administering surfactant into the lungs of neonates has resulted in significant improvement in the outcome of premature neonates. [80] [81] [82] The incidences of pulmonary gas leaks, hyaline membrane disease, deaths, bronchopulmonary dysplasia, and pulmonary interstitial emphysema are lower following surfactant administration. Frequently, surfactant is given as a liquid (i.e., 5 mL of fluid per kilogram are given into the trachea at birth), which may briefly reduce the oxygen saturation. Subsequently, the arterial oxygen saturation (Sa O_2) increases rapidly in most instances, as does the compliance of the lung. The latter may result in overinflation of the lung and the development of lung injury or a pulmonary gas leak if ventilation is not reduced.

/das/book/view/29494766/875/648.html

VASCULAR RESUSCITATION

Vascular resuscitation is a much neglected aspect of neonatal resuscitation. Few textbooks even mention it, despite the fact that neonates are often hypovolemic at birth. Those who are premature and asphyxiated near the end of labor are especially likely to be hypovolemic.

If the neonate's condition does not improve rapidly with ventilation and tactile stimulation, an umbilical artery catheter should be inserted to measure blood gases and pH, to measure arterial pressure, to expand blood volume, and to administer drugs. Most preterm neonates weighing less than 1,250 g at birth, and 1 to 3 percent of term neonates require an umbilical artery catheter during resuscitation. It also may be helpful to insert a central venous line to determine the adequacy of blood volume replacement.

Insertion of Intravascular Catheters

Umbilical Artery Catheterization

A stopcock should be attached to one end of a 3.5 or 5.0 French umbilical artery catheter and the catheter and stopcock flushed with sterile saline containing 1 to 2 units of heparin per milliliter of fluid. The stump of the umbilical cord is grasped with a clamp and the cord held straight up in the air. The abdomen and umbilical cord are sterilized with an iodine-containing solution and the abdomen is sterilely draped. Next, a sterile umbilical tape is tied loosely around the cord, and the cord is cut cleanly with a scalpel, leaving 2 cm of stump. The stump is firmly grasped with the gloved fingers of one hand, and one of the two thick-walled umbilical arteries is dilated with a curved iris forceps. With the stopcock partially open, a 3.5 French umbilical artery catheter is inserted into the artery if the neonate weighs less than 1,500 g or a 5 French catheter is used if the neonate weighs 1,500 g or more. Some resistance may be encountered when the catheter has been advanced 3 to 5 cm into the vessel, but this resistance can usually be overcome by applying steady pressure to the catheter. If the catheter will not advance, a second catheter should be inserted into the other artery while leaving the first catheter in place. This maneuver often causes one or the other vessel to relax and permits one of the catheters to be advanced into the aorta. When blood appears in the catheter, the stopcock should be closed, blood should be withdrawn from the catheter, and all air should be removed from the system. (The accidental injection of small amounts of air [<0.1 mL] may obstruct blood flow to the legs for several hours.) The catheter should

be attached to a pressure transducer and the arterial pressure measured.

Figure 58-5 (Figure Not Available) shows a catheter (Oximetrix Company, Mountain View, Calif) that is part of a fiberoptic system that makes it possible to measure arterial oxygen saturation and arterial blood pressure simultaneously. Because the catheter is precalibrated, the correct oxygen saturation is measured as soon as the tip of the catheter comes into contact with blood. This device is helpful in resuscitating asphyxiated neonates. [50]

Umbilical Venous Catheterization

The stump of the umbilical cord is prepared, grasped, and tied as described previously. The single, large, thin-walled umbilical vein is grasped with iris forceps and the catheter inserted 3 to 5 cm into the vessel with a twisting motion. The stopcock must be closed to prevent aspiration of air through the catheter if the patient takes a deep breath. The catheter is connected to a pressure transducer, and the intravascular pressure is displayed on an oscilloscope or polygraph. When the catheter tip enters the thoracic vena cava, the pressure tracing deflects negatively with each spontaneous inspiration. When the catheter tip is in an intra-abdominal vein, the deflection is positive during inspiration. Once the catheter tip is in the intrathoracic vena cava, the catheter should be fixed in place and the P_{O_2} of the blood measured. If the P_{O_2} exceeds 40 mm Hg, the catheter tip is probably in the left atrium and should be withdrawn into the right atrium or inferior vena cava. It is imperative that no air be injected through venous catheters because the air may enter the systemic circulation through the foramen ovale and occlude a coronary or cerebral artery. If it does, the neonate may die or suffer CNS damage. If the catheter "tickles" the atrial septum, the neonate may suffer arrhythmias. Withdrawal of the catheter a short distance will solve the problem.

Correction of Acidosis

Respiratory acidosis is corrected by controlling ventilation. Metabolic acidosis is corrected by infusing sodium bicarbonate. Bicarbonate is less expensive and does not cause the severe hypoglycemia, hypocalcemia, hypokalemia, and apnea that can occur with administering tromethamine (Tham). In addition, the volume of sodium bicarbonate required to correct the same amount of acidosis is one-third that of Tham. This reduces the likelihood of inducing hypervolemia with sodium bicarbonate.

Several potentially serious problems are associated with administering sodium bicarbonate:

1. Sodium bicarbonate is hypertonic, about 1,800 mOsm/L. If a large volume of sodium bicarbonate is administered rapidly (more than 1 mEq/kg/min), the intravascular volume may expand rapidly and cause intracranial hemorrhage.
2. The complete reaction of hydrogen ions with 50 mEq of bicarbonate generates approximately 1,250 mL of CO_2. If ventilation is adequate, the CO_2 is quickly exhaled, and the Pa $_{CO_2}$ rises 1 to 3 mm Hg. If ventilation is inadequate, as it is in asphyxiated neonates, the Pa $_{CO_2}$ increases significantly, and, because the CO_2 freely diffuses into cells, may lead to cardiac arrest. Because it dilates cerebral vessels, Pa $_{CO_2}$ increases cerebral blood flow and may cause intracranial hemorrhage. To prevent the rise in Pa $_{CO_2}$, ventilation should be controlled. Alkali should not be infused to correct metabolic acidosis unless ventilation is adequate.
3. Administering bicarbonate may also induce hypotension (Fig. 58-9) (Figure Not Available) . This occurs because acidotic, hypovolemic neonates have intense peripheral vasoconstriction, which preserves their arterial blood pressure. Correcting the acidosis reduces the PVR and induces hypotension because the neonate's blood volume is now inadequate to fill the expanded vascular space.

4. Sodium bicarbonate may also interfere with myocardial function, especially if the acidosis for which it was given is ongoing. [83] [84] This is rare clinically in neonates.
5. Until recently, it was believed that the CO_2 produced by the reaction of bicarbonate with hydrogen ions decreased the intracellular pH of brain. However, this is

not the case. [85]

Figure 58-9 (Figure Not Available) The effects of sodium bicarbonate on aortic blood pressure (P_{AO}), heart rate, and hematocrit level. Note that hypotension occurred following administration of sodium bicarbonate. The hematocrit level decreased as fluid was "pulled" into the intravascular space to compensate for the hypovolemia that was present since birth. Raising pH decreased the peripheral vasoconstriction produced by the preexisting acidosis. Giving albumin increased the aortic pressure to normal. On the basis of the final hematocrit level, the initial blood volume was approximately 30 percent less than predicted. *(From Phibbs. [101] Courtesy of Ross Products Division, Abbott Laboratories Inc., Columbus, OH.)*

Who Requires Alkali Therapy?

Despite the potential problems associated with bicarbonate administration, there are situations in which it is useful. If the Apgar score is 2 or less at 2 minutes or 5 or less at 5 minutes despite tactile stimulation and controlled ventilation with oxygen, the neonate should be given 2 mEq/kg of sodium bicarbonate while the lungs are being ventilated. Bicarbonate should not be infused into a catheter whose tip rests in the liver, because the hypertonic solution may cause hepatic necrosis. Ventilation should be controlled as the drug is infused. Blood gases and pH should be measured. If the pH is below 7.00 and the Pa_{CO_2} is below 35 mm Hg, one-fourth of the base deficit should be corrected with sodium bicarbonate. If the pH is above 7.10, ventilation of the lungs should be continued and arterial pH and blood gases remeasured in 5 minutes. If the pH is 7.15 or above on the repeat measurement, ventilation of the lungs should continue and bicarbonate therapy should be delayed. If the repeat blood gas shows a decrease or no change in pH, one-fourth of the base deficit should be corrected with bicarbonate. Figure 58-10 (Figure Not Available) shows the effects of sodium bicarbonate on the Pa_{O_2} of a group of asphyxiated neonates whose ventilation was held constant. No significant increase in Pa_{O_2} occurred until the pH was above 7.10 to 7.20, the point at which Rudolph and Yuen [18] found their most significant decrease in PVR. It is unclear in the neonates we have treated whether the increase in Pa_{O_2} was due to the increase in pHa or to expansion of blood volume by bicarbonate.

Metabolic acidosis occurs when tissue perfusion is poor. At birth, underperfusion is usually due to hypovolemia or

Figure 58-10 (Figure Not Available) The effects of the rapid infusion of sodium bicarbonate on Pa_{O_2} and pH when ventilation was held constant. The Pa_{O_2} increased when the pH increased above 7.10 to 7.20. *(From Gregory [97])*

heart failure (congenital heart disease, including congenital bradycardia and severe acidosis). Heart failure usually occurs when the pH falls below 7.00. Raising the pH to 7.15 or higher usually improves cardiac output. As a result of this increase, liver perfusion increases and metabolic acids are metabolized. If heart failure is due to cardiac disease (congenital bradycardia from arrhythmias, erythroblastosis fetalis, congenital cardiac anomalies), the cardiac output should be increased with a continuous infusion of isoproterenol (starting with 0.05 mug/kg/min and increasing the dose as necessary) or a transvenous pacemaker should be inserted. In these patients, cardiac output is usually best when the heart rate is raised to 160 to 190 beats/min. Hypoglycemia may also cause heart failure, but hypoglycemia is uncommon in asphyxiated neonates. If it is low, the blood glucose concentration should be increased to normal (50-90 mg/dL) by infusing 5 mL/kg of 10 percent dextrose in water over 3 to 5 minutes. This infusion should be followed with a continuous infusion of enough glucose to maintain a normal glucose concentration.

If the acidosis is due to hypovolemia, as it usually is, the blood volume should be expanded.

Expansion of Intravascular Volume

Approximately 60 percent of asphyxiated preterm neonates weighing less than 1,500 g are hypovolemic at birth because their umbilical cord was clamped and cut earlier than usual (see Fig. 58-7) (Figure Not Available) so that resuscitation could begin. Term neonates are hypovolemic if the umbilical cord is clamped early or if the cord is wound tightly around the neck and must be cut to deliver the neonate. Hypovolemia also occurs with intrauterine asphyxia, with placental abruption, or with transection of the placenta during cesarean section.

Detection of Hypovolemia

Hypovolemia is detected by measuring the arterial blood pressure and by physical examination (skin color, perfusion, capillary refill time, pulse volume, and extremity temperature) (Table 58-3) . After 24 hours of age, urine volume and specific gravity measurements are also helpful.

The arterial pressure can be measured with a Doppler system or an indwelling arterial catheter. Table 58-4 shows the systolic, diastolic, and mean arterial pressures during the first 12 hours after birth. The increase in pressure should be noted with increasing gestational age. If no pressure transducer is available, the umbilical artery catheter can be connected to a venous manometer and the height of the column of water displaced by blood (in centimeters) divided by 13.6 (the density of mercury) to obtain the mean arterial pressure (MAP). MAP is a more useful determinant of the adequacy of intravascular volume than the systolic or diastolic pressure.

Central venous pressure (CVP) measurements are helpful in detecting hypovolemia and in determining the adequacy of fluid replacement. Changes in CVP are more important than a single CVP determination. The venous pressure of normal neonates is 4 to 8 cm H_2O. If the CVP is less than 4 cm H_2O, hypovolemia should be suspected.

TABLE 58-3 -- Relationship of Skin Color, Capillary Refill Time, Pulse Volume, and Extremity Temperature to Hypovolemia

AMOUNT OF VOLUME DEPLETION (%)	SKIN COLOR	CAPILLARY REFILL TIME (SECONDS)	POSTERIOR TIBIAL PULSE VOLUME	SKIN TEMPERATURE
None	Pink	<2	++++	Warm
5	Pale	3-4	++	Cold from midcalf and midforearm out
10	Gray	4-5	0	Cold midthigh and upper arm out
15	Mottled	>5	0	Entire extremity cold

Symbols: ++++, full; ++, moderately full; 0, markedly diminished or absent

Hypovolemic neonates are usually pale and have poor capillary refill and poor perfusion. Their extremities are cold and their pulses (especially the radial and posterior tibial pulses) weak or absent. Those neonates who are intoxicated with alcohol or magnesium are usually pink, peripherally dilated, and hypotensive and may be acidotic.

Treatment of Hypovolemia

The key to treating hypovolemia is intravascular volume expansion. This can best be done with blood; but albumin, plasma, and crystalloid are also used for this purpose. If it is suspected that the neonate will be hypovolemic at birth, maternal blood should be cross matched against one unit of O-negative packed red blood cells and one unit of O-negative whole blood. Both units of blood should be brought to the delivery room in separate "cold packs" (a sealed plastic ice chest containing dry ice) just before the neonate is born. If blood is not needed, it can be returned unopened to the blood bank within 4 hours.

If cross matched blood is not available at the time of delivery, the placenta can be cleansed with iodine and blood can be withdrawn from the umbilical vein and artery with sterile syringes containing 1 to 2 units of heparin per mL of blood collected. These vessels usually contain a large amount of blood, especially if the umbilical cord was clamped immediately after birth. [56] The blood should be passed through a blood filter before it is given to the neonate to eliminate blood clots and debris. There is no concern about incompatibility of blood types because this blood was part of the circulating blood volume of the neonate before the umbilical cord was clamped. We usually reserve transfusing placental blood for emergencies for fear of causing an infection, although this has never occurred. If no source of blood is available (or is not required due to an adequate hematocrit level), the intravascular volume can be expanded with 1 to 2 g/kg of 25 percent albumin, 10 mL/kg of

plasma, or 10 mL/kg of lactated Ringer solution.

On occasion, enormous volumes of blood are required to raise the arterial blood pressure to normal levels. Rarely, more than 50 percent of the blood volume (85 mL/kg) in term neonates and 100 mL/kg in preterm neonates must be replaced (Fig. 58-11). This is especially true if the placenta is transected during a cesarean section. However, in most cases, less than 10 to 20 (Figure Not Available) mL/kg will restore a normal MAP.

Besides indicating the absolute arterial blood pressure, the arterial pressure tracing provides other information helpful to the evaluation of the adequacy of intravascular volume. A decrease in systolic pressure of more than 5 mm Hg with each inspiration suggests that the neonate is hypovolemic (see Fig. 58-11) (Figure Not Available) . It can also be seen that increasing the blood volume eliminates the swings in arterial pressure induced by inspiration.

Care must be taken not to overexpand the intravascular volume and cause hypertension, especially in preterm neonates. Hypertension may disrupt the intracerebral vessels and cause intracranial hemorrhage [86] if cerebrovascular

TABLE 58-4 -- Average Systolic, Diastolic, and Mean Arterial Blood Pressures (mm Hg) During the First 12 Hours of Life in Normal Infants

autoregulation is absent, [87] [88] which it usually is in asphyxiated neonates. [89] [90] [91]

OTHER CAUSES OF HYPOTENSION

Hypoglycemia, hypocalcemia, and hypermagnesemia can also cause hypotension. The hypotension caused by alcohol or magnesium intoxication usually responds to blood-volume expansion, or better still, to an infusion of dopamine. The arterial blood pressure of hypermagnesemic neonates also may increase with a bolus of 100 to 200 mg/kg of calcium gluconate (given over 5 minutes) and a continuous infusion of 100 to 300 mg/kg/d of the drug.

Polycythemia (hematocrit level >65%) may also cause hypotension due to increased PVR and decreased left ventricular filling pressures. Polycythemia occurs with delayed clamping of or with stripping blood from the umbilical cord. The hyperviscosity that accompanies polycythemia also increases PVR, reduces pulmonary blood flow, and increases right-to-left shunting of blood through the ductus arteriosus and foramen ovale. Hyperviscosity also increases the systemic vascular resistance. The combination of hypoxia and increased vascular resistance causes cardiorespiratory failure. Alleviating polycythemia improves the cardiovascular status of the patient. An exchange transfusion with plasma or saline with albumin (4 g albumin/100 mL saline) can be used to reduce the hematocrit level to 50 to 55 percent. Late sequelae of polycythemia include cardiac and renal failure and CNS injury.

CARDIAC MASSAGE

If the heart rate at 1 minute or less of age is below 100 beats/min, the trachea should be intubated, the lungs ventilated with oxygen, and closed chest massage begun. Both thumbs are placed at the junction of the lower and middle third of the body of the sternum, and the fingers, which encircle the chest, should be used to support the back (Fig. 58-12). The sternum is compressed 1 to 2 cm (approximately one-third the distance to the anterior vertebral bodies) at a rate of 100 to 150 (Figure Not Available) times per minute. It is not necessary to interrupt ventilation of the lungs during cardiac massage and vice versa, although the American Heart Association suggests that this be done. [89] Cardiac output is often greater when cardiac massages and ventilation are simultaneous. The effectiveness of cardiac massage is determined by measuring the blood gases and pH and the arterial pressure generated and by examining the pupils. If the cardiac massage and ventilation are effective, the pupils will be in the midposition or constricted. If the pupils are dilated, and no atropine has been given, cerebral blood flow and oxygenation are inadequate.

Ideally, each chest compression should generate a systolic pressure of 80 mm Hg because pressure is related to cardiac output during CPR. [92] This pressure plus a cardiac massage rate of about 120 times per minute will maintain a diastolic pressure of 20 to 25 mm Hg, a level that is adequate to

Figure 58-12 (Figure Not Available) Closed chest massage. For simplification, ventilation is not shown. *(From Gregory [97])*

TABLE 58-5 -- Drugs Used During Resuscitation[a]

DRUG	INDICATION	DOSE	ROUTE	RESPONSE	COMPLICATION
Atropine	Bradycardia	0.03 mg/kg	IV	Increased heart rate	Marked tachycardia, diminished cardiac output
Calcium gluconate	Low cardiac output	100 mg/kg over 5-10 minutes (ECG monitoring)		Improved cardiac arrhythmias	Bradycardia
Epinephrine	"Flat-line" ECG	0.1 mL/kg of a 1:10,000 solution	IV	"Flat-line" ECG converted to some rhythmic response	Hypertension; ventricular fibrillation
Isoproterenol	Bradycardia, hypotension, low cardiac output	4 mg/250 mL of 5 percent dextrose. Start at 0.01 mug/kg/min and increase until heart rate increases	IV	Increased heart rate, improved cardiac output if heart rate output	Arrhythmias, low cardiac more than 180-220/min
Dopamine	Hypotension	40 mg/100 mL. Start at 5 mug/kg/min and increase until desired effect is achieved	IV	Increased arterial pressure; improved cardiac output, perfusion, and urine output	Arrhythmias-- uncommon

ECG, electrocardiogram

[a] Doses given are, in general, starting doses and may have to be increased. Most drugs tend to be more effective when pH > 7.15.

maintain coronary artery perfusion in neonates during diastole. Failure to generate these pressures and rates allows the diastolic pressure to fall below 10 mm Hg, which is inadequate to perfuse the coronary arteries during diastole.

RESUSCITATION DRUGS

Table 58-5 lists drugs and the usual starting doses used during resuscitation of the newborn. Birchfield et al [93] have reviewed the use of drugs in neonatal resuscitation. [93] Severe acidosis (pH <7.0) may decrease the effectiveness of these drugs. Therefore, the pH should be raised above 7.20 as soon as possible. All drugs should be infused in the smallest volume of fluid possible to reduce the risk of inducing hypervolemia. To do so, drugs such as isoproterenol must be administered in high concentrations (16 mug/mL). However, it should be remembered that the dead space of the catheter is filled with the same concentration of the drug. If the contents of the catheter are flushed into the patient by infusing fluid or another drug, serious cardiac arrhythmias or cardiac arrest may occur. To avoid these complications, the dead space of the catheter and stopcock should be cleared by withdrawing 1.5 mL of blood and fluid. It is preferable to infuse potent cardiac and vasoactive drugs into a separate intravenous line.

Hyperglycemia can significantly augment the effects of hypoxia on ischemia. [94] It increases the extent of CNS damage and reduces the survival of patients who can be resuscitated from cardiac arrest. [95] [96] Consequently, glucose should be given only to neonates who are hypoglycemic. The blood glucose concentration should be measured by a glucometer. If the blood glucose concentration is low, one should give a bolus of glucose (0.5-1.0 mL/kg of 10% dextrose) and begin a constant infusion of 5 to 7 mg/kg/min of glucose. Repeat the glucose measurement in 10 minutes and then as necessary.

WHEN TO DISCONTINUE THERAPY

The decision to stop resuscitation is a personal one. It is usually based on one's own experience and the desires of the parents. In making the decision, the physician must consider the probability of neurologic damage and the likelihood of even seminormality. If the chances of a productive, useful life are poor, consideration should be given to discontinuing all resuscitative efforts.

CASE REPORT

This case summarizes the concepts presented in this chapter.

The neonatologists and anesthesiologists at the University of California, San Francisco, were notified of the impending birth of a 1,500 g, appropriate-for-gestational-age neonate by a mother whose membranes had ruptured 24 hours earlier. Labor had progressed despite the use of tocolytic agents. The obstetricians typed and crossmatched the mother's blood against one unit of O-negative packed red blood cells and one unit of whole blood so that blood would be available in the delivery room to transfuse the neonate during resuscitation if the blood volume or hematocrit level were low. Both units of blood were in the delivery room in separate plastic cold packs before the neonate's birth.

Before the neonate was born, arterial and venous pressure transducers and an umbilical Sa_{O_2} catheter were calibrated. A blood-gas machine and a centrifuge were moved into the resuscitation area so that blood gas, pH, and hematocrit data would be available within 2 minutes of obtaining the blood sample.

An anesthesiologist, attending neonatologist, neonatology fellow, pediatric resident, and two neonatal nurses provided care for the patient during resuscitation.

The neonate was born vaginally. Her mouth and nose were suctioned and her umbilical cord clamped and transected. She was handed to a waiting anesthesiologist and dried with a towel as she was quickly taken from the delivery room to the resuscitation room (a distance of 20 feet). The umbilical cord was clamped and cut immediately after birth because the patient was apneic and because her heart rate was about 100 beats/min. Under the assumption that she would be hypovolemic, we were prepared to infuse blood if her MAP was more than 2 standard deviations below the average MAP for a patient of her gestational age.

We weighed the neonate immediately on her arrival in the resuscitation area. This took less than 10 seconds. Knowing her correct weight allowed us to administer the appropriate doses of drugs, fluids, and blood during resuscitation. After weighing the neonate, we placed her on the sterile resuscitation table, inserted needle electrodes under her skin to continuously measure the ECG and heart rate, and intubated her trachea. Ventilation was controlled with 25 cm H_2O pressure and 100 percent oxygen. The first inspiration was held for 2 seconds. After the first breath, ventilation was controlled at a rate of 60 breaths/min; pressures of 20/5 cm H_2O were applied during each breath. Every fifth inspiration was held for 2 seconds in an attempt to improve the distribution of ventilation and increase removal of fluid from the lung. By this time, the neonate was 1.5 minutes old. A pulse oximeter was applied to her hand and her Sa_{O_2} was less than 80 percent.

A nurse held the umbilical cord up in the air while the abdomen and umbilical cord were sterilized with povidone-iodine; then the abdomen was covered with sterile towels. Next, we placed an umbilical tape 1.0 cm above the point where the umbilical cord entered the skin and tied the tape loosely. We were careful not to include the skin of the abdomen in the tie. We then grasped the umbilical cord and tie with the thumb and index finger of one hand to control bleeding, cut off the umbilical cord, and discarded the unwanted portion of the umbilical cord. Next, the artery was dilated with a pair of curved iris forceps; a Shaw umbilical Sa_{O_2} catheter was inserted into one of the thick-walled umbilical arteries. The catheter was advanced until blood flowed back into the catheter. When this occurred, the stopcock was closed and the catheter was advanced an additional 2 cm. The catheter was then connected to the pressure transducer and all air was removed from the system; then the arterial blood pressure was measured.

As the initial Sa_{O_2} was less than 80 percent, we increased the peak inspiratory pressure to 25 cm H_2O and increased the respiratory rate to 80 breaths/min. A sample of blood was obtained for blood gases, pH, hematocrit level, electrolyte determinations, and blood culture and sensitivity of organisms to antibiotics. Because it is often difficult to distinguish hyaline membrane disease from an intrauterine pneumonia, the neonate was given ampicillin (50 mg/kg) and gentamicin (2.5 mg/kg) through the umbilical artery catheter. The neonate was now 5 minutes old.

The neonate's initial MAP was 24 mm Hg and her systolic and diastolic pressures 40/20 mm Hg. Because she was hypotensive, as well as hypoxic and acidotic (Pa_{O_2} 38 mm Hg, Pa_{CO_2} 60 mm Hg, pH 7.02, base deficit 6.0 mEq/L) and because her hematocrit level was adequate (45%), ventilation was kept constant and she was transfused with 5 mL/kg of whole blood. (Hypotension increases right-to-left shunting of blood through the lung, foramen ovale, and ductus arteriosus of hypoxic, acidotic neonates.) The blood transfusion raised the MAP to 26 mm Hg. However, within 2 minutes, the pressure fell to 24 mm Hg. The Sa_{O_2} was 68 percent. Transfusing another 5 mL/kg of whole blood raised the MAP to 28 mm Hg, the lower limits of normal for neonates of this gestational age. Simultaneous with raising the MAP, the Sa_{O_2} rose to 82 percent. A second blood gas measurement showed a Pa_{O_2} of 46 mm Hg, Pa_{CO_2} 53 mm Hg, and pH 7.15. Because the pHa had increased and the Pa_{CO_2} had decreased and because the MAP was stable, we continued to ventilate her lungs rather than administer bicarbonate. Five minutes later, the MAP had increased to 30 mm Hg and 100 percent Sa_{O_2} had been achieved. Another sample of blood was obtained. The Pa_{O_2} was 138 mm Hg, Pa_{CO_2} 37 mm Hg, and pH a 7.27. During the next 10 minutes, the Sa_{O_2} remained above 90 percent despite a progressive reduction of F_{IO_2} to 0.75. On repeat testing, the Pa_{O_2} was 70 mm Hg, Pa_{CO_2} 29 mm Hg, and pH 7.46. Because of the increased pHa and the decreased Pa_{CO_2}, we reduced the ventilatory rate to 60 breaths/min. We continued to reduce the F_{IO_2} as long as the Sa_{O_2} remained between 87 and 94 percent. Fifteen minutes later, when the F_{IO_2} was 0.50, we obtained another blood gas (Pa_{O_2} 68 mm Hg, Pa_{CO_2} 35 mm Hg, pHa 7.42). The MAP was 32 mm Hg and the Sa_{O_2} and F_{IO_2} were stable for the next 15 minutes. A repeat blood gas was similar to the previous one. Consequently, we transferred the patient to the neonatal intensive care unit.

The neonate had mild hyaline membrane disease. By the 3rd day of life, her condition was improved; mechanical ventilation was discontinued and the endotracheal tube removed. She was discharged from the hospital on the 48th day of life and was doing well. Present-day treatment would include giving 5 mg/kg of Exosurf into the endotracheal tube and continuing ventilation. This would improve oxygenation more rapidly once the blood volume was adequate.

This case illustrates several basic points:

1. Resuscitation of severely ill neonates involves all the technology and people required to resuscitate an older child or adult from cardiac arrest. One person cannot do all the things required to resuscitate a neonate. It is essential, therefore, to notify those who are going to resuscitate the patient in time for them to arrive in the delivery room before the patient is born.
2. Neonates who are severely depressed at birth are often hypovolemic and require immediate blood volume expansion. Failure to correct the hypovolemia makes it difficult to correct the hypoxia and acidosis.
3. Blood gases and pHa change rapidly during resuscitation. Therefore, the results of these determinations should be immediately available so that the inspired oxygen concentration and the ventilation pressures and rates can be changed as necessary. Being told the blood-gas results 30 minutes after the blood sample was obtained is of little value, because the blood gases and pH will almost certainly have changed during that time.
4. The equipment required for resuscitation must always be available in the delivery room. One should not wait for an emergency to occur before finding the resuscitation

equipment. The equipment needed includes heating lamps and heating blankets to maintain the neonate's body temperature normal, umbilical arterial catheters, surgical instruments to insert an umbilical artery catheter, pressure transducers and monitors to measure intravascular pressures, and equipment to intubate the trachea and ventilate the lungs.

A hospital that cannot provide the care outlined in this case report should transfer mothers with high-risk pregnancies to a referral hospital early in their course of labor.

Chapter 59 - Pediatric Anesthesia

Charles J. Cote

INTRODUCTION

The provision of safe anesthesia for the pediatric patient depends on a clear understanding of the physiologic, pharmacologic, and psychologic differences between children and adults. Special consideration must be given to premature infants, as well as to those with congenital malformations. This chapter describes how the unique characteristics of pediatric patients influence the safe conduct of anesthesia.

DEVELOPMENTAL PHYSIOLOGY OF THE INFANT

Organogenesis takes place within 8 weeks of conception; organ function develops during the second trimester; and the infant gains weight, primarily muscle and fat, during the third trimester. [1] Therefore, any physiologic or pharmacologic injury or stress during the first trimester may cause abnormal organogenesis; in the second trimester, it may cause abnormal organ functional development, and in the third trimester, smaller organs or reduced muscle and fat mass. [2] Injuries and stress take the form of congenital viral infections, exposure to drugs, nutritional insufficiency (caloric or vascular), or other maternal illness. [3] A genetic predisposition to developmental malformations can also produce adverse effects. Such interruptions in normal growth and development may cause a variety of physiologic abnormalities ranging from simple premature birth to a constellation of congenital malformations.

A premature infant is one born before 37 weeks of gestation; a postmature infant is one born after 42 weeks of gestation. Any infant less than 2,500 g is considered a low-birth-weight infant. Plotting weight against gestational age (GA) allows classification into three general categories: small for GA, appropriate for GA, or large for GA (Fig. 59-1) (Figure Not Available) . Infants who are small or large for GA age often have developmental problems or difficulties associated with maternal disease (Table 59-1) (Table Not Available) . A careful physical and neurologic examination at birth (the Dubowitz scale), modified for extreme prematurity, allows a fairly accurate estimate of GA. [4] [5] The anesthesiologist should be aware of this type of evaluation so that potential problems with the anesthetic regimen can be anticipated. A perinatal history regarding problems in the mother (e.g., maternal drug abuse, maternal infection) is valuable for anesthetic management. In the weeks following birth, measures of weight, height, and head circumference are plotted on standard developmental curves; deviations from the normal (i.e., crossing developmental lines) usually indicate severe physiologic injury. The anesthesiologist should examine the growth chart to evaluate how the child is developing.

Cardiovascular System

The cardiovascular system undergoes dramatic physiologic and maturational changes during the first year of life. *In utero,* most of the cardiac output is directed from the placenta across the foramen ovale into the ascending aorta (oxygenated blood). Superior vena caval blood (deoxygenated)

Figure 59-1 (Figure Not Available) Plotting birth weight against gestational age for neonates determines whether infants are small, appropriate, or large for gestational age. Babies who are either small or large for gestational age are particularly likely to have a variety of problems such as metabolic, developmental, infectious, or structural abnormalities, as well as drug addiction and withdrawal. *(Modified from Battaglia [249])*

is directed to both the pulmonary artery and the ductus arteriosus. Thus, pulmonary blood flow is minimal. At birth, certain events change hemodynamic interactions such that the fetal circulation becomes an adult-type circulation. [6] Specifically, the placenta is removed from the circulation, and exposure of blood entering the ductus arteriosus to oxygen induces ductal closure. As a result of the combined effects of lung expansion and exposure of blood to oxygen, peripheral vascular resistance rises rapidly while pulmonary vascular resistance decreases. The fall in pulmonary vascular resistance occurs rapidly on the first day of life and continues to decrease gradually during the next several years as the architecture of the pulmonary vessels changes. An increase in pressures on the left side of the heart (caused by the increase in peripheral vascular resistance) induces mechanical closure of the foramen ovale. Although closure of the ductus arteriosus probably occurs primarily in response to a rise in arterial oxygen concentration, its successful completion requires arterial muscular tissue. [7] The finding that such tissue is less prevalent in premature infants may account, in part, for the high incidence of patent ductus arteriosus among premature infants. True mechanical closure by fibrosis does not occur until 2 to 3 weeks of age. [6] [7]

During this critical period, the infant readily reverts from the adult circulation to a fetal type of circulation; this state is called transitional circulation. Many factors (hypoxia, hypercarbia, anesthesia-induced changes in peripheral vascular tone) can affect this precarious balance, resulting in a rapid return to fetal circulation. When this reversal occurs, pulmonary artery pressure increases to systemic levels, blood is shunted past the lungs via the patent foramen ovale, and the ductus arteriosus may reopen, allowing blood to shunt at the ductal level. A rapid downhill spiral may occur, causing severe hypoxemia; this explains why hypoxemic events in infants are often prolonged despite adequate pulmonary ventilation with 100 percent oxygen.

Risk factors increasing the likelihood of prolonged transitional circulation include prematurity, infection, acidosis, pulmonary disease resulting in hypercarbia or hypoxemia (aspiration of meconium), hypothermia, and congenital heart disease. Care must be directed to keeping the infant warm, maintaining normal arterial oxygen and carbon dioxide tensions, and minimizing anesthetic-induced myocardial depression.

The myocardial structure of the heart, particularly the volume of cellular mass devoted to contractility, is significantly less developed in the neonate than in the adult. These differences and others produce a leftward displacement of the cardiac function curve and less compliant ventricles. This developmental myocardial immaturity accounts for the tendency toward biventricular failure, sensitivity to volume loading, poor tolerance to increased afterload, and heart rate-dependent cardiac output. [8] [9]

Pulmonary System

The pulmonary system is not capable of sustaining life until both the pulmonary airways and the vascular system have matured sufficiently to allow exchange of oxygen from "air" to the blood stream across the pulmonary alveolar/vascular bed. Independent life is not possible until GA is 24 to 26 weeks. Alveoli increase in number and size until the child is approximately 8 years old [10] ; further growth manifests as an increase in the size of the alveoli and airways. At term, a full complement of surface-active proteins helps maintain patency

---

TABLE 59-1 -- Common Neonatal Problems Associated With Weight and Gestational Age

(Not Available)

Modified from Todres [255]

of the airways. If a child is born prematurely and these proteins are insufficient, respiratory failure (respiratory distress syndrome) may follow.

Several anatomic differences make respiration less efficient for the infant. The small diameter of the airways increases resistance to air flow; resistance is inversely

proportional to the radius raised to the fourth power. The airway of the infant is highly compliant and poorly supported by surrounding structures. The chest wall is also highly compliant, so that the ribs provide little support for the lungs; that is, negative intrathoracic pressure is poorly maintained. Thus, each breath is accompanied by functional airway closure. [11] Dead-space ventilation is similar to that in adults; however, oxygen consumption is two to three times as high as in the adult. In the premature infant, the work of breathing is approximately three times that of the adult, and this work can be increased significantly by cold stress or partial airway obstruction. These differences partially explain the high respiratory rate of the infant and the rapidity with which hemoglobin desaturation can occur. [12]

Another important factor is the composition of diaphragmatic and intercostal muscles. These muscles do not achieve the adult configuration of type 1 muscle fibers until the child is approximately 2 years old [13] (Fig. 59-2) . Because type I muscle fibers provide the ability to perform repeated exercise and because the newborn and the infant are somewhat deficient in type I muscle fibers, any factor that increases the work of breathing contributes to the early fatigue of the respiratory muscles. Fatigue, in turn, leads to apnea or carbon dioxide retention and respiratory failure. Infants have often been described as obligate nasal breathers; however, approximately 8 percent of premature neonates (postconceptual age [PCA], 31-32 wk) and 40 percent of term newborns can convert to oral breathing in the presence of nasal airway obstruction. Nearly all infants can convert to oral breathing by 5 months of age. [14]

Differences in airway anatomy make the potential for technical airway difficulties greater in infants than in teenagers or adults. The airway of the infant differs in five ways [15] [16] : (1) the relatively large size of the infant's tongue in relation to the oropharynx increases the likelihood of airway obstruction and technical difficulties during laryngoscopy; (2) the larynx is located higher in the neck, thus making straight blades more useful than curved blades; (3) the epiglottis is shaped differently, being short and stubby, and is angled over the laryngeal inlet; control with the laryngoscope blade is therefore more difficult; (4) the vocal cords are angled, so that a "blindly" passed endotracheal tube may easily lodge in the anterior commissure rather than slide into the trachea; and (5) the infant larynx is funnel-shaped, the narrowest portion occurring at the cricoid cartilage (Fig. 59-3) (Figure Not Available) . In the adult, an endotracheal tube that passes the vocal cords will readily pass into the trachea, because the glottic opening is the narrowest portion of the larynx. In the infant or young child, an endotracheal tube that easily passes

Figure 59-2 The composition of the diaphragm and intercostal muscles changes markedly during the first 2 years of life. The number of type I muscle fibers is inversely related to age and may account in part for the ease of inducing respiratory fatigue as the work of breathing increases. *(Data from Keens et al [13])*

Figure 59-3 (Figure Not Available) The narrower part of the adult larynx (cylindric shape) (left) occurs at the glottic opening, whereas the narrowest part of the infant larynx (funnel shape) (right) occurs at the level of the cricoid cartilage. The normal adult configuration of the larynx is not achieved until the teenage years. This anatomic difference is one of the reasons why uncuffed endotracheal tubes are preferred for children younger than 10 years of age. A, anterior; cricoid, cricoid cartilage; P, posterior; thyroid cart, thyroid cartilage. *(From Cote and Todres [250])*

the vocal cords may be tight in the subglottic region because of the narrowing at the cricoid cartilage. For this reason, uncuffed endotracheal tubes are the preferred choice for patients younger than 10 years of age.

Kidneys

Renal function is markedly diminished in the neonate because of low perfusion pressure and immature glomerular and tubular function (Fig. 59-4) . Nearly complete maturation of glomerular filtration and tubular function occurs by approximately 20 weeks after birth, although maturation is somewhat delayed in premature infants. Complete maturation of renal function occurs by about 2 years of age. [17] [18] Thus, the ability to handle free water and solute loads may be impaired in the neonate, and the half-life of medications excreted by means of glomerular filtration will be prolonged. [19]

Liver

At term, the functional maturity of the liver is somewhat incomplete. Most enzyme systems for drug metabolism are developed but are not yet induced (stimulated) by the agents they metabolize. As the infant grows, the ability to metabolize medications increases rapidly in two ways: (1) hepatic blood flow increases, and more drug is delivered to the liver; and (2) the enzyme systems develop and are induced. [20] [21] [22] Conjugation reactions are often impaired in the neonate, resulting in jaundice; diminished degradation reactions lead to long drug half-lives. Thus, it is common to have a longer drug elimination half-life in the neonate but a shorter drug half-life in the infant and older child than in the adult.

The premature neonatal liver has minimal glycogen stores and is unable to handle large protein loads. This difference accounts for the tendency to hypoglycemia and acidemia and for the failure to gain weight when the diet contains too much protein. Additionally, plasma levels of albumin and other proteins necessary for binding of drugs are lower in term newborns (and are even lower in premature infants) than in older infants. This condition has clinical implications regarding neonatal coagulopathy (e.g., the need for vitamin K at birth), as well as for drug binding and pharmacodynamics: the lower the albumin value, the less protein binding and the greater the levels of free drug. [23] [24]

Figure 59-4 Glomerular filtration rate is markedly impaired at birth, but it develops rapidly during the first year of life. The ability of the kidney to handle large amounts of solutes and water is also limited during the first several months of life. These developmental changes have significant implications for drug excretion and fluid therapy, particularly during the first 4 weeks of life. Maturation of renal function may be delayed in the sick neonate. *(Data from McCrory [251])*

Gastrointestinal System

At birth, the gastric pH is alkalotic; by the second day of life, pH is in the normal physiologic range for older patients. The ability to coordinate swallowing with respiration does not fully mature until the infant is 4 to 5 months of age. Therefore, the incidence of gastroesophageal reflux in newborns is high. [25] In general, if a developmental problem occurs within the gastrointestinal system, symptoms will occur within 24 to 36 hours of birth. Upper intestinal abnormalities manifest as vomiting and regurgitation, whereas lower intestinal abnormalities produce abdominal distention and failure to pass meconium.

Thermoregulation

The infant is particularly vulnerable to hypothermia because of both the large ratio of body surface area to weight and a limited ability to cope with cold stress (Ch. 37) . The premature infant is even more susceptible because of very thin skin and limited fat stores. The infant may compensate by means of shivering and nonshivering (cellular) thermogenesis. The minimal ability to shiver during the first 3 months of life makes cellular thermogenesis (metabolism of brown fat) the principal method of heat production. [26] These factors underscore the importance of minimizing heat loss. Heat lost by conduction is reduced by placing the baby on a warming mattress and warming the operating room. Heat lost through convection is minimized by keeping the infant in an incubator, covered with blankets. The infant's head should also be covered. Heat lost through radiation is decreased by use of a double-shelled incubator during transport. Heat lost through evaporation is lessened by humidification of inspired gases, the use of plastic wrap to decrease water loss through the skin, and the warming of preparation solutions. Anesthesia also alters the normal thermoregulatory mechanisms, particularly in neonates. [27] [28] [29] Heated air-warming devices are particularly useful in neonates. [30]

/das/book/view/29494766/875/658.html

PHARMACOLOGY AND PHARMACODYNAMICS

The response of the infant and child (and particularly the neonate) to medication is modified by many factors: body composition, protein binding, body temperature, distribution of cardiac output, maturation of the blood-brain barrier, and relative size (as well as functional maturity) of the liver and kidneys. [19] [20] [21] [22] [23] [24] [31]

The body compartments (fat, muscle, water) change with age (Fig. 59-5) . Total body water content is significantly higher in the premature than in the term infant and in the term infant than in the 2-year-old. [1] Fat and muscle content increase with age. These alterations in body composition have several clinical implications for the neonate: (1) a drug that is water soluble has a larger volume of distribution and usually requires a larger initial dose to achieve the desired blood level (e.g., most antibiotics, succinylcholine); (2) because there is less fat, a drug that depends on redistribution into fat for termination of its action has a longer clinical effect (e.g., thiopental); and (3) a drug that redistributes into muscle may have a longer clinical effect (e.g., fentanyl, for which, however, saturation of muscle tissue has not been demonstrated).

In addition to these very basic concepts, other important factors play a role: delayed excretion resulting from the larger volume of distribution, immature hepatic and renal function, and altered drug excretion caused by lower protein binding. Further perturbations in drug pharmacodynamics and pharmacokinetics occur with extreme prematurity and with factors such as sepsis, congestive heart failure, and poor nutritional state. [20] [21] [22] [31]

Older children tend to have mature renal and hepatic function, normal adult values for protein, and fat and muscle content approaching adult values. More of the cardiac output is diverted to the liver and kidneys--which also weigh more in relation to body mass--in older children than in infants. These factors usually mean that most medications have a shorter half-life in children older than 2 years of age

Figure 59-5 Body composition changes rapidly in premature and term infants during the first 12 months of life. Their high water content provides a large volume of distribution for water-soluble medications, whereas their low fat and muscle content provides a small reservoir for drugs that depend on redistribution into these tissues for termination of drug effects. Thus, body composition may significantly affect pharmacokinetics and pharmacodynamics. *(Data from Friis-Hansen [1])*

than in adults. As the child approaches adulthood, the half-life of many drugs lengthens. In general, most medications have a prolonged elimination half-life in premature and term infants, a shortened half-life in children older than 2 years of age up to the early teen years, and a lengthening of half-life in teenagers approaching adulthood.

Inhaled Anesthetics

The expired minimum alveolar concentration (MAC) of inhaled anesthetic required in pediatric patients changes with age (Fig. 59-6) . [32] [33] [34] [35] [36] [37] (Ch. 4) . Carefully controlled studies show that the anesthetic requirement is lower for the premature infant than for the term neonate and lower for the term neonate than for the 3-month-old child. Infants are known to have a greater anesthetic requirement than older

Figure 59-6 The minimum alveolar concentration (MAC) for four commonly used inhalation anesthetics is plotted versus age. Note that MAC is highest in infants 3 to 6 months of age. The reasons for this are not clear. *(Data from a number of studies [32] [34] [36] [37] [60] [252] [253] [254])*

children or adults; the reasons have not been adequately explained. This fact, combined with the need for deeper planes of anesthesia to achieve satisfactory conditions for endotracheal intubation, places the infant in a precarious position between anesthetic overdose (from a cardiovascular standpoint) and inadequate depth of anesthesia (for endotracheal intubation). [38] The early administration of muscle relaxants and narcotics probably decreases this possibility. [39]

The uptake of potent anesthetics is more rapid in children because of increased respiratory rates and cardiac index and a greater proportional distribution of cardiac output to vessel-rich organs. This rapid rise in blood anesthetic levels probably explains in part why it is so easy to give an overdose to infants and small children. Age-related differences in blood/gas partition coefficients may also facilitate a more rapid rise in alveolar concentration in infants. [40] [41] Other factors include the state of hydration (e.g., excessive fasting would make a small infant relatively dehydrated) and the type of anesthesia circuit used. For example, a Mapleson D has a smaller volume than a circle system and therefore less volume to achieve equilibration when the concentration of anesthetic agent exiting the vaporizer increases. With a Mapleson D circuit, the fresh gas flow is introduced into the system at the airway, entering directly into the patient's lungs. These factors facilitate a very rapid rise in blood anesthetic concentration and the potential for anesthetic overdose.

Halothane

Halothane does not have a noxious smell and is still commonly used for the gaseous induction of anesthesia; sevoflurane appears to be slightly less noxious and is being increasingly used for induction with a change to halothane after induction because of cost restraints. Studies of induction and awakening with various anesthetics have found no clinically important differences in rapidity of awakening among

halothane, enflurane, and isoflurane. [42] [43] [44] [45] [46] However, airway-related problems occur less frequently with halothane and sevoflurane than with enflurane, isoflurane, or desflurane. [46] [47] [48] [49] There is nearly always a statistically significant but clinically unimportant difference in the rapidity of awakening when comparing halothane with either desflurane or sevoflurane (usually 3-5 min). [42] [43] [44] [45] [46] I often induce anesthesia with sevoflurane and then use halothane for maintenance in order to reduce costs, to be able to use very low fresh gas flows, and to avoid any unknown issues regarding possible toxic metabolites. Halothane or sevoflurane is the anesthetic of choice for induction of anesthesia by mask or for children with airway problems.

A 1987 report describing seven cases (one fatal) of "halothane hepatitis" concluded that children should not undergo repeated exposure to halothane [50] (Ch. 6) . It is important to place this report in proper perspective. To date, millions of children have been anesthetized with halothane. Perhaps a dozen instances of halothane hepatitis, and one or two deaths, have been reported. This is a remarkable safety record for any medication. If halothane hepatitis were a clinically important issue for

children, dozens--perhaps hundreds--of cases would have been reported. Furthermore, the recommendation to avoid halothane in children was made by internists without the opinion of pediatric anesthesiologists, who would have determined the risk/benefit ratio for halothane. Therefore, it is not in the best interest of the patient or the anesthesiologist to discard this anesthetic until more scientific data are presented. [51] There is little logic in inducing anesthesia with halothane and then changing to enflurane or isoflurane, unless one is particularly interested in the differing effects of anesthetics on the cardiovascular or central nervous system (CNS). It may, however, make some sense to use other anesthetics or techniques in teenage patients and adults.

Another concern with halothane is sensitization of the myocardium to arrhythmias because of exogenous and endogenous catecholamines. Most arrhythmias associated with halothane anesthesia in children are caused by either hypercarbia or an inadequate level of anesthesia. [52] Up to 10 mug of epinephrine per kilogram body weight may be used with minimal risk of cardiac arrhythmias in pediatric patients. [53]

Halothane is a potent myocardial depressant, which can have profound effects on the neonate and on the child with congenital heart disease. [39] [54] Such depression is responsible for the occasional inability to give critically ill patients sufficient concentrations of anesthetics to provide "anesthesia" without inducing severe hypotension. In this circumstance, the liberal use of short-acting narcotics with light concentrations of halothane generally provides the desired response.

Isoflurane

Isoflurane is purported to have some advantages over halothane: less myocardial depression, preservation of heart rate, and greater reduction in cerebral metabolic rate for oxygen. [55] [56] [57] Although these properties may be beneficial in selected patients, clear advantages have yet to be demonstrated, because equivalent depression of the neonatal heart has been demonstrated with both halothane and isoflurane. [58] [59] The major disadvantage of isoflurane is its noxious smell, which is unacceptable to many pediatric patients, and the greater incidence of airway-related events (laryngospasm, coughing). [48] [49]

Desflurane

Desflurane has a gas partition coefficient similar to that of nitrous oxide. [60] Unfortunately, it has been found to cause an unacceptable incidence of coughing, secretions, and laryngospasm during the gaseous induction of anesthesia in children. [47] Gaseous induction of anesthesia with halothane followed by use of desflurane for maintenance of and recovery from anesthesia may be reasonable. This changeover, unlike a similar change to enflurane or isoflurane, may be clinically important, because the gas partition coefficient clearly favors rapid excretion. This difference would appear to be more important for longer cases, in which there is the potential for the accumulation of potent agent within fat, than for brief cases, in which such accumulation is less likely, or for neurosurgical and spinal fusion procedures, in which early assessment of mental and neurologic status is important.

The MAC for desflurane is age-dependent: 9.2 percent for neonates, 9.4 percent for infants 1 to 6 months old, 9.9 percent for infants 6 to 12 months old, 8.7 percent for 1 to 3 year olds, and 8 percent for 5 to 12 year olds. [60] Interestingly, nitrous oxide does not appear to contribute to the MAC of desflurane to the same degree as it does with other potent inhalation agents. [33] There is virtually no hepatic metabolism of this agent, a feature that clearly sets it apart from the other currently available potent anesthetics. The one major concern is the occasional hypertension and tachycardia resulting from sympathetic activation with rapid increases in inspired desflurane concentration. [61] [62] [63] [64] [65] I have observed this effect primarily in teenagers, but I have seen it in infants as well. A further concern is the potential for carbon monoxide poisoning (also possible with isoflurane) [66] ; this can be prevented by rehydration of Baralyme prior to use with desflurane. [67]

Sevoflurane

Sevoflurane is a potent agent that also has a gas partition coefficient similar to that of nitrous oxide. Broad clinical experience has shown that it is less pungent than isoflurane and desflurane; some investigators believe that it is superior or equivalent to halothane for gaseous induction. [42] [68] [69] [70] [71] As with all potent agents, the MAC is highest in infants: 3 percent for neonates, 3.3 percent for infants 1 to 6 months old, and 2.5 percent for children older than 6 months. [32] [34] My personal experience has been very favorable for induction of anesthesia. I generally induce anesthesia with sevoflurane and then change to halothane for maintenance in order to reduce costs. Metabolic breakdown and release of fluoride do not appear to be a significant issue even with prolonged anesthetic regimens. [32] [44] Several concerns have been raised regarding the production of toxic metabolites resulting from interaction with the carbon dioxide absorbant. [72] [73] Compound A appears to be nephrotoxic, at least in animal models [74] ; conflicting data have been presented regarding the clinical importance of this observation. [73] [75] [76] [77] [78] [79] [80] [81] Studies of low flow (2 L/min) and prolonged anesthesia have not demonstrated

significant alteration of the usual markers of renal function. However, there have been reports of altered renal threshold for glucose after prolonged sevoflurane anesthesia as well as transient albuminuria. [82] [83] The clinical importance of these observations remains to be clarified. It would appear for the moment that the more conservative approach would be to limit exposure to sevoflurane, that is, to use it for induction and then change to another agent for maintenance or to use sevoflurane for brief cases.

One further observation is that I have found inadequate suppression of airway reflexes for bronchoscopy performed with spontaneous ventilation; supplementation with intravenous propofol and/or muscle relaxation seems to be required with sevoflurane. Halothane appears to still be a superior inhalation agent for this procedure.

Drugs Used to Induce Anesthesia

Methohexital

Methohexital is generally administered intravenously at a concentration of 1 percent and a dose of approximately 1 to 2 mg/kg [84] (Ch. 8) . Problems associated with intravenous administration include burning, hiccup, apnea, and extrapyramidal-like movement. Methohexital has a shorter elimination half-life than thiopental. Its principal use in my practice has been by rectal administration for induction of anesthesia and for prolonged sedation during radiologic procedures (10% solution). [85] Usually, 25 to 30 mg/kg per rectum produces sleep within 8 to 10 minutes. I normally limit rectal administration to children, up to 20 kg, 10 months to 5 to 6 years of age, who are still in diapers and who are afraid to separate from their parents. This is a reliable drug for induction of anesthesia and has minimal side effects, the most common being soiling. Occasionally, obstructive apnea occurs, so that a means of ventilating the patient must be available; pulse oximetry is recommended. [86] Because it can cause seizures, methohexital is contraindicated in patients with temporal lobe epilepsy. [87] Children receiving seizure medications generally require larger doses.

Thiopental

Intravenous bolus administration of 2.5 percent thiopental, 5 to 6 mg/kg, is sufficient to induce anesthesia in most healthy, unpremedicated pediatric patients [85] [89] (Ch. 8) . Termination of effect occurs through redistribution of the drug in fat; thiopental should be used with caution in children who have low fat stores, such as neonates or malnourished infants. Limiting the total dose to 10 mg/kg or less in older patients minimizes the possibility of prolongation of anesthesia caused by residual barbiturate sedation. Thiopental (30 mg/kg per rectum) may also be administered rectally if methohexital is contraindicated.

Propofol

Propofol is highly lipophilic and rapidly distributes into and out of the vessel-rich organs; its rapid redistribution, hepatic glucuronidation, and high renal clearance account for the rapid termination of its effect. As with barbiturates, the induction dose is higher in younger patients (2.9 mg/kg for infants <2 y) than in older patients (2.2 mg/kg for patients 6-12 y). [90] [91] [92] This may be related in part to a larger central volume and greater clearance in the younger patients. [93] The major drawback of propofol is pain on intravenous administration, particularly through small veins. As little as 0.2 mg/kg lidocaine (mixed with the propofol) has been effective in reducing but not eliminating this discomfort. [94] Another method for minimizing pain is to use a small-gauge (22- to 24-gauge) catheter and to administer the drug through a large antecubital vein. [91] Propofol is particularly useful for the brief and repeated sedation needed for radiotherapy in children with central venous lines; a constant infusion is also a useful means for sedating children undergoing radiologic procedures. [95] A modest reduction in systolic blood pressure often accompanies bolus administration. [96] Propofol has been associated with a reduced rate of postoperative vomiting. [97] [98]

Ketamine

Ketamine, a phencyclidine derivative, causes central dissociation while providing analgesia and amnesia (Ch. 9) . Intravenous administration of doses as low as 1.0 mg/kg produce sedation sufficient for a smooth transition to general anesthesia. Larger doses (10 mg/kg IM) provide sufficient analgesia for insertion of invasive monitoring devices prior to induction of anesthesia (cardiac surgery) or in patients having limited venous access. The patient-to-patient variability in response to this drug is relatively large. A major side effect, increased production of secretions, usually requires administration of an antisialagogue. Other undesirable side effects include vomiting and dreaming; the occurrence of dreaming may be obviated by concomitant administration of a benzodiazepine. Ketamine is useful for induction of anesthesia in the hypovolemic patient.

Contraindications to the use of ketamine in children include the presence of an active upper respiratory tract infection, increased intracranial pressure, open-globe injury, and the presence of a psychiatric or seizure disorder. Ketamine does not preserve the gag reflex and thus should not be used as the sole anesthetic for patients with a full stomach or hiatus hernia. [99] Ketamine may be administered rectally (10 mg/kg), orally (6-10 mg/kg), or intranasally (3-6 mg/kg). [100] [101] [102] [103] [104] The combination of oral ketamine (4-6 mg/kg), oral midazolam (0.4 mg/kg), and oral atropine (0.03 mg/kg) provides a well-sedated patient.

Sedative-Hypnotic Drugs

These drugs are discussed in detail in Chapter 9 .

Droperidol

The primary use of droperidol in pediatrics is as an antiemetic; doses as high as 75 mug/kg have been recommended for patients undergoing surgery for strabismus, although prolonged sedation may result. [105]

Benzodiazepines

Oral absorption of diazepam is more rapid in children than in adults; 0.1 to 0.3 mg/kg orally usually provides excellent sedation within 1 hour. Intravenous administration is painful and is not well tolerated; diazepam may also be administered rectally. Because the liver is the main site of degradation, this medication should be given with caution to any patient with hepatic disease. [106] Diazepam has an extremely long half-life in neonates (80 h) and may be contraindicated until the infant is 6 months of age or until hepatic metabolic pathways have matured. [107]

Midazolam is water soluble and therefore is not painful on intravenous administration. Midazolam is the only benzodiazepine approved by the U.S. Food and Drug Administration for use in neonates. It should be noted that because of its water solubility, midazolam takes three times as long to reach a peak electroencephalographic effect when compared with the more fat-soluble diazepam. The clinical importance of this finding is that one should wait at least 3 minutes between intravenous doses in order to avoid a "stacking" of effect. [108] The short elimination half-life (~2 h) as compared with diazepam (18 h) offers an advantage for use as a premedicant in children. Midazolam is rapidly absorbed after intramuscular (0.1-0.15 mg/kg, maximum 7.5 mg), oral (0.5-0.75 mg/kg, maximum 20 mg), rectal (0.75-1.0 mg/kg, maximum 20 mg), nasal (0.2 mg/kg), or sublingual (0.2 mg/kg) administration. [109] [110] [111] [112] [113] There is less patient upset following sublingual than following nasal administration. [114] The major problem with oral or sublingual administration is the strong aftertaste. A manufactured, flavored oral formulation is now available. The sedation achieved is usually not sleep (even with doses
3.0 mg/kg rectal) [113] but rather it is a compliant, happy state. If sleep occurs, a relative overdose has probably been given. Mid-azolam must always be used with caution when it is administered with narcotics because of the potential for respiratory depression. [115] One important interaction is that erythromycin produces a clinically important delay in midazolam metabolism because of cytochrome P-450 inhibition; either midazolam should be avoided or the dose should be reduced by 50 percent in such patients. [116] One further concern is that, with nasal administration, there is the theoretical possibility of CNS toxicity as a result of drug entering the CNS along neural connections (olfactory nerves). [117] Because neurotoxicity has never been examined and because most children cry with nasal administration, I believe that this route should generally be avoided. [118]

Narcotics

Morphine is the oldest commonly used long-acting narcotic (Ch. 10) . Its use in neonates remains controversial because early studies carried out in newborn infants suggest that morphine produces greater respiratory depression than meperidine. Greater brain levels of morphine were found in neonatal than in adult rats; this finding suggests that permeability of the blood-brain barrier may account in part for the apparent sensitivity of the human neonate to morphine. [119] This rationale led to the common belief that infants are sensitive to the effect of narcotics. More recent studies found age-dependent pharmacokinetics. The newborn has a lower clearance of morphine, and therefore, a lower dose results in higher plasma values because of a longer elimination half-life. [120] Term infants older than 10 days may clear morphine more rapidly than adults.

The issue of respiratory sensitivity and the age at which it decreases in humans has yet to be resolved; animal studies suggest that there appears to be a difference between morphine and fentanyl that may not relate to transport of drug into the brain. [121] Some of these effects may therefore be due to changes in pharmacodynamics rather than to maturation of the blood-brain barrier. Until further studies are carried out, morphine should be administered with caution in the neonate and premature infant who is not in the intensive care unit. Infants older than 6 months probably have a normal adult response to morphine.

Meperidine, a long-acting synthetic narcotic, received great attention when it was found to cause less respiratory depression in newborns than morphine. [122] This difference may be related, in part, to the finding that meperidine is much more lipophilic than morphine and therefore is able to cross the blood-brain barrier more readily. Thus, effects of the blood-brain barrier would be much less significant for meperidine than for morphine. As with all drugs administered to neonates, there is a large patient-to-patient variability in metabolism and response. [123] Meperidine may not be appropriate for long-term administration because of the accumulation of the toxic metabolite normeperidine. [124]

Fentanyl is the most commonly used narcotic in infants and children. [125] Its major advantages relate to its rapid onset and brief duration of action. This narcotic is more lipophilic than meperidine. In essence, the effects of the blood-brain barrier are of no importance with the use of this narcotic. Infants older than 3 months had a lower incidence of apnea than adults given fentanyl [126] ; animal studies further confirm pharmacodynamic differences between fentanyl and morphine. [121] Termination of the effect of low doses of fentanyl results primarily from redistribution, whereas termination of the effect of high doses depends on elimination. High doses of fentanyl achieve properties of long-acting narcotics.

Fentanyl induces a very stable cardiovascular response while providing an anesthetic state. The dosage required to produce anesthesia varies considerably, depending on the patient's age, the surgical procedure, the health of the patient, and the use of anesthetic adjuvants. [127] Neonates having abdominal surgery have a longer fentanyl half-life than neonates undergoing other procedures; hepatic blood flow--and factors that greatly increase or decrease hepatic blood flow--may alter the pharmacokinetics of this drug. [128] Impaired hepatic function may also play a role in altered kinetics with increased intra-abdominal pressure. [129] Therefore, the pharmacokinetic and pharmacodynamic profile is very different and more variable for neonates than for older children. A dose of 12.5 mug/kg produces anesthesia in full-term neonates undergoing abdominal surgery, whereas higher doses (30-100 mug/kg) have been used for cardiac surgery. These doses are safe in children whose ventilation will be controlled postoperatively; much lower doses (2-10 mug/kg) should be used with other anesthetics if ventilation is not to be controlled postoperatively. Because the cardiac output of neonates is determined by heart rate, fentanyl-induced

---

bradycardia may require concomitant administration of a vagolytic drug, such as atropine or pancuronium.

Transoral mucosal administration (5-15 mug/kg) results in reasonably rapid absorption, with peak blood levels achieved within 15 to 30 minutes. [130] Children may

have a lower bioavailability compared with adults. [131] Because vomiting and desaturation have been reported, [132] [133] [134] it is likely that this form of premedication will be of greater use for painful procedures outside the operating room and for postoperative analgesia. [135] [136] Our experience has been that the incidence of serious adverse effects (desaturation, vomiting) prior to anesthetic induction was zero in the 21 children in whom my colleagues and I induced anesthesia within 10 minutes of completion of the Oralet. [137] It is likely that the adverse effects increase with a longer time between completion and induction of anesthesia; these effects may also relate to the dose (mug/kg) administered.

Alfentanil is more rapidly eliminated than fentanyl; its pharmacokinetics is independent of dose. [138] This feature may provide a margin of safety because the greater the administered dose, the greater the elimination. Children may have increased clearance compared with adults. [139] As with any narcotic, there is important patient-to-patient variability in pharmacokinetics and pharmacodynamics in neonates and in patients with impaired hepatic blood flow. [140] [141]

Sufentanil has been used primarily for cardiac anesthesia; age-dependent kinetics is also evident, particularly during the first month of life. [142] Children are able to clear sufentanil more rapidly than are adults. This drug must be administered with caution, because severe bradycardia and asystole have been reported when a vagolytic agent was not administered simultaneously. [143] This narcotic has also been administered nasally as a premedicant (2 mug/kg); however, desaturation may follow. [114]

Muscle Relaxants

These drugs are discussed in detail in Chapter 12 .

Depolarizing Muscle Relaxants

Succinylcholine is highly water soluble and rapidly redistributes into the extracellular fluid volume. For this reason, the dose required for intravenous administration in infants (2.0 mg/kg) is approximately twice that for older patients (1.0 mg/kg). Succinylcholine is the only short acting relaxant that is effective when given intramuscularly. Reliable muscle relaxation occurs within 3 to 4 minutes after 5 mg/kg in infants and 4 mg/kg intramuscularly in children older than 6 months. [144] The skeletal muscle relaxation produced by intramuscular administration may last up to 20 minutes; more rapid onset is not achieved by splitting the dose into two injections or by changing the concentration. In an emergency situation, succinylcholine may be administered intralingually. [145]

Cardiac arrhythmias frequently follow intravenous administration, especially during halothane anesthesia. Intravenous administration of atropine (but not intramuscular administration of the drug as a premedication) reduces the incidence of arrhythmias. Cardiac sinus arrest may follow the first dose of succinylcholine, but it is more common after repeated bolus administration; this may occur in patients of any age. Although the incidence of bradycardia is low in older patients, I have observed one 13-year-old patient who developed asystole for approximately 30 to 45 seconds following a single dose of succinylcholine administered with thiopental but not atropine; this occurred prior to intubation and with 100 percent oxygen saturation. Therefore, atropine probably should be given intravenously just prior to the first dose of succinylcholine in all children, including teenagers.

Succinylcholine has received much attention because of the severity of its possible complications. The potential for rhabdomyolysis, hyperkalemia, masseter spasm, and malignant hyperthermia suggests that routine use of succinylcholine should be abandoned. Two studies, flawed because of their retrospective nature, reported a 1 percent incidence of masseter spasm after administration of succinylcholine during halothane anesthesia. [146] [147] This has not been my experience. Increased jaw muscle tone following succinylcholine has been observed; masseter spasm may be a normal variant. [148] Masseter tetany, which prevents any mouth opening, may represent an extreme variation in increased masseter muscle tone and may be the reaction associated with malignant hyperthermia. I have observed this twice; neither patient developed malignant hyperthermia, but one did have creatine phosphokinase values of more than 20,000 IU the next morning.

With the foregoing cautions in mind, one should not yet abandon succinylcholine, which is the only commercially available short-acting muscle relaxant that provides a dependable, rapid onset of action. However, this drug should be limited to patients who have a full stomach, to treat laryngospasm, and intramuscularly to patients with difficult intravenous access when control of the airway is deemed essential. Until a short-acting nondepolarizing relaxant becomes available, succinylcholine remains the drug of choice when rapid onset of muscle relaxation is needed.

Nondepolarizing Muscle Relaxants

Comparison of infants with older children or adults regarding their response to nondepolarizing muscle relaxants shows that infants are generally more sensitive to these drugs and that their response varies to a greater degree. Although the relationship among volume of distribution, maturation of renal function, and neuromuscular blockade (e.g., actual dose of *d*-tubocurarine per kilogram body weight) is similar for patients of all ages, the greater volume of distribution of the neonate results in a slower rate of excretion and hence a prolongation of the effect. Neuromuscular blockade occurs at a lower blood concentration. [149] This observation is probably true for all nondepolarizing muscle relaxants.

The choice of nondepolarizing muscle relaxant depends on the side effects desired and the duration of muscle relaxation required. If tachycardia is desired (e.g., with fentanyl anesthesia), pancuronium would be the choice. Vecuronium and atracurium are useful for shorter procedures in infants and children or may be administered as a constant infusion. [150] [151] The methods of excretion of atracurium and cisatracurium (Hofmann elimination and ester hydrolysis)

---

make these relaxants particularly useful in newborns. [152] [153] Vecuronium is valuable because no histamine is released; however, the duration of action is prolonged in newborns, a feature that makes it similar to pancuronium. [154]

Mivacurium, a short-acting nondepolarizing relaxant, may offer the advantage of providing satisfactory conditions for endotracheal intubation for brief surgical procedures. A dose of 0.2 to 0.3 mg/kg provides adequate relaxation within 2 minutes; spontaneous 95 percent twitch recovery occurs within 20 minutes. [155] This drug is ideal for administration by constant infusion because there does not appear to be any drug accumulation. Pipecuronium and doxacurium are long-acting, nondepolarizing relaxants; their role has yet to be defined for children, but in general, the duration of action is shorter than in adults. [156] [157]

Rocuronium is the newest intermediate acting nondepolarizing relaxant. It has a clinical profile similar to those of vecuronium and atracurium, [158] [159] but it offers the advantage that it can be administered intramuscularly. One study observed that acceptable conditions for intubation are produced within 3 to 4 minutes following 1,000 mug/kg intramuscular rocuronium in infants and 1,800 mug/kg for children older than 1 year of age; these effects were more dependable with deltoid rather than quadriceps muscle injection. [160] This onset time is similar to that produced with intramuscular succinylcholine; however, the duration of action is approximately 1 hour, a feature that could be a distinct disadvantage for a brief procedure. The onset of neuromuscular blockade is also nearly the same as with succinylcholine when administered intravenously but in very high doses (1,200 mug/kg). I have used this dose with thiopental (5-6 mg/kg) for rapid sequence induction following preoxygenation in patients in whom succinylcholine could present an added risk. Most patients can be intubated at 45 to 60 seconds. The disadvantage is that the duration of action is 60 to 90 minutes, a property that limits its usefulness to either long cases or acceptance that prolonged neuromuscular blockade is more desirable than the potential risk from succinylcholine.

Table 59-2 provides commonly recommended guidelines for dosages. Because of the extreme variability in response, the doses of long-acting muscle relaxants used for infants should be titrated carefully, starting with one-third to one-half the usual dose used in older patients. I recommend antagonism of neuromuscular blockade in all neonates and small infants, even if they have recovered clinically, because any increase in the work of breathing may cause fatigue and respiratory failure. Useful signs of reversal are the ability of the infant to lift the legs and arms and recovery of the train-of-four response to peripheral nerve stimulation. [161]

Premedication

The many published reports on premedication have produced approximately the same results; almost all sedatives are effective. The important issue is effectiveness for individual anesthesiologists at their own institutions. The need for premedication must be individualized according to the underlying medical conditions, the length of surgery, the desired induction of anesthesia, and the psychologic makeup of the child and family. Premedication normally is not necessary for the usual 6-month-old child, but it is warranted for the 10- to 12-month-old who is afraid to be separated from the parents. Induction of anesthesia with a rectally administered

anesthetic (e.g., methohexital) allows the child to fall asleep in a parent's arms. Oral midazolam generally results in a very compliant child who will be separated from the parents without crying. A review of prior anesthetic records is particularly helpful in ascertaining how the child has responded in the past. The most difficult patients are those who have had many surgical procedures. This type of patient may require premedication the night before and the morning of surgery.

TABLE 59-2 -- Recommended Guidelines for Doses of Nondepolarizing Muscle Relaxants and Their Antagonists in Children

	MAINTENANCE DOSE (ED_{95}) (mg/kg) DURING ANESTHESIA WITH		SUGGESTED DOSE (mg/kg) FOR TRACHEAL INTUBATION ($2 \times ED_{95}$)
	N_2O/O_2	*HALOTHANE*	
Muscle relaxant [a]			
d-Tubocurarine	0.60	0.30	0.80
Pancuronium	0.08	0.06	0.10-0.15
Metocurine	0.34	0.15	0.50-0.60
Atracurium	0.30	0.20	0.50-0.60
Cisatracurium	0.10	0.080	0.10
Vecuronium	0.08	0.06	0.10-0.15
Mivacurium	0.10	0.10	0.20-0.25
Doxacurium	0.030	0.030	0.050-0.060
Pipecuronium	0.080	0.080	0.080-0.120
Reversal agents [b]			
Edrophonium	(0.3-1.0 mg/kg) + atropine (0.01-0.02 mg/kg)		
Neostigmine	(0.02-0.06 mg/kg) + atropine (0.01-0.02 mg/kg)		

[a] The response of premature and term neonates (who may be more sensitive to the drugs) to muscle relaxants varies greatly from patient to patient. Therefore, all doses should be titrated to response.
[b] The dose of reversal agent given to antagonize nondepolarizing neuromuscular blockade should be determined by the degree of residual neuromuscular blockade (i.e., dose should be titrated to clinical effect).

Premedications may be administered orally, intramuscularly, intravenously, rectally, sublingually, or nasally. Although most of these routes are effective and reliable, each has drawbacks as well. [162] Oral premedications have a slow onset. Intramuscular medications hurt and may result in sterile abscess. Intravenous medications may hurt during injection or at the start of infusion. Rectal medications sometimes make the patient feel uncomfortable, cause defecation, and occasionally burn. Nasal medications can be irritating, although absorption is rapid. Sublingual medications may provide the best compromise, that is, relatively rapid absorption without causing pain. Drug taste and patient cooperation are the main determinants of success. There is still no ideal premedication or route of administration.

Anticholinergic drugs are not routinely administered intramuscularly to children because these agents are painful on administration and do not significantly reduce laryngeal reflexes during induction of anesthesia. On the other hand, atropine (0.02 mg/kg) administered orally or intramuscularly less than 45 minutes before induction, does reduce the incidence of hypotension during induction with potent inhaled anesthetics, but only in infants younger than 6 months. [163] Oral atropine may be reasonable for these infants.

Histamine$_2$ (H_2)-blocking drugs are frequently used to reduce the potential for pulmonary aspiration of acid gastric contents. Because the true incidence of pulmonary aspiration of gastric contents during routine elective pediatric surgery is approximately 1 in 1,000 cases, histamine blocking agents and metoclopramide should be reserved for patients at greatest risk: those with gastroesophageal reflux, potentially difficult airway problems, endoscopic procedures, a history of previous esophageal surgery, procedures performed in the Trendelenburg position, and urgent but not emergency nonelective procedures. [164]

ANESTHESIA FOR PEDIATRIC AND NEONATAL SURGERY

Preoperative Preparation

The preoperative visit and preparation of the child for surgery are more important than the choice of premedication. [165] During this time, the anesthesiologist evaluates the medical condition of the child, the needs of the planned surgical procedure, and the psychologic makeup of the patient and family. The anesthesiologist also formulates the approach to induction of anesthesia, explains the possibilities regarding induction, and helps to soothe family concerns. Because anxiety felt by the parents may be transferred to the child, any practice that reduces anxiety in the parents may also reduce anxiety in the child. Therefore, the anesthesiologist should explain in great detail what the child and family can expect and what will be done to ensure the utmost safety. The more information the parents and child have, the more easily they will deal with the stress of surgery and hospitalization. Presurgical programs such as videotapes, literature, and hospital tours also help. [162] [166] [167] [168]

After chart review, physical examination, and the furnishing of information regarding the approximate time and length of surgery, the anesthesiologist should describe to the child what anesthesia is and what will be done to ensure good care. The purpose of all monitoring devices should be explained to the patient and family. Children need to understand that none of these devices will hurt and that they can watch during application. If an intravenous line will be started, the child needs to be told that "numbing" medicine will be used. Any special monitoring devices, such as an arterial line, a central venous line, a nasogastric tube or urine catheter, should also be described to the parents, with assurances that these devices will be inserted after induction of anesthesia. Part of this informed consent is also a description of the anesthesiologist's role in the operating room. It is vital to explain to the family that the anesthetic "prescription" will be tailored to meet their child's medical as well as surgical needs. I like to use the phrase "anesthetic prescription" because we are physicians, just like surgeons or pediatricians, and it is important for families to clearly understand that.

Children think in very concrete terms, so care must be taken to avoid misunderstandings. It is important to explain to children that the sleep caused by anesthetic drugs differs from normal sleep. They should know that the anesthesia medicines keep them from awakening during surgery and from remembering the operation. It should also be explained to the children that the anesthesia medicines will be removed at the end of surgery, and that they will then wake up and return to their parents. This type of explanation does not require a significant amount of time and goes a long way toward reassuring the child and family about the quality of care provided.

The issue of pain must not be avoided. Children need to be reassured that everything possible will be done to minimize pain on awakening. Therefore, it should be stressed that pain medications will be administered and that local infiltration nerve blocks, patient-controlled analgesia, or continuous epidural or caudal infusions will be used. Recovery room or intensive care must also be described so that there are no surprises.

Fasting

The approach to preoperative fasting has undergone extensive reevaluation. Several studies have found no difference in gastric residual volume or pH in children allowed to ingest unlimited clear liquids (water, apple juice) up until 2 to 3 hours prior to anesthetic induction compared with standard fasting. [169] [170] This provides a more humane approach for both children and their parents without increasing the risk of pulmonary aspiration of gastric contents. [164] Infants and young children have a higher metabolic rate and a larger ratio of body surface area to weight than adults and become dehydrated more easily than adults. The major advantage of the liberalized fasting guidelines may be a reduced incidence of hypovolemia at the time of anesthetic induction. My approach is to restrict milk and solids after midnight but to allow unlimited clear fluids up to 3 hours prior to induction of anesthesia; if there is a change in the operative schedule, I still feel comfortable with 2 hours of fasting (Table 59-3) . Infants who are breast-fed may have their last breast milk 4 hours prior to anesthetic induction. I consider breast milk to be equivalent to formula because the fat content

TABLE 59-3 -- Fasting Guidelines for Pediatric Patients

AGE	FASTING TIME (h)	
	MILK AND SOLIDS	*CLEAR LIQUIDS*
< 6 mo	4	2
6-36 mo	6	3
> 36 mo	8	3

varies with maternal diet, and delayed gastric emptying may result. [171]

Induction of Anesthesia

The method of inducing anesthesia is determined by a number of factors: the medical condition of the patient, the surgical procedure, the level of anxiety of the child, the ability to cooperate and communicate (because of age, mental handicap, language barrier), the presence or absence of a full stomach, and others. [172]

Inhaled Induction of Anesthesia via Mask

Infants

Mask inductions are usually used in infants younger than 10 to 12 months because this age group readily separates from the parents. Induction by mask is accomplished most easily by holding the end of the anesthesia circuit (a Mapleson D circuit is preferred by some anesthesiologists for patients less than 10 kg) in a cupped hand over the infant's face; the other hand can adjust the concentration of anesthetic. Allowing the neonate and small infant to suck on a rubber nipple or on a finger generally prevents crying during induction of anesthesia. As the infant loses consciousness, the anesthesia mask is added to improve delivery and to decrease operating room pollution. This is the most dangerous time during induction, because it is very easy to misjudge the depth of anesthesia and to depress the heart. Once anesthesia has been induced, it is critical to rapidly reduce the inspired concentration of halothane (1.0-1.5%) or sevoflurane (2-2.5%) and to keep it at this level or lower until an intravenous line is in place. After the intravenous line is inserted, one may either deepen the plane of anesthesia or add a muscle relaxant. *It is*

dangerous to proceed directly to a deep plane of anesthesia without having an intravenous line in place; without this precaution, resuscitation would be difficult.

The second most dangerous point occurs immediately after endotracheal intubation. If the vaporizer has not been closed prior to laryngoscopy, it is easy to forget that a high inspired concentration is being delivered and, during the checking for breath sounds, perhaps to give an overdose of inhaled anesthetics. Therefore, the prudent anesthesiologist discontinues all anesthetics until laryngoscopy and endotracheal intubation have been completed. With a Mapleson D circuit, a high concentration of anesthetic can be delivered more easily because the anesthetic enters directly at the airway. In contrast, changes made at the vaporizer of a circle system take a longer time to achieve equilibration with the circuit; therefore, the inspired concentration of anesthetic rises more gradually. Particular caution should be used when changing from sevoflurane to halothane because the myocardium-depressant effects of these drugs are additive.

Older Pediatric Patients

Successful, psychologically atraumatic induction of anesthesia by mask in the older pediatric patient requires that the patient understand and cooperate. Several different techniques may be employed. One method is to play a game. For example, the smaller child may be asked to "blow up the balloon." The slightly older child (up to adult) may be receptive to hypnotic suggestions during induction. The young child may be susceptible to a suggestion that the anesthesia mask is an "airplane pilot's mask" and that the smell of halothane or sevoflurane is "oxygen" or "aviation fuel." During this type of induction, the operating room must be free of distractions, and the anesthesiologist must be able to communicate with the child. The use of constant conversation and a 0.25 to 0.5 percent increase in the inspired concentration of anesthetic every third or fourth breath usually produce a smooth transition to general anesthesia. Often the patient will breath-hold. If so, one should not attempt to assist respirations, because that action often elicits coughing or laryngospasm. The anesthesiologist must be certain, however, that airway obstruction and laryngospasm can be differentiated from breath-holding. Observing the chest wall and abdomen helps to identify airway obstruction, which creates a rocking-type movement of the chest and abdomen (when the diaphragm descends, the abdomen appears to expand, but the chest does not). As soon as the child loses consciousness, the inspired concentration of anesthetic can be reduced, and an intravenous line can be inserted. Should laryngospasm occur, closing the pop-off valve and creating approximately 10 cm H_2O of positive pressure while allowing the child to breathe spontaneously often allows gas exchange. If this procedure is not effective, administration of rapid positive-pressure breaths, while avoiding inflation of the stomach, often disrupts the laryngospasm. Obviously, administration of a muscle relaxant also breaks the laryngospasm; succinylcholine remains the agent of choice in an emergency situation.

A third method of induction uses flavored masks. Various flavored scents (Loran Oils, Inc., Lansing, Mich) are available to reduce the noxious smell of the anesthetics; the child can select a favorite scent.

The fourth method, the single-breath technique, requires a very cooperative patient who can follow instructions. Using an unattached anesthesia mask, the anesthesiologist should demonstrate the procedure to the child, who then rehearses the following steps: a full inspiration, a full expiration, placement of the mask on the child's face at exactly the end of expiration, another full inspiration held as long as possible, and then normal breathing. Prior to induction, the anesthesia circuit is filled with either 5 percent halothane or 8 percent sevoflurane in 60 percent nitrous oxide. The circuit

bag must be emptied and filled several times so that the entire circuit is filled with 5 percent halothane or 8 percent sevoflurane. If the patient fully cooperates, this procedure generally produces loss of the eyelid reflex in less than 1 minute. Occasionally, a patient does not take a full breath or becomes frightened. If the child is partially anesthetized, induction takes slightly longer, but the child usually does not remember the induction. If the child panics prior to inhalation of anesthetic, induction should not be forced, and an alternative plan should be undertaken.

The Difficult Airway

The child facing a potentially difficult laryngoscopic procedure should have, at most, light sedation before induction of anesthesia by mask in order to maintain spontaneous respiration (Ch. 39) . In this way, breath sounds can be used to guide successful tracheal intubation. When normal airway anatomy cannot be confirmed visually, placing a stylet in the endotracheal tube and bending the tip of the tube acutely allow placement of the tip of the tube in the midline just posterior to the epiglottis. One can then listen for breath sounds exiting from the end of the endotracheal tube. If the patient is not breathing spontaneously, this advantage may be lost. Fiberoptic techniques are also valuable in this circumstance. Generally, the nasal approach, with the child's head flat on the table (no anterior head displacement) is the optimal route and position. The laryngeal mask airway and fiberoptic intubation through the laryngeal mask airway are reasonable alternatives. [173]

The Child With Stridor

The child with intrathoracic airway obstruction has expiratory stridor and prolonged expiration (bronchiolitis, asthma, intrathoracic foreign body). In contrast, the child with extrathoracic upper respiratory obstruction has inspiratory stridor (epiglottitis, laryngotracheobronchitis, laryngeal foreign body). When agitated or crying, such patients have dynamic collapse of the airway (Fig. 59-7) (Figure Not Available) , which can markedly worsen airway obstruction and may lead to respiratory failure and hypoxemia. Therefore, events that can upset the child (drawing of blood gases, venipuncture for blood tests, and separation from the parents) must be minimized.

I have found the following procedure effective for inducing anesthesia in the child with stridor. In order to minimize patient upset, the patient is brought to the operating room with the mother or father, who holds the child during the induction. Induction of anesthesia with halothane or sevoflurane in oxygen by mask is the preferred method, because maintaining spontaneous respiration is critical. As soon as the child loses consciousness, the parent is escorted out of the operating room. With the patient lightly anesthetized and after infiltration of local anesthetic, an intravenous line is inserted. This allows withdrawal of blood samples and deepening of the plane of anesthesia. Hydration is begun with lactated Ringer solution (10-20 mL/kg), and atropine (0.02 mg/kg) is given. If stridor worsens or if mild laryngospasm occurs, the pop-off valve is closed sufficiently to develop 10 cm H_2O of positive end-expiratory airway pressure. This procedure relieves most instances of airway obstruction caused by dynamic collapse of the airway when the child attempts to inspire against an obstructed airway (Fig. 59-8) (Figure Not Available) . As the level of anesthesia deepens, gentle assisting of ventilation may be necessary; however, maintaining spontaneous respiratory efforts is important.

Any child with airway obstruction has a long, slow induction of anesthesia before becoming sufficiently anesthetized to allow laryngoscopy and endotracheal intubation. The issue of a full stomach is secondary to the airway problem; rapid induction of anesthesia is contraindicated in these patients.

The child with laryngotracheobronchitis or epiglottitis usually requires an uncuffed endotracheal tube that is 0.5 to 1.0 mm (internal diameter) smaller than normal; the use of a stylet facilitates its insertion.

Figure 59-7 (Figure Not Available) The infant and young child have highly compliant airway structures. With normal respiration, some dynamic collapse of the extrathoracic upper airway occurs (broken line). When a child has upper airway obstruction, as in epiglottitis, laryngotracheobronchitis, and extrathoracic foreign body (hatched area), and struggles to breathe against this obstruction, dynamic collapse of the trachea increases. This increase in dynamic collapse (dotted line) augments mechanical obstruction of the airway. Therefore, until the airway is secured, it is important to avoid procedures that will upset the child. *(Modified from Cote and Todres [250])*

Figure 59-8 (Figure Not Available) When a child has upper airway obstruction caused by laryngospasm (A) or mechanical obstruction (B), application of approximately 10 cm H_2O of positive end-expiratory pressure (PEEP) (arrows) during spontaneous breathing often relieves obstruction. That is, PEEP helps to keep the vocal cords apart (A) and the airway open (B, broken lines). If this simple maneuver does not relieve obstruction, more vigorous positive-pressure ventilation may be necessary. Airway obstruction caused by the tongue requires insertion of an appropriately sized oral airway. *(Modified from Cote and Todres [250])*

The surgical team should be mobilized and prepared to perform an emergency tracheotomy should total airway obstruction occur and mask ventilation or endotracheal intubation not be possible. A detailed discussion of airway problems is beyond the scope of this chapter, but it is addressed in Chapter 39 .

Rectal Induction

Many different medications may be administered rectally for induction of anesthesia (methohexital, thiopental, ketamine, midazolam). The main advantage of this approach is that the child falls asleep in the parent's arms or, as is the case with midazolam, separates atraumatically from the parents. [85] [113] [174] This technique is no more intimidating than taking a rectal temperature, but it is generally reserved for children still in diapers. Care must be taken not to allow the child to see the rectal catheter or syringe, which would appear very large to the child. My experience has been that rectal administration of 10 percent methohexital (25-30 mug/kg) reliably induces anesthesia within 8 to 10 minutes. [85] Oxygen desaturation is not usually a problem unless the child's head is allowed to flex forward, thereby causing airway obstruction. [86]

Intramuscular Induction

Many medications, such as methohexital (10 mg/kg), ketamine (1-10 mg/kg), or midazolam (0.1-0.15 mg/kg), are administered intramuscularly for premedication or induction of anesthesia. The main advantage of this route of administration is its reliability; the main disadvantage is that it is painful.

Intravenous Induction

Intravenous induction of anesthesia is the most reliable and rapid technique. The main disadvantage is that starting an intravenous line can be painful and threatening for the child. An intravenous induction may be preferable when induction by mask is contraindicated (e.g., in the presence of reflux esophagitis or a full stomach). A two-needle technique using a butterfly-type catheter with a 25-gauge needle is suitable for induction of anesthesia, followed by placement of an intravenous catheter once anesthesia is safely induced. Older children often allow insertion of an intravenous catheter after administration of 50 percent nitrous oxide and local anesthetic. It is important to emphasize to the child that this will not be an excessively painful procedure. Occasionally, children cry with local anesthetic infiltration and become hysterical when they see the intravenous catheter. Two maneuvers help to minimize this response: (1) do not allow the patient to see the catheter; (2) puncture the anesthetized area with a needle, ask the child to look at the needle, and then ask whether there is any sensation. Often the child is astounded at the lack of pain and stops crying. The use of eutectic mixture of local anesthetic (Emla) cream, if time permits, may also provide analgesia without the need for a painful injection. [175]

The Patient With a Full Stomach

The child with a full stomach must be treated the same as an adult with a full stomach; that is, they both should undergo a rapid-sequence induction of anesthesia and application of cricoid pressure. Because oxygen consumption is much greater, hemoglobin desaturation occurs more rapidly in the child than in the adult and more rapidly in the infant

---

than in the child. [12] Additionally, the child may be uncooperative and may refuse to breathe oxygen prior to induction of anesthesia, that is, refuse preoxygenation. In this circumstance, the best that can be done is to enrich the environment with oxygen. Additional equipment that should be available includes two suction catheters (if one becomes blocked, another would be immediately available) and two laryngoscopes with handles (if the bulb, contact, or battery fails, another would be immediately available). While the child is breathing oxygen, atropine (0.02 mg/kg,
0.6 mg) may be administered intravenously to prevent reflexinduced or succinylcholine-induced bradycardia and to delay the bradycardia of hypoxemia should any of these events occur. Because of its rapid onset of neuromuscular blockade, succinylcholine is still the muscle relaxant of choice in this circumstance and should be administered in a dose of 1 to 2 mg/kg immediately after thiopental (5-6 mg/kg). [88] Cricoid pressure is applied gently after the child loses consciousness. Children should be told that they may "feel someone touching you on the neck" as they fall asleep and that this is "normal." In children, the head-up position does not significantly increase protection from pulmonary aspiration of acid gastric contents. [176] In patients in whom succinylcholine is contraindicated, rocuronium (1.2 mg/kg) often provides adequate conditions for intubation within 30 seconds of administration; however, the duration of neuromuscular blockade is 60 to 90 minutes [177] [178] [179] (Ch. 39).

Endotracheal Tubes

For most children, the proper size of endotracheal tube and the proper distance of insertion relative to the alveolar ridge of the mandible or maxilla are moderately constant. Published formulas are estimates that may need to be modified based on physical examination or unusual patient size. Table 59-4 provides a guide to choosing the proper size of endotracheal tube and the recommended distance for insertion. Uncuffed endotracheal tubes are preferred for patients younger than 10 years; a small gas leak should be evident around the tube at peak inflation pressures of 20 to 30 cm H_2O.

Intravenous Fluid and Transfusion Therapy

Intravenous Fluids

The approach to intravenous fluid therapy in the child must consider the high metabolic demands and the high ratio of body surface area to weight (Ch. 45) . The basis for calculating maintenance fluids derives from data by Holliday and Segar, [180] who found that daily fluid requirements depend directly on metabolic demand, specifically, that 100 mL of water is required for each 100 calories of expended energy. Relating this to weight produces hourly fluid requirements of 4 mL/kg for children up to 10 kg, an additional 2 mL/kg for each kilogram above 10 kg up to 20 kg, and an additional 1 mL/kg for each kilogram above 20 kg (Table 59-5) . Thus, a 25-kg child would require 65 mL/h, that is, (10 × 4) + (10 × 2) + (5 × 1) = 65. This amount does not include fluid deficits, third-space losses, modifications because of hypothermia or hyperthermia, or requirements caused by unusual metabolic demands. In general, deficits caused by restriction of food and fluids are calculated

TABLE 59-4 -- Recommended Sizes and Distance of Insertion of Endotracheal Tubes and Laryngoscope Blades for Use in Pediatric Patients

AGE OF PATIENT	RECOMMENDED		
	INTERNAL DIAMETER OF ENDOTRACHEAL TUBE (mm)	*SIZE OF LARYNGOSCOPE STRAIGHT BLADE*	*DISTANCE OF INSERTION[a] (cm)*
Premature (<1,250 g)	2.5	0	6-7
Full term	3.0	0-1	8-10
1 y	4.0	1	11
2 y	5.0	1-1.5	12
6 y	5.5	1.5-2	15
10 y	6.5	2-3	17
18 y	7-8	3	19

[a] Inserting the endotracheal tube this distance from the alveolar ridge of the mandible or maxilla places the distal end of the tube in the midtrachea.

TABLE 59-5 -- Calculation of Maintenance Fluid Requirements for Pediatric Patients

WEIGHT (kg)	HOURLY FLUID REQUIREMENTS (mL)	24-H FLUID REQUIREMENTS (mL)
<10	4 mL/kg	100 mL/kg

11-20	40 mL + 2 mL/kg > 10	1,000 mL + 50 mL/kg > 10
>20	60 mL + 1 mL/kg > 20	1,500 mL + 20 mL/kg > 20

by multiplying the hourly maintenance rate times the number of hours of restriction; 50 percent of the resulting deficit is replaced in the first hour and 25 percent in each of the next 2 hours. Third-space losses are replenished according to the surgical procedure and may vary from 1 mL/kg/h for a minor surgical procedure to as much as 15 mL/kg/h for major abdominal procedures (e.g., surgical repair of an omphalocele).

The composition of the intravenous fluid is also a concern. Because greater hypoxic brain damage was found to occur in animals having high blood glucose levels, some anesthesiologists recommend not using glucose-containing solutions routinely, especially for brief operative procedures. [181] However, a concern about unrecognized hypoglycemia was the motivating factor regarding the routine use of glucose-containing solutions in children, particularly patients who have not had food or fluids for a longer than usual time or those who have diminished glycogen stores. [182] [183] [184] The data are inadequate to eliminate glucose completely, because the relevance of the animal data is not clear, and the true incidence of hypoglycemia is not known in all populations of food-restricted children. This issue is further complicated because there are different values used to define hypoglycemia, which vary with patient age.

Despite limited data, modification of current practice can be proposed for long surgical procedures or for patients believed to be at risk for hypoglycemia. A balanced salt solution (e.g., lactated Ringer solution) should be used for all deficits and third-space losses, and 5 percent dextrose in 0.45 percent normal saline should be administered by "piggyback" infusion at maintenance rates. This procedure minimizes the chance of a bolus administration of glucose and satisfies the concern for unrecognized hypoglycemia or accidental hyperglycemia. The routine use of 5 percent dextrose and lactated Ringer solution as the initial replacement for fluid deficit and for maintenance is discouraged.

The fluid management of the term neonate and premature infant must take into account other variables. The amount of insensible water loss is inversely proportional to GA. The younger and more physically immature the patient is, the higher the skin permeability, the ratio of body surface area to weight, and the metabolic demand. In addition, the use of radiant warmers and phototherapy increases insensible water loss. On the other hand, use of a heated humidifier and warm air mattress preserves body heat and reduces insensible water loss.

The finding that the neonatal kidney is unable to excrete large amounts of excess water or electrolytes must also be considered. As described earlier, the volume of extracellular fluid in the newborn is very large. During the first days of life, some of this excess water is excreted. Therefore, term newborns have reduced fluid requirements for the first week of life. The daily fluid requirements for the term newborn for the following days after birth are: day 1, 70 mL/kg; day 3, 80 mL/kg; day 5, 90 mL/kg; and day 7, 120 mL/kg. Daily fluid requirements would be slightly higher for the premature infant. Sodium and potassium concentrations are usually kept at 2 to 3 mEq/100 mL.

An additional area of concern is the use of 10 percent dextrose in water for newborns. This fluid has been recommended to prevent hypoglycemia and is continued for the first several days of life until glucose values are stable. Infants of diabetic mothers or of mothers given large amounts of glucose just before delivery may require greater concentrations of glucose for protection against rebound hypoglycemia. Infants unable to tolerate oral feeding may continue to receive intravenous 10 percent glucose solutions and may even require peripheral or central alimentation. Some infants have been transferred to our institution with severe and potentially life-threatening hyperglycemia, that is, blood glucose levels of 700 to 900 mg/dL, as the result of overzealous use of this type of glucose therapy. This solution should be used with caution if infants require surgery and it is unclear that 10 percent dextrose in water is still necessary at that time. Every effort should be made to reduce bolus administration of glucose (an infusion pump should be used); blood sugar levels should be monitored and the solution infused at maintenance rates.

Packed Red Blood Cells

The use of blood products in pediatric surgical patients has diminished greatly because of the fear of transmission of disease, particularly the human immunodeficiency virus (HIV), even through blood that has tested negative (estimated to be 1:400,000 units of blood) [185] [186] (Ch. 46) . Because HIV and other disease-causing viruses, such as hepatitis, can be transmitted with as little as 10 mL of packed red blood cells (PRBC), administration of any blood product requires clear, medically defensible clinical indications that preferably are recorded on the anesthetic record.

When caring for children, it is very important to think in terms of blood volumes and portions of blood volumes lost, rather than units, because a unit of blood may constitute several blood volumes in the premature infant but only a fraction of the blood volume of the robust teenager.

These considerations govern calculation of the maximal allowable blood loss (MABL) resulting in an acceptable hematocrit level. The MABL takes into account the effect of patient age, weight, and starting hematocrit level on blood volume. In general, blood volume is approximately 100 to 120 mL/kg for the premature infant, 90 mL/kg for the full-term infant, 80 mL/kg for the child 3 to 12 months old, and 70 mL/kg for the child older than 1 year. These are merely estimates of blood volume. The individual patient's blood volume is calculated by simple proportion by multiplying the patient's weight by the estimated blood volume (EBV) per kilogram. Although several formulas are available, a simple relationship is easiest to remember:

Thus, if a 3-year-old child weighs 15 kg and has a starting hematocrit level of 38 percent and if clinical judgment estimates the desired postoperative hematocrit level to be 25 percent, the calculation would be as follows:

Then MABL would be replaced with 3 mL of lactated Ringer solution per milliliter of blood loss, that is, 3 mL

of lactated Ringer solution times the 359 mL of blood loss = 1,077 mL of lactated Ringer solution. If blood loss is less than or equal to MABL and no further significant blood loss occurs or is anticipated in the postoperative period, there is no need for transfusion of PRBC. If, however, significant postoperative bleeding occurs or is anticipated, discussion of potential transfusion needs with the surgeon is very important. Normally, the child who has had adequate replacement of intravascular volume deficits tolerates anemia very well. There is sufficient time to make the decision to transfuse by observing postoperative urinary output, heart rate, respiratory rate, and overall cardiovascular stability. Unfortunately, no one formula permits a definitive decision. The development of lactic acidosis is a late sign of inadequate oxygen-carrying capacity.

If the child has reached the MABL and significantly more blood loss is expected during surgery, the child should receive PRBC in sufficient quantity to maintain the hematocrit level in the 20 percent range. The entire loss of red cell mass should not be replaced unless clinically indicated if this would expose the child to additional units of blood products. Hematocrit levels in the low 20 percent range are usually well tolerated by most children, the exception being premature infants, term newborns, and patients with cyanotic congenital heart disease or those with respiratory failure who are in need of a high oxygen carrying capacity. Because the incidence of apnea is higher in neonates and premature infants who have hematocrit levels lower than 30 percent, it would be prudent to discuss with both the surgeon and neonatologist the minimal target hematocrit level for such patients and to document the discussion in the patient record. [187] [188] Older children having a history of sickle cell disease may require preoperative transfusion and should be managed in conjunction with their attending hematologist. [189] [190]

Fresh Frozen Plasma

Fresh frozen plasma (FFP) is administered to replenish clotting factors lost during massive blood transfusion (usually defined as exceeding one blood volume), for disseminated intravascular coagulopathy, or for congenital clotting-factor deficit (Ch. 46) . The anesthesiologist initiates and guides therapy with FFP during massive blood loss, whereas the hematologist's advice is sought when either of the other two conditions exists.

Patients with known clotting factor deficits, such as those with massive thermal injury or coagulopathy, may require transfusion of FFP before blood loss exceeds one blood volume. In contrast, healthy patients who do not have coagulation factor deficits at the beginning of surgery do not need FFP until blood loss exceeds one and probably one and one-half blood volumes. [191] This generalization applies to patients given PRBC; patients given whole blood do not need FFP, even when blood loss exceeds several blood volumes. [192] Despite a blood loss of one blood volume, prolongation of the prothrombin time (PT) and the partial thromboplastin time (PTT) is only minor. [191]

Blood loss exceeding one to one and one-half blood volumes (replaced entirely with PRBC and crystalloid, albumin, or other nonblood products), often necessitates transfusion of FFP. However, the decision to administer FFP should be based on observed coagulopathy and documented prolongation of the PT and PTT. Obtaining these test results from the laboratory often takes longer than desired. In this circumstance, a note should be written that blood loss has exceeded one blood volume and that abnormal oozing has occurred in the surgical field. A patient should never be given FFP to correct bleeding that is surgical in nature.

No studies on children have yet clearly defined what values for PT and PTT are associated with pathologic bleeding that require transfusion of FFP to replace clotting factors. However, if associated with abnormal oozing, a PT exceeding 15 seconds or a PTT longer than 60 seconds seems to warrant correction. If these abnormalities exist but oozing does not occur and the surgical field is relatively safe from the complications of hematoma formation, as in orthopedic surgery versus neurosurgery, it seems appropriate to observe the patient and to withhold transfusion of FFP.

The volume of FFP required to correct prolongation of the PT and PTT depends on the severity of the clotting factor deficit and the presence or absence of consumptive coagulopathy. In general, FFP therapy may require replacement of 30 percent or more of the patient's blood volume. Transfusion of FFP at rates exceeding 1.0 mL/kg/min is sometimes followed by severe ionized hypocalcemia, especially if FFP is administered during anesthesia with a potent inhaled anesthetic [193] [194] (Fig. 59-9) (Figure Not Available) . Therefore, exogenous calcium chloride (2.5-5 mg/kg) or calcium gluconate (7.5-15 mg/kg) should be administered during rapid transfusion of FFP. [195] Ionized hypocalcemia occurs very frequently in neonates given FFP, possibly because of their decreased ability to mobilize calcium and to metabolize citrate; patients undergoing liver transplantation or those with compromised hepatic function or perfusion may also be at increased risk because of a decreased ability to metabolize citrate.

Platelets

Thrombocytopenia may occur as a result of disease processes (idiopathic thrombocytopenic purpura, chemotherapy, infection, disseminated intravascular coagulopathy) or as a result of dilution during massive blood loss (Ch. 46) . Children whose platelet count has fallen because of idiopathic thrombocytopenic purpura or chemotherapy generally tolerate platelet counts as low as 15,000/mm ^{3} without need for platelet transfusion. In contrast, patients whose platelet count has decreased because of dilution (massive blood loss) generally require platelet transfusion when the count is 50,000/mm ^{3} or less. [196]

The reason for this disparity is not known. However, in my experience, the preoperative platelet count has been extremely valuable in predicting intraoperative platelet requirements. [196] Children who begin surgery with elevated platelet counts may not require platelet transfusion despite blood loss of four or more blood volumes. Conversely, children who begin surgery with low platelet counts (100,000/mm^3) may require platelet transfusion when blood loss is one or two blood volumes. Children who begin surgery with a normal platelet count (150,000-350,000/mm^3) usually do not require platelet transfusion until two blood volumes or more are lost (Fig. 59-10) .

Figure 59-9 (Figure Not Available) Ionized hypocalcemia always accompanies administration of citrated blood products (fresh frozen plasma, citrated whole blood). Fresh frozen plasma has the highest concentration of citrate per unit volume of any blood product and is the most likely to cause ionized hypocalcemia during rapid infusion. Studies in children with severe thermal injuries suggest that rates exceeding 1.0 mL/kg/min produce severe ionized hypocalcemia. If there is no further administration of citrated blood products, this abnormality will correct itself because of metabolism of the citrate. However, patients with impaired hepatic blood flow (infants, liver transplant patients, trauma patients) may need exogenous calcium therapy. * $P < 0.001$; $P < 0.0021$ compared with baseline. *(From Cote et al [193])*

Whenever platelets are administered, the anesthesia record should document the reason for the transfusion, and every effort should be made to obtain a platelet count before transfusion. Clinical oozing is the desirable indication for platelet transfusion, unless the potential for bleeding would be critical to survival, such as during neurosurgery, cardiac surgery, or major organ transplantation. The initial volume of platelets transfused is approximately 0.1 to 0.3 U/kg; the increase in platelet count obtained with this amount of transfusion varies considerably and depends on the presence or absence of platelet antibodies and on the rate of platelet consumption.

Monitoring the Pediatric Patient

The complexity of monitoring applied to the pediatric patient must be consistent with the severity of the underlying medical condition and the planned surgical procedure.

Figure 59-10 Dilutional thrombocytopenia occurs whenever massive blood loss takes place. The need for platelet transfusion, however, depends on the starting platelet count. Patients who started with low platelet counts developed dilutional thrombocytopenia after blood loss of one or two blood volumes, whereas patients who started with very high platelet counts did not require transfusions of platelets. Broken lines and -O- represent three patients with initial low platelet counts, and broken lines alone represent two children with initial low platelet counts. *(Data from Cote et al [196])*

Routine Monitoring

Minimal monitoring during anesthesia should include a precordial or esophageal stethoscope, a blood pressure cuff, an electrocardiogram (ECG), a temperature probe, a pulse oximeter, and possibly an infrared carbon dioxide and anesthetic agent analyzer. The last three devices provide early warning of impending disaster that may go unobserved until the appearance of late clinical signs such as cyanosis, bradycardia, severe hypotension, or absence of breath sounds. Prospective studies have shown that children younger than 6 months have a higher incidence of critical events. [197] [198] [199] [200] In some studies, these events occurred with greater frequency and severity when oximetry was not available to the anesthesiologist. [197] [198] The incidence of critical events was several times higher in American Society of Anesthesiologists (ASA) physical status III and IV patients than in ASA physical status I and II patients. Several factors may account for these results: the high metabolic rate of small children, the technical difficulty of caring for infants, or the difficulty of estimating actual delivered ventilation when various circuit configurations are available.

The use of the capnograph and pulse oximeter is not without problems, particularly the high incidence of false alarms from movement artifact, light interference, and electrocautery. [201] One of the main drawbacks of capnography in small children is the inaccuracy of the recording obtained when using nonrebreathing circuits. The best method of avoiding artifact is to sample the expired gases at some point within the endotracheal tube [202] [203] or to use the circle system even in small infants. [204] In general, the concentration of carbon dioxide in expired gases is within 2 to 3 mm Hg of that in arterial blood. [203] However, severe pulmonary disease or atelectasis may produce a large difference in these two values. In this type of patient, the gradient between arterial and expired carbon dioxide levels may be used to estimate the severity of the shunting. When such shunts exist, measurement of expired carbon dioxide levels may be used only to monitor trends. Ultimately, the most important monitors are the eyes, ears, and hands of the anesthesiologist, who must gather all the information provided by the patient and by the monitors applied to

the patient, consolidate the information into an accurate picture, and respond accordingly.

Special Monitoring

Arterial and central venous catheters should be used in pediatric patients whenever such monitors contribute to management of safe anesthesia. The anesthesiologist should not alter the decision to place these monitors simply because the patient is small or because the anesthesiologist is uncomfortable applying the technique to a pediatric patient. If these monitors are indicated, they should be inserted by the anesthesiologist, surgeon, cardiologist, or neonatologist. It is critical to pay special attention to the volume of fluid and heparin infused; special care must be taken to avoid introduction of air bubbles. Pulmonary artery flow-directed catheters are rarely indicated in pediatric patients, because right- and left-sided cardiac pressures are almost identical. However, occasionally the occurrence of pulmonary artery hypertension or severe multisystem failure makes this monitor particularly useful.

Multilumen catheters are very valuable in the care of critically ill patients. These devices make possible the simultaneous intravenous administration of a variety of fluids, vasopressors, and antibiotics. The greatest risk from these devices is the false sense of security created by having three intravenous ports. Specifically, if a rapid infusion of colloid or even crystalloid became necessary, the long, narrow lumen would severely limit the rate of infusion and could prevent adequate rapid volume replacement. [205] [206] If the need for rapid volume expansion could possibly arise, a separate large-bore intravenous catheter should be inserted. Short-term cannulation of the femoral or brachiocephalic vein is reasonable and may be lifesaving.

Pediatric Equipment

The anesthesiologist caring for a pediatric patient must be prepared for the unexpected, particularly an undiagnosed congenital malformation or a difficult endotracheal intubation. Having designated pediatric carts containing pediatric equipment is a convenient way of providing optimal care in a variety of locations in and outside the operating room. These carts contain intravenous catheters of various sizes, butterfly needles (scalp vein needles), ECG pads, blood pressure cuffs, precordial stethoscopes, esophageal stethoscopes in both adult and pediatric sizes, arm boards, intravenous fluids in pediatric-size containers, pediatric laryngoscope blades and handles, oral airways, endotracheal tubes, stylets, masks of various sizes, tape, drugs for resuscitation as well as commonly administered medications, and syringes, especially tuberculin syringes, for more precise administration of drugs.

Anesthesia Circuit

Much has been written about the advantages and disadvantages of various anesthesia circuits for use in pediatric patients [207] [208] [209] (Ch. 7) . Most of the attention has been directed to the neonate and ways of reducing the work of breathing while preventing rebreathing. Nonrebreathing circuits provide the advantage of minimal work of breathing because they have no valves to be opened by the patient's respiratory efforts. [208] The rate of induction of anesthesia may be more rapid because the volume of the nonrebreathing circuit is less, because no equilibration with the carbon dioxide canister is required, and because anesthetic gases are delivered immediately at the airway. Additionally, because the volume of the nonrebreathing circuit is small as compared with that of the circle system, the compression and compliance volume will be significantly less. [209] [210] This improves the ability to observe respiratory efforts, as reflected by movement of the anesthesia bag, as well as the ability to estimate pulmonary compliance. Thus, the actual delivered ventilation, when used in conjunction with a ventilator, may be greater with a Mapleson D system than with a circle system (Fig. 59-11) (Figure Not Available) . The Mapleson D circuit is more sensitive to changes in fresh gas flow (i.e., an increase or decrease in minute ventilation) or to the addition of a humidifier

Figure 59-11 (Figure Not Available) Eight types of anesthesia circuits were compared regarding ventilatory losses (circuit efficiency) as a result of compression of anesthetic gases (compression volume) and stretching of the circuit (compliance volume). Compression volume and compliance volume losses vary by as much as a factor of five, depending on the volume of the circuit and the material from which it is constructed. Low-volume, low-compliance circuits (Mapleson D systems) are the most efficient and give the anesthesiologist the greatest amount of tactile feedback regarding tidal volume and lung compliance in small patients. Although large-volume, high-compliance circuits (adult circle systems) can be used in small patients, it is very difficult to estimate tidal volume and lung compliance, because circuit-related losses in compression and compliance volumes are so large. *(From Cote et al [210])*

(decreased minute ventilation) during mechanical ventilation.

The Mapleson D circuit is an excellent circuit and for the foregoing reasons has been recommended for use in children who weigh less than 10 kg. Nevertheless, one must understand the clinical implications associated with this circuit in order to use the system safely. A pediatric circle system is adequate even for neonates as long as one understands the implications: large compression volume losses, longer time to equilibrate, perhaps a decreased ability to determine changes in compliance. [209] [211]

Neonatal Anesthesia

The neonate has unique requirements for equipment, intravenous access, fluid and drug therapy, anesthetic dosage, and environmental control (Ch. 58) . The many neonatal procedures are too numerous to describe in this limited space. However, the basic anesthetic management is the same for all neonates. An understanding of the basic differences in physiology, pharmacologic and pharmacodynamic response, and the underlying pathology of the surgical problem is essential for development of a safe anesthesia plan. Most of the complications that arise are attributable to a lack of understanding of these special considerations prior to induction of anesthesia. The care of neonates is fraught with danger, sudden changes, unexpected responses, and the unknown congenital problem. If anesthesiologists are to deliver optimum pediatric anesthesia care, they must always be prepared for the unexpected, have the proper size and variety of equipment available, and obtain the highest level of support, both in the operating room and in the intensive care unit.

Children younger than 1 year have a higher incidence of complications than older children. [197] [198] [199] [200] [212] [213] These complications relate to oxygenation, ventilation, airway management, and response to anesthetic agents and medications; they occur more frequently in ASA physical status III and IV patients. The neonate, particularly the premature infant, functions on a marginal basis, so that any type of stress is usually poorly tolerated. This vulnerability may relate to the technical difficulty of taking care of small patients, the immaturity of their organ systems (especially the cardiovascular, pulmonary, renal, hepatic, and nervous systems), the high metabolic rate, the large ratio of body surface area to weight, and the ease of miscalculating a drug dose.

When caring for infants and neonates, special attention must be paid to all aspects of anesthesia and surgical management. The anesthesiologist must devote particular care to the calculation of drug dosage and the dilution of drugs. Prevention of paradoxic air emboli requires that all air be vented from intravenous devices and syringes prior to use (aspiration of each intravenous injection port to remove air trapped at these junctions). A volume of air that is clinically unimportant to the adult may prove catastrophic to the infant. Warming of preparation solutions and irrigation fluids prior to application minimizes heat loss. Intravenous fluids should be administered with volume-limiting devices; infusion pumps are particularly helpful in preventing overadministration of intravenous fluid. The composition and infusion rate of flush solutions should be noted and calculated into maintenance fluid therapy.

Every effort must be made to maintain the infant's temperature to minimize thermal stress. The operating room environment should be warmed so that the whole operating room constitutes a giant incubator. In addition, the infant weighing up to 10 kg benefits from a warming blanket, whereas most patients benefit from heated humidification of inspired gases, particularly when a nonrebreathing circuit is used. Heated air mattress devices are particularly useful for maintaining temperature.

Monitoring of expired concentrations of carbon dioxide will be less accurate if the sample is taken at the Y-connector; endotracheal tubes having a built-in sampling port may improve the accuracy of monitoring. Pulse oximetry is definitely of great value, not only in diagnosing hypoxemia, but also in preventing extreme hyperoxia. Maintaining oxygen saturation at 93 to 95 percent keeps the preterm infant on the steep side of the oxygen-hemoglobin dissociation curve. This consideration is important to infants still susceptible to retinopathy of prematurity, that is, those younger than 44 weeks' PCA. Because these infants have the highest oxygen consumption, an oxygen saturation in the 93 to 95 percent range can result in hypoxemia within seconds. When managing such a delicate balance, and bearing in mind the slight inaccuracies of these monitors, [214] the anesthesiologist must

be extremely vigilant and prepared to respond rapidly to changes in oxygen saturation. Keeping arterial carbon dioxide values within the normal range (35-45 mm Hg) may also be important in preventing retinopathy of prematurity. [215] However, many other factors beyond the control of the anesthesiologist often contribute to the development of this condition. [216] [217]

The Stress Response

There is little doubt that the neonate, even the extremely premature infant, is capable of feeling pain and responding to painful stimuli; what actually constitutes a state of "anesthesia" has yet to be proved. [218] [219] No child should be denied analgesia or anesthesia because of size or age. Clearly, the cardiovascular system of the premature infant rarely tolerates the cardiovascular-depressant effects of potent inhaled anesthetics. However, the narcotics (e.g., fentanyl, sufentanil, alfentanil, remifentanil) are usually well tolerated even by critically ill infants. These potent narcotics must be carefully titrated to response, and the anesthesiologist must always be wary of narcotic-induced bradycardia and its consequences on cardiac output. Low concentrations of potent inhaled anesthetics can be used with narcotics, thus providing a way of controlling hemodynamic responses without significantly depressing the myocardium. The relative merits of one anesthetic technique over another are not clear, and the few studies examining this issue are poorly controlled. [220] Narcotics and inhaled anesthetics suppress the hormonal responses to pain. [221] The important result of the provocative studies undertaken to clarify this issue is that they have heightened everyone's awareness of the need to provide adequate anesthesia and analgesia for the neonate.

Special Problems

Meningomyelocele

Meningomyelocele (hernial protrusion of a part of the meninges and spinal cord through a defect in the vertebral column) is a relatively common neonatal abnormality that requires surgery. The following should be considered in addition to the usual concerns for management of the neonate: (1) the possibility of underestimating fluid and blood loss from the defect; (2) the high association of this condition with hydrocephalus; (3) the possibility of cranial nerve palsy, resulting in inspiratory stridor; and (4) the potential for brain-stem herniation. The anesthesiologist must establish adequate intravenous access and invasive monitoring if appropriate, replace all fluid deficits, including loss from the defect (usually with normal saline), and ensure that crossmatched blood is available. Latex allergy precautions should be used with these patients for their first and all subsequent anesthetics. [222]

Pyloric Stenosis

Pyloric stenosis normally presents in the first 3 to 6 weeks of life. The following are major concerns for the anesthesiologist: (1) a full stomach, often filled with barium sulfate; (2) metabolic alkalosis with hypochloremia and hypokalemia; and (3) severe dehydration.

This operation is never a surgical emergency. The patients should be carefully evaluated, and severe metabolic imbalance should be corrected prior to surgery. The stomach should be suctioned with a wide-bore catheter in the supine, right, and left lateral positions immediately before induction of anesthesia, and as much barium as possible should be removed. [223] [224] Patients with pyloric stenosis can be managed with awake endotracheal intubation or rapid-sequence induction of anesthesia. Arguments can be made for either type of induction, and selection depends on the skill and familiarity of the anesthesiologist with that technique.

Omphalocele and Gastroschisis

Omphalocele and gastroschisis are major defects in closure of the abdominal wall, resulting in exposure of viscera that are either covered (omphalocele) or not covered (gastroschisis) by peritoneum. The major problems with these defects include the following: (1) severe dehydration and massive fluid loss, both from the exposed visceral surfaces and from third-space losses caused by partial bowel obstruction; (2) heat loss; (3) the difficulty of surgical closure; and (4) the high association of this condition with prematurity and other congenital defects, including cardiac abnormalities.

These patients must be cared for expeditiously to minimize the potential for infection and the compromise of bowel function and to reverse the loss of fluid and heat. Adequate intravenous access and invasive monitoring are usually necessary. The liberal use of muscle relaxants provides optimal surgical conditions for closure of the defect; hypotension secondary to tension on a major organ (liver) or caval compression is common. If the surgeon is unable to close the defect in one procedure, a staged procedure is planned. In either situation, postoperative ventilation is necessary until the abdominal wall has had time to stretch to accommodate the viscera. Intravenous alimentation may also play a vital role in the rapid recovery of these patients. A small percentage of patients with omphalocele also have Beckwith-Wiedemann syndrome, a condition characterized by profound hypoglycemia, hyperviscosity syndrome, and associated visceromegaly. It should be noted that increased abdominal pressure following closure may compromise hepatic function and may markedly alter drug metabolism. [126] [125]

Tracheoesophageal Fistula Anomaly

The tracheoesophageal fistula anomaly has five or more configurations, most of which present as an inability to swallow because of esophageal atresia (the ending of the esophagus in a blind pouch). Neonates may have aspiration pneumonitis from a distal fistula connecting the stomach to the trachea through the esophagus or from a proximal connection of the esophagus with the trachea. The characteristic diagnostic test is the inability to pass a suction catheter into the stomach. Additionally, this anomaly may be a part of a

---

larger constellation of anomalies known as the VATER syndrome (V, vertebral; A, anal; TE, tracheoesophageal; R, renal). Any patient who presents with tracheoesophageal fistula or esophageal atresia should be suspected of having the other anomalies described earlier, as well as the potential for congenital heart disease.

The major issues for management of safe anesthesia include the following: aspiration pneumonia; overdistention of the stomach because of entry of air directly into the stomach through the fistula; inability to ventilate the patient because of the large size of the fistula; problems associated with other anomalies, particularly a patent ductus arteriosus (shunting); and postoperative intensive care.

For management of anesthesia, the child should not receive any feedings, should have a catheter placed in the esophagus to drain saliva, and should be placed prone in a head-up position. If the child has pneumonia, treatment should be initiated; surgery may be postponed until pneumonitis improves or clears. The child may be a candidate for gastrostomy to provide a means of nutrition during recovery from pneumonitis. Anesthesia evaluation should center around the pulmonary and cardiovascular systems. Generally, an awake intubation is performed, and the endotracheal tube is intentionally passed into the right main stem bronchus; the endotracheal tube is then slowly withdrawn until breath sounds are heard on the left. Often this technique ensures that the tip of the endotracheal tube is placed beyond the origin of the fistula, thus avoiding massive distention of the stomach. Care must be taken to avoid rupturing the stomach; therefore, spontaneous and gently assisted ventilation may be appropriate until gastrostomy is performed. A change in the distance of insertion of the endotracheal tube of as little as 1 to 2 mm may determine whether the anesthesiologist is ventilating both lungs, one lung, or the fistula. Therefore, because a change in oxygen saturation may be the first indication that all is not well, the pulse oximeter is one of the most useful monitors in managing these patients. [225] Taping the stethoscope to the left side of the chest in the axilla also decreases the possibility of unrecognized endobronchial intubation.

Diaphragmatic Hernia

Infants with diaphragmatic hernia usually present on the first day of life with respiratory distress and a scaphoid abdomen. The abnormality is a herniation of the abdominal viscera through a defect in the diaphragm, most commonly the foramen of Bochdalek on the left side. Almost all the abdominal viscera, including the liver and spleen, may be above the diaphragm. The GA at which herniation occurs may determine the degree of lung hypoplasia.

Anesthesia concerns include hypoxemia and hypotension caused by overdistention of the stomach and herniation across the midline, hypoxemia because of primary pulmonary hypoplasia, hypoxemia due to pulmonary hypertension, and systemic hypotension caused by kinking of major blood vessels, particularly those of the liver. In general, the anesthesiologist's ability to control arterial carbon dioxide tension (Pa_{CO_2}) reflects the severity of lung pathology and therefore survival. An inability to

reduce Pa CO_2 is associated with poor prognosis. [226] Extracorporeal membrane oxygenation has reduced the mortality associated with this condition. In addition, the urgency for surgical intervention has diminished, giving way to a desire to stabilize the infant and minimize stress. [227] At some centers, the common practice is to postpone surgery on infants with diaphragmatic hernia until their condition has been stabilized for several days.

Anesthesia management for patients with diaphragmatic hernia includes the following:

1. An awake endotracheal intubation without bag-and-mask-assisted ventilation prevents overdistention of the stomach and herniation across the midline.
2. Insertion of an arterial line and close observation of the surgical field are most helpful in diagnosing impairment of venous return or cardiac output.
3. Blunting of the stress response is accomplished by providing analgesia with narcotics (usually fentanyl) and by controlling respiration with muscle relaxants (usually pancuronium).
4. Careful control of ventilation and oxygenation prevents sudden increases in pulmonary artery pressure (Pa CO_2 is maintained at less than 40 mm Hg and Pa O_2 at more than 100 mm Hg). Pulse oximetry is helpful in diagnosing subclinical episodes of hypoxemia.
5. Hypothermia is avoided in order to decrease the oxygen consumption needed for thermogenesis.
6. Anesthetic agents that could depress the myocardium are avoided until the chest is decompressed.
7. To prevent bowel distention, nitrous oxide is not given.
8. The anesthesiologist should be alert to the development of a barotrauma-induced pneumothorax on the ipsilateral or contralateral side.
9. The anesthesiologist should ensure adequate intravenous access for maintenance of a constant circulating blood volume.
10. Postoperative intensive care should be planned.

The Former Preterm Infant

Since the early retrospective reports noting the high incidence of postoperative apnea in former preterm infants (GA <37 wk), several studies have tried to define the population at risk [187] [228] [229] [230] [231] [232] [233] [234] [235] [236] (Ch. 58) . Most studies have found the majority of infants who develop postanesthesia apnea to be less than 46 weeks' PCA; however, apnea has been reported in infants up to 60 weeks' PCA. [231] The conclusions reached by each of these studies were limited by the relatively small number of patients. I had the opportunity to obtain and analyze the original data from eight prospective studies. [187] [228] [229] [230] [231] [234] [236] [237] A combined analysis examining risk for apnea included only patients undergoing inguinal hernia repair and not receiving special treatment such as caffeine or regional anesthesia. [188] The following risk factors were examined: a history of respiratory distress syndrome, bronchopulmonary dysplasia, neonatal apnea, necrotizing enterocolitis, ongoing apnea at the time of surgery, use of narcotics or long-acting muscle relaxants, anemia (hematocrit level <30%), GA, and PCA. The only two risk factors that stood out across all ages were GA and PCA. The incidence of apnea was inversely related to both GA and PCA.

Figure 59-12 (Figure Not Available) Predicted probability of apnea for all patients, by gestational age and weeks of postconceptual age. Patients with anemia are represented by the horizontal hatched line. Bottom marks indicate the number of data points by postconceptual age. The risk for apnea diminishes for infants born at a later gestational age. The shaded boxes represent the overall rates of apnea for infants within that gestational age range. The probability of apnea was the same regardless of postconceptual age or gestational age for infants with anemia (horizontal hatched line). *(From Cote et al [188])*

For example, if two infants were now 42 weeks' PCA yet one was born at 28 and the other at 36 weeks' GA, the 28-week-GA infant would have approximately twice the potential for apnea (Fig. 59-12) (Figure Not Available) . The incidence of apnea was higher in institutions that collected data with continuous recording devices compared with those that relied on impedance pneumography or nursing observations. Anemia (hematocrit level <30%) is an independent risk factor associated with apnea in former preterm infants (see Fig. 59-12) (Figure Not Available) . What makes this risk factor unique is that the risk of apnea in anemic former preterm infants is not altered by GA or PCA; that is, the risk of apnea would appear to be the same for an anemic 60-week-PCA infant as for an anemic 45-week-PCA infant. Even after eliminating infants with an obvious apnea spell in recovery and infants who were anemic, the risk for apnea does not decrease to less than 1 percent with 95 percent statistical confidence until PCA of 56 weeks with GA of 32 weeks or PCA of 54 weeks with GA of 35 weeks. It would therefore seem prudent to admit all former preterm infants younger than 55 weeks' PCA to monitored beds and all anemic former preterm infants.

Although the risk of apnea may be less with regional anesthesia, apnea may still occur and may even be increased if regional anesthesia is combined with sedation (ketamine, midazolam). [230] [235] [238] [239] There are insufficient numbers of well-controlled studies of regional versus general anesthesia to determine whether the risk is significantly reduced.

Part of the problem of how to treat these children is that we do not know the clinical importance of brief apnea/bradycardia spells that do not require intervention. Because cerebral blood flow is markedly reduced with heart rates lower than 80 beats/min, even brief apnea associated with bradycardia may have adverse effects. [240] The problem faced by the clinician is how to manage former preterm infants scheduled for outpatient procedures. Information concerning the true incidence of postoperative apnea is still very limited because the available data have been collected from so many institutions. Nevertheless, one can conclude that the incidence of apnea is inversely related to PCA and GA, and anemia is also an independent risk factor. [188] More prospective studies need to address whether regional techniques are safer than general anesthesia. Studies must also include methods (nasal thermistry or capnography) for detecting obstructed respiration, which is often missed by chest wall impedance monitoring. Pulse oximetry would help to define the severity of desaturation, and ECG monitoring would help define episodes of bradycardia, which may reduce cerebral blood flow. Kurth and LeBard [234] demonstrated that up to 12 percent of apnea spells are accompanied by desaturation to below 80 percent. It would seem reasonable that the combination of desaturation and bradycardia would be of more physiologic importance than simple documentation of pauses in respiration.

Because the available data are so confusing, it would appear that outpatient anesthesia should be considered only when former preterm infants have had a totally unremarkable neonatal history and are currently healthy. If there is any question, the prudent anesthesiologist will plan on postoperative admission and monitoring. If appropriate facilities are not available, the premature infant who is less than 60 weeks' PCA should be referred to an institution that has such facilities. High-dose caffeine (10 mg/kg) has been recommended. [229] This may be an effective therapy; however, the half-life of caffeine in older former preterm infants is only 6 hours, [241] and the first apnea spells following anesthesia may not manifest until 12 hours. [188] Therefore, one cannot administer caffeine and send the infant home and assume that the problem is treated.

To make the issue even more complex, I have observed a full-term infant who became apneic following general anesthesia. This infant had periodic breathing, which is distinctly unusual in a full-term infant. [242] We still do not know with certainty which patients are truly anesthetized safely on an outpatient basis and at what PCA and GA.

Regional Anesthesia and Analgesia

Most regional anesthesia techniques used in the adult can be administered safely to the pediatric patient as long as strict attention is paid to the dose of local anesthetic, the dose of epinephrine, the route of administration, and the use of proper equipment [243] [244] (Ch. 44) . Perhaps the greatest advance in pediatric anesthesia has been the development of methods producing postoperative analgesia (Chs. 69 and 70) . Miniaturized needles and catheters and infusion pumps have made this feasible. Caudal anesthesia, caudal narcotics, regional blocks, and patient-controlled analgesia have all been accepted by anesthesiologists and patients. Each institution and practitioner must decide which method works best, given each particular practice setting. Obviously, until dosage guidelines and safety standards for monitoring are well established, some of these techniques must be limited to medical centers familiar with their use in children. [245]

It is my practice to supplement the analgesia of either opioid or regional techniques with 40 mg/kg rectal acetaminophen at the beginning of the procedure. A dose-finding study [246] and several others demonstrated that 40 mg/kg rectal acetaminophen places the majority of patients in the therapeutic range for antipyresis (we do not know the plasma levels associated with analgesia in children) within 60 to 180 minutes, hence the need to insert the suppositories at the beginning of the procedure rather than the end of it. [247] [248] It should be noted that suppositories should not be cut because the drug is not evenly distributed within the matrix; combinations of suppository doses are the best means of achieving a dose close to 40 mg/kg.

Regional nerve blocks and direct local infiltration of surgical wounds with long-acting local anesthetics are simple yet very effective methods of providing pain relief for all children. In most institutions, it is now rare for a pediatric patient to awaken from anesthesia without some form of regional block. This practice has been especially helpful in the outpatient population; parents are encouraged to start analgesics when they observe their child becoming irritable but prior to complete dissipation of the block. This approach usually provides a smooth transition from general anesthesia and a pain-free patient.

Chapters 42 to 44 discuss regional anesthesia and analgesia in detail, with Chapter 44 placing special emphasis on pediatrics.

Chapter 60 - Anesthesia for Orthopedic Surgery

Nigel E. Sharrock
John J. Savarese

INTRODUCTION

Perhaps no other subspecialty of anesthesia requires facility with a greater variety of anesthetic techniques than orthopedic anesthesia. As an alternative to general anesthesia, many procedures may perhaps be better managed in orthopedic patients under regional techniques or with combined regional/general anesthetic techniques (Chs. 42 and 43) .

In addition to requiring familiarity with an array of regional anesthetic procedures, orthopedic anesthesia is demanding, requiring a high degree of skill and a facility with other anesthetic techniques such as bronchoscopic intubation for complex airway problems (Ch. 39) , hypotensive anesthesia (Ch. 41) , hemodilution, intraoperative cell saver techniques for minimizing intraoperative blood loss (Ch. 47) , and invasive hemodynamic (Chs. 30 and 31) and evoked potential monitoring (Ch. 35) . Although many of the procedures are short, others are long, necessitating attention to body positioning (Ch. 26) , maintenance of normothermia, fluid balance, and preservation of peripheral blood flow, especially in reimplantation procedures. Factors causing perioperative morbidity and mortality in orthopedics may be different from those of other surgical specialties and thus may demand a different focus of attention.

SPECIFIC PROBLEMS OF THE ORTHOPEDIC PATIENT

Rheumatoid Arthritis

Rheumatoid arthritis is a disease of unknown origin characterized by immune-mediated synovitis. [1] The patients who present the most significant challenge to the anesthesiologist are those with advanced disease having deformity, instability, and destruction of many joints throughout the body. The cervical spine, hips, shoulders, knees, elbows, ankles, wrists, and metacarpophalangeal joints may all be affected. [1] Although cardiac valvular lesions, pericarditis, and pulmonary interstitial fibrosis do occur, these secondary features of the disease are usually not clinically significant. On the other hand, there is an increased incidence of ischemic heart disease (presumably secondary to corticosteroid treatment), cancer (secondary to chemotherapeutic agents), and infections, all of which contribute to only a 50 percent 5-year survival in advanced cases. [2] These patients also have an impaired immune system, wasted musculature, and underlying hypermetabolism. All these factors contribute to an increased rate of postoperative infections and other complications. [3]

TABLE 60-1 -- Orthopedic Patients in Whom Intubation of the Trachea May Be Difficult

DIAGNOSIS	CAUSE(S) OF DIFFICULTY
Ankylosing spondylitis	Fusion of cervical spine
Juvenile rheumatoid arthritis	Ankylosis of cervical spine
	Hypoplasia of mandible
Adult rheumatoid arthritis	Multiple deformity
	Ankylosis and instability of the cervical spine
Prior spine fusion	Ankylosis and limited extension of the cervical spine
Congenital deformities of the cervical spine	
Epiphyseal dysplasia	
Dwarfism (achondroplasia) [245]	
Fractured cervical spine [246]	Limited motion
	Risk of quadriplegia

TABLE 60-2 -- Causes of Atlantoaxial (C1-C2) Instability

Rheumatoid arthritis
Down syndrome
Ankylosing spondylitis
Mucopolysaccharidoses (e.g., Morquio disease)
Note: Patients are stable in extension, but flexion may compress the spinal cord or medulla oblongata.

The anesthesiologist's immediate concerns, however, tend to be technical. Arterial lines may be difficult to place because of small calcific radial arteries that may be inaccessible, owing to flexion deformities of the wrist joint. These patients have a high incidence of carpal tunnel syndrome, which may predispose them to recurrent symptoms postoperatively if radial artery lines are inserted. [4] Central venous lines may be difficult to insert because of fusion and flexion of the neck. The lumbar spine, however, is not often affected in rheumatoid arthritis, so spinal anesthesia and epidural anesthesia are usually straightforward. [5]

Other technical problems of concern are airway management and cervical spine instability. [6] [7] The trachea may be difficult to intubate for a number of reasons (Table 60-1) that are most prominent in those with juvenile rheumatoid arthritis. Atlantoaxial instability (Table 60-2) develops in many patients with adult onset of rheumatoid arthritis. [8] [9] [10] [11] Symptoms include neck pain, headache, or neurologic symptoms in the arms or legs with neck motion. [10] Atlantoaxial subluxation develops from erosion of ligaments by rheumatoid involvement of the bursae around the odontoid process of C2 (Fig. 60-1) . Acute subluxation may result in cord compression and/or compression of the vertebral arteries with quadriparesis or sudden death. Subluxation occurs with flexion of the neck (Fig. 60-2) . Anesthetic management must prevent flexion of the neck and maintain stability of the cervical spine. This may be accomplished by tracheal intubation using a flexible bronchoscope under topical anesthesia and positioning the patient while the patient is still awake. Regional anesthesia with the patient minimally sedated and the neck stabilized is a reasonable perioperative alternative.

Patients with severe rheumatoid arthritis may develop airway obstruction postoperatively from narcotics or sedatives. [12] Therefore, judicious use of narcotics or epidural analgesia for pain relief should be considered postoperatively, together with the administration of nasal oxygen and pulse oximetry if feasible. Cardiopulmonary resuscitation is difficult in rheumatoid patients (Ch. 25) , and emergency tracheotomy is almost impossible in severe cases (Ch. 39) . Jet ventilation by means of a percutaneous catheter through the cricothyroid membrane may be required. [13]

Ankylosing Spondylitis

Ankylosing spondylitis, which is more common in men than women, involves ossification of ligaments at their attachment

Figure 60-1 Magnetic resonance image of a patient with advanced rheumatoid arthritis demonstrating invagination of the odontoid process of C2 (arrow) through the foramen magnum compressing the brain stem. Note the degeneration of C4 and C5, a common problem in rheumatoid arthritis.

Figure 60-2 Computed tomographic scan of the neck demonstrates moderate subluxation of C1 and C2. The odontoid (single arrow) tends to compress the spinal cord (double arrow) against the posterior arch of C1, especially during neck flexion.

to bone. Progressive ossification involves the joint cartilage and disk space of the axial skeleton, with eventual ankylosis. Arthritis and ankylosis may also develop in the hips, shoulders, and costovertebral joints. [14]

Lung function is somewhat impaired from the development of rigidity of the rib cage. Vital capacity is minimally reduced if diaphragmatic activity is preserved. [15] Aortic regurgitation and bundle branch block may develop, necessitating aortic valve replacement or pacemaker insertion. [16] There is an ever-present risk of spine fracture and cervical spine instability in these patients, so careful positioning in the operating room is important [17] (Tables 60-3 and 60-4) .

Anesthetic considerations include (1) use of fiberoptic techniques for tracheal intubation, [13] [18] [19] (2) positioning the patient while the patient is awake, and (3) the choice of axillary rather than interscalene blocks when using regional techniques in the upper extremity. Caudal anesthesia can be readily obtained. The vertebral column is usually fused, making lumbar epidural or spinal anesthesia difficult or impossible. In patients who can still move their neck, fusion of the lumbar spine may be incomplete, [20] enabling epidural or spinal anesthesia to be performed successfully.

POSITIONING FOR ORTHOPEDIC SURGERY

Patients are placed in a variety of positions for orthopedic procedures (Ch. 26) . Improper positioning may result in intraoperative or postoperative problems such as those described below.

Air embolism (Ch. 52) can occur when the operative field is above the level of the heart. This is a potential problem in surgery of the cervical spine or the shoulder in the sitting position, in total hip replacement in the lateral decubitus position, or in lumbar spine surgery in the prone position. Air embolism should be considered if untoward circulatory compromise occurs in any of these settings, although it is rare. [21] [22] [23] [24]

Stretch or malposition of joints may occur during anesthesia and might account for a variety of nonspecific postoperative discomforts in the back or the extremities. Patients with rheumatoid arthritis, osteoporosis, osteogenesis imperfecta, or contractures must be carefully positioned to avoid ligamentous or bony injury.

Direct pressure, especially over bony prominences, may cause tissue ischemia and/or necrosis, particularly after prolonged

TABLE 60-3 -- Anesthetic Problems of the Prone Position

Airway
Endotracheal tube kinking or dislodgement
Edema of upper airway in prolonged cases may cause postoperative respiratory obstruction.
Blood vessels
Arterial or venous occlusion of the upper extremity (check with pulse oximeter on the finger)
Kinking of the femoral vein with marked flexion of the hips; this may predispose to postoperative deep vein thrombosis
During lumbar laminectomy, abdominal pressure increases may cause elevation of epidural venous pressure, contributing to intraoperative bleeding.
Nerves
Brachial plexus stretch or compression
Ulnar nerve compression due to pressure medial to the olecranon
Peroneal nerve compression due to lateral pressure over the head of the fibula
Lateral femoral cutaneous nerve trauma due to pressure over the iliac crest
Head and neck
Gross hyperflexion or hyperextension of the neck [247] [248]
External pressure over the eyes may result in retinal injury due to compression. [26] [249]
Lack of lubrication or coverage of eyes may result in corneal abrasion.
Headrest may cause pressure injury of supraorbital nerve.
Excessive rotation of the neck may contribute to brachial plexus problems or kinking of the vertebral artery. [250]
Lumbar
Excessive lordosis may lead to neurologic injury. [251] [252]

TABLE 60-4 -- Sites of Peripheral Nerve Injury in Orthopedics

NERVE INJURY SITE	CAUSE	COMMENT
Upper extremity		
Brachial plexus	Abduction, external rotation, or extension of shoulder	Usually resolves within several months
	Traction of shoulder	
Ulnar nerve	Pressure at the elbow	Not uncommon
	Traction of C8-T1 dermatomes over the 1st rib	Postoperative palsy results in numbness of ring and fifth fingers
Radial nerve	Pressure behind the arm	Results in wristdrop
Anterior interosseous nerve	Pressure at the distal elbow laterally	Bandages or external pressure [253]
Head		
Supraorbital nerve	Pressure on the supraorbital ridge when lying prone	Results in numbness of forehead
Lower extremity		
Lateral femoral cutaneous nerve of the thigh	Pressure over anterior iliac crest in lateral or prone position or over lateral thigh	Results in numbness of the lateral aspect of the thigh and knee
Femoral nerve	Pressure to the groin of the dependent limb in the lateral decubitus position	Results in numbness of the anterior thigh and medial aspect of lower leg
Common peroneal nerve	Pressure below the head of the fibula	May be due to compartment syndrome
		Results in footdrop

Ankle	Pressure from Esmarch bandage	Pressures beneath Esmarch bandage can be much higher than believed

Checklist:
1. Check for preoperative nerve dysfunction.
2. Check tourniquet problems--duration and pressure.
3. Check postoperative position, splints, tight bandages; rule out compartment syndrome.
4. Check intraoperative surgical factors.
5. Risk of neuropraxia is more common in prolonged surgery.

---

surgery when hypotensive anesthesia is used. Direct pressure on the soft tissues of the orbit when lying prone may lead to retinal artery occlusion, [25] [26] [27] [28] and direct pressure over other peripheral nerves may result in postoperative neurapraxia. [29] [30] [31] [32]

Compression of the veins and/or arteries supplying either the upper or lower extremity may occur. Prolonged venous obstruction at the axillary vein is best alleviated with an axillary roll positioned beneath the upper thorax. Similarly, with patients in the lateral decubitus position, stabilizing posts must be positioned carefully over the groin so as not to interfere with venous return at the level of the femoral vein. Arterial obstruction of a limb may be checked by the use of a pulse oximeter [33] or by palpating the pulse of a distal artery. Venous obstruction may lead to a compartment syndrome with edema, neurapraxia, elevation of creatine phosphokinase level, and myoglobinuria postoperatively. [34]

Positioning of the rheumatoid patient is very important; care must be taken not to flex the neck excessively. Regional anesthesia is particularly suitable for these patients, because neck stability can be maintained by the patients themselves, particularly if only light to moderate sedation is given. In addition, other joints that should not be moved beyond the normal range of motion will be protected by the conscious patient. Excessive motion may occur when these patients are moved in the anesthetized paralyzed state, resulting in neurapraxia, joint dislocation or stretch, or muscle trauma.

The prone position may, in particular, lead to a variety of episodes of minor or major trauma, [35] [36] which are listed in Table 60-3 .

Malpositioning of the extremities may lead to various stretch or compression-induced neurapraxias, [29] [30] [31] [32] as listed in Table 60-4 .

CHOICE OF ANESTHETIC TECHNIQUE

In most cases, the choice of regional or general anesthesia in orthopedics depends on some or all of the following factors: patient preference, state of health of the patient, expertise of the anesthesiologist, duration of the procedure, surgeon's preference, and practice pattern in the hospital. In general, most extremity procedures can be performed using regional anesthesia alone with light sedation. More complicated operations such as allograft replacements, major tumor surgery, reconstructive procedures, and repair of major trauma may be performed using general anesthesia alone. Alternatively, combined techniques using continuous regional anesthesia (e.g., lumbar epidural and axillary or femoral sheath techniques) supplemented with light general anesthesia using a laryngeal mask airway may be particularly useful, incorporating many of the benefits of regional anesthesia with a sedated patient and a "secured" airway. [37]

MAJOR ORTHOPEDIC PROCEDURES

Major operations require special preparation on the part of the anesthesiologist, increased attention to the details of intraoperative monitoring and fluid management, and active participation whenever possible in postoperative pain management.

Management of Blood Loss

Major orthopedic procedures are associated with significant blood loss [38] (Chs. 46 and 47) . Public awareness of the dangers of transfusion has increased dramatically as a result of

---

the acquired immunodeficiency syndrome epidemic as well as a recognition of other risks of transfusion, such as hepatitis, malaria, and, more recently, bovine spongiform encephalitis in Great Britain. [39] [40] [41] A plan to minimize homologous transfusion for all patients undergoing joint replacement, tumor resections, or major spine surgery should be established. This may begin with predonation of autologous blood, [42] preoperative erythropoietin [43] (e.g., in Jehovah's Witnesses [44] or patients with preoperative anemia), intraoperative hemodilution, [45] [46] induced hypotension, [47] conduction anesthesia, use of a cell saver, [48] [49] preservation of normothermia, [50] or by tolerating lower hematocrit values postoperatively (lowering the so-called transfusion trigger [51]) and the use of antifibrinolytic agents. [52] [53] In practice, combination of several of these modalities is most effective in reducing homologous transfusion. At The Hospital for Special Surgery, most patients predonate autologous blood and receive hypotensive anesthesia, and the transfusion trigger has been lowered into the mid 20s. Cell savers, which are expensive and have certain risks, [54] are used selectively in the operating room for major spine surgery for scoliosis. Antifibrinolytic drugs and postoperative cell salvage are probably best used when expected blood loss exceeds 2 L but is unwarranted in more minor procedures due to the risks of aprotinin. [52] [55] [56] [57]

Monitoring Requirements

Optimal intraoperative hemodynamic function requires invasive monitoring and careful fluid management. For these reasons, in longer, more complicated procedures such as those discussed in this chapter, in which major blood loss and massive fluid shifts may be anticipated, the monitoring standards listed in Table 60-5 should be considered.

Total Hip Replacement

Background

Anesthetic management of total hip replacement varies according to the complexity of the surgery, complications that may arise during the surgery, and the medical status of the patient. Complex procedures such as those involving acetabular bone grafting, insertion of a long-stem femoral prosthesis, [58] removal of a prosthesis, revision surgery, or surgery in patients with acetabular protrusion (which entails a risk of entering the pelvic cavity and/or the iliac vessels) complicate the management of the anesthetic.

Anesthetic Management

Monitoring

Because most candidates for total hip replacement have only a limited ability to exercise, their cardiopulmonary function can be difficult to assess. This often elderly population frequently has underlying systemic diseases. Fluid administration must be carefully managed during this type of

TABLE 60-5 -- Suggested Management of Major Orthopedic Procedures

PROCEDURE	AVERAGE DURATION (H)	RANGE OF BLOOD LOSS (UNITS)	SUGGESTED MONITORING OR SPECIAL TECHNIQUES
Total hip	1-4	1-6	Autologous blood donation
			Arterial cannula
			Central venous pressure
			Foley catheter (optional)
			Epidural catheter (optional for postoperative pain treatment)
			Induced hypotension
			Cell saver (revision)
Total knee	1.5-3	0-2 (with tourniquet)	Autologous blood donation
			Arterial cannula
			Foley catheter (optional)
			Epidural catheter (for postoperative analgesia)
Major spinal surgery	3-8	1-10	Autologous blood donation
			Arterial cannula
			Central venous pressure
			Foley catheter
			Induced hypotension
			Evoked potential monitoring
			Wake-up test

Major allograft surgery	2-8	2-10	Autologous blood donation Arterial cannula Central venous pressure Foley catheter Induced hypotension and/or hemodilution Epidural catheter (for postoperative analgesia)
Major pelvic resections	2-8	2-10	Autologous blood donation Arterial cannula Central venous pressure Foley catheter Induced hypotension and/or hemodilution Epidural catheter (for postoperative analgesia) Evoked potential monitoring

extensive surgery. Furthermore, there is an increased likelihood to develop hypoxemia and/or pulmonary edema due to pulmonary endothelial injury from fat or bone marrow emboli [59] and from ventilation/perfusion mismatching (see Positioning and Tables 60-3 and 60-4) . It is, therefore, reasonable to use invasive hemodynamic monitoring periopera- tively in the elderly or medically compromised patient undergoing total hip replacement, especially when this involves complex or revision surgery.

Blood Loss

Extensive studies during and after total hip replacement show that use of either hypotensive or regional (epidural or spinal) anesthesia reduces the blood loss by 30 to 50 percent. [60] [61] Lowering intraoperative mean arterial pressure to 50 mm Hg reduces blood loss more effectively than a mean arterial pressure of 60 mm Hg. [62]

Blood loss during total hip replacement is significantly greater during revision surgery. In these patients, several modalities to reduce the risk of homologous transfusion should be used, including preoperative donation of autologous blood, induced hypotension, or hemodilution. Cell savers can be used if blood loss is expected to be greater than 1 L. With the use of hypotensive epidural anesthesia, intraoperative blood losses of more than 300 mL are unusual, limiting the need for the cell saver or antifibrinolytic agents.

Positioning

The majority of total hip replacements are performed with the patient in the lateral decubitus position. This creates a potential ventilation/perfusion mismatch with resultant hypoxemia, a problem that appears most often in patients with underlying lung disease. The lateral decubitus position can create neurovascular problems as well because the dependent shoulder presses on the axillary artery and brachial plexus, [63] and the anterior stabilizing post compresses the femoral triangle. [33] These problems can be minimized by placing an axillary roll beneath the upper thorax and by careful positioning of the anterior stabilizing post at the dependent groin. Patients who are given hypotensive anesthesia may be at greater risk of neurovascular injury, because less extrinsic pressure is required to compress a less tense vessel. [26]

Cement Fixation

The quality of the cement-bone interface is improved if there is no blood covering the cancellous bone as the cement is applied. Hypotensive anesthesia has been shown radiographically to improve the quality of cement bone fixation, [64] because it reduces bleeding from bone. [62]

Intraoperative Hypotension

Profound hypotension immediately after insertion of cemented femoral prostheses has resulted in cardiac arrest

TABLE 60-6 -- Patients at Risk of Acute Hypotension/Cardiac Arrest During Total Joint Replacement

Long-stem cemented primary total hip replacement
Metastatic cancer [71] [254]
Removal of hardware after intertrochanteric hip fracture [58]

Revision of long-stem cemented femoral component
Cemented prosthesis to distal femur
Fracture below femoral component
Cemented long femoral stem total knee replacement [86] [87]

and death [58] [65] [66] [67] (Ch. 41) . These events are not seen with noncemented prostheses. Nowadays, this is distinctly uncommon during elective primary total hip replacement but not uncommon in certain high-risk groups (Table 60-6) . Therefore, it seems likely that hypotension is related in some way to the use of cement (Fig. 60-3) (Figure Not Available) . Two possible explanations are that (1) it may be caused by direct vasodilation and/or cardiac depression from methyl methacrylate or (2) it may be due to the forced entry of air, fat, or bone marrow into the venous system with resultant pulmonary emboli. [65] Large echogenic emboli have been described after insertion of femoral prostheses; this supports the concept that the circulatory collapse is embolic [68] rather than from a toxic effect of the methyl methacrylate. Attempts to minimize this complication have included (1) the use of a plug in the femoral shaft to limit the distal spread of cement in the femur, [69] (2) venting of entrapped air, and (3) waiting for cement to become more viscous before its insertion. These maneuvers minimize the disruption of bone marrow in the distal femur, thereby preventing catastrophic fat/bone marrow pulmonary embolism. Embolization can also be reduced by carefully lavaging the femoral canal. [70] By contrast, in the high-risk group, extensive reaming of the femur occurs, disrupting more bone marrow; and with pressurization with cement, significant marrow is forced into the circulation. This can be seen with transesophageal echocardiography [65] [68] [71] [72] (Fig. 60-4) (Figure Not Available) .

Echogenic material is noted with reaming the femur, after insertion of the cemented femoral component, [65] [68] [71] [72] and with relocation of the hip joint. [73] Large emboli may be observed in the right side of the heart, obstructing the right ventricular outflow tract leading to right-sided heart failure, hypotension, and cardiac arrest. Small emboli traverse the right side of the heart and embolize to the lung. These may increase pulmonary artery pressure but are less likely to cause intraoperative cardiac arrest. In patients with a patent foramen ovale, emboli may pass into the systemic circulation, causing myocardial infarction or stroke. [71] It is curious that although patent foramen ovale is common, severe systemic manifestations of fat emboli are uncommon after total hip replacement even though the majority of patients have evidence of fat embolization during surgery. Fat may also pass through the pulmonary circulation, contributing to systemic manifestation of fat embolism after surgery. [74] Whether this contributes to acute delirium or persistent decline in cognitive function is unclear. [75] [76] [77] [78]

Hypotension may occur with impaction of the femoral component or after relocation of the hip joint (see Fig. 60-3) (Figure Not Available) . With impaction of the

femoral component, the embolic

Figure 60-3 (Figure Not Available) An 85-year-old woman undergoing primary total hip replacement, status post Richard screw with a long side plate. She had a history of chronic obstructive lung disease and osteoporosis. Pulmonary and radial artery pressures were stable until a 200-mm cemented femoral component was inserted (point A). One minute after impaction of the femoral component, pulmonary artery pressure increased acutely (point C) and arterial pressure decreased to 30 mm Hg. Epinephrine, 25 mug, was injected through the distal port of the pulmonary artery catheter (point D). This resulted in a rapid restoration of arterial pressure, a transient tachycardia, and stabilization of the pulmonary artery pressure. The hip was relocated at point B, which resulted in no change in pulmonary artery pressure. *(From Sharrock et al [256])*

material can be forced directly into the venous system. On the other hand, obstruction of the femoral vein occurs during insertion of the femoral component so that fat or bone marrow is usually retained in the femoral vein until the hip joint is relocated. As soon as the obstruction of the vein is relieved, the emboli pass toward the right side of the heart. This process can be monitored with transesophageal echocardiography or by using oximetric pulmonary artery catheters [79] (Fig. 60-5) . An acute decline in mixed venous oxygen saturation occurs in conjunction with a rise in pulmonary artery pressure with release of an obstructed femoral vein containing embolic material.

An effective treatment for the acute hypotension is intravenous epinephrine (4-50 mug) as soon as the hypotension is noted. [56] The dose depends on the degree of hypotension. In the high-risk group, epinephrine (10-20 mug) is injected through the distal port of a pulmonary artery catheter the moment any reduction in arterial pressure is noted after impaction of the long-stem cemented femoral component. If cardiac arrest occurs, much larger doses of epinephrine will be needed to resuscitate the patient.

Hypoxia has been described immediately after insertion of a cemented femoral prosthesis and for up to 5 days into the postoperative period. In the event of hypoxemia, one must first ascertain whether it has a specific cause, such as atelectasis of the dependent lung, hypoventilation, or fluid overload. Even with no specific cause, hypoxemia may persist for some days after hip surgery. [80] It may be a result of the embolic effects of femoral shaft cement or fat embolism. [81] Pulmonary emboli with cement or bone marrow increase pulmonary artery pressures in dogs [82] and humans, [79] but it is unclear whether this is directly responsible for the hypoxemia observed. Postoperative management should include nasal oxygen, pulse oximetry (if necessary for several days), [59] judicious use of narcotics to provide analgesia and yet avoid hypoventilation or airway obstruction, appropriate fluid management, and diuresis. Hypoxia and fluid overload may further increase pulmonary pressures and thus increase the likelihood of pulmonary edema or right-sided heart failure. Postoperative hypoxia is more common in patients who snore. [83]

Total Knee Replacement

Background

Patients who need total knee replacement frequently have severe rheumatoid arthritis, degenerative osteoarthritis, or other significant comorbidities that compound the difficulties of the operation. The average duration of the procedure is 1 to 3 hours (see Table 60-5) .

Anesthetic Management

Unilateral Versus Bilateral Total Knee Replacement

There is considerable debate in the orthopedic literature about the wisdom of performing one-stage bilateral total knee replacement. [84] [85] Knee arthritis is frequently bilateral, and patients appreciate the opportunity to have both replacements performed at the same time so they have only one period of rehabilitation and can "get it over with." On the other hand, patients undergoing bilateral total knee replacement have a higher rate of postoperative complications and require much more perioperative interventions so some selection process is required. However, if patients have appropriate hemodynamic monitoring, postoperative epidural

Figure 60-4 (Figure Not Available) Right atrium during echocardiography. *(A)* Multiple small emboli in the right atrium. *(B)* A large embolus 7 cm in length, which is probably a cast of the femoral vein. *(From Christie et al [73])*

analgesia, and a 24- to 48-hour period of surveillance in a high-dependency unit, the outcome is usually excellent.

Cement

When acrylic cement is applied to the cavities of the tibia, femur, and patella, acute hemodynamic responses seldom follow. Such responses do occur, however, when *long-stem* femoral prostheses are inserted after extensive femoral reaming. [86] [87] Lesser degrees of femoral reaming may reduce the incidence of embolic events, but the significance of these events is unclear. Pressures in the femoral canal of 300 mm Hg or more have been recorded during impaction of the femoral component, [88] although this does not appear to adversely affect arterial oxygen or pulmonary artery pressures. [89]

Figure 60-5 Pulmonary artery oxygen saturation during total hip replacement is recorded from an oximetric pulmonary artery catheter (American Edwards, Baxter Healthcare Corporation, Irvine, Calif). Note the acute fall in pulmonary artery oxygen saturation after relocation of the hip at minute 62 after trial reduction (T) with 8 minutes of potential venous occlusion and minute 74 after final reduction (F) with 12 minutes of potential venous occlusion. *(From Sharrock et al [75])*

On release of the tourniquet after insertion of a cemented total knee replacement, showers of fine emboli are detectable in the right side of the heart. This has been associated with an increase in pulmonary vascular resistance during general anesthesia. [90] Both the severity of metabolic injury [89] and the echogenic material [90] were similar with intramedullary and extramedullary fixation, suggesting that the emboli are thrombi rather than bone marrow. [90] Echogenic material has also been observed during total shoulder replacement. [91]

Blood Loss

The intraoperative use of tourniquets makes blood loss negligible, but postoperative drainage averages 500 to 1,000 mL per knee. [92] Therefore, postoperative monitoring, possibly in the postanesthetic care unit, for 24 hours or more may be necessary in high-risk patients until wound drainage slows. Patients undergoing bilateral procedures are at additional risk of becoming hypovolemic during the first few hours after the operation. Preoperative autologous blood donation can minimize homologous transfusions in this setting.

Fibrinolytic activity increases when the tourniquet is inflated. [93] This observation provided the rationale for the use of antifibrinolytic agents to minimize blood loss after total knee replacement. Although aprotinin has not been clinically proven to be useful in this setting, [94] tranexamic acid is cost effective in unilateral total knee replacement. [53] [95] [96]

Postoperative Pain Management

Total knee replacement is associated with significantly more pain than total hip replacement, and the use of continuous passive motion devices or early mobilization

of the knee increases the pain (Ch. 69) . Epidural analgesia for 24 to 72 hours effectively controls the pain. [97] [98] Femoral/sciatic blocks or intrathecal morphine can be used to provide analgesia for 8 to 24 hours.

Femoral nerve catheter technique can be used for several days. The particular technique depends on the availability of postoperative pain services.

Thoracolumbar Spine Surgery

Major thoracolumbar spine surgery is usually used to correct deformity (e.g., scoliosis), to stabilize fractures, [99] or for resection of tumors. [100]

The basic aim of surgery for scoliosis is to prevent progression of the curvature of the spine, maintain posture, and prevent progression of pulmonary dysfunction. Scoliosis can be congenital or can develop during adolescence or later in life. Comorbidities in adolescent scoliosis include restrictive lung disease, which may lead to pulmonary hypertension, and an increased incidence of malignant hyperpyrexia. Patients with congenital scoliosis may have congenital heart disease, airway abnormalities, and preexisting neurologic deficits. Patients with neuromuscular disease such as Duchenne muscular dystrophy, poliomyelitis, dysautonomia, spinal-cord injury, and neurofibromatosis may also develop scoliosis, which can lead to extremely complex management problems. [101]

Perioperative considerations include intraoperative positioning, spinal-cord monitoring, minimizing of blood loss, and postoperative respiratory care. Many of these patients undergo both anterior and posterior procedures, which may be staged or performed under one anesthetic. The anterior procedure is often performed by thoracotomy. Postoperative ventilatory support and pain management are more complex in patients who have had double procedures and in those with preoperative neuromuscular disorders or dysautonomia.

Problems of surgery and anesthesia in the prone position are listed in Table 60-3 . Particular attention should be focused on positioning of the neck, arms, and eyes to protect pressure points adequately, particularly if hypotensive anesthesia is to be used in longer surgical procedures. Patients may be moved slightly as a result of surgical manipulation after a wake-up test or after alterations in the position of the table. Therefore, reassessment of patient positioning is advisable at regular and pertinent intervals intraoperatively.

Monitoring

Somatosensory Evoked Potentials

Intraoperative spinal-cord function monitoring is important if correction of spinal curvature is to be undertaken. Distraction of the spine may lead to ischemia of the spinal cord because anterior spinal artery flow may be compromised.

There are two approaches to spinal-cord function monitoring: (1) somatosensory evoked potential (SSEP) monitoring [102] (Ch. 35) and (2) the so-called wake-up test. Disruption of spinal cord function results in changes in both amplitude and latency of SSEPs. [103] The SSEPs, however, can also be altered by the use of inhalation agents. On the other hand, they are less disturbed by the nitrous oxide-narcotic-relaxant technique and minimally disturbed by intravenous anesthesia. It is less clear whether deliberate hypotension or moderate hypothermia influences the interpretation of SSEPs, but profound hypotension and shock do cause significant inhibition of the responses. SSEP monitoring may be also used when placing pedicle screws [104] or using other spinal instrumentation or during cervical spine surgery. [105]

Wake-Up Test

SSEPs assess posterior spinal cord function. A reduction in anterior spinal artery blood flow, however, produces ischemia of the anterior regions of the cord, which may result in motor weakness of the lower extremities. In some cases this may occur without observed alterations in SSEPs. For this reason, a wake-up test has been extensively used in many centers in addition to SSEPs during scoliosis surgery. [106]

Patients receive nitrous oxide-narcotic-relaxant anesthesia throughout the procedure. Volatile anesthetics are not

administered. The wake-up test can be performed by discontinuing nitrous oxide and, using peripheral nerve stimulation, ensuring that neuromuscular blockade is relatively shallow (two or three twitches on train-of-four stimulation). Within 3 to 5 minutes from discontinuation of nitrous oxide, patients will usually respond to verbal commands to move their hands and their feet. The presence of motion in the feet suggests that there is not complete ischemia of the spinal cord.

Use of potent anesthetic vapors may delay wake-up for as much as 30 minutes. Intraoperative antagonism of narcosis or of neuromuscular blockade should not be done, because this may cause overly sudden alertness and dangerously excessive movement on the operating table. In the partially paralyzed narcotized state, however, this technique is easy to perform and has worthwhile predictive value regarding the safety of spinal-cord distraction. It is not psychologically traumatic to the patient because amnesia is nearly complete and there is no recollection of pain or discomfort. Anesthesia is reinduced as soon as movement is demonstrated. Motor-evoked potential monitoring has recently been introduced because it should be a better monitor of ischemia in the anterior spinal cord, avoiding the need for a wake-up test. [107] [108]

Conservation of Blood Resources

Because major blood loss is to be expected, autologous blood donation (3 to 4 units if possible), [109] [110] intraoperative hemodilution, use of the cell saver, and induced hypotension should all be considered [102] [110] [112] (Chs. 41 and 47) . Antifibrinolytic agents such as aprotinin reduce blood loss and homologous transfusion in selected cases.

Hemodynamics

Because blood loss during spinal procedures is considerable (2 to 10 units, depending on how many segments are to be fused), moderate levels of hypotension (to a mean of 55 to 60 mm Hg) will effectively reduce blood loss, limiting the likelihood of homologous blood transfusion. Invasive monitoring should be carried out with arterial lines, central venous or pulmonary artery catheters, and Foley catheters for fluid management and replacement therapy.

Postoperative Care

Postoperatively, patients with significant comorbidity should be carefully monitored. [113] Patients with neuromuscular diseases, significant restrictive pulmonary disease, congenital heart disease, or evidence of right-sided heart failure may require ventilation for 24 hours or longer. Admission to an intensive care unit should be planned in advance to ensure precise hemodynamic and fluid monitoring and to allow maximum therapy for pain relief during this time. Intrathecal narcotics [114] [115] or epidural analgesia may also be used for postoperative analgesia. Postoperative hyponatremia sometimes occurs and has been attributed to inappropriate antidiuretic hormone secretion. [116]

Cervical Spine Surgery

Surgery on the cervical spine for trauma, tumor, arthritis, spinal stenosis, or instability has a number of complications. [117] [118] Posterior cervical decompression may be performed in the sitting position, increasing the risk of air embolism, or in the prone position, increasing the risk from external pressure on the eyes. [26] Intubation may be difficult, owing to instability of the spine (as in neck fracture or C1-C2 instability) or to a complex airway due to neck deformity as in rheumatoid arthritis. [8] [11] If any question exists, these patients are best intubated with the aid of a fiberoptic bronchoscope and positioned while they are "awake" (in fact, sedated and amnesic) to be certain that the anesthetic maneuvers have not compromised the spinal cord. An armored endotracheal tube is often preferable to minimize kinking due to retractors or movement during surgery.

Cervical spine surgery may be complicated by injury to the spinal cord during surgery, leading to postoperative quadriplegia with respiratory impairment. [8] For this reason, SSEPs are often used during these procedures to monitor surgical manipulations. Patients with rheumatoid arthritis undergoing cervical spine surgery in the prone position should receive minimal intraoperative fluid, be intubated with the aid of a fiberoptic bronchoscope, and have their neck maintained in a neutral position; and after surgery, they should be kept head up for 3 to 5 hours to minimize the risk of upper airway obstruction after extubation. [119] [120] The potential respiratory difficulty is presumably from upper airway edema secondary to trauma during intubation, excessive fluid, and prolonged dependency. [120] Cervical spine surgery can be performed using local anesthesia to avoid some of these problems. [19] [121]

Lumbar Spine Surgery

Modern lumbar spine surgery ranges from disk excision through tiny incisions to extensive anterior/posterior fusions with allografts, [122] [123] bone grafts, pedicle screws, [124] and so on, which may be associated with excessive blood loss, prolonged dependency, positioning problems, and neurologic monitoring with SSEPs and/or electromyograms. The anesthetic techniques must be adapted to the particular surgery. Although traditionally, these cases have been performed with general anesthesia, spinal or epidural anesthesia is being more commonly performed for simple disk excision. [125] Lumbar spine fusion can be performed with low thoracic epidural anesthesia (usually in combination with general anesthesia). The virtues of epidural anesthesia are less bleeding and improved postoperative epidural analgesia. [126] Epidural catheters can also be placed by either the anesthesiologist or surgeon during scoliosis surgery to facilitate postoperative analgesia.

Major Allograft or Autograft Transplantation Surgery

Background

Major segmental skeletal defects, particularly in the long bones of the extremities, may occur as a result of tumor resection, [127]

Figure 60-6 (Figure Not Available) Three months after en bloc resection and reconstruction with a vascularized fibular graft augmented with autogenous cancellous graft using external fixation for immobilization. *(From Hsu et al [125])*

trauma, or osteonecrosis. Repair of these lesions to eventually permit weight bearing in the legs or restoration of mechanical function to the arms requires bone grafting. Either banked allografts obtained from living or dead donors or vascularized autografts, usually of the fibula, are used to bridge resultant bony gaps [128] [129] (Fig. 60-6) (Figure Not Available) . The duration of these procedures is long (2-10 hours), and many candidates may be debilitated as a result of radiation therapy, chemotherapy, or chronic infection.

Frequently, tumor resection is followed by immediate replacement grafting. The surgical procedure consists of two phases for the anesthesiologist: first, the surgical resection is often bloody, requiring attention to details of fluid management and blood conservation and replacement; second, subsequent fitting of the graft and fixation to adjacent structures followed by wound closure may require several hours of reconstructive surgery. Major anesthetic considerations are monitoring requirements, fluid and transfusion therapy, and postoperative pain relief (see Table 60-5) . In longer procedures, meticulous attention to prevention of pressure necrosis, neurapraxia, joint stiffness, and arthralgia is necessary.

Anesthetic Management

Whatever the choice of anesthetic technique, intraoperative hemodilution combined with deliberate (induced) hypotension should be strongly considered because it is desirable to limit blood loss and to provide as dry a surgical field as possible during the procedure (Chs. 41 and 47) . Preservation of the vascularized graft is vitally important. [130] [131] Patient temperature, circulatory blood volume, and cardiac output must be maintained and, if possible, graft flow augmented by a sympathetic blockade. Other measures include intravenous mannitol and anticoagulation with heparin. Postoperatively, these patients should be kept in special care units so that the wounds can be monitored for graft patency by visual inspection, Doppler flow probe, and pulse oximetry monitoring.

Pelvic and Sacral Resections/Fractures

Background

Major bony resections of the sacrum or pelvis are performed as primary treatment of usually cancerous bone tumors. Major pelvic surgery is also done for repair of complicated pelvic or acetabular fractures. As in major spinal or hip surgery, care in positioning for a long procedure is important, because many of these operations are done in the lateral or prone positions (see Table 60-3) .

Anesthetic Management

Measures for conservation of blood resources and body heat should be carefully followed (Chs. 37 , 41 , and 47) . Invasive monitoring may be essential, and improved postoperative analgesia by means of epidural catheters should be strongly considered [132] (see Table 60-5) .

If the dissection is to involve major pelvic vasculature or nerve roots, the following additional measures might be taken: pulse oximetry in the lower extremity (toe) will aid in judging adequacy of circulation, and SSEP monitoring of L4-L5 to S2 nerve roots may help to lessen the possibility of nerve damage during en bloc dissections of the sacrum (see Table 60-5) or during repair of pelvic fractures. If SSEP monitoring is used, epidural anesthesia and inhalation anesthetics may be contraindicated. Additional large-bore intravenous cannulas may be needed in anticipation of rapid fluid and blood infusion during major resections.

REGIONAL ANESTHESIA OF THE EXTREMITIES

Upper Extremity

Orthopedic procedures in the arm may be performed under a variety of brachial plexus block techniques, with intravenous regional anesthesia, or by using combinations of individual nerve blocks in the arm (Ch. 43) . The selection of a particular technique depends on the need for a tourniquet and on the site of anticipated surgery.

The deep structures of the shoulder are largely innervated by the C5 and C6 dermatomes. This explains why shoulder surgery can be performed under interscalene

block alone, [133] [134] although skin infiltration may be necessary if the skin incision extends toward the axilla. Open-shoulder surgery or arthroscopy performed in the sitting position under interscalene block may be complicated by episodes of bradycardia and/or hypotension in up to 20 percent of cases. [135] These are believed to be vasovagal reactions that are best prevented by fluid loading and pretreatment with intravenous atropine or beta blockers. [136] Excessive absorption of fluid may also occur. [137]

Elbow surgery can be performed by either interscalene or axillary blocks, [138] or by a combination of both. [139] Alkalinization of local anesthetics has been shown to more effectively anesthetize the C8-T1 dermatomes during interscalene blocks. [140] Intercostobrachial blocks (T1-T2) in the axilla may be necessary as a supplement to axillary blocks if medial incisions are performed in the upper arm.

Hand and forearm surgery can be performed with the use of any of the above techniques. Axillary blocks may be preferable for surgery of the medial aspect of the hand and forearm (C7-C8, T1) because this area is sometimes incompletely blocked by the interscalene approach. Continuous axillary blocks may be preferable for prolonged cases. Intravenous regional anesthesia is most applicable for shorter cases.

Peripheral nerve blocks at the wrist or hand can be performed with a long-acting anesthetic such as bupivacaine or ropivacaine to provide postoperative pain relief and facilitate discharge after ambulatory surgery.

Lower Extremity

Essentially, all lower extremity surgery can be performed with spinal, epidural, or combined spinal-epidural anesthesia with variable degrees of sedation (including use of a laryngeal mask airway). Alternatively, nerve blocks can be used alone or in combination with general anesthesia. Knee arthroscopy is usually performed on an outpatient basis with spinal anesthesia using pencil-point needles, [141] with combined spinal-epidural anesthesia, [142] or with femoral block with an intra-articular local anesthetic. Transient radicular irritation is an unresolved problem after outpatient knee arthroscopy under spinal anesthesia. [143]

Surgery of the forefoot can be performed satisfactorily under ankle or midtarsal block [144] or by anesthetizing the branches of the sciatic and femoral nerves proximally. The common peroneal nerve can be anesthetized as it courses superficially below the head of the fibula, or both branches of the sciatic nerve can be blocked in the popliteal fossa. In any surgery involving the medial aspect of the foot, the saphenous branch of the femoral nerve must be anesthetized either at the level of the ankle or perhaps higher up (e.g., inferomedial to the knee). These techniques preclude the use of thigh tourniquets. For ankle blocks, Esmarch bandages or tourniquets applied immediately above the ankle enable at least 2 hours of surgery to be performed without tourniquet pain. [144] [145]

Ankle surgery *cannot* be reliably performed using an ankle block. Epidural anesthesia for ankle surgery is satisfactory, but onset of analgesia may be delayed for up to 30 minutes until complete anesthesia of the L5-S1 nerve roots develops. [146] [147] [148] The addition of an epidural narcotic, epinephrine, clonidine, or bicarbonate [147] [148] to the local anesthetic may also enhance the quality of the anesthesia. Caudal anesthesia is an option in patients with prior lumbar spine surgery, as is spinal anesthesia. Sciatic blocks in combination with femoral or saphenous nerve block are suitable for ankle surgery. The deep structures of the ankle are all innervated by branches of the sciatic nerve, which explains why sciatic or popliteal blocks alone are usually sufficient to reduce ankle fractures and provide excellent postoperative analgesia after ankle surgery. [149]

Femoral and/or sciatic blocks may also be used for surgery of the thigh or the leg. [150] The blocks required depend on the site of the surgery and the necessity for a tourniquet. Three-in-one blocks (femoral plexus block) may be used for knee arthroscopy provided that prolonged tourniquet times can be avoided. A number of sciatic block techniques have been described that are perfectly adequate for surgery below the knee if tourniquets are not used.

Femoral nerve blocks can be performed preoperatively or postoperatively for analgesia. They are particularly effective in providing analgesia for hip or femur fractures [150] [151] and for pain after knee surgery.

POSTOPERATIVE ANALGESIA IN ORTHOPEDICS

Pain after orthopedic surgery depends on the site and extent of surgery and the preoperative use of analgesics by the patient (Ch. 69) . The techniques used are further defined by the facilities available in the hospital. Without a postoperative pain service, systemic narcotics may be the mainstay of therapy. On the other hand, if a postoperative pain service is available, a variety of continuous infusions or patient-controlled analgesia modalities can be used to optimize pain therapy and augment recovery.

Orthopedic surgery lends itself to regional anesthesia. Peripheral blocks with bupivacaine or ropivacaine can provide 12 to 24 hours of significant analgesia, which is often sufficient to eliminate the need for intramuscular or intravenous narcotics. Alternatively, infusions of local anesthetic by means of catheters inserted into the femoral, [152] popliteal, [153] or brachial plexus [154] may provide significant postoperative analgesia. Intra-articular injections of local anesthetic [155] [156] or narcotic [157] [158] can provide effective analgesia, facilitating early discharge after ambulatory surgery.

Epidural analgesia with a combination of low-dose local anesthetic (e.g., 0.05% to 0.1% bupivacaine) in combination with a narcotic (e.g., 2-5 mug/mL fentanyl) provides excellent analgesia after lower extremity surgery. These can be administered as infusions (3-10 mL/h) with patient-controlled analgesia. The rates have to be adjusted to accommodate for changing pain patterns and accumulation of drugs. Nonsteroidal anti-inflammatory drugs can be used to augment the analgesia, [159] [160] although their use is not routinely recommended. [161] Higher doses are required after knee surgery than after hip surgery. Intrathecal infusions of bupivacaine are not recommended for postoperative pain control in orthopedic procedures. [162]

Effective analgesia with epidural infusions or peripheral blockade reduces narcotic requirements, provides better analgesia, reduces catabolism, [163] and results in improved rates of rehabilitation after total knee replacement. [164] [165] To optimize the potential advantage of the analgesia, early rehabilitation should be encouraged. [166]

There are several limitations to the use of catheter techniques for postoperative analgesia after orthopedic surgery. First, as stated earlier, their use is contingent on an effective pain service operating with the cooperation of the nurses and orthopedic surgeons. Second, these modalities must be used in conjunction with the perioperative management of thromboembolism. The risk of epidural catheters is increased when low-molecular-weight heparin is used, [167] [168] whereas there appears to be minimal risk with aspirin or warfarin. [169] At The Hospital for Special Surgery, almost all patients undergoing total hip or knee replacement receive postoperative epidural analgesia for 24 to 72 hours postoperatively. Patients are concurrently given aspirin or warfarin (Coumadin) after surgery in combination with foot pumps, foot exercises, and early ambulation. Low-molecular-weight heparin is not used in conjunction with epidural analgesia. No clinical epidural hematomas have been noted (>2,000 cases are performed annually at The Hospital for Special Surgery).

The final complicating factor relates to persistent lower extremity nerve injury. Patients who are at risk of developing a compartment syndrome should not have epidural infusions of local anesthetic or lower extremity nerve blocks because these may mask the early diagnostic signs (excessive pain, numbness, or muscle weakness). [170] [171] This applies particularly to patients with fractures of the tibia and fibula. [172] A related problem concerns the use of epidural analgesia in patients who are at risk of developing nerve injuries after surgery, particularly peroneal palsy after complicated total knee replacement. [173] [174] Patients with valgus deformities and those undergoing high tibial osteotomy are at risk of developing peroneal palsy after surgery. [175] If the palsy is diagnosed early, the knee can be flexed, bandages changed, and so on to limit injury to the nerve. An epidural infusion can delay the diagnosis, increasing the risk of permanent nerve damage. In these cases, it is preferable to avoid epidural analgesia altogether to avoid confusion and focus on early detection of potential neurologic deterioration. Epidural anesthesia and analgesia can be used to remove an infected prosthesis because the risk of epidural abscess in this setting is negligible. [176]

COMPLICATIONS OF ORTHOPEDIC SURGERY

Tourniquet Problems

Tourniquets are applied around upper or lower extremities to eliminate intraoperative bleeding and thereby provide better operative conditions. Unfortunately, the tourniquet is unphysiologic and is associated with a number of disadvantages (Table 60-7) .

Local Effects of Tourniquet Inflation

Mitochondrial partial pressure of oxygen decreases to zero within 8 minutes of inflating a tourniquet. Anaerobic metabolism then begins. Decrease of nicotinamide adenine dinucleotide and creatine phosphate stores in muscle occurs

TABLE 60-7 -- Physiologic Changes Caused by Limb Tourniquets

Neurologic effects
Abolition of somatosensory evoked potentials and nerve conduction occurs within 30 minutes.
Application for more than 60 minutes causes tourniquet pain and hypertension.
Application for more than 2 hours may result in postoperative neurapraxia.
Evidence of nerve injury may occur at a skin level underlying the edge of the tourniquet.
Muscle changes
Cellular hypoxia develops within 8 minutes.
Cellular creatine declines.
Progressive cellular acidosis occurs.
Endothelial capillary leak develops after 2 hours.
Limb becomes progressively colder.
Systemic effects of tourniquet inflation
Elevation in arterial and pulmonary artery pressures develops. This is usually slight to moderate if only one limb is occluded.
Systemic effects of tourniquet release
Transient fall in core temperature [186]
Transient metabolic acidosis
Transient fall in central venous oxygen tension (but systemic hypoxemia unusual)
Release of acid metabolites into central circulation (e.g., thromboxane)
Transient fall in pulmonary and systemic arterial pressures
Transient increase in end-tidal CO_2
Increased oxygen consumption [255]

over the next 30 to 60 minutes. [177] Cellular acidosis (pH < 6.5) rapidly ensues. [177] [178] Hypoxia and acidosis result in the release of myoglobin, [179] intracellular enzymes, and potassium. [180] Thromboxane is released locally with disruption of endothelial integrity. [181] Tissue edema develops if tourniquets are inflated more than 60 minutes; closure of ankle incisions may then be difficult. [182] The limb loses heat and may approach room temperature with time. Injury to muscle beneath the tourniquet may delay rehabilitation. [183]

Metabolic Response to Tourniquet Release

With deflation of the tourniquet and reperfusion of the extremity, a washout of metabolic byproducts occurs. [184] A decrease in core body temperature of 0.7°C typically occurs within 90 seconds of deflation of a lower limb tourniquet, [185] [186] and venous oxygen saturation [187] may fall 20 percent in 30 to 60 seconds. Increases in end-tidal carbon dioxide are typically noted, [188] but decreases in arterial oxygen saturation are infrequent unless significant pulmonary shunting exists. [189]

Hemodynamic Responses

The causes of hemodynamic responses are the initial inflation of the tourniquet, subsequent prolonged tourniquet inflation, and an immediate response after tourniquet deflation (Fig. 60-7) .

Figure 60-7 The hemodynamic effect of thigh tourniquet inflation (single bar) and deflation (double bar) in an 86-year-old man with hypertension undergoing total knee replacement. Note the changes in pulmonary and systemic artery pressures with both inflation and deflation of the tourniquet. The persistent elevation in pulmonary artery pressure after reinflation of the tourniquet after deflation (after third bar) may represent transient myocardial dysfunction.

Tourniquet Inflation

Inflation of the tourniquet and exsanguination of the limb result in an expansion of central venous blood volume and a theoretical rise in peripheral vascular resistance. In ordinary practice, this results in small increases in central venous or arterial pressures. [190] [191] However, patients with extensive varicose veins or poor ventricular compliance may experience considerable increases in pulmonary artery pressure (see Fig. 60-7) . Bilateral simultaneous tourniquet inflation of the lower extremities may result in significant elevations in central venous pressure. [190] [192]

Tourniquet Deflation

Deflation of the tourniquet with reperfusion of the ischemic limb is frequently associated with decreases in both central venous and arterial pressures. [193] These can be profound (see Fig. 60-7) and have resulted in cardiac arrests. [194] Contributing factors include sudden reduction in peripheral vascular resistance with pooling of blood in the extremity, acute blood loss, and the circulatory effects of the ischemic metabolites (e.g., thromboxane). [181]

Prolonged Inflation

Forty-five to 60 minutes after tourniquet inflation patients under general anesthesia may develop systemic hypertension. [195] The reason for this rather consistent timing is not entirely clear, but it may reflect a critical level of cellular ischemia in the muscle or nerve. Attempts to reduce blood pressure by deepening anesthesia are not always successful, and vasodilators such as hydralazine, nifedipine, or labetalol may be necessary. [195]

Tourniquet Pain

Patients receiving spinal or epidural anesthesia may develop a poorly defined aching or burning sensation in the

distal extremity about 1 hour after tourniquet inflation. [196] [197] Attempts to relieve "tourniquet pain" with intravenous narcotics are not always successful. Tourniquet pain may, however, be relieved by deflating the tourniquet for 10 to 15 minutes and then reinflating it. This correlates with correction of cellular acidosis. [198] Our experience has demonstrated that a complete brachial plexus block using long-acting local anesthetics is not associated with tourniquet pain for as long as 3 to 4 hours. Neither stellate ganglion nor intercostobrachial nerve blocks are effective in relieving tourniquet pain of the upper extremity. [199] These observations taken together suggest that tourniquet pain may be related in some manner to the quality or intensity of somatic neural blockade. [199] Experience with spinal anesthesia also suggests that the intensity of blockade may be more important than the anesthetic level in preventing tourniquet pain, because isobaric spinal anesthesia has a lower incidence of tourniquet pain than hyperbaric spinal anesthesia. [200]

Neurologic Consequences

Neurologic problems may occur when tourniquets are inflated for long periods (>2 hours) or excessive inflation pressures are used. A shear force is applied to nerve trunks at the edges of the tourniquet. [201] Within 30 minutes of inflating a tourniquet, nerve conduction ceases. [202] [203] This may reflect either axonal hypoxia or the direct result of extrinsic pressure on the nerves beneath the tourniquet. [204] In clinical practice, tourniquets should be deflated every 90 to 120 minutes to minimize the risk of postoperative neurapraxias. [178] [198] Alternatively, tourniquet pressure can be lowered to 250 mm Hg while maintaining systolic pressures at 90 to 100 mm Hg. This provides a pressure gradient of 150 mm Hg between the tourniquet and systolic pressure, more than enough to maintain an exsanguinated limb. Anesthesiologists who use regional anesthesia may be implicated when postoperative neurapraxias were in fact secondary to tourniquet injury. Recognition of the adverse effects of tourniquets has led many to perform surgery without a tourniquet [205] [206] [207] or to limit the duration of its use. [208]

Fat Embolism

A certain degree of lung dysfunction occurs in all patients after long bone fractures, but clinically significant fat embolism syndrome as such develops in only 10 to 15 percent of these patients. Signs include hypoxia, tachycardia, mental status changes, and petechiae on the conjunctiva, axilla, or upper thorax. Fat globules in the urine are nondiagnostic, but lung infiltrates seen on chest radiograph confirm the presence of lung injury. [209] [210] [211]

The pathophysiology of fat embolism represents capillary endothelial breakdown causing pericapillary hemorrhagic exudates most apparent in the lungs and brain. Pulmonary edema and hypoxemia occur as a result of pulmonary exudates. Hypoxia and areas of cerebral edema may account for the variable neurologic abnormalities seen.

The more severe cases of fat embolism involve fractures of the femur and tibia. Delays in fixation of bones and extensive reaming of the medullary canals contribute to perioperative morbidity [212] and to the severity of fat embolism syndrome. Efforts to surgically correct fractures early and minimize trauma to the bone marrow lessen the degree of fat/bone marrow embolism. Patients with coexisting lung injury are at additional risk of fat embolism. Evidence suggests that fat may pass to the systemic circulation through a patent foramen ovale [71] [72] or by transpulmonary passage. [74] The chemical composition of the fat may even contribute to this process. [213] For this reason, it is preferable to minimize pulmonary artery hypertension to reduce transpulmonary passage of fat and limit pulmonary endothelial transudation of fluid.

Treatment includes early recognition, oxygen administration, and judicious fluid management. Corticosteroids in large doses shortly after major trauma have been found to minimize the clinical presentation of fat embolism but are probably not necessary in most cases if oxygen therapy is administered. With appropriate fluid management, adequate ventilation, and the prevention of hypoxemia, outcome is usually excellent.

Deep Vein Thrombosis

Deep vein thrombosis is a common problem in orthopedics, [214] and pulmonary embolism is a major cause of postoperative mortality. [215] [216] [217] Rates are low after upper extremity surgery, spine surgery, [218] and knee arthroscopy (3%), [219] but more common after total hip replacement (30-50%), [220] [221] [222] total knee replacement (40-60%), [164] [223] [224] and trauma to the lower extremities (20-50%). Proximal deep vein thrombosis (popliteal femoral or iliac vessels) is more common after total hip replacement (10-20%) [221] [222] [225] and more likely to cause pulmonary embolism.

The emboli form during surgery during periods of venous stasis in the presence of surgical injury. During total knee replacement, there is absolute stasis with the tourniquet inflated, and on release of the tourniquet, acute increases in markers of coagulation can be detected in blood [226] (Fig. 60-8) (Figure Not Available) . Concurrently, thromboemboli can be detected in the right side of the heart on echocardiography. [227] During total hip replacement, obstruction of the femoral vein occurs during surgery on the femur. [79] [228] [229] When obstruction of the vein is relieved when the hip is relocated, an increase in markers of thrombosis is noted (Fig. 60-9) (Figure Not Available) and echogenic material can be seen on echocardiography. Efforts to reduce deep vein thrombosis during surgery should be directed during these phases of venous occlusion. Maneuvers include reducing the duration of surgery (surgeon's responsibility), [225] augmenting lower extremity blood flow during surgery to reduce venous stasis, [230] and finally, administering anticoagulants during this phase of surgery. [79] If 15 to 20 units/kg of unfractionated heparin is administered before surgery on the femur, fibrin formation can be suppressed and deep vein thrombosis rates reduced to 6%. [231]

Epidural or spinal anesthesia reduces deep vein thrombosis rates after total knee replacement by 20% (from 50% to 40%) [164] and after total hip replacement by approximately 40%. [232] [233] Deep vein thrombosis rates during total hip replacement performed with epidural anesthesia can be reduced to 10% with the concurrent use of low-dose epinephrine

Figure 60-8 (Figure Not Available) Fibrinopeptide A in patients receiving general or epidural anesthesia. Determinations were made before the induction of anesthesia (sample 1), 20 minutes after the start of the surgical procedure (sample 2), 45 seconds after deflation of the tourniquet at the end of surgery (sample 3) and 1 hour postoperatively (sample 4). Values are mean ± SEM. Note the increase in fibrinopeptide A after deflation of the tourniquet (sample 3) representing thrombosis in the leg while the tourniquet was inflated. *(From Sharrock et al [226])*

infusions. [225] [234] The mechanism of action of epinephrine is unknown, [235] but it does augment lower extremity blood flow during epidural anesthesia, thereby minimizing venous stasis. [230]

Postoperative epidural analgesia does not appear to provide additional benefit in reducing deep vein thrombosis rates. [223] Epidural infusion of 0.1% bupivacaine does not increase femoral venous blood flow, whereas simple flexion/extension exercises of the foot do increase extremity blood flow. [236] The benefit of epidural analgesia may be that it facilitates early ambulation, which is beneficial in prophylaxis of deep vein thrombosis.

There is a controversy about using epidural anesthesia and heparin. [167] The effects of heparin and epidural anesthesia on deep vein thrombosis prophylaxis are, in fact, additive. [233] [237] Deep vein thrombosis rates of 33% are noted using low-molecular-weight heparin with general anesthesia, whereas rates of 19% are noted with low-molecular-weight heparin and epidural anesthesia. [233] Perioperative anticoagulants are necessary if general anesthesia is used, but the question is whether low-molecular-weight heparin is useful (or in fact dangerous) when used in conjunction with conduction anesthesia. [167]

Postoperative modalities to reduce deep vein thrombosis that can safely be used in conjunction with epidural anesthesia include pneumatic compression boots, [238] foot pumps, [239] [240] foot exercises, [236] early ambulation, aspirin, and low-dose warfarin started the day after surgery. Anticoagulation is not generally recommended after knee arthroscopy or spine surgery. In high-risk cases, vena cava filters may be placed preoperatively.

Figure 60-9 (Figure Not Available) Changes in fibrinopeptide A and D-dimer in patients receiving saline (n = 12) or intravenous heparin (1000 units) (*n* = 11). Determinations were made before the epidural anesthetic (1), after implantation of the acetabular component--1 to 2 minutes before operating on the femur (2), 45 seconds after relocation of hip joint after the cemented femoral component had been inserted (3), and 1 hour postoperatively in the postanesthesia care unit (4). Patients received either intravenous heparin (1000 units) or saline immediately after insertion of the acetabular component (event 2). Note a suppression of fibrinopeptide A after insertion of a cemented femoral component in patients receiving heparin compared to saline (*P* = .006) (event 3), reflecting inhibition of thrombosis with heparin. D-dimer was not affected by heparin administration demonstrating that heparin did not suppress fibrinolysis. Values are mean ± standard error of the mean. *(From Sharrock et al [79])*

The role of the anesthesiologist in the prevention of deep vein thrombosis will change with a recognition of the role of anesthesia in the prevention of thrombosis and a realization that the thrombi form in the operating room rather than after surgery. Because they form during "our watch," anesthesiologists have an opportunity and a responsibility to prevent thrombi from forming.

PEDIATRIC ORTHOPEDIC ANESTHESIA PRACTICE

A subset of pediatric patients may have to undergo repeated hospitalization and orthopedic surgical procedures (Chs. 44 and 59) . These include children with cerebral palsy, congenital spine deformities, juvenile rheumatoid arthritis, osteogenesis imperfecta, epiphyseal dysplasia, and various forms of scoliosis. Many of these patients suffer from pain, disability, and social isolation. They therefore deserve additional care and sympathy as well as excellence of clinical practice to overcome sometimes formidable technical difficulties.

Cerebral Palsy

Children with cerebral palsy may present technical difficulties because of contractures that make intraoperative positioning difficult. Many of these children were born prematurely and suffer the residua of bronchopleural dysplasia with tracheomalacia, irritable airways, and residual lung dysfunction. In addition, they may develop recurrent aspiration due to gastroesophageal reflux. Hypothalamic dysfunction may be a component of the cerebral palsy, making perioperative hypothermia more likely.

The tracheas of patients with certain congenital deformities of the spine may be difficult to intubate for technical reasons (see Table 60-1) . Therefore, fiberoptic laryngoscopy (with pediatric equipment) or regional anesthesia may be necessary. Generalized ligamentous laxity of the cervical spine and atlantoaxial subluxation or stenosis of the foramen magnum may predispose these patients to spinal cord compression with potential quadriparesis during anesthesia.

Juvenile Rheumatoid Arthritis

Children with juvenile rheumatoid arthritis tend to develop fusion of the cervical spine and premature closure of epiphyseal plates, leading to hypoplastic mandible and fixed neck. Oral intubation of the trachea in this setting is essentially impossible. Regional anesthesia can also be complicated in this group because of a characteristic lumbar lordosis and an inability to abduct the shoulder. These factors make lumbar epidural and axillary blocks technically more difficult. Central venous lines may also be difficult to insert because an inability of the child to rotate the head is combined with the forward flexion of the neck. [241]

Regional Anesthesia in Pediatrics

Spinal, caudal, and lumbar epidural anesthesia, transarterial axillary blocks, or lower extremity blocks with the aid of a nerve stimulator may be performed in adequately sedated patients in whom cooperation to define paresthesias is not always obtainable [242] [243] (Chs. 44 and 59) . Regional approaches should be considered when surgery is relatively minor and of shorter duration. [244] Emergence from anesthesia is facilitated by optimal analgesia.

Chapter 61 - Anesthesia for the Elderly

Stanley Muravchick

INTRODUCTION

Although established at the beginning of this century, [1] the specialty of geriatrics has only recently been given the funding and attention appropriate to a medical discipline describing approximately one-fourth of the surgical population. Determining the age at which people, as a group, are considered "elderly" also remains an arbitrary process. Some descriptors of agedness use estimates of life expectancy, an actuarial term describing the average number of years of life members of a specific population may reasonably anticipate, given the environmental and socioeconomic constraints that prevail at time of birth. The determination of the percentage of a population having more or less than a given number of remaining years of life also quantifies the agedness of a population but, similarly, requires an arbitrary subdivision of society into two or more groups. In any case, both methods identify the norm rather than the extreme.

Life span is an idealized biologic standard describing maximal obtainable age. At approximately 110 to 115 years, it is a species-specific value that has not changed throughout history. It is the theoretical maximum lifetime of our biological machinery, a goal realized only when all vital organ systems function optimally in a benign environment. Life expectancy, in contrast, measures typical longevity under more realistic conditions, including the inevitable consequences of malnutrition, environmental pollution, trauma, and disease.

Despite great advances in medical therapeutics, nutrition, and concepts of fitness, a large percentage of our aging population will continue to have chronic disease. These persons will become a major health care burden, especially as life expectancy moves into the 9th decade of life. [2] Surgical intervention and the need for perioperative care and pain control will become even more commonplace in the elderly than it is now. This chapter provides an overview of current concepts regarding age-related physiologic changes in major organ systems, a summary of common age-related disease processes, and a review of the relationship of these factors to the management of anesthesia and perioperative risk.

GERONTOLOGY: THE STUDY OF AGING

For administrative and epidemiologic purposes, it is customary to consider the geriatric era as beginning at 65 years of age. However, some specialized applications classify persons 65 to 74 years of age as "elderly," those 75 to 84 years as "aged," and those 85 years and older as "very old." In the absence of disease, active "elderly" persons maintain adequate normal daily functioning without major changes in lifestyle and with only minor adjustment in the level of activity. As they become "aged," however, limitations in musculoskeletal strength, coordination, and quickness compel them to modify their daily routines dramatically. Favorable environmental, genetic, or perhaps socioeconomic circumstances ultimately determine who will survive to become "very old." In this chapter, however, the terms "elderly" and "geriatric" will be used in their most common sense--as synonyms for persons 65 years of age and older.

Aging is a progressive, universally prevalent physiologic process that produces measurable changes in the structure and decremental alteration of the function of tissues and organs (Table 61-1) . Changes that are not universal or that do not increase in severity or magnitude in proportion to chronologic age are probably not manifestations of aging but, rather, are usually signs or symptoms of age-related disease. Although the mechanism is not yet entirely understood at either a cellular or biochemical level, decreased cellular energy production due to deterioration of the mitochondrial genome, especially in cardiac and neural tissues,

TABLE 61-1 -- Summary of Anatomic and Functional Consequences of Aging on Body Tissues and Major Organ Systems

TISSUE/SYSTEM	ANATOMIC CHANGE	FUNCTIONAL CHANGE
Body composition	Loss of skeletal muscle and other lean tissue components, increased lipid fraction	Prolonged drug effects; decreased metabolism and heat production, decreased resting cardiac output
Nervous system	Loss of neuronal tissue mass, deafferentation, reduced central neurotransmitter activity	Decreased neural plasticity, decreased anesthetic requirement, impaired autonomic homeostasis
Cardiovascular system	Decreased elasticity, reduced beta-adrenergic responsiveness	Decreased cardiac and arterial compliance, decreased maximal heart rate and cardiac output
Pulmonary system	Increased thoracic stiffness, decreased lung recoil, reduced alveolar surface area	Reduced vital capacity, increased work of breathing, impaired efficiency of gas exchange
Renal/hepatic system	Decreased vascularity and perfusion, loss of tissue mass	Decreased drug clearance, inability to withstand salt or water loads
Blood and immune systems	Thymic involution, resorption of bone marrow	Decreased immune competence, loss of hematopoietic reserve

may play a fundamental role in the age-related decline of organ system capacity. [3]

Two general experimental designs have been used to evaluate the effects of aging. Cross-sectional studies investigate young and elderly populations or "cohorts" simultaneously. They are easy to design and execute, but results may be distorted by the subtle manifestations of age-related disease or cohort-specific environmental factors (such as nutritional deficiency or chronic environmental contamination). In effect, cross-sectional studies may demonstrate differences between young and older adults that are real but actually not caused by aging itself. In contrast, longitudinal studies obtain repeated measurements of specific variables over long periods of time in an aging population. Investigators can thereby eliminate from final study those subjects who ultimately show obvious signs of age-related disease. The study group, in effect, acts as its own control because all subjects are from the same cohort. Although longitudinal studies are difficult and expensive to perform and are administratively complex, the data they provide are inherently superior to data obtained from cross-sectional studies.

Analysis of data from the Baltimore Longitudinal Study of Aging, Framingham study, or other longitudinal studies suggests that the difference between maximal and basal organ function inevitably declines, slowly at first during middle adulthood and then more rapidly during the geriatric era (Fig. 61-1) . In fact, most of the recent dramatic improvement in our understanding of the physiology of aging has come from improved experimental design and from the opportunity to review established data and to exclude investigations describing age-related changes due to processes other than aging itself. There are marked differences between individuals with regard to their maximal capacities at somatic maturity, near the end of the 3rd decade of life, as well as in the rate at which those capacities decline. This explains the well-known clinical phenomenon in which some

Figure 61-1 Geriatric individuals who appear to be physiologically "young" or "old" have lesser or greater rates of decline, respectively, than average, but they may also have significantly different maximal capacities than young adults. Organ system functional reserve is defined as the difference between maximal (broken lines) and basal (solid line) function.

elderly patients appear to be "physiologically young" whereas others of the same age seem much less robust because of lesser organ capacity. However, loss of organ system functional reserve, that is, the difference between maximal and basal organ function, remains a constant hallmark of physiologic processes of aging.

Because physicians realize that physiologic or functional age is not always consistent with chronologic age, many attempts have been made to identify specific anatomic or biologic markers such as protein structure that can distinguish the two. However, the primary value of these biologic markers seems to be in quantitating the effectiveness of "antiaging" therapies such as severe restriction of caloric intake or the use of antioxidants to reduce formation of free radicals. Functional variables have also been used, singly or in combination, with inconsistent results in efforts to distinguish between chronologic and physiologic age. For clinical purposes, however, no parameter has been shown to be more valid or more useful than chronologic age in predicting age-related changes in organ systems or the proximity of death. [4]

/das/book/view/29494766/875/675.html

BODY COMPOSITION AND METABOLISM

Drug disposition and excretion are largely determined by body composition and the adequacy of hepatic and renal function. The extent to which aging alters the pharmacokinetics of anesthetic agents and adjuvant drugs reflects, in large part, the changes in the quality and quantity of body tissues that occur after somatic maturity but before complete senescence (approximately the 8th decade). By 60 years of age, for example, body weight is approximately 25 percent higher in men and 18 percent higher in women than in mature young adults. After 60 years of age, however, body weight decreases rapidly, returning to values comparable with, or somewhat below, those of young adulthood. In contrast, body composition changes progressively and irreversibly throughout the middle adult years and into the geriatric era. Aging steadily increases the relative ratio of lipid to aqueous body tissues (Fig. 61-2) and thereby increases the fraction of total body mass functioning as a reservoir for anesthetics and other lipid-soluble drugs.

As they age, women undergo a particularly dramatic increase in total body lipid. Simultaneously, however, osteoporosis produces marked loss of bone and there is a significant reduction of intracellular water that reflects the attrition of metabolically active tissues and other components of lean body mass, with little net overall change in total body weight. Elderly men, on the other hand, undergo a more generalized, multicompartmental loss of tissue mass and experience moderate reductions of both adipose tissue and bone mass. Unlike aging women, aging men also have a dramatic contraction of both intracellular and interstitial water, owing to atrophy (approximately 6 kg) of skeletal muscle mass. However, these changes in total body water in men may be due, at least in part, to subclinical age-related hypertensive disease. [5]

All elderly patients have a virtually universal, progressive decrease in their ability to handle a glucose load. Healthy persons older than 45 years of age require 90 to 95 minutes for return to fasting glucose levels after a 25-g intravenous

Figure 61-2 Body fat increases throughout the middle adult years, but in physically active older men (left) body weight has declined by the geriatric era as a result of the loss of lean tissue mass and subsequent contraction of total body water (cross-hatched areas). In contrast, older women (right) typically experience little change in total body weight because they have a more persistent trend of increasing body fat (diagonal lines) that offsets resorption of skeletal elements (open bars) and loss of lean tissue mass.

glucose challenge; their younger counterparts require, on average, only 65 minutes. The mechanism of glucose intolerance in the elderly is probably insulin antagonism or impairment of insulin function because there is no consistent evidence suggesting decreased rates of insulin secretion or inappropriate timing of insulin release in response to a glucose load. The age-related decrease in lean body mass, tissues that provide storage for carbohydrates, may also be a factor. Although it has not been demonstrated that hyperglycemia is more common or more severe in elderly patients, inability to handle carbohydrate loads, whatever the cause, suggests that elderly patients should not be given large amounts of carbohydrates intravenously as part of perioperative fluid management.

Other functional consequences of loss of muscle tissue are a 30 to 50 percent decrease in maximal oxygen consumption in physically active men and highly significant reductions in resting oxygen consumption in both men and women. There is progressively increasing variability in aerobic capacity between older subjects, although many older athletes are capable of impressive rates of maximal oxygen consumption that in some cases may equal those of sedentary adults 40 years their junior. Nevertheless, basal resting metabolic activity decreases in direct proportion to the age-related attrition of lean tissue mass. Not surprisingly, production of body heat declines in a parallel fashion, contributing to a reduced ability to maintain core temperature in cold environments such as an operating room. [6] In fact, despite normal hypothalamic thermostatic set-points, the intraoperative and postoperative core body temperatures of geriatric patients frequently fall to values below those seen in their young adult counterparts, and rewarming is significantly slower. [7]

Plasma volume is a major determinant of "alpha-phase" pharmacokinetics that describe the molecular aspects of drug redistribution from plasma to various well-perfused compartments immediately after intravenous injection. Plasma volume has long been assumed to decrease with age in a manner similar to that for intracellular water. On the contrary, however, it is now known to be well maintained in healthy and physically active men and women. Many of the classic pharmacokinetic studies of aging demonstrated reduced initial volumes of drug distribution in the elderly because the data were obtained from small numbers of hospitalized patients. Such results are not representative of the elderly population at large, however, although in the perioperative setting many elderly patients indeed have reduced initial distribution volumes for injected drugs because they are bedridden, deconditioned, chronically ill, or hypertensive. Also, they may be receiving diuretics or other drugs having disruptive effects on blood volume homeostasis.

The injection of anesthetic drugs according to a standard dosage schedule based solely on total body weight may explain, at least in part, the higher than expected drug concentrations widely noted during the alpha phase in pharmacologic studies of the elderly. This factor may explain, at least in part, the clinical observation that older adults have an increased sensitivity to anesthetic drugs. [8] Nevertheless, considerable controversy exists as to which drugs commonly used in anesthetic practice truly have altered pharmacodynamics in the elderly and only give the appearance of increased potency because of these age-related changes in early-phase pharmacokinetics. [9] However, with the exception of meperidine, decreases in serum albumin and reduced protein binding clearly have little overall effect on the bioavailability of anesthetic and adjuvant drugs. [10] Similarly, age does not appear to affect absorption of drugs administered orally, a practice growing in frequency because of the increase in outpatient anesthesia.

BLOOD FUNCTIONS

In the absence of disease, aging produces little effect on circulating red blood cell mass, white blood cell count, the number or function of platelets, or coagulation. [11] Hypercoagulability and peripheral thrombosis is common in older adults with vascular and metabolic disease but does not appear to be related to aging itself. Total bone marrow mass and spleen size fall progressively with increasing age, reducing the hematopoietic response to imposed anemia. Erythrocyte fragility increases, although not enough to decrease erythrocyte life expectancy *in vivo.*[12] In any case, clinically significant anemia or disorders of hemostasis in the elderly are always due to disease and not to physiologic processes of aging. In contrast, the obvious susceptibility of even healthy elderly patients to life-threatening infection does imply that aging depresses the selectivity and the effectiveness of immune responses. This decrease in immune responsiveness is almost certainly related to the anatomic involution of the thymus gland that begins during young adulthood and to the altered function of T lymphocytes. [13] Thymic hormones also disappear rapidly after adolescence. However, the few studies of adrenocortical and endocrine functions that have been done indicate that the neuroendocrine response to stress is generally intact or only modestly compromised in geriatric subjects as compared with young adults. [14] [15]

HEPATIC FUNCTION

By the age of 80 years the size of the liver usually declines by as much as 40 percent (Ch. 17) . [16] Because splanchnic blood flow decreases in proportion to the loss of tissue mass, the decrease in hepatic blood flow is significant, even when expressed as a percentage of cardiac output. Thus, aging alters the perfusion patterns of major organs and the relative distribution of cardiac output. Functional indices confirm the assumption that loss of hepatic mass significantly impairs hepatic function. For example, after the 7th decade of life, even healthy older persons who have no other evidence of hepatic dysfunction produce sulfobromophthalein sodium (Bromsulphalein) retention test results in the abnormal range. Although elderly men often have low plasma cholinesterase activity, [17] both microsomal and nonmicrosomal enzyme activity is virtually the same in hepatic tissue specimens (normal liver histology confirmed by biopsy) taken from young and elderly adults. This suggests that in the absence of disease there is probably little qualitative change in hepatocellular enzymatic function with advancing age. [18]

However, some subtle but important gender-specific metabolic changes may occur within this organ system, especially those involved in oxidative phase I forms of drug metabolism, because elderly women maintain normal rates of hepatic clearance for several of the benzodiazepines more frequently than do men. [19] Whatever the true nature of age-related enzymatic effects, it is the quantitative loss of functional hepatic tissue and subsequently reduced liver perfusion that appear to be most important in the marked age-related decrease in the clearance from plasma of opiates, barbiturates, benzodiazepines, propofol, etomidate, most nondepolarizing relaxants, and other drugs requiring hepatic biotransformation.

RENAL FUNCTION

As in virtually all major organs, most of the effects of aging in the kidney are caused by tissue atrophy (Ch. 18) . [20] Maximum young adult bilateral renal tissue mass reaches 270 g, but about 30 percent of that is lost by the 8th decade. There is a parallel decline in the total number of nephron units. Loss of tissue mass would be even greater if parenchymal and cortical atrophy were not offset to some extent by an increase in fat and by diffuse interstitial fibrosis. Aging also compromises renal function through its profound effects on renal vasculature. Total renal blood flow decreases approximately 10 percent per decade in the adult years, although the majority of the loss occurs in the renal cortex and the renal medulla is largely spared. Microscopic examination confirms the disappearance of the kidney's functional units with age: as many as one-half of the glomeruli present in young adults may be gone or rendered nonfunctional by 80 years of age. Glomerular sclerosis also produces anatomic, and perhaps functional, continuity between afferent

Figure 61-3 Data from studies of healthy adult men of various ages show that average serum creatinine concentrations (solid circles, far right axis) stay relatively constant throughout adulthood because they reflect an equilibrium between the declining daily cre-atinine load to be excreted (open diamonds, right axis) and the age-related compromise of glomerular filtration as estimated by the rate of creatinine clearance (solid squares, left axis).

and efferent arterioles, further impairing the efficiency of renal filtration.

Overall, renal plasma flow (RPF) declines more sharply than would be expected solely from the change in renal tissue mass because renal vascular fine structure is especially compromised. However, glomerular filtration rate (GFR) decreases at the rate of 8 mL/min/1.73 m^2 /decade, more slowly than RPF because of compensatory increases in filtration fraction. Creatinine clearance declines about 40 percent between the years of somatic maturity and senescence, yet measurements of serum creatinine concentration remain within normal guidelines in the elderly despite impaired GFR because of the marked atrophy of skeletal muscle mass, particularly in men, that progressively reduces creatinine load (Fig. 61-3) . Although the residual renal function in elderly patients is sufficient to avoid gross azotemia or uremia when demands are basal, the renal functional reserve needed to withstand extreme imposed water and electrolyte imbalance is minimal.

The elderly patient also has a lower responsiveness to antidiuretic hormone, decreased maximal absorption rate for glucose, impaired ability to conserve sodium or concentrate urine, and functional hypoaldosteronism. Loss of lean body mass also reduces total body stores of exchangeable potassium and predisposes to iatrogenic hypokalemia. Elderly surgical patients do not require a special fluid replacement schedule but do require meticulous calculation and monitoring of fluid and electrolyte balance.

Reduced renal vascularity and redistributed cardiac output in the elderly also imply increased susceptibility to renal ischemia. Acute renal failure is, in fact, responsible for at least one-fifth of perioperative deaths among elderly surgical patients. Among geriatric patients who undergo surgery, 30 percent have preexisting renal dysfunction. The prevalence of renal disease not only increases perioperative risk of acute renal insufficiency or failure but also affects the duration of action of many anesthetic and adjuvant drugs. A major pharmacokinetic consequence of age-related changes in renal function is prolongation of the elimination half-time of anesthetic drugs and any metabolites requiring renal clearance (Table 61-2) . In many cases, even though agents such as metocurine are predominantly water soluble and therefore dispersed in a smaller steady-state volume of distribution, the advantage of having a smaller volume to clear is more than offset by the reduction in the rate of clearance. Thus, excretion of these drugs still takes longer in elderly patients than in younger patients.

CENTRAL NERVOUS SYSTEM

Although the age-related changes in both structure and function of the human brain and nervous system are well known, [21] their interrelationship is less well understood (Ch. 19) . As for many organ systems, uncertainty persists because of the inability to distinguish the effects of aging from those of age-related disease. For example, neurofibrillary tangles were once considered the nonspecific manifestations of the aging process within the nervous system. They are now known to be the sequelae of a pathologic deficiency of acetylcholine in the cerebral cortex, clinically manifested as Alzheimer disease. Other "senile" forms of neurologic dysfunction, in particular those with a neurohumoral basis, may also turn out to be age-related diseases rather than inevitable characteristics of the aging nervous system.

Nevertheless, a number of anatomic changes can be considered to be unequivocal hallmarks of aging of the central nervous system (CNS). For one thing, aging reduces brain size. At autopsy, the average weight of the 80-year-old brain is approximately 18 percent lower than that of the 30-year-old brain. Noninvasive, radiographic estimates confirm that the portion of the intracranial volume occupied by brain tissue decreases from 92 to 87 percent over these 5 decades. [22] The most rapid decrease in brain mass (and the greatest

TABLE 61-2 -- Major Effects of Aging on the Pharmacology of Anesthetics and Adjuvant Drugs

	AGE-RELATED CHANGES IN	
	PHYSIOLOGY	***PHARMACOLOGY***
Induction agents	Decreased volumes of distribution	Reduced dose requirement
Thiopental	CNS changes	Prolonged drug effect
Etomidate	Altered distribution of cardiac output	
Propofol		
Opiates	Decreased volumes of distribution	High initial plasma levels
Morphine	Decreased hepatic blood flow	Prolonged drug effect
Fentanyl	CNS changes	Reduced dose requirement
Alfentanil		
Benzodiazepines	Decreased liver mass and blood flow	Prolonged drug effect
Chlordiazepoxide	CNS changes	Reduced dose requirement
Diazepam		
Alprazolam		
Neuromuscular blocking drugs	Disseminated neurogenic atrophy	Same or increased dose requirement
(Nondepolarizers)	Decreased hepatic/renal function	Prolonged drug effect
(Succinylcholine)	Decreased plasma levels of cholinesterase in men	Reduced dose requirement in men
Inhaled anesthetics	CNS changes	Reduced dose requirement

CNS, central nervous system.

compensatory increase in cerebrospinal fluid volume) appears to occur after the 6th decade of life. Whether viewed grossly or radiographically, the cerebral sulci of the very old, even those free of disease, are frequently as much as 35 percent larger than those of young adults. In effect, aging produces a form of low-pressure hydrocephalus.

Most of this tissue shrinkage reflects loss of neurons, not atrophy of the supportive glial cells, which normally constitute almost one-half of total brain mass. Across the entire span of life, the rate of neuronal attrition is 50,000 cells per day, the initial neuron "pool" being approximately 10 billion. This average figure may be misleading, however, because neuronal loss is highly selective by region and by functional role, and the actual rate of loss may vary greatly at different ages. The most highly specialized neuronal subpopulations, particularly those involved with synthesis of neurotransmitter substances, undergo the greatest degree of age-related attrition. Of the neurons in the cerebral and cerebellar cortices, thalamus, locus ceruleus, and basal ganglia, for example, 30 to 50 percent disappear by the end of the 9th decade of life. Age-related loss of neuronal tissue and reduced complexity of synaptic interconnections have been confirmed by microanatomic analysis and radiographically as a decrease in brain tissue radiodensity.

On the other hand, the higher, more complex aspects of "crystallized intelligence" such as language skills, aesthetics, and personality do not appear to decline with increasing age. Despite the long-established bias that aging is associated with an inevitable "senile" deterioration of mental function, most recent studies suggest that storage of information, comprehension, and long-term memory are well maintained in healthy persons through even the 8th decade. However, some decrease in short-term memory, visual and auditory reaction time, and other aspects of "fluid intelligence" that require immediate processing or rapid retrieval of information probably does inevitably occur. In general, throughout the adult life span nervous system functioning is maintained at levels close to those seen at somatic maturity in young adults. Anatomic and functional redundancy compensate for the progressive deterioration of cellular elements and the breakdown of the complex system of neuronal interconnections making up the neuropil.

The intrinsic mechanisms that couple cerebral electrical activity, metabolism, and blood flow remain similarly intact in healthy elderly persons. [23] Although total brain blood flow does decrease approximately 20 percent from maximal values seen in the young adult, this change occurs in proportion to age-related changes in neuronal density. Regional cortical and subcortical adjustments to local metabolic demands occur in the same manner in the elderly as in young adults. Autoregulation of cerebrovascular resistance in response to changes in arterial blood pressure is also well maintained, and the cerebral vasoconstrictor response to hyperventilation remains intact in normal brain tissue. [24] However, patients who have risk factors for stroke and atherogenesis have lower cerebral vasomotor reactivity, especially in response to hypoxia. Still, intentional hyperventilation and the customary relative blood pressure perfusion guidelines used for neurosurgical anesthesia are probably appropriate and effective regardless of patient age, at least for persons free of cerebrovascular disease. Clinically, the rarity of intraoperative stroke despite inevitable marked fluctuations in blood pressure and respiratory parameters supports experimental data indicating that aging is not inevitably associated with "hardening of the

arteries" and inadequate cerebral perfusion. In the healthy elderly individual, decreased cerebral blood flow is a consequence, rather than a cause, of brain tissue atrophy.

Coincident with neuronal loss in specialized areas of the aging brain are generalized depletions of dopamine, norepinephrine, tyrosine, serotonin, and perhaps other neurotransmitters. Simultaneously, there is increased activity of

---

catabolic neurotransmitter enzymes such as monoamine oxidase and catechol *O*-methyltransferase. In the aging brain, the upregulation or increase in number of neurotransmitter receptor sites that appears in young neural tissues in response to any reduction in neurotransmitter activity is less vigorous. CNS "plasticity," the ability to reroute neuronal pathways to compensate for neural injury, is still present but slower and less complete than in children or young adults, and therefore recovery from stroke or traumatic injury is slower and often less complete in the elderly. In addition, receptors for dopamine may have a reduced affinity for neurotransmitter molecules. [25]

PERIPHERAL NERVOUS SYSTEM AND NEUROMUSCULAR FUNCTION

Aging produces a generalized increase in the thresholds for virtually all forms of perception, including vision, hearing, touch, sense of joint position, smell, and peripheral pain and temperature responses (Fig. 61-4) (Ch. 20) . This process of progressive deafferentation may be accelerated by degenerative changes at specialized sense organs. For example, the decrease in the density of pain-sensing Meissner corpuscles in the skin of elderly persons is almost exponential. However, anatomic changes at more central sites are also responsible--specifically, simultaneous attrition of afferent conduction pathways in the peripheral nervous system and spinal cord, as well as reduced velocity and amplitude of electrical transmission in the remaining pathways.

A corresponding deterioration of electrical conduction occurs along motor pathways. The velocity of peripheral motor nerve conduction decreases by approximately 0.15 m/s/y. Impairment of corticospinal transmission may also increase the time between intention and onset of voluntary motor activity. Dynamic muscle strength, control, and the ability to maintain steadiness in the extremities is 20 to 50 percent lower by 80 years of age, although isometric muscle strength is well maintained. Aging skeletal muscle undergoes no dramatic or generalized changes and its enzymatic machinery remains relatively intact, but the neuromuscular junctions show thickening of the postjunctional membrane and spread beyond the usual end-plate areas. [26] Motor end-plate proliferation and the extrajunctional spread of atypical cholinergic receptors are generally regarded as signs of disseminated neurogenic atrophy. This may occur gradually but progressively in older adults because failing proximodistal protoplasmic transport in aging motor neurons reduces the myotrophic support normally provided to skeletal muscle. The increase in the number of cholinergic receptors at the end plate and surrounding areas might compensate for the age-related decline in the number and density of motor end-plate units. However, sensitivity to competitive neuromuscular blocking drugs probably does not decrease significantly. The increased sensitivity to succinylcholine seen in some elderly men is due to reduced plasma cholinesterase enzyme concentrations and not to changes at the neuromuscular junction itself.

AUTONOMIC FUNCTION

Although neurons in sympathoadrenal pathways, as in the rest of the peripheral nervous system, undergo attrition and fibrosis and adrenal mass decreases 15 percent by 80 years of age, plasma levels of norepinephrine, both at rest and in response to exercise-induced stress, are two to four times higher in the elderly than in young subjects (Chs. 14 and 16) . [27] Epinephrine levels are highly variable and do not demonstrate a clear-cut relationship to age itself. In any case, in older adults high catecholamine levels may not be clinically apparent because they are masked by the marked reduction in autonomic end-organ responsiveness associated with aging. Laboratory studies have confirmed that there is a significant impairment of the ability of beta-adrenergic agonists to enhance the velocity and force of cardiac contraction or to increase the rate of electrical discharge of excitable tissues. Elderly human subjects clearly have lower maximal chronotropic responses to isoproterenol, and vascular relaxation mediated by beta-adrenergic receptors decreases in the elderly. [28] Mechanisms possibly accounting for this endogenous beta-blockade of aging include attrition of receptors, reduced affinity for agonist molecules, and impairment of adenylate cyclase activation, perhaps because of decreased cell membrane fluidity. Pharmacologic data demonstrating a decreased affinity of the beta receptors to

Figure 61-4 Aging increases the thresholds, represented here on a logarithmic scale, for the perception of or autonomic response to all forms of sensory and afferent input.

both agonist and antagonist molecules suggest that qualitative, rather than quantitative, changes are responsible.

The complex, integrated autonomic reflex responses that maintain cardiovascular homeostasis in young adults progressively and universally decrease in elderly persons. Baroreflex responsiveness, the vasoconstrictor response to cold stress, and beat-to-beat heart rate responses after postural change are less rapid in onset, smaller in magnitude, and less effective in stabilizing blood pressure in elderly subjects than in young adults. [29] The autonomic nervous system of the elderly patient is, in effect, underdamped and less tightly self-regulated. Therefore, anesthetic agents that disrupt end-organ function or reduce plasma catecholamines, or techniques such as spinal or epidural anesthesia that produce rapid sympathectomy, are more likely to cause hypotension in elderly surgical patients than in young patients. The tendency of this fragile balance to be "disintegrated" will be even more obvious if endogenous autonomic activity has been very high before surgery to compensate for significant end-organ disease, a situation common, for example, in patients with congestive heart failure.

INFLUENCE OF AGE ON DRUG DISTRIBUTION AND METABOLISM

Many drugs used in the practice of anesthesia undergo biotransformation before elimination from the body. Metabolism is extensive for barbiturates, benzodiazepines, narcotic analgesics, and intravenous agents including ketamine, etomidate, and propofol: only minor quantities of such drugs are excreted in their intact form. Enzyme systems responsible for drug metabolism are present in many tissues, the liver being the most important source of those that metabolize drugs used in anesthesia. Of particular significance are the activities of the microsomal mixed function oxidase enzyme system, which catalyzes phase I reactions (e.g., dealkylation and ring hydroxylation) and the enzymes responsible for phase II reactions (conjugation).

Reductions in hepatic blood flow and liver tissue mass would decrease the clearance rates of drugs exhibiting flow-dependent hepatic metabolism. Drugs dependent on hepatic blood flow for metabolism that have high clearance rates include morphine, meperidine, fentanyl, sufentanil, methohexital, ketamine, etomidate, propofol, and possibly midazolam. Although, in theory, clearance of such drugs should decrease dramatically in elderly patients, only limited clinical or experimental evidence exists to support the general conclusion that aging itself inevitably leads to decreased rates of metabolism of such drugs or of other agents used in anesthesia. Several factors are responsible for the lack of consistent information regarding changes in drug metabolism with aging in humans. These include the following:

1. The general problem of wide interindividual variations in rates of drug metabolism, especially those due to gender, race, and ethnic background.
2. Complexities in the metabolic pathways for certain drugs (e.g., benzodiazepines) and the pharmacologic activity of their primary and even secondary metabolites.
3. The difficulty of including the possible role of extrinsic factors (e.g., hormones, alcohol, and tobacco) that also affect drug metabolism.
4. Deficiencies of experimental study design, in particular, a lack of suitable young adult control subjects.

Of even more fundamental concern is the utility of pharmacokinetic data organized in the form of a classic multicompartment model for predicting the clinical effects of anesthetic agents that are given intravenously. It is unclear whether conclusions drawn from studies of the effect of aging on steady-state drug concentrations can reliably anticipate the effects of age on the timing or on the intensity of drug effects within the CNS or at other tissue effector sites. For thiopental, propofol, and perhaps many other drugs used in anesthetic practice, termination of clinical drug effect occurs primarily as a result of the rapid intercompartmental transfer and redistribution rather than as a direct consequence of the eventual molecular biotransformation or excretion of the injected agent. Therefore, rate constants for intercompartmental drug transfer, although these are rarely provided in clinical pharmacokinetic studies, must be compared to predict the behavior of these drugs in a typical clinical setting.

Consequently, traditional pharmacokinetic parameters such as steady-state drug distribution volume or metabolic clearance may be more appropriate for describing the long-term disposition of drug molecules than for analyzing the effect of aging on anesthetic drug effects. There is growing interest in replacing pharmacokinetic parameters derived from simple compartmental models with a more complex but realistic analysis of context-sensitive pharmacokinetics that pays special attention to the movement of drugs between compartments. [30] Little is known about the effect of aging on rate constants for intercompartmental drug transfer, however. There is even controversy as to whether the "correct" number of compartments needed for a useful model can be established. The high plasma concentrations of morphine and fentanyl seen in older adults immediately after intravenous injection [31] were once assumed to be due to decreased plasma volume, but with blood volume now shown to be well maintained in healthy older adults, they may actually reflect more complex age-related changes in alpha-phase pharmacokinetics that determine drug molecule redistribution from the central compartment. [32]

ANALGESIC AND ANESTHETIC REQUIREMENT

Although simple age-related changes in the structure and function of the nervous system are measurable and consistent, their net effect on generalized, pain-related neurologic function in healthy elderly persons is still controversial (Chs. 8 to 10 and 29) . The available data do not support the conclusion that decreasing afferentation in the form of loss of receptors and the dropout of peripheral nerve fibers is necessarily associated with a clinically significant increase in pain threshold or a decreased need for analgesic or local anesthetic agents. The importance of amplification and selectivity of afferent input within the spinal cord, thalamus, and perhaps other sites within the aging nervous system has not been studied adequately. In fact, evidence suggests that

Figure 61-5 With advancing age, anesthetic requirement for unsedated human subjects expressed as relative median effective dose (ED_{50}) or its inhalational equivalent, minimum alveolar concentration (MAC), is progressively and consistently reduced. Despite many differences in chemical structure and clinical pharmacology, anesthetic requirement declines both for inhalational (C,D,H,I,S) and for intravenous (T) anesthetics.

elderly patients have elevated thresholds for discrete, superficial discomfort but reduced thresholds for severe or visceral pain, or for pain associated with illness or with incapacitating injury likely to lead to reduced independence. [33]

The consequences of aging of the nervous system on anesthetic requirements are less complex. Anesthetic requirement is typically quantified by the minimum alveolar concentration (MAC) of an inhaled anesthetic or the median effective dose (ED_{50}) of an intravenously administered anesthetic that is required to abolish response to a stimulus in 50 percent of subjects. With increasing age, the relative MAC or ED_{50} requirement decreases progressively. [34] [35] [36] This decrease occurs for all anesthetic drugs, even the latest inhalational agents such as desflurane and sevoflurane (Fig. 61-5) , and can be as great as 30 percent for those patients who are well into the geriatric era. Although the mechanism for this increasing sensitivity to anesthetic agents is unknown, its remarkable consistency suggests that it is a basically physiologic, rather than pharmacologic, process. In fact, the rate of change in anesthetic requirement parallels the rate of loss of cortical neurons and the reduction in neuronal density within the cortex, the decreases in absolute cerebral metabolic rate and absolute cerebral blood flow, and the age-related reduction in brain neurotransmitter activity.

CARDIOVASCULAR FUNCTION

Analysis of cardiovascular function in the elderly requires careful identification of disease-related conditions. Cardiovascular disease is present in 50 to 65 percent of the elderly, and coronary disease has been found in even completely symptom-free septuagenarians. For the surgical population in general, approximately 10 percent of all perioperative deaths are directly related to cardiovascular abnormalities. Cardiovascular disorders, in fact, account for one-half or more of all the mortality in the geriatric subpopulation (Fig. 61-6) . Geriatric surgical patients have higher rates of both overt and subclinical disease than those found in the surgical patient population as a whole. In one classic study, preoperative pulmonary artery catheterization of deconditioned elderly patients demonstrated that fewer than 15 percent were physiologically normal with respect to hemodynamic and respiratory function, and almost 25 percent had severe and intractable functional abnormalities increasing the likelihood of perioperative death. [37]

In the absence of obvious disease, the major anatomic changes seen in the aging human heart are primarily an increase in ventricular wall thickness and the increasing severity of myocardial fibrosis and valvular fibrocalcification. Therefore, as ventricular compliance decreases, relatively small changes in intravascular volume or venous capacitance become increasingly important determinants of circulatory stability. In effect, aging makes patients volume-dependent yet volume-intolerant because increased cardiac chamber stiffness in elderly patients means that their hemodynamic functioning is optimal only within a narrow range of end-diastolic pressure and volume. Age-related increases in large artery stiffness also increase impedance to the ejection of stroke volume and elevate the aortic systolic pressure associated with any given stroke volume. These higher aortic pressures may then cause reactive hypertrophy and further stiffening of the left ventricular wall. Finally, loss of arterial elasticity also produces a widening of arterial pulse pressure and reduction of the diastolic pressure that largely determines coronary artery perfusion. [38]

However, overall integrated cardiovascular function changes less than would be expected from the structural alterations of the heart that are associated with aging. Classic data indicated a dramatic and progressive decrease in cardiac index that was almost linear with age. However, these data were obtained from deconditioned elderly persons who had a variety of cardiovascular diseases, and therefore, in retrospect, they appear to demonstrate the consequences of age-related disease and not the effects of aging itself on the healthy aging cardiovascular system. There is recent evidence [39] that exercise training can significantly ameliorate the cardiovascular stiffness that is generally thought of as a hallmark of the effects of aging on cardiovascular structure

Figure 61-6 The components of mortality in the elderly population, 1988 data reported in 1991 by the National Center for Health Statistics. Epidemiologic analysis suggests that the probability of death from cardiac, vascular, and pulmonary causes, as well as death from accident, all increase dramatically in the oldest fractions of the geriatric age group, with malignancy and metabolic disorders playing a lesser role.

and function. In fact, more recent studies confirm that the resting cardiac index of fit, active elderly persons is reduced only in direct proportion to their reduced skeletal muscle mass and metabolic rate associated with the inevitable reduction of lean tissue mass.

Exercise-trained older men and women achieve and maintain impressively high levels of cardiac output and maximal oxygen consumption. [40] Nevertheless, aging imposes a ceiling on maximal cardiac output that reflects both reduced maximal heart rate and the age-related prolongation of time required for both myocardial contraction and relaxation. [41] Maximal cardiac output decreases approximately 1 percent per year starting from middle adulthood. Both at rest and at moderate levels of exercise, an increase in left ventricular diastolic volume in response to augmented preload compensate for slower heart rate in elderly persons. Thus, stroke volume, and therefore cardiac output, increases appropriately in response to aerobic demand because of the Frank-Starling mechanism rather than by tachycardia or augmentation of ejection fraction through stimulation of beta-adrenergic agonists characteristic of children and young adults. [42] However, because aging produces ventricular hypertrophy and decreased chamber elasticity, diastolic ventricular filling is slower and more dependent on atrial contraction. Therefore, loss of sinus rhythm and the atrial "kick" it produces severely compromises cardiac output in older adults, and diastolic dysfunction is a far more common cause of hemodynamic insufficiency than in young adults. [43]

VENTILATION AND PULMONARY FUNCTION

The effects of age on the manifold functions of the lung have been comprehensively described (Chs. 15 and 24) . [44] Lung tissue elasticity is the anatomic property most affected by age in this system. With advancing age there is qualitative deterioration of lung elastin rather than simple loss of elastic tissue as had once been thought. In any case, aging is associated with an inevitable and progressive loss of lung recoil, making aging lungs more compliant but unfortunately also reducing the tethering effect that normally maintains patency of the small airways and helps to ensure appropriate and homogeneous distribution of inspired gases. In addition, the breakdown of alveolar septa reduces the total alveolar surface area available to participate in molecular gas exchange. As a result, the elderly patient has progressive increases in both anatomic and alveolar dead space (Fig. 61-7) . The nonuniform loss of elasticity may also explain the progressively more severe mismatching of ventilation and perfusion that occurs in elderly persons. [45]

Calcification decreases chest-wall compliance and makes the thorax of older adults more rigid. Therefore, despite increased lung compliance, total pulmonary compliance changes very little. Within the thorax, loss of lung recoil means that residual volume increases at the expense of expiratory reserve volume. Therefore, with little change in total lung capacity, functional residual capacity (FRC) increases modestly but progressively at the expense of vital capacity (VC) (Fig. 61-8) . Closing volume and closing capacity also increase until they overlap FRC. Thus, in the elderly, small airways may close even during tidal breathing. This condition or the heterogeneous pattern of increased compliance in different areas of the lung may account for the relentless widening of the alveolar-arterial gradient for oxygen that impairs oxygenation and the increased dead-space fraction that reduces the efficiency of carbon dioxide elimination.

Fibrosis and calcification of the chest wall also lessen the effectiveness of the respiratory "bellows" and restrict, to some degree, the pulmonary mechanics of elderly persons. This rigidity, manifested clinically as reductions in forced expiratory volume in 1 second and in midmaximal expiratory flow rate, also increases the work of breathing and ultimately limits maximal breathing capacity. Elderly persons also have marked reduction in the ventilatory response to imposed hypoxia and hypercapnia, [46] although moment-to-moment

Figure 61-7 Alveolar-arterial oxygen gradient (left axis) and dead space fraction (Vd/Vt, right axis) both increase progressively with age but are significantly influenced by body position.

regulation of ventilation appears to be unimpaired. Furthermore, the elderly have increased periodic breathing (i.e., apnea) during sleep, which makes them more likely to have apnea and airway obstruction in the recovery room. [47] The higher incidence of apnea and episodic respiration observed in elderly patients given parenteral narcotics probably reflects the transiently high initial plasma concentrations of these drugs in the elderly rather than a true increase in sensitivity to the respiratory depressant properties of the drugs.

PSYCHOSOCIAL ISSUES

Most surgical patients are psychologically fit but have a variety of concerns, many that are profoundly distressing, about their impending surgery. The elderly do not differ fundamentally in this regard from their younger counterparts, but they are aware that they have decreased functional reserve in many areas. Consequently, they have particularly acute concerns regarding the possibility of irreversible loss of ability to meet the demands of independent normal daily activity and the possibility of long-term institutionalization. Social, financial, and sensory isolation are additional sources of anxiety for elderly surgical patients. At a subconscious or emotional level, they may also sense a greater proximity to, and possibility of, their own death. On the other hand, many older adults seem to face cancer with less anger and with greater equanimity than do young or middle-aged patients.

Competence in the context of patient participation in perioperative decision-making does not specifically require general orientation to time or place, although acute confusion or delirium states due to imposed factors such as sleep deprivation or drug therapy must be medically corrected before assessment of competence. [48] Evaluation of an elderly patient's mental status and competence must be included in virtually every interaction between patient and physician. Unfortunately, "ageism" among physicians makes many of them less likely to take an elderly patient's questions or concerns regarding health care as seriously as those that come from a young adult. Persistent misconceptions that aging somehow necessarily diminishes intellectual or rational capacity, patronizing attitudes toward perceived parent figures, cultural bias, and subconscious emotional reaction to a physician's own fear of aging and disability all combine to reduce the objectivity with which a physician can listen to, and heed, elderly patients' attempts to participate in their own health-care decisions.

In most cases, however, there is no medical reason to expect that an elderly patient does not meet generally accepted legal standards of mental competence. The fundamental ability of the elderly surgical patient to seek, consider, and consent to surgical treatment should be assumed intact. Nevertheless, the standards for assessment of competence by the physicians participating in the perioperative care of an elderly patient may be substantially higher than those used for young adult patients. [49] Although most legal doctrines are generic and therefore do not specifically

Figure 61-8 Aging increases residual volume (RV) at the expense of vital capacity (VC), because total lung capacity (TLC), the sum of all component volumes, remains relatively unchanged unless physical stature is markedly compromised. Functional residual capacity (FRC), the volume of the lung at rest, increases as aging progressively compromises lung elastic recoil and allows residual volume (RV) to expand and closing capacity (CC) to infringe upon normal tidal breathing.

identify the elderly patient as a special subpopulation with unique status, failure to take age-related psychologic, social, economic, and physiologic factors into account when making judgments regarding the patient's decision-making capacity could nevertheless be regarded as a deviation from the "accepted standard of care" imposed on the medical community, especially in the course of legal actions that occur after an adverse outcome.

Before surgery, elderly patients may be increasingly preoccupied with the events of their past. Patient and respectful listening may help the anesthesiologist properly prepare that patient psychologically for surgery in a way that cannot be accomplished pharmacologically. If, however, the elderly patient appears overly fixed on a trivial event or past experience, such preoccupation may indicate endogenous or reactive depression. Endogenous depression is associated with a higher risk of postoperative morbidity and mortality, and recovery from endogenous depression in the elderly is often prolonged. The elderly do have a higher incidence of emotional disturbance and psychologic abnormalities than the surgical population at large. Elderly patients with personality disorders may be particularly manipulative, histrionic, hypochondriacal, demanding, or theatrical.

The compression of the majority of serious illness and disability into the geriatric portion of life span makes decisions regarding continuation of life support and do-notresuscitate (DNR) orders particularly important for geriatric surgical patients. Although accrediting organizations require hospitals to have a DNR policy, to be effective and useful that policy must include provisions for perioperative modification or temporary suspension, on a case-by-case basis, when surgical patients with DNR status require anesthesia for invasive procedures. [50] Evidence from studies of nursing home and hospitalized elderly patients suggest that cardiopulmonary resuscitation (CPR), in fact, is rarely effective in the debilitated patients most likely to receive DNR status. However, the arbitrary assignment of DNR status to those elderly patients believed by their physicians to be "poor candidates for resuscitation" because of a low expected probability of success remains in fundamental conflict with the general principle of patient autonomy. This need not be a significant dilemma, however, because a majority of those elderly patients who are least likely to respond to CPR will, in response to direct and candid discussion of this issue, voluntarily accept DNR status if it is suggested to them. [51]

PERIOPERATIVE RISK AND OUTCOME

As in all forms of epidemiologic investigation, direct comparisons of surveys of perioperative morbidity and mortality should be preceded by careful review to identify any significant differences in methodology and definition of key terms (such as *perioperative* and *morbidity*) (Ch. 22) . [52] Because intraoperative mortality is now rare and because intensive care facilities frequently prolong short-term survival of patients who cannot recover after surgery, the current standard for comparing the rate of perioperative complications should be at least 30 days from the time of surgery.

In the past, some effort was made to distinguish complications due to anesthesia from those not related to anesthesia. Classic studies, from an era in which anesthetic routines were far simpler and postoperative care less intense than now, have suggested that anesthesia-related morbidity probably accounts for approximately 10 percent of complications seen perioperatively. However, the complex interaction between pathophysiologic, pharmacologic, and technical interventions in modern surgery frequently makes it impossible to establish a clear or single cause of perioperative morbidity or death. Therefore, most modern studies simply present data as gross perioperative survival.

Ample and consistent evidence shows that major morbidity and mortality occur more frequently in elderly surgical patients than in younger counterparts undergoing comparable surgery. Current estimates of 30-day perioperative mortality for adequately prepared surgical patients 65 years of age or older are 5 to 10 percent. [53] [54] [55] Although this value is less than one-half that reported 3 or 4 decades ago, it is still three to five times that for young adults. One-year mortality for debilitated geriatric patients approaches 20 percent, although this figure includes many nonsurgical factors. [56]

Three major risk factors appear to determine mortality rates for elderly patients: the need to perform surgery on an emergency basis, the operative site, and the physical status of the patient at the time of surgery. The mechanism by which emergency surgery increases risk 3- to 10-fold is itself probably multifactorial. The personnel, facilities, and time available for emergency surgery are not always equivalent to those normally used for elective surgery. Inadequate preparation and cursory preoperative evaluation, commonplace in elderly patients in general, are likely to be even more haphazard in an emergency. Correctable deficiencies in circulating blood volume, electrolyte imbalance, or impaired oxygen transport may be present in almost two-thirds of the patients having an emergency. In addition, the nature of the surgical lesion and its acute consequences (e.g., as hemorrhage, dehydration, ischemia, and acidosis) may critically reduce already-limited organ system reserve or even injure the elderly patient irreversibly. Finally, infection and sepsis continue to be major causes of death in elderly patients despite vigorous intravenous antibiotic therapies, perhaps because of pervasive age-related deterioration of the vigor and the selectiveness of immune responsiveness in older adults. Whatever the cause, perioperative mortality in elderly patients undergoing emergency surgery remains high.

The importance of the site of surgery as a major determinant of perioperative risk in the elderly applies equally for emergency and elective surgery. Truly superficial operations, such as cataract surgery, incur very few deaths. In contrast, surgical entry into a major body cavity greatly increases the risk of morbidity and mortality. Colon resection and other forms of bowel surgery have mortality rates comparable with those for intrathoracic and major vascular procedures. For the elderly, the risk of death is 10 to 20 times greater for these types of procedures than for inguinal herniorrhaphy or transurethral prostatectomy.

The guidelines of the American Society of Anesthesiologists provide clinical quantification of the severity of disease. In general, the greater the average age of a surgical population, the greater the prevalence of age-related disease, and thus the poorer the physical status of the group. [57] The preoperative physical status of elderly patients clearly correlates with perioperative morbidity (Fig. 61-9) . Therefore, much of the increased risk once ascribed to aging itself--on the vague and theoretical grounds of "decreased vitality"--has now been properly attributed to the impaired physical status associated with age-related disease. Almost one-half of the typical elderly surgical patient population has hypertension, with or without coronary artery disease. Significant portions also have chronic renal, hepatic, pulmonary, and metabolic diseases such as diabetes, which have widespread effects on multiple organ systems and increase the risk of anesthesia despite continuing therapy. In fact, most fatal perioperative myocardial infarctions are not first-time infarcts but reinfarctions in patients with preexisting cardiac disease. Similarly, the most accurate predictor of postoperative pulmonary complications is simply the presence of preoperative pulmonary disease.

Thus, the perception of inevitably increased perioperative morbidity and mortality with advancing age actually reflects the obvious relationship between preoperative physical status and perioperative outcome. Certainly, decreased organ system reserve, especially in very old patients, contributes to the complex interactions by which aging is associated with an increased rate of perioperative mortality (Fig. 61-10) . Adverse drug reactions also play a progressively larger role in perioperative morbidity in older adults who require drug therapy for the treatment of age-related disease (Fig. 61-11) .

ANESTHETIC MANAGEMENT

Debilitated and sickly older patients are particularly prone to perioperative complications, but healthy older surgical patients should do well. In fact, for many types of surgery the likelihood of perioperative morbidity and mortality may not be significantly higher in fit, healthy octogenarians than in young adults undergoing similar procedures. [58] [59] [60] Whatever the age of the patient, a satisfactory and uncomplicated anesthetic course requires (1) an anesthetic plan compatible with the patient's physical status and the type of surgery, (2) consistent monitoring, and (3) careful attention to detail. No additional or unique major principles need to be observed when caring for the elderly patient,

Figure 61-9 Large-scale prospective studies confirm that physical status (PS), here quantified by the American Society of Anesthesiologists (ASA) classification system, is a major determinant of perioperative morbidity. A high prevalence of poor physical status (ASA PS 3 and 4) is largely responsible for the high rate of complications associated with surgery in the elderly.

Figure 61-10 Increased rate of complications and a greater likelihood of perioperative mortality in elderly subjects reflects the interaction of the effects of aging on organ system functional reserve and the consequences of age-related disease and its therapy. Polypharmacy and the need for medical intervention further amplify the likelihood of adverse outcome.

and there is no "best" anesthetic agent or technique for the elderly. Dozens of retrospective and prospective studies have arrived at the same conclusions: no significant difference in outcome can be attributed solely or predominantly to use of any specific anesthetic agent, and no clear and objective benefit can be demonstrated for using regional anesthesia rather than general anesthesia. [61] [62] [63] Peripheral neurologic complications and sequelae such as neurapraxias are more common in older adults after regional anesthesia than in young adults. [64] On the other hand, there is less short-term disruption of postoperative mental functioning when spinal anesthesia, without sedation, is given to elderly patients rather than general anesthesia. [65] Probably only "pure" local infiltration anesthesia given without the addition of intravenous sedation, in those limited circumstances where this approach is practical, can approach the ideal of morbidity-free outcome.

Consequently, selection of anesthetic techniques and specific drugs for elderly patients requires careful review of the patient's physical condition and analysis of the nature and severity of age-related and coexisting disease processes. As in younger patients, administration of an inhaled anesthetic having marked myocardial depressant properties must be done with extreme caution if the patient has intractable congestive heart failure and low cardiac output. Similarly, the acute pharmacologic sympathectomy associated with high thoracic levels of spinal anesthesia is unlikely to be well tolerated in a hypertensive, debilitated elderly person who has reduced circulating blood volume and is being given diuretics. As detailed previously, some loss of renal, cardiac, hepatic, and pulmonary functional reserve is an inevitable consequence of aging even in the healthy, fit patient. Although remaining organ system reserve is adequate to meet small to moderate amounts of imposed stress, complex anesthetic techniques that put a heavy demand on these organs while simultaneously disrupting autonomic function are, at best, difficult to manage and, at worst, a threat to patient survival.

The anesthetic plan for an elderly patient should, however, acknowledge the effect of age on anesthetic requirement. Sensitivity of the cerebral cortex to fentanyl, alfentanil, and midazolam all appear to increase with advancing age. [66] [67] [68] Regardless of whether these observations are due to true age-related alterations of pharmacodynamics or whether they are simply pharmacokinetically produced variations in apparent drug sensitivity due to high initial injected drug concentrations in plasma, dosage of etomidate, barbiturates, propofol, narcotics, or benzodiazepines should be reduced 20 to 40 percent in elderly patients. [69] [70] Increased use of intravenous agents such as remifentanil and cisatracurium that do not require organ-based elimination clearance for the termination of their clinical effects also will facilitate prompt and predictable recovery in older adults.

Segmental dose requirements for epidural anesthetics seem to change in a complex manner with age, perhaps reflecting increased resistance to injection and reduced overall compliance of the epidural space. Dose requirements change insignificantly after injection of small volumes of local anesthetic solutions, whereas injection of large volumes may be followed by markedly exaggerated cephalad spread of the drug in older adults. [71] On the other hand, after subarachnoid injection of local anesthetics or narcotics, there appears to be a somewhat more rapid onset of maximum sensory level and slight prolongation of effective analgesia but not significant change in overall pharmacodynamics. [72]

Traditional nondepolarizing muscle relaxants are required in about the same quantity in elderly as in younger patients to provide equal levels of paralysis, although, in general, their duration of action is prolonged because of decreased rates of clearance from the plasma/extracellular fluid compartment from which they exert their primary effects. [73] [74] Neither the rate of onset nor the peak effectiveness of anticholinesterase drugs used to antagonize neuromuscular blockade (e.g., neostigmine and edrophonium) is altered significantly by processes of aging. However, the incidence of cardiac arrhythmias after neostigmine is higher in elderly patients who have cardiovascular disease. [75] In the elderly, the action of all of these drugs may be prolonged if they require hepatic or renal elimination and/or biotransformation. [76]

Figure 61-11 The incidence of adverse drug reactions rises progressively after early middle age in all modern industrialized societies in which elderly adults have facilitated access to the medical therapy needed to control the symptoms of age-related disease.

The value of consistent cardiac and neuromuscular monitoring arises from the greater variability and unpredictability of the elderly in their response to the complex drug environment inherent in surgery.

The need for increased attention to detail in the perioperative management of elderly surgical patients has already been implied in earlier discussions of intravenous fluid therapy, inspired oxygen concentration, and metabolic support. In addition, reduced skin and soft tissue perfusion make the elderly more prone to ischemic pressure lesions. Agerelated osteoporosis and arthritis may increase the likelihood for iatrogenic injury if positioning for surgery is not done with great care, and decreased lacrimation makes eye protection even more critical than in younger patients. The reduced responsiveness of protective airway reflexes in the elderly [77] may justify routine protection against regurgitation and aspiration of gastric contents. Anesthesiologists must search for and protect prosthetic devices worn or implanted preoperatively and must aggressively conserve body heat intraoperatively to avoid the cardiovascular and metabolic stress of postoperative hypothermia, although decreased skeletal muscle mass and impaired thermoregulation markedly limit the severity of postoperative shivering in elderly adults. [78] Nevertheless,

supplemental oxygen administration should be strongly considered for at least 24 hours after surgery to compensate for the inevitable decrease in efficiency of oxygenation that follows surgery in all patients. This concern is of particular importance to elderly patients, who have impaired efficiency of oxygen extraction and decreased response to hypoxia.

Although nervous system function usually returns quickly and completely after anesthesia, the neurologic examination may be grossly abnormal for up to 40 minutes postoperatively. Subsequent failure of an elderly patient to return spontaneously to preoperative levels of nervous system function almost always reflects prolonged anesthetic effects. Nevertheless, postoperative delirium, disorientation, and acute brain syndromes do occur commonly in older patients and may be due to disordered metabolic states (hypoglycemia or hyperglycemia, hypoxia, hypothermia, or hypercarbia) or expressions of subclinical age-related neurologic disease. [79] Gross nervous system injuries in the elderly patient usually result from cerebral ischemia or embolism. Such injuries are distinguishable from residual drug effects by their severity, focal nature, and the absence of conspicuous improvement in the first few hours after anesthesia and surgery. More subtle forms of residual nervous system dysfunction may, on the other hand, be unique to the geriatric population. Impaired spatial and verbal cognition, as well as memory deficits, may persist beyond the first week after surgery in as many as 25 percent of elderly surgical patients. [80] New electroencephalographic findings appear postoperatively in more than one-third of this surgical subpopulation. In one study, 13 percent of elderly patients had some form of long-term memory loss or "serious mental deterioration."

Although the cause of intermediate- and long-term nervous system dysfunction in the elderly is not known, such dysfunction does not appear to be related to the choice of anesthetic itself. [81] Multiple and complex causes, including isolation and inactivity, anemia, alcoholism, a history of psychologic pathology, or the degree of emotional support provided to the patient and the nature of the surgical outcome, have been suggested. [82] Experimental observations of the inactivation of the enzyme methionine synthase in brain tissue by nitrous oxide suggested that a pharmacologic mechanism is also possible, because this enzyme is essential for memory because it requires the synthesis of nucleic acids. Although permanent nervous system damage is rare, many elderly surgical patients require weeks or months to gain full recovery of all aspects of preoperative mental status, for reasons that remain unknown. [83]

SUMMARY

Rapid recent improvement in our understanding of the physiology and pharmacology of aging has occurred in large part because investigators have been able to separate the effects of aging per se from the consequences of age-related

---

disease. Aging produces progressive atrophy, fibrosis, and loss of elasticity in virtually all tissues and organs. The structural and functional consequences of these changes are measurable from the period of peak somatic maturity, in the 3rd decade of life, through the middle adult years, and then into the period of accelerated senescence during the 8th decade of life. In the absence of disease, organ function remains adequate to meet basal requirements and even moderate demands, but the functional reserve capacity and the maximal capacity of all major organ systems are significantly reduced.

As a group, elderly patients are at greater risk of perioperative morbidity and mortality than their younger counterparts because of the high incidence of coexisting disease. Increased rate and severity of complications may also reflect decreased autonomic homeostasis and a reduced capacity to tolerate or compensate for imposed pathology or surgical stress. Optimal anesthetic management of elderly patients requires adequate diagnosis and treatment of concurrent diseases, meticulous attention to the details of preparation and positioning, and use of monitoring techniques permitting adjustments in dosage appropriate to the altered requirements for anesthetic and adjuvant drugs. Although advanced age (i.e., older than 85 years) is itself a risk factor for patients with severe or multiorgan dysfunction, chronologic age can no longer be considered a contraindication to well-managed anesthesia and surgery in a geriatric subject.

Chapter 62 - Anesthesia for Trauma

John K. Stene
Christopher M. Grande

INTRODUCTION

More than 90,000 Americans die from traumatic causes each year. [1] Injury ranks as the fourth leading cause of death in the United States, following heart disease, cancer, and cerebrovascular disease. Major public health campaigns in this country have successfully reduced mortality from infectious diseases, heart disease, cerebrovascular disease, and, to a limited extent, cancer. Although public health campaigns to combat traumatic injuries have had impact, mostly by reducing mortality from motor vehicle accidents, increasing violent trauma such as gunshot wounds continues to threaten American lives. Currently, for Americans younger than 40 years, trauma is the most common cause of death. However, the mortality rate from trauma is merely the proverbial tip of the iceberg. Because the mortality rate from individual injuries has been decreasing with the organization of trauma centers and improved techniques of trauma care, the total number of injuries has increased faster than the number of trauma deaths. In 1993, approximately 90,000 individuals in the United States died of accidental injuries, for a rate of 34.9 deaths per 100,000 population, the second lowest accidental death rate on record. [1] In the same year there were an estimated 18,200,000 disabling accidental injuries, or about 2,080 injuries every hour, and the 90,000 accidental deaths amounted to 1 every 6 minutes--and these numbers exclude the rising level of intentional injuries caused by attempted or successful suicides and homicides. [1] Thus, anesthesiologists are being faced with anesthetizing an increasing number of trauma patients.

Trauma anesthesia continues to evolve into a distinct area of interest and is one of the fastest growing areas of anesthesia specialization. Interestingly, data compiled from several studies in the United States suggest that an anesthesiologist may be more likely to be in attendance at the arrival of a trauma patient in a hospital that is not a trauma center. This is because a higher portion of trauma patients are triaged to nontrauma centers; therefore, a hospital that is not a trauma center may overall receive more injured patients than a trauma center, especially in urban settings. This emphasizes the implication that all anesthesiologists will likely have significant and unpredictable exposure to trauma patients.

Trauma Centers

Trauma centers have a decided impact on the practice of anesthesia. The regionalization of trauma care into trauma centers not only efficiently utilizes hospital resources, but also provides adequate case experience to develop and sustain the skills of the anesthesia and surgical staff. Trauma center organizations recognize trauma as a specific surgical disease that requires highly trained anesthesia care for optimal outcomes. [2] Table 62-1 outlines the organization of trauma centers. It has been demonstrated that there is a wide variation in the duties of anesthesiologists in trauma care worldwide. Largely in the United States the surgeon concentrates on surgical diagnosis and treatment, and the anesthesiologist provides a secure airway, adequate ventilation, appropriate intravenous fluid management, and required sedation or anesthesia to facilitate the surgical therapy. The trauma anesthesiologist sometimes performs this mission in the field, in the emergency room, or in the critical care unit, as well as in the operating room. In some parts of the world, anesthesiologists are actively involved in prehospital (emergency medical service) care and transportation of trauma patients. [3] [4] Table 62-2 (Table Not Available) lists some of the possible tasks that trauma anesthesiologists assume. Anesthesiologists

TABLE 62-1 -- Trauma Center Organization

	LEVEL 1 : REGIONAL RESOURCE TRAUMA CENTER	LEVEL 2 : COMMUNITY TRAUMA CENTER	LEVEL 3 : RURAL TRAUMA HOSPITAL
Philosophy	Identical community and hospital commitment to excellent care of severe and urgent injuries		Best community commitment to stabilization and transport of severe and urgent injuries
Annual incidence	600-1,000 cases	350-600 cases	----
Facilities			
Emergency room	Lighted heliport 24 h/d with trauma-experienced MD staffing	Lighted heliport 24 h/d with trauma-experienced MD staffing	24 h/d with trauma-experienced MD staffing

Anesthesia personnel	Anesthesiologist with trauma experience 24 h/d	CRNA or anesthesiologist experienced with trauma 24 h/d	In-house anesthesia coverage (MD or CRNA) 24 h/d
Surgery personnel	24 h/d general surgeon and neurosurgeon experienced in trauma; consultants rapidly available	24 h/d general surgeon and neurosurgeon experienced in trauma; consultants rapidly available	Promptly available general surgeon; 24 h/d neurosurgeon availability highly desirable
Surgery case load	At least 50 severe and urgently injured patients per trauma general surgeon per year Level 1 trauma center must make a commitment to trauma training and research	At least 50 severe and urgently injured patients per trauma general surgeon per year	

working in hospitals without trauma centers find their expertise in airway management and monitoring of critically ill patients to be invaluable to the care of the occasional trauma patient.

Scoring Systems

The development of trauma centers has been accelerated by the use of indices of trauma severity [5] (Table 62-3) . The Injury Severity Score, an anatomic scale composed of the sum of squares of the Abbreviated Injury Scale from the three most severely injured body regions, is used retrospectively to compare outcomes in trauma centers. Prospective physiologic scoring systems such as the revised Trauma Score and the Pediatric Trauma Score are used to predict outcome and direct patients to appropriate facilities. [5] [6] The Glasgow Coma Scale (GCS) is a useful prognostic tool for patients with acute head injuries. [7] The American Society of Anesthesiologists Physical Status score has been demonstrated

TABLE 62-2 -- Potential Roles of the Anesthesiologist in the Care of a Trauma Patient

to predict mortality from blunt trauma, but it is not very useful for discriminating small differences in severely injured patients. [8]

MECHANISMS OF INJURY

Human physiologic response to injury is uniform enough to justify the term *traumatic disease* despite the myriad causes of trauma. [9] [10] [11] However, the mechanism of injury is important, because it determines the pattern of injury, and this knowledge focuses the treatment priorities for that patient. For example, acute oxygen deprivation from drowning requires immediate attention to restoring oxygen delivery to the cardiopulmonary system, to prevent massive cellular necrosis. Penetrating thoracic trauma requires immediate placement of a chest tube to drain extrapulmonary pleural air and blood. Such a patient may often require no further surgery. Blunt chest trauma requires immediate attention to gas exchange because widespread pulmonary contusion complicates instability of the chest wall. A diagnosis of myocardial contusion and traumatic aneurysm of the thoracic aorta must be immediately excluded.

Blunt Versus Penetration Trauma

The distinction between blunt and penetrating trauma is important because the therapeutic approach is quite different. Blunt trauma, most commonly from motor vehicle accidents or falls, results in widespread energy transfer to the body. When the limits of load tolerance are exceeded, tissues are disrupted. Multiple fractures, soft tissue contusions

or avulsions, and rupture of visceral organs occur, depending on the amount of energy transfer. The physics of the impact determines the sites of energy transfer and thus causes characteristic clusters of injuries. [12]

Penetrating trauma injures tissues as the energy behind the penetrating instrument causes stretching and crushing of tissues. Anatomic injury is confined to the penetration track along which tissues were stretched and crushed. The energy dissipation profiles of different weapons (knives and bullets) determine the anatomic depth and extent of maximum injury. [13]

Trauma patients' deaths demonstrate a trimodal distribution. In the first and largest peak of the distribution curve, death from either blunt or penetrating trauma occurs immediately following widespread laceration of the brain or major blood vessels, including the heart. Such patients can rarely be saved. In the second peak, exsanguination from vascular injuries causes death within a few hours without medical treatment. Victims of penetrating trauma who survive their immediate injury need rapid surgical hemostasis of bleeding arteries and veins within the wound tract. Victims of blunt trauma need careful diagnosis and stabilization prior to surgical correction of hemorrhage from widespread injuries. Frequently, these injuries result in multiple small vessel bleeding, especially from fracture sites. Inadequate or delayed shock resuscitation or surgical treatment leads to late deaths from infection, sepsis, or multiorgan failure. [2] [14]

Neck and Airway Trauma

Penetrating injuries to the neck from gunshot wounds, stab wounds, or penetrating foreign bodies (e.g., construction tools, car parts) are potentially life-threatening because of the anatomic proximity of cardiovascular, aerodigestive, glandular, and neurologic systems in the neck. [15] However, blunt trauma mechanisms can also result in significant injuries to these areas. The anesthesiologist is initially most interested in vascular and airway injuries that need rapid surgical intervention. Knowledge of potential wound tracts, as discussed by Fackler, [13] helps to predict potential injuries. Early airway management with endotracheal intubation is recommended to protect patients from closure of the airway secondary to an expanding hematoma. Anesthetic induction prior to endotracheal intubation is recommended to prevent dislodgement of a hemostatic clot by coughing and straining during intubation. [15] However, when an airway injury is suspected, anesthetic induction and airway control must proceed with caution. [16]

Penetrating injury to the larynx or trachea is diagnosed by air bubbling through the penetration tract, hoarseness, and dysphonia. Distal tracheal injuries may be managed by inserting a cuffed tube through the penetrating wound into the trachea, followed by tracheal repair around the tube, which is left as a tracheostomy tube. Laryngeal injuries require primary repair around a stent with a distal tracheostomy for ventilation. However, these injuries may require lifesaving endotracheal intubation, performed carefully with a small tube, prior to tracheotomy. The laryngotracheal cartilage must be repaired during the initial surgery, with mucosal closure and stent placement for several weeks to prevent stenosis. Cases of complete transection with laryngotracheal separation depend on submucosal elastic tissue to maintain airway patency and approximation of the structures. Disastrous consequences can be suffered with inappropriate attempts at translaryngeal intubation and/or institution of positive pressure ventilation. [16]

All penetrating injuries to the lower or upper neck require preoperative angiography because of the inaccessibility of major arteries. Some surgeons explore midneck injuries before performing arteriography. [15]

The anesthesiologist must be aware of the potential for venous air embolism until injured cervical veins are ligated or repaired. The patient should be kept in a flat or slightly head-down position; positive-pressure ventilation is used to increase venous pressure in the neck.

Thoracic Trauma

Blunt chest trauma, such as commonly occurs when an unbelted driver strikes the steering wheel during an automobile accident (Fig. 62-1) (Figure Not Available) , can directly injure the cardiopulmonary systems. [17] Besides direct injuries affecting

Figure 62-1 (Figure Not Available) Patterns of injury for unbelted driver in head-on collisions. (A) Down-and-under mechanism. (B) Up-and-over mechanism. Note that the patient will exhibit characteristic clusters of injuries, including head and neck, chest, abdomen, and lower extremity fractures, depending on how the body strikes the steering wheel. *(From Parr and Grande [7])*

Numeric range	1-5	0-7.84		3-15		1--minor injury to	3-75	Skeletal trauma	
	Higher score more serious disease	SBP × Wgt + RR × Wgt + GCS × Wgt = TS		Lower score more serious coma		6--virtually unsurvivable	Any AIS of 6 means automatic 75 ISS	None	+2
						9-- cannot evaluate		Closed	+1
		Lower score more serious injury						Open or multiple	-1
								-6-+12	
Patient example	25-year old man, unhelmeted motorcycle rider, struck by truck: subdural hematoma 100 mL, crushed pelvis, and superficial perforation of bladder. Presented to emergency room with blood pressure 80/40, heart rate 135/min, delayed capillary refill, respirations 30/min with retractive efforts, opens eyes to pain, no verbal response, withdraws all four extremities from pain.								
Score	4E	3 × .7326 = 2.20		2 + 1 + 4 = 7		Subdural AIS4	$4^2 + 4^2 + 3^2 = 41$		
		3 × .2908 = 0.89				Crushed pelvis AIS4			
		2 × .9368 = 1.87				Superficial bladder perforation AIS3			
		4.96							

Glassgow Coma Scale adapted from Teasdale and Jennett, [6ξ] copyright by The Lancet, Ltd.

See Ref. [6] for more detailed discussion.

the cardiopulmonary system, indirect effects of shock and air embolism can affect the central nervous system (CNS) and can complicate anesthetic management. If a traumatic tear of the thoracic aorta is demonstrated, the patient will require an immediate operation. Optimum anesthesia care for repair of a traumatic thoracic aortic

aneurysm requires intra-arterial and pulmonary artery monitoring; therefore, advanced preparation for the surgical anesthetic regimen should start as soon as the diagnosis is suggested by a wide mediastinum on an upright chest roentgenogram prior to arteriographic confirmation. A well-prepared trauma anesthesia care team will be able to appropriately monitor and anesthetize a patient with a traumatic thoracic aortic aneurysm without life-threatening delays of the surgery. Some cardiac surgeons accept transesophageal echocardiographic imaging of an aortic injury as an indication to operate, whereas others require an aortogram revealing the injury.

Other lesions caused by blunt chest trauma that require surgical correction include extensive pulmonary lacerations with a continuous air leak (bronchopleural fistula) and hemorrhage, lacerated intercostal arteries, and traumatic tracheobronchial laceration. These lesions may be surgically corrected following a period of observation with closed thoracostomy drainage. These lesions are diagnosed when a bronchopleural air leak or intrapleural hemorrhage persists following trauma. Hemopericardium or pneumopericardium requires immediate pericardiocentesis to relieve tamponade, followed by a surgical pericardial window to prevent reaccumulation. Traumatic lacerations of the heart either are rapidly fatal or bleed slowly enough to allow careful surgical repair. Arterial air embolism is a complication of blunt as well as penetrating chest trauma. Deep lacerations of the lung from jagged-edged rib fractures allow continuity of the air and vascular spaces. Thus, air can enter the pulmonary venous drainage and the systemic arterial circulation. [18] Long-term care of the patient with multiple rib fractures is enhanced by continuous regional anesthesia to reduce respiratory compromise from splinting. [19] [20] [21]

Closed Head Injury With Open Femur Fracture

Front-seat occupants of modern automobiles with knee bolsters built into the dashboard frequently suffer open femur fractures during an accident that significantly deforms the passenger space (Chs. 35 ,. 52 , and 60). These same victims also frequently suffer head injury if they are not using a seat belt. [12]

Optimum care of an open femur fracture requires operative reduction and fixation within a few hours of the injury. An intramedullary rod provides the most stable internal fixation and allows rapid post-traumatic mobilization of the patient.

High-energy fractures of the femur cause the release of large amounts of bone marrow fat into the circulation. Postfracture hypoxic respiratory failure occurs as the circulating fat released from the fracture collects in the pulmonary vascular system. Early operative stabilization of the fracture under general anesthesia with positive-pressure ventilation prevents mild postfracture hypoxia from developing into severe adult respiratory distress syndrome (ARDS) and fat emboli syndrome. [22]

Prior to anesthetic induction for open reduction with internal fixation of the femur fracture, the patient's closed head injury must be evaluated. Patients with minimal impairment on neurologic examination may have significant brain injury that would cause them to decompensate during anesthesia. Therefore, these patients require a baseline neurologic examination, a computed tomography (CT) scan of the brain, and the placement of an intracranial pressure recording device if there is any question about structural brain injury (Ch. 56) . The prevention of secondary brain injury requires the strict avoidance of hypotension and hypoxia. Therefore, these patients should be monitored by an indwelling arterial catheter. The association of cervical spine fractures with closed head injuries requires a careful evaluation of the patient's cervical spine for fractures and stability.

Postoperative pain management by continuous epidural analgesia is an excellent choice for these patients because analgesia can be provided without depression of consciousness, thus permitting continuous neurologic evaluation.

PREOPERATIVE PREPARATION

The orderly progression of history, physical examination, diagnosis, and treatment must often be abandoned with trauma patients, because resuscitation has priority over diagnosis to ensure a successful outcome (Chs. 23 and 25). Resuscitation protocols, such as outlined in the Advanced Trauma Life Support manual, are designed to identify and correct the most life-threatening problems first. Knowledge of mechanisms of injury is used as described earlier to focus on probable injuries. Following a rapid (30- to 45-second) initial assessment, immediate treatment is initiated. After initial resuscitation is complete, a secondary survey is begun to rule out all occult injuries [23] (Table 62-4) (Table Not Available) .

The anesthesiologist is primarily concerned with preserving CNS function, maintaining adequate respiratory gas exchange, and achieving circulatory homeostasis. [24] CNS function is protected by ensuring an adequate flow of well-oxygenated arterial blood to the brain and by preventing secondary spinal cord damage due to movement of an unstable spinal fracture. Initial evaluation of the patient's GCS, pupil reactivity, and four-extremity motor function provides a baseline of neurologic function prior to extensive therapeutic maneuvers. Intracranial swelling leading to brain death following trauma is a major cause of traumatic death. [25] Endotracheal intubation and mild hyperventilation (Pa CO_2 35 mm Hg) should be initiated on all comatose trauma patients prior to pharmacologic therapy (e.g., with mannitol) aimed at reducing cerebral swelling. The indication for immediate endotracheal intubation and mild hyperventilation varies from trauma center to trauma center, ranging from a GCS of 7 or lower to a GCS of 9 or lower. Intubation in the field prior to transport is most beneficial to comatose patients, because they receive early airway protection from aspiration as well as mild hyperventilation with oxygen. Care must be taken to stabilize the cervical spine during intubation because of the increased association of cervical spine injury with head and facial injuries in blunt trauma. [12] [26]

TABLE 62-4 -- Sequence of Management of Trauma Patients

(Not Available)

From Parr and Grande [69]

Endotracheal Intubation Techniques

Airway control is vital to improve pulmonary gas exchange during resuscitation from hemorrhagic shock, as well as to protect the patient from aspiration (Ch. 39) . [27] Table 62-5 lists the indications for immediate endotracheal intubation of trauma patients. The trauma patient who cannot maintain a patent, protected airway should have a cuffed tube placed in the trachea. Oral or nasal airways have no role in the initial management of the unstable trauma patient, except to maintain a patent airway temporarily during preparation for endotracheal intubation.

Orotracheal intubation facilitated by the use of muscle relaxants is the technique of choice for intubating the trachea of trauma patients. Despite concerns about the unstable cervical spine raised by radiographic postmortem studies of a few victims who died of devastating total-body crush injuries, [28] a well-conducted oral endotracheal intubation can

TABLE 62-5 -- Indications for Endotracheal Intubation

Cardiac arrest

be performed without spinal cord damage. Cervical spine stabilization during intubation can be adequately performed with manual immobilization of the head and neck on a long spine board (Fig. 62-2) (Figure Not Available) . An emergency room comparison of muscle relaxant-facilitated oral intubation and blind nasal intubation demonstrated a high rate of complications, including aspiration, in the group receiving blind nasal intubation. [29]

Correctly applied cricoid pressure protects the airway from aspiration of stomach contents (see Ch. 39 and Fig. 62-2) (Figure Not Available) . Cricoid pressure prevents insufflating the stomach with air during mask ventilation prior to intubation in addition to preventing regurgitation of gastric contents into the mouth. [30] The trauma patient with cervical spine stabilization cannot be easily moved to drain gastric contents from the mouth; therefore, prevention of regurgitation is essential. Nonparticulate antacids can be instilled into the stomach to buffer gastric acidity prior to intubation. H_2-histamine antagonists and metoclopramide may be administered intravenously to raise the pH and reduce the volume of gastric contents if these agents are given 0.5 to 1 hour prior to tracheal intubation. [31] Ultimately, the best protection from aspiration for the trauma patient is smooth, well-conducted intubation and extubation delayed until the patient has competent airway reflexes.

Administering oxygen via mask-and-bag ventilation, using cricoid pressure to protect the airway, improves oxygenation prior to endotracheal intubation. In the past, we described this technique as "modified rapid-sequence induction" and believed it to be an important component of difficult airway management for trauma patients. [32] Many trauma patients, on analysis with pulse oximetry or admission blood gas measurements, exhibit significant degrees of oxygen desaturation because of central respiratory dysfunction, deranged chest wall mechanics, or intrapulmonary ventilation/perfusion abnormalities. These considerations become more important in terms of the danger of inducing hypoxic arrhythmias on intubation or during anesthetic induction of the hypermetabolic head-injured patient, who may exhibit deleterious changes from both hypoxia and hypercarbia. Testing the ability to ventilate the airway provides the anesthesiologist with the knowledge that the patient's ventilation can be supported if endotracheal intubation fails. It is our opinion that in many trauma patients these factors, ensuring adequate oxygenation, outweigh the risk of regurgitation through cricoid pressure and possible aspiration pneumonia. Emergency tracheotomy, for a patient whose injuries or preexisting airway anatomy prevent intubation, is best performed while adequate ventilation and oxygenation are maintained. At the minimum, a brief test of the airway with positive-pressure ventilation (with an assistant applying cricoid pressure) is as important in the tense emergency situation as during elective surgery. Table 62-6 summarizes pharmacologic

adjuvants to assist orotracheal intubation for trauma patients.

In patients who cannot be ventilated by a mask, an oral, nasal, or surgical (tracheotomy) approach can be used for awake tracheal intubation. The algorithm developed by the American Society of Anesthesiologists Task Force on Difficult Airway Management [33] is complete and generally applicable. However, in cases of severe trauma, the "rolling thunder" approach to management often precludes retreating

Figure 62-2 (Figure Not Available) The emergency intubation technique for a trauma patient with suspected cervical spine fracture and a full stomach requires keeping the patient supine on a long spine board. An assistant stabilizes the patient's neck by holding a hand over each ear while keeping the patient's shoulders and occiput firmly placed on the board, with the patient's gaze directed straight up. A second assistant maintains cricoid pressure. Well-applied cricoid pressure prevents insufflation of air into the stomach as well as fluid regurgitation from the stomach into the mouth. Thus, the patient can safely be ventilated by mask and bag prior to laryngoscopy and intubation. Manual preoxygenation by face mask increases the margin of safety in potentially difficult intubations because of cervical spine stabilization. *(From Stene [71])*

to or continuing with mask ventilation. In these cases, a definitive airway is achieved by translaryngeal or surgical techniques within the first moments of patient care. In recent years, the laryngeal mask airway has found a niche in providing a rapid route to ventilate difficult-to-intubate trauma patients, whereas a definitive airway is achieved via tracheostomy or intubation through newer versions of the laryngeal mask airway. [34] [35]

Unstable mandibular or maxillofacial fractures may make mask ventilation impossible, and an awake intubation frequently relieves life-threatening airway obstruction. Direct laryngoscopy is frequently superior to fiberoptic bronchoscopic intubation in these patients because the bronchoscope is often not available on an emergency basis, and upper airway bleeding may preclude adequate visualization (Ch. 39) .

Controlled tracheal intubation in the elective setting of a patient with known cervical spine fracture should be performed with the patient awake, having the airway properly prepared with local anesthetics, antisialogogues, etc. with use of a fiberoptic bronchoscope either orally or nasally. Thus, the patient can demonstrate neurologic function before and after intubation.

Tracheotomy is reserved for those patients who cannot be intubated translaryngeally. Massive disruption of the floor of the mouth by penetrating injury and disruption of the larynx or cervical trachea are two indications for emergency tracheotomy. However, it is frequently worth one attempt to intubate patients carefully with a small endotracheal tube prior to tracheotomy unless open laryngeal cartilage is seen during direct laryngoscopy. The cricothyrotomy route is the preferred route for an emergency primary tracheotomy. [23] Although the prolonged care of many patients with maxillofacial injuries and brain trauma is improved by an intraoperative tracheotomy, the presence of highly skilled anesthesiologists in a trauma center will minimize the number of emergency cricothyrotomies needed for airway control. We believe that anesthesiologists working with a high volume of trauma patients should be comfortable with the technique of cricothyrotomy with both a needle and a tracheostomy tube.

Shock Resuscitation

Resuscitation from hemorrhagic shock requires rapid administration of intravenous fluids to ensure the circulation of well-oxygenated blood from the lungs to the brain and other vital organs (Chs. 45 to 47). Initially, intravenous fluids can be introduced into the venous drainage of the bone marrow via an intraosseous needle if all peripheral veins are collapsed. [36] Eventually, large-bore intravenous catheters must be placed either percutaneously or by cutdown. Large-bore introducer sheaths for pulmonary artery catheters can be placed percutaneously in large central veins, reducing the need for cutdowns. [37] Rapid infusion devices using mechanical pumps or gas pressure to force fluid through low-resistance tubing allow adequate resuscitation through only two intravenous catheters. If disruption of either the superior or the inferior vena cava is suspected, intravenous catheters should be placed to provide infusion into the heart through the other vena cava. Therefore, intravenous catheters should be placed above and below the diaphragm in patients with severe trauma to the chest or abdomen. Warming of intravenous

TABLE 62-6 -- Intravenous Anesthetic Drugs for Endotracheal Intubation

CONDITION	HYPNOSIS	MUSCLE RELAXATION	ANALGESIA	AMNESIA
[a] GCS = 3, flaccid, unresponsive	None	None	None	None
Cardiac arrest	None	None	None	None
Shock, syst BP < 80 mm Hg	None	Succinylcholine 1.5 mg/kg or vecuronium 0.28 mg/kg or rocuronium 1.2 mg/kg	Fentanyl 0.5-1 mug/kg as needed or nalbuphine 0.25-0.5 mg/kg	Scopolamine 0.5 mg IV or midazolam 1-2 mg if BP increases
Hypotension, syst BP 80-100 mm Hg	Thiopental 0.3-1 mg/kg (titrate to effect) or midazolam 0.1-0.3 mg/kg (titrate to effect) or ketamine 1 mg/kg or etomidate 0.1-0.2 mg/kg	Succinylcholine 1.5 mg/kg or vecuronium 0.28 mg/kg or rocuronium 1.2 mg/kg	Fentanyl 1-2 mug/kg or nalbuphine 0.5-1.0 mg/kg	Midazolam 1-2 mg if not used for hypnosis
[a] Head injury, GCS 4-9 with hypertension	Thiopental 2-5 mg/kg or etomidate 0.2-0.3 mg/kg	Rocuronium 1.2 mg/kg or vercuronium 0.28 mg/kg or succinylcholine 1.5 mg/kg (if postintubation motor examination needed quickly)	Fentanyl 1-2 mug/kg or sufentanil 0.1-0.2 mug/kg	Midazolam 1-2 mg if not used for hypnosis
Combative, BP normal to elevated	Thiopental 2-5 mg/kg (titrate to effect) or midazolam 0.2-0.3 mg/kg (titrate to effect) or etomidate 0.2-0.3 mg/kg (titrate to effect)	Rocuronium 1.2 mg/kg or vecuronium 0.28 mg/kg or succinylcholine 1.5 mg/kg	Fentanyl 1-2 mug/kg or sufentanil 0.1-0.2 mug/kg or nalbuphine 0.5-1.0 mg/kg (may require frequent redosing)	Midazolam 1-2 mg if not used for hypnosis

[a] Lidocaine 1.5 mg/kg may be useful to attenuate increases in intracranial pressure with intubation.

fluids is extremely important if the trauma patient requires several exchanges of blood volume (i.e., "massive transfusion"). Hypothermia decreases the effectiveness of hemorrhagic shock resuscitation. Various devices are available to heat fluids prior to administration, the most effective of which use water-perfused heat exchangers similar to cardiopulmonary bypass apparatus. In extreme cases the patient's blood can be circulated, under arterial pressure, through an extracorporeal circuit and heat exchanger to warm profoundly hypothermic patients rapidly. [38]

The choice of the initial administered fluid is based on the priority of first restoring blood volume, next hemoglobin concentration, and finally coagulation. Although lactated Ringer solution and whole blood were used with great success in the Vietnam War, experiments suggest that a colloid-containing fluid improves outcome, especially if packed red blood cells comprise the hemoglobin source. [39] [40] [41] Either albumin or colloidal starch solutions appear effective for traumatic shock resuscitation. [41] [42] Whole blood is superior to packed red cells for replacement of hemorrhagic losses because these losses involved whole blood. However, packed cells are preferred for emergency administration of universal donor (type O) blood to minimize plasma antibodies. Salt and water must be administered along with blood to replace loss of water and electrolytes from the circulatory system, especially to extravascular edema induced by injury and inflammation. [43] The potential for disease transmission by transfusion--human immunodeficiency virus, acquired immunodeficiency syndrome, hepatitis--has caused the formulation of revised guidelines for transfusion of blood and blood products. The tendency is to adopt lower thresholds for triggering replacement. Previously, hematocrits in the range of 28 to 30 percent were favored on the basis of balancing rheologic factors and oxygen-carrying capacity toward optimal oxygen delivery at the cellular level. Currently,

hematocrits in the range of 18 to 22 percent are being accepted in patients who can tolerate such levels. It is not yet clear which patients (especially if they are pregnant, geriatric, or recovering from severe hypovolemic shock) fit within this group.

Proponents of crystalloid use claim that such solutions replace extracellular water more effectively than colloidal solutions. Colloidal solutions preserve intravascular volume and microcirculatory blood flow more efficiently than crystalloids and they increase cardiac output and oxygen delivery, as well as blood pressure, at much lower infused volume than do crystalloid solutions. Crystalloid solutions may merely restore blood pressure without increasing cardiac output. [41] This controversy has been sharpened by a study that suggests that resuscitation of trauma victims with large volumes of crystalloid to achieve high normal blood pressure prior to surgical hemostasis causes excessive hemorrhage and mortality. [44] Current research into shock resuscitation is focused on defining measures of adequate tissue perfusion. This would allow fluid resuscitation to be judiciously administered to maintain tissue perfusion without diluting the patient's hemostatic efforts and causing excessive edema. [45]

Mixtures of hypertonic saline (7.5%) and colloid (dextran) have been used with promising results for resuscitation of trauma patients. [46] Hypertonic saline alone rapidly restored

blood pressure in patients in hemorrhagic shock, but its effect was relatively short-lived; combining the hypertonic saline with a colloid such as dextran prolonged the effective resuscitation. The optimal concentrations are believed to be a 4-mL/kg bolus of 7.5 percent sodium chloride in 12 percent dextran 70. [47] Despite the large quantity of sodium in this resuscitation regimen, hypertonic saline is thought to be beneficial in head injury. [48]

Platelets and coagulation proteins as well as red blood cells are contained in shed blood. Replacement of a patient's blood volume several times over leads to a coagulopathy secondary to thrombocytopenia and possibly consumption of fibrinogen and other coagulation enzymes. [49] Platelet counts lower than 70,000/mm^3 of blood indicate the need for immediate platelet transfusion. Platelet survival in bank blood is limited to a few days. Therefore, in the patient with massive volume replacement, platelet counts rapidly decrease. It is always preferable to wait for surgical hemostasis prior to platelet administration; otherwise, the transfused platelets will merely be lost to further hemorrhage.

Restoration of oxygen consumption to higher than normal levels is currently the best end point of resuscitation after hemostasis is achieved. Accumulative oxygen debt beyond a critical amount is the lethal insult in hemorrhagic shock. [50] Rapid repayment of the oxygen debt by increased oxygen delivery to the tissues with transiently elevated oxygen consumption heralds survival from critical illness. [51]

Practical Intravenous Fluid Management of Trauma Patients

During initial resuscitation, the anesthesiologist estimates the patient's blood loss by evaluating vital signs (Table 62-7) (Table Not Available) . For losses less than or equal to 30 percent of blood volume, crystalloid replacement of three times the volume of shed blood provides adequate resuscitation as long as hemorrhage is controlled. Patients with losses greater than 30 percent of blood volume or with continuing hemorrhage should receive colloid solutions and blood equal to the blood volume lost along with crystalloid equal to one to three times the volume of blood lost. These patients need ventilation with 100 percent oxygen to maximize oxygen delivery to the tissues until hemoglobin can be replaced. Patients with hemorrhage greater than or equal to 40 percent of blood volume require immediate red blood cell transfusion, along with the colloid or crystalloid resuscitation fluids. Type O (universal donor) packed cells can be safely administered to these patients without typing or crossmatch. Rh-negative units are reserved for women of childbearing age. If transfusion is begun with type O blood, it is generally recommended that after two units such transfusions continue with type O blood.

Following initial assessment of blood loss and planned fluid replacements, the anesthesiologist monitors the patient's response to therapy to guide further fluid therapy. Volume of fluid replacement and hemoglobin concentration are prescribed to achieve and maintain a maximal oxygen consumption--a plateau in the curve of oxygen consumption versus oxygen delivery. Normalization of the base excess (deficit) on arterial blood gases is another indicator that oxygen debt has been repaid. Levels of mixed venous lactate have been used in a similar fashion. Coagulation function is monitored, and appropriate replacement therapy is prescribed.

Preanesthetic History

Preanesthetic history includes information from the scene of the accident, either from witnesses or from the patient's own description. Information about how the injury occurred (i.e., "mechanism of trauma") helps the anesthesiologist to prepare for surgical correction of occult injuries. For example, an unbelted driver who sustained bilateral femur fractures in a frontal collision may have a traumatic aneurysm of the thoracic aorta from sudden chest deceleration on the steering wheel.

Preoperative information concerning allergies, preexisting diseases, previous operations, and drug therapy is as important in the trauma patient as in any other surgical patient. Although trauma patients must be treated as patients with full stomachs, careful inquiry into time and type of last oral intake reveals a variable potential for quantity and quality of stomach contents. [31] Self-medication with psychoactive drugs and alcohol is a particular problem with trauma patients. Careful questioning frequently reveals a pattern of substance abuse followed by injury, which is especially prevalent in chronic alcoholics. [52] Besides ethanol, trauma patients frequently are intoxicated with marijuana, cocaine, phencyclidine, and opioids. A history of chronic substance abuse or acute intoxication alerts the anesthesiologist to prepare for unusual responses to anesthetic drugs [53] (Table 62-8) .

Physical Examination

Trauma patients require a physical examination and laboratory testing, as do other surgical patients, but with concentration

TABLE 62-7 -- Changes in Vital Signs with Percent Blood Volume Lost by Hemorrhage

(Not Available)

Modified from American College of Surgeons [23]

TABLE 62-8 -- Common "Street Drugs" Complicating Trauma Anesthesia

DRUG	COMPLICATION
Ethanol	Chronic abusers have frequent serious injuries and require larger doses of many anesthetic drugs. Acute intoxication is additive with anesthetic drugs and reduces anesthesia requirements. Serum osmolarity may be used to estimate blood alcohol level. Delirium tremens from withdrawal may complicate post-traumatic care, and should be covered with benzodiazepine.
Opioids (e.g., heroin)	Chronic abusers have low pain tolerance, require increased doses of opioids, and may acutely withdraw with opioid antagonists. Frequent severe infections, including human immunodeficiency virus, complicate intravenous use. Patients may transmit viral diseases to the anesthesiologist. Acute withdrawal complicates post-traumatic care. Avoid use of antagonists.
Cocaine	Chronic abusers have paranoid delusions, labile blood pressure with extreme hypertension, and difficult vascular access. Acute toxicity causes seizures, ventricular fibrillation, and sudden death. Depression is common following withdrawal.
Marijuana	This drug is frequently mixed with ethanol. Chronic abusers have bronchitis. Acute toxicity is associated with tachycardia hypotension, injected sclera, and somnolence.

Phencyclidine (PCP)	Psychotomimetic effects are long lasting. Bizarre, violent behavior occurs, including apparently painless self-mutilation. Hallucinations are common. Acute intoxication resembles ketamine anesthesia with open-eyed stare, active laryngeal reflexes, hypertension, and tachycardia. Patients need special treatment for extended periods until drug-free.

on the respiratory, circulatory, and nervous systems. The status of the CNS is evaluated with a brief neurologic examination, including level of consciousness (GCS), pupil size, pupil reactivity, and motor function of each extremity. If the trachea is not intubated, the examination includes evaluation of the upper airway for potential intubation problems. Immobilization of the cervical spine increases the difficulty of intubation. The anesthesiologist should examine the patient's chest for signs of pneumothorax, myocardial contusion, and pericardial tamponade. The circulatory system is evaluated for signs of hemorrhagic shock and blood loss. Preexisting blood loss can be quantified according to changes in vital signs, as indicated in Table 62-7 (Table Not Available) . Arterial blood gases, chest radiographs, cervical spine roentgenograms, hemoglobin and hematocrit measurements, serum glucose, urea nitrogen, creatinine, and electrolytes as well as an electrocardiogram (ECG) round out the laboratory analysis.

Monitoring

Trauma patients require at least basic noninvasive monitoring in accordance with the minimal standards for surgical patients of the American Society of Anesthesiologists, [54] regardless of the anesthetizing location--emergency room, diagnostic area, radiology suite, operating room, or critical care unit (Chs. 28 to 38).

More invasive monitoring is indicated to evaluate the patient's response to therapy. Urinary output via an indwelling urethral catheter (Foley catheter) is an important indicator of fluid balance and renal perfusion. The urinary catheter is also a diagnostic tool for trauma to the urinary tract that causes hematuria. Oxygen consumption can be calculated from the pulmonary artery catheter measurements by using the product of cardiac output times the difference between the arterial oxygen pressure (Pa_{O_2}) and pulmonary artery oxygen content. Mortality from trauma varies inversely with post-traumatic oxygen consumption. [55] Therefore, early placement of a pulmonary artery catheter in appropriate patients cannot be overemphasized. Table 62-9 summarizes monitoring choices for the trauma patient.

INTRAOPERATIVE MANAGEMENT

General anesthesia is the technique of choice for patients with multiple injuries. Regional anesthesia may seem attractive because it causes little interference with the patient's cardiopulmonary function and avoids airway manipulation. However, patients with serious trauma benefit from endotracheal intubation and mechanical ventilation and are unlikely to cooperate with lying still during prolonged surgery. Sympathetic blockade from spinal or epidural anesthesia interferes with the homeostatic compensation for hemorrhage. Therefore, regional anesthesia is most useful for isolated limb trauma, for example, brachial plexus block for a forearm fracture.

TABLE 62-9 -- Monitoring Choices for Trauma Patients

Noninvasive	
Essential	ECG for heart rate, noninvasive blood pressure, respiratory rate, temperature, Sa o_2 , ET co_2 with waveform
Optional	Concentrations of anesthetic and respiratory gases (e.g., mass spectrometry, transcutaneous)
Invasive	Foley catheter urine output, intra-arterial pressure catheter, central venous pressure catheter, transesophageal echocardiography
Indications for pulmonary artery catheter	Massive hemorrhage Pretraumatic heart disease Multiple systems injuries/Mechanism of injury Monitoring of cardiac output and oxygen consumption Optimization of fluid therapy in head-injured patient

ECG, electrocardiography; Sa o_2 , arterial oxygen saturation; ET co_2 , end-tidal carbon dioxide pressure

Anesthesia Plan

General anesthesia can be administered safely in the patient with multiple injuries by choosing drugs that minimize cardiovascular depression and intracranial hypertension. Small doses of highly lipophilic drugs such as thiopental, etomidate, and sufentanil can be titrated to desired anesthetic effect without producing profound hypotension. Although pharmacokinetic data during hemorrhagic shock are limited, clinically these patients appear to reach desired drug effects from extremely small intravenous doses. The reduction in blood volume probably concentrates the delivered dose at the active site in the brain, and reduced hepatic blood flow may prolong clearance of the drug. However, normal doses of muscle relaxants need to be used to achieve the rapid paralysis necessary for endotracheal intubation. The drugs outlined in Table 62-6 for induction of anesthesia and endotracheal intubation are useful in the operating room as well as the emergency room.

Because the maintenance of cardiovascular homeostasis with cerebral perfusion by well-oxygenated blood has a higher priority than hypnosis or amnesia in the trauma patient, drug contraindications are extremely important for trauma anesthesia. Contraindicated drugs include ketamine for the head-injured patient, because it increases intracranial pressure as well as arterial pressure (Ch. 52) . Ketamine may actually cause hypotension in patients with high sympathetic tone. [56] Succinylcholine is contraindicated because of exaggerated hyperkalemia more than 24 hours after upper motor neuron (spinal cord) injury and more than 24 hours following major burns (Ch. 12) . The inadvertent use of succinylcholine in these patients can be treated with intravenous calcium, glucose, and insulin as well as cardiopulmonary resuscitation to support the circulation until the serum potassium falls to levels consistent with normal cardiac function. Table 62-10 outlines the adverse effects of succinylcholine. Short-acting, nondepolarizing neuromuscular blocking drugs such as mivacurium have a much longer onset time than succinylcholine, but they do terminate action rapidly. Large doses (several multiples of the ED_{95}) of vecuronium and rocuronium have been used to decrease onset time for neuromuscular blockade. However, this maneuver also prolongs the duration of neuromuscular blockade. Whether this issue is of any clinical significance is

TABLE 62-10 -- Adverse Effects Associated With Succinylcholine

Hyperkalemia, particularly following burns, spinal cord injuries, and generalized major trauma; there has been a single case report of a marked hyperkalemic response to succinylcholine in a patient with a closed head injury without peripheral paralysis
Increased intracranial and intraocular pressures, the practical importance of which is controversial
Increased intragastric pressure, although counterbalanced by the increase in lower esophageal pressure, which reduces or eliminates the increased risk of regurgitation
Muscle pains, more likely to concern the patient with minor injuries who ambulates soon after surgery
Prolonged paralysis in patients with atypical pseudocholinesterase
Cardiac arrhythmias, particularly bradycardiac after repeat doses
Trigger for malignant hyperthermia

debatable, however, as acute trauma patients requiring emergency airway management rarely can be awakened as a failsafe to failed intubation. Rather, management will usually proceed to placement of an LMA, Combitube, or another device, or a surgical airway is performed.

Nitrous oxide is contraindicated in patients with potentially closed air spaces in which this anesthetic will accumulate, such as patients with pneumothorax, pneumocephaly, and gas-filled bowel loops (Ch. 2) . Its use in head-injured patients is controversial, but at low concentrations its contribution to cerebral blood flow/metabolism imbalance is probably minimal. [57] Nitrous oxide has also been demonstrated to decrease cardiac output when combined with opioids. [58] Thus, the use of nitrous oxide should be specifically indicated for trauma patients, not used routinely. Anesthesia machines should be equipped to deliver air, oxygen, and nitrous oxide for use with these patients so that air-oxygen mixtures may be used to decrease the inspired oxygen fraction (F_{IO_2}). Finally, halogenated hydrocarbon vapors should only be used with mild hyperventilation for patients with head injuries.

Common Intraoperative Problems

Despite the complexities of the injuries in a patient with multiple trauma, certain intraoperative problems occur frequently. Some problems--prolonged anesthesia, hypothermia, and massive transfusion--are consequences of long and difficult surgery in a patient with uncontrolled hemorrhage. Other complications, namely, facial

trauma, burns, hypoxia, fever, and malignant hyperthermia (MH), are a result of specific injuries or patient characteristics. The pregnant patient, the very young patient, and the very old patient present special problems for trauma anesthesia. Finally, cardiac arrest (usually electromechanical dissociation) is the terminal event for acute trauma victims who die in the operating room.

Prolonged Surgery

Prolonged operations require prolonged anesthetic regimens. Optimal outcome for an unstable multiply injured patient is achieved if all injuries can be corrected at the time of initial surgery. The victim of blunt trauma with multiple fractures especially benefits from early fracture fixation that reduces ongoing hemorrhage, intravascular release of bone marrow, and postoperative complications of immobilization. [9] [22] The anesthesiologist must treat the operating room as an intensive care unit for these patients. During surgery that approaches or exceeds 24 hours, patients need daily replacement of electrolytes and minerals as well as replacement of blood loss and third-space loss of water.

Hypothermia

Maintenance of temperature homeostasis challenges anesthesiologists caring for multiply injured patients (Chs. 37 and 52). Many patients enter the trauma center with low body temperature, and an inverse relationship between

temperature and trauma score has been noted. [59] Prolonged exposure to a cold operating room, evaporative heat loss from the respiratory tract, infusions of cold fluids, and loss of heat production secondary to shock cause decreased core temperature in most patients. All skin surfaces not in the surgical field should be covered to reduce convective and radiant heat loss. Humidification of inspired gases reduces evaporative heat loss from the lung, and saturation of inspired gases with water heated higher than body temperature produces active warming of the patient. All intravenous fluids should be warmed; modern equipment is available, with heat exchangers capable of warming fluids to 37°C at very rapid infusion rates. Other techniques of temperature maintenance include warming of the operating room to more than 22°C, irrigation of open body cavities with warm saline, and continuous arteriovenous rewarming. [38]

Massive Blood Transfusion

Prolonged surgical attempts to achieve hemostasis may require the anesthesiologist to replace massive amounts of fluids (Chs. 45 and 46). After their blood volume has been replaced several times, patients frequently develop dilutional thrombocytopenia, prolonged clotting times, and transient reductions in calcium ion concentration. Coagulopathy is treated with appropriate factor replacement. Maintenance of normothermia is especially critical to maintain normal hemostatic coagulation function. [60] Temperature correction of prothrombin time and partial thromboplastin time often reveals a hypothermia-induced reversible coagulopathy in cold patients who are clinically coagulopathic but who have normal coagulation studies measured at 37°C in the laboratory. The anesthesiologist should monitor the coagulation status to prescribe replacement therapy accurately. [49] Calcium replacement is initiated when ionized calcium levels decrease secondary to citrate chelation or when hypotension occurs despite adequate volume replacement. [61] The bivalent cation Ca^{2+} is the active form of calcium, and replacement based on calcium concentrations should be based on measured ionized calcium, not total calcium.

Maxillofacial Injuries

Maxillofacial trauma with fractures of the mandible and/or midface frequently compromise the patient's airway and cause difficult tracheal intubation conditions (Ch. 63) . Awake intubation, via either direct laryngoscopy or fiberoptic bronchoscopy, is indicated. Mask ventilation frequently is impossible because of facial skeletal deformity, excessive intraoral bleeding, or basilar skull fractures with cerebrospinal fluid rhinorrhea. Many patients with maxillofacial trauma have associated head and cervical spine injuries. [26] A tracheostomy is the most secure route of tracheal intubation for patients with facial trauma who will require prolonged ventilatory support. Postoperative intramaxillary fixation and nasal packing may make reintubation impossible if the endotracheal tube is dislodged. Because most of these patients can be intubated translaryngeally, it is safer to perform the tracheotomy over an endotracheal tube. A tracheostomy tube with appropriate stay sutures placed next to the stoma can be replaced if required. The laryngeal mask airway or Combitube (Sheridan) can be used to support ventilation and oxygenation during tracheostomy in some patients with maxillofacial injuries that are extremely difficult to intubate.

Fever commonly occurs in patients with panfacial fractures who are undergoing open reduction and fixation of these fractures. This fever is probably secondary to bacteremia from fractures through the paranasal sinuses and can be differentiated from MH by the absence of combined respiratory and metabolic acidosis on blood gas analysis.

Malignant Hyperthermia

MH is a relatively rare complication of anesthesia, which may occur in the trauma patient (Ch. 27) . The pain of trauma, especially fractures, may trigger MH without the presence of anesthetics. [62] The treatment of MH is the same in the trauma patient as in elective surgical patients. However, it may be necessary to complete the operation to save the trauma patient's life. All operating rooms should have an adequate supply of dantrolene to start therapy for a patient with MH.

Thermal Injury

Burns are one of the most severe forms of trauma that a patient can survive. Burn patients present anesthetic challenges, because they have difficult vascular access, fluid and electrolyte imbalances, increased requirements of nondepolarizing muscle relaxants, and temperature regulation problems. Patients with significant full-thickness burns should be managed in a specialized burn center that can cope with the critical care and infection control of burn patients. Circumferential burns may require an immediate escharotomy to retain limb blood flow or chest expansions. [63]

Hypoxia

Intraoperative hypoxia in an acute trauma patient is usually secondary to an occult pneumothorax that has expanded or to pulmonary embolism with bone marrow contents (fat emboli syndrome) (Ch. 72) . Nitrous oxide should be avoided in patients with suspected pneumothorax. Immediate needle decompression followed by chest tube drainage should be started as soon as a pneumothorax is identified. Hypoxia secondary to long-bone fractures responds to mechanical ventilation and early fracture fixation, which reduces continuous seeding of marrow fat into the venous circulation. [22] Prolonged delay in fixation of isolated long-bone fractures while the patient breathes spontaneously frequently causes acute ARDS and classic fat embolism syndrome. [10] [23] Similarly, if patients are extubated immediately following fracture fixation despite evidence of poor oxygenation and a large pulmonary venous admixture, they will develop ARDS and probably the fat emboli syndrome. These patients benefit from mechanical ventilation with positive end-expiratory pressure (PEEP) titrated to reduce the intrapulmonary shunt until the ARDS resolves. [9] [22] [24]

Cardiac Arrest

Cardiac arrest following blunt trauma and hemorrhagic shock carries an abysmal prognosis (Chs. 75 and 76). When the heart finally arrests from low perfusion, significant ischemic damage has already occurred in other organ systems. Cardiac arrest in the operating room during emergency trauma surgery usually occurs with a rapidly falling arterial pressure, electromechanical dissociation, and ventricular standstill. Profound hypothermia usually heralds cardiac demise and may be the result of massive cellular necrosis as well as the cause of cardiac arrest.

Pregnant and Pediatric Trauma Patients

Pregnant women are not excluded from major trauma, which is assuming an increasing role in maternal mortality in recent years [64] (Chs. 57 and 59). Care of the pregnant patient is organized toward saving both mother and fetus. Frequently, however, profound maternal shock kills the fetus, and rapid operative termination of

the pregnancy becomes necessary to save the mother's life. Anesthesia for the pregnant trauma victim must be designed to minimize risk to the fetus. Second- and third-trimester patients should receive fetal heart rate monitoring, with patient positioning (left lateral uterine displacement) to maximize uterine blood flow and fetal heart rate. Teratogenic anesthetic drugs put the fetus at risk in early pregnancy; therefore, intravenous anesthesia is the technique of choice for early pregnancy. [64] Occasionally, a mother receives a devastating brain injury but retains a viable fetus. Artificial life support can maintain the mother until the fetus reaches an age appropriate for delivery. Outcomes of such pregnancies are not uniformly successful, and such life support places a tremendous burden on the intensive care unit staff if continued for more than about 2 days.

Care of the pediatric trauma patient follows the same principles as care of the adult trauma patient. Seriously injured children benefit from early intubation because hypoxia rapidly develops in the hypoventilating child. Accurate fluid replacement is critical in injured children to avoid prolonged ischemia and fluid overload. Well-informed anesthesia care and postoperative pediatric critical care will help to reduce the childhood mortality rate from trauma. Seriously injured children should be transferred to a pediatric trauma center for follow-up care as soon as they are sufficiently stable. [65]

POSTOPERATIVE PERIOD

The seriously injured patient requires major therapeutic interventions postoperatively--both acute critical care and prolonged rehabilitative therapy. The extensive high-technology therapy required to restore the trauma victim to maximum post-traumatic functional levels adds to the high cost of trauma care. [14] Total care of trauma patients is one of the most costly medical endeavors in the United States. Anesthesiologists are especially concerned with the postanesthesia recovery room and the critical care unit.

Postanesthetic Care Unit

Recovery room problems uncommonly seen in the trauma patient include vomiting and aspiration on emergence, delayed recovery from anesthesia, emergence delirium, and incomplete preoperative diagnosis (Ch. 68). Because patients who had eaten just prior to an accident have a high probability of delayed gastric emptying, they may vomit on emergence from anesthesia. Tracheal extubation of trauma patients following emergency surgery should be delayed until the patient has recovered gag and cough reflexes to protect the airway. [31] Criteria for extubating patients following trauma surgery also include the ability to maintain adequate spontaneous respiration, secretion clearance, and oxygenation.

Emergency surgery to correct traumatic injuries frequently must occur so precipitously that a patient does not receive a complete work-up; only the most life-threatening condition is diagnosed and treated. These patients need completion of their surgical diagnosis in the recovery room. One of the most troubling examples of postoperative diagnosis is the patient who does not wake up promptly from anesthesia because of an unsuspected head injury or drug intoxication. The anesthesiologist can assist in the differential diagnosis by demonstrating neuromuscular transmission and end-tidal anesthetic concentrations, possibly administering narcotic and benzodiazopine antagonists (if appropriate; see below), and collecting blood, urine, and gastric contents for toxicologic screening. The patient's family may provide information about the patient's medical or surgical history as well as pretraumatic ingestion of drugs or alcohol.

In contrast to trauma patients with prolonged coma in the recovery room, others emerge from anesthesia in a delirious state. Combative persons who awaken with pain and confusion in a recovery room following emergency surgery that they cannot remember are bound to be agitated. Besides disorientation and fear, drug intoxication or withdrawal may cause emergence delirium. Common approaches to these problems include administration of antagonist drugs such as naloxone, flumazenil, and physostigmine. However, although use of these drugs may be appropriate, it should be remembered that such use can cause complications in trauma patients (e.g., naloxone can trigger acute withdrawal syndrome, cause cardiac arrest, or cause pulmonary edema and may elevate intracranial pressure in head-injured patients). Patients who are disoriented because of their injuries are treated by reassurance and analgesics. Agitation may occur from a head injury or hypoxia, so these diagnoses must be excluded. Delirium from drug abuse requires sedation of the patient and identification of the offending agents for definitive care. [53]

Critical Care Unit

The critical care unit is reserved for the most unstable trauma patients (Ch. 71). Sepsis and multisystem organ failure are the most common causes of postoperative death of trauma victims. [9] [10] [14] Careful attention to metabolic and nutritional support and optimal cardiopulmonary support are necessary to give these patients their best chance of survival. Prophylactically, rapid and complete resuscitation helps to prevent ARDS, sepsis, and multisystem organ failure. [66]

ARDS is a particular problem for anesthesiologists because these patients frequently develop surgical problems while convalescing in the critical care unit and require anesthesia for surgical correction. The anesthetic must be delivered through a ventilator capable of maintaining high minute volumes with elevated airway pressures. Most gas-powered anesthesia ventilators cannot deliver high minute ventilation to a patient who requires high levels of PEEP to maintain oxygenation. Treatment of ARDS is supportive while the lung heals itself. Prevention of ARDS follows the principles of prevention of multisystem organ failure (i.e., prevent prolonged tissue ischemia during resuscitation). Pharmacologic therapy for ARDS has proved to be disappointing. Much developmental work is proceeding on alternate methods of oxygenation to be used in emergency situations. [67]

Transportation

One complication of trauma care is the continuous need to transport critically ill patients throughout the hospital [24] (Ch. 66) . Patients suffering from multiple blunt trauma frequently have associated head injuries and require multiple brain CT scans for diagnosis and follow-up of treatment regimens.

CT, magnetic resonance imaging, and radionuclide imaging techniques are used to outline the extent of injury in other body regions besides the head. Because these imaging techniques require fixed specialized equipment, patients must be moved to the imaging area.

Critically ill patients require portable, battery-operated monitors for intra-arterial, intracranial, and pulmonary artery pressures as well as ECG, pulse oximetry, and, ideally, capnography. The biomedical industry is placing more attention on miniaturizing these monitors and developing patient-sensor interfaces that are resistant to motion artifacts. Ventilation during transportation is more consistent when delivered by a portable ventilator than by hand. At least one critical care ventilator (Siemens 900C) can be powered by an automobile storage battery during transport, so that the patient can be maintained on constant ventilator settings. Patients with head injury who have intracranial pressure that is critically sensitive to Pa CO_2 should be transported with constant ventilation. The development of portable, battery-powered carbon dioxide monitors will facilitate monitoring ventilation during patient transport. Transportation by helicopter or ambulance accentuates all the problems of transportation of critically ill patients and is a frontier of trauma care in which anesthesiologists can have a vital impact.

SUMMARY

Trauma care is becoming an increasingly important part of modern medical practice as advances in care reduce the mortality from other diseases. Organizational changes for the delivery of emergency care have had a tremendous impact on trauma morbidity and mortality. The challenge for the 1990s is to reduce the mortality from trauma for patients who arrive at the hospital alive. The term "golden hour" was coined to describe the window of opportunity to treat a seriously injured patient successfully and is used to accentuate the need for trauma center development. This term emphasizes the need for rapid response to treat traumatic shock and to transport injured patients to definitive treatment centers. The future challenge for anesthesiologists and trauma surgeons is to prevent death from irreversible shock and to extend the treatment window of opportunity to a golden 2 hours by perfecting in-hospital treatment of seriously injured patients. The goal of treatment is to provide cardiopulmonary cerebral resuscitation for the critically injured patient. Such optimum care will give the trauma patient a chance to return to functional life. Efforts are currently underway worldwide to increase the level of involvement of anesthesiologists in clinical traumatology and research. These efforts are being coordinated under the auspices of the International Trauma Anesthesia and Critical Care Society.

Chapter 63 - Anesthesia for Eye, Ear, Nose, and Throat Surgery

John V. Donlon Jr.

ANESTHESIA FOR EYE SURGERY

Introduction

Anesthetic management can contribute to the success or failure of ophthalmic surgery. A closed-claims analysis by Gild et al [1] found that 30 percent of eye injury claims associated with anesthesia were characterized by patient movement during ophthalmic surgery. Blindness was the outcome in all cases. Although most problems occurred during general anesthesia, one of every four appeared under monitored anesthesia care. Clinical strategies to ensure patient immobility during ophthalmic surgery are essential.

Patient selection, preoperative evaluation, preparation, monitoring, sedation, and local anesthesia techniques are especially important for safe outpatient cataract surgery in the elderly (Chs. 61 and 65) . An understanding of eye anatomy and of the effect of anesthetics on intraocular pressure (IOP) and eye physiology is important when making anesthetic management decisions concerning such situations as strabismus, open eye injuries, performance of local anesthetic techniques, intravitreal gas injections, electroretinographic studies, oculocardiac reflex, and retinopathy of prematurity. [2]

Local Anesthesia

Many ophthalmic procedures, such as cataract extraction, corneal transplants, trabeculectomy, lid surgery, and even vitrectomy or repair of a detached retina, can be performed safely in an outpatient setting, using regional anesthesia and mild sedation. The number of outpatient ophthalmic procedures will increase as health-care costs are contained and the population continues to age. The elderly constitute a large percentage of the 4 million people in the United States who have vision problems related to cataracts. For example, 46 percent of people more than 75 years of age have cataracts. [3]

These elderly ophthalmologic patients frequently also have associated diseases of concern to the anesthesiologist. Congestive heart failure, hypertension, diabetes, angina, chronic lung disease, senility, parkinsonism, and arthritis are all problems that can disrupt a smooth procedure.

Preoperative Evaluation and Preparation

Successful local anesthesia for eye surgery begins with preoperative screening, patient selection, and preparation for anesthesia. Although the general principles of preoperative evaluation and medication are standard (Ch. 23) , specific considerations are important for ophthalmic surgery and anesthesia. Patients with chronic spontaneous cough, shortness of breath while lying flat, parkinsonian head tremor, Alzheimer disease, or claustrophobia may be very difficult to manage with regional anesthesia and light sedation. These patients may best be managed with a general anesthetic. Every effort must be made to help the patient understand the procedure. Hearing aids and dentures should be left in place. Patients are less embarrassed and

may even breathe better with dentures in place. The presence of an interpreter to explain the procedure and the need for cooperation helps to overcome any language barrier. The interpreter should be present at the time of peribulbar block, the most stressful part of the procedure.

Whenever possible, medication regimens should not be interrupted. Treatments for asthma, hypertension, angina, congestive heart failure, or diabetes should be continued throughout the day of surgery. Patients with postnasal drip should be given a drying agent before surgery, and those with gastric esophageal reflux should at least receive metoclopramide (0.15 mg/kg IV).

A thorough explanation of the technique, monitoring, and safety precautions involved in regional anesthesia for eye surgery allays patient anxiety and increases acceptance and cooperation in most cases. Thus, the preoperative anesthesia interview is most important in obtaining cooperation and patient acceptance. Still, premedication can be helpful in lessening anxiety and enhancing amnesia during injection for peribulbar block. The patient must be calm, cooperative, and aware during the operation, and the reflexes should not be obtunded, nor should the airway be obstructed. In the outpatient setting, intramuscular premedication is unnecessary, but proper sedation levels can be achieved by intravenous titration while monitoring effect. The patient should be monitored during the block process and provided with supplemental oxygen.

The ideal sedating drug prior to eye block would ensure amnesia for the block, decrease the discomfort of the injection, and limit patient motion while producing no cardiovascular or significant respiratory side effects. Many agents and combinations have been used for sedation during monitored anesthesia care, including alfentanil, remifentanil, midazolam, and propofol. [4] [5] [6] [7] [8] Benzodiazepines are synergistic with narcotics and increase the risk of apnea. [9] Altered pharmacodynamics with age require decreasing narcotic doses in the elderly. [10]

Propofol in small (20-mg) incremental intravenous doses has been used to achieve amnesia for regional eye blocks. [11] Propofol provides no analgesia for the block needle insertion, and semiconscious patients may have a startle response.

Remifentanil (0.3-0.5 mug/kg IV) has a 90- to 120-second onset time and a 5-minute duration. The patient is calm and cooperative although aware during the eye block but does not move or startle. A small supplement of midazolam (0.5-1.5 mg IV) may be added to this sedation regimen, but it is synergistic and increases the risk of temporary apnea. Midazolam has a 2- to 3-minute onset and 45- to 60-minute duration of action.

Infusions of propofol or narcotic are not necessary during eye surgery. The eye block provides the necessary analgesia and akinesia. The patient should remain awake and aware, but calm and cooperative, during the procedure.

Gold et al [6] noted a 13 percent incidence of nausea and vomiting associated with remifentanil infusion. Low-dose (30 mug IV) bolus injections of remifentanil are not expected to cause nausea or vomiting.

If a narcotic must be used, an antiemetic drug such as droperidol (0.01 mg/kg IV), ondansetron (0.06 mg/kg IV), or dolasetron (0.20 mg/kg IV) may also be given to counteract the tendency of narcotics to cause nausea and vomiting.

Monitoring

Standard monitoring for regional anesthesia for ophthalmic surgery (Chs. 42 and 43) includes observation of arterial blood pressures, the electrocardiogram (ECG),

and the pulse oximeter. If possible, peribulbar block should be performed in a special block area at least 20 minutes before the start of surgery. This interval allows time for the block to become effective, for the use a Honan cuff to lower IOP, and for the patient to begin to recover from sedation. The Honan cuff pressure or the block injection may induce an oculocardiac reflex vagal response that causes bradycardia and nausea. Open eye surgery should not proceed if nausea exists; this complaint should be treated and allowed to subside before proceeding.

Monitoring in the operating room is also standard (Chs. 42 and 43) , but special precautions must be taken because the patient's face is covered by drapes. Respirations may be monitored by direct vision and placing a CO_2 sampler near the mouth. A 4:1, air-oxygen facemask having a total flow rate of at least 10 L/min should be used to supplement oxygen and to prevent accumulation of CO_2 under the drapes surrounding the face. These drapes should be tented away from the patient, to prevent claustrophobia and to permit free flow of air.

Postoperative Care

Postoperative care and discharge are standard (Chs. 65 and 68) . The patient is discharged into the care of a responsible adult who provides help when the patient is walking and eating, as well as home care the night after surgery. Moreover, written instructions from the surgeon are provided. Regional anesthesia for eye surgery is generally safe even for elderly patients having a history of myocardial infarction. [12] However, 26 percent of high-risk (diabetes, hypertension) ambulatory patients having retina surgery under local anesthesia had at least one silent myocardial ischemic event within 18 hours of surgery. [13] These events were usually associated with an increased heart rate. Therefore, the cardiac medication regimen should be continued in the perioperative period, and the use of prophylactic beta-blockers should be considered. [14]

Regional Eye Blocks

Wong [15] and Troll [16] reviewed regional anesthesia techniques for intraocular surgery in detail and presented an excellent description of important orbital anatomy. Techniques for peribulbar/retrobulbar blocks, facial nerve blocks, and choice of anesthetic mixture and types of needles were discussed. Complications associated with retro-bulbar versus peribulbar techniques were discussed and compared. Peribulbar anesthesia carries a lower risk of serious complications. Anesthesiologists can easily acquire expertise in this area on a par with that of ophthalmologists. The importance of a detailed knowledge of orbital anatomy and physiology and attention to detail cannot be overemphasized. [15]

Peribulbar Block

Hamilton et al [17] showed that safe, comfortable, and effective analgesia and akinesia of the eye can be obtained using a peribulbar block; that is, local anesthetic is injected outside the muscle cone. Hamilton and colleagues used their "customized peribulbar block" in more than 10,000 patients without the occurrence of complications (brain-stem anesthesia, retrobulbar hemorrhage, atrophy of the optic nerve, or spread of anesthetic to the contralateral orbit).

Davis and Mandel [18] reviewed 16,225 peribulbar blocks and found them to be effective, with a very low complication rate. Globe perforation occurred in a patient with an eye axial length of 23.5 mm, using a harp needle via a superonasal approach. Akinesia was achieved in 95 percent of patients, and the reinjection rate was about 10 percent. Amaurosis is usually not expected with peribulbar blocks. Disadvantages of peribulbar blocks include the following: large injected volumes (6-8 mL), causing increased IOP [19] ; slower onset (7-12 min); possible globe perforation; myotoxicity of local anesthetic on inferior rectus muscle causing vertical diplopia. [20] [21] [22] [23] [24]

The customized peribulbar block described by Hamilton and coworkers [17] requires attention to detail to maximize patient comfort and good analgesia and to minimize complications. Dull, short-beveled needles are usually recommended to minimize the risk of bleeding and perforation of the globe. Careful placement of the needle and an aspiration check of its contents decrease the risk of vessel perforation. Hamilton and coworkers [17] recommended making the initial injection through the inferior fornix of the conjunctiva, rather than transcutaneously after topical application of 0.5 percent proparacaine. The needle is not inserted beyond 25 mm, because large vessels and the optic nerve are more likely to be encountered with deeper retrobulbar penetration. No attempt is made to pierce the muscle cone.

The traditional practice of having the patient look upward and in, to make the muscle cone more accessible, also brings the optic nerve and vascular structures closer to the tip of the needle, thus increasing the risk of retrobulbar hemorrhage, optic nerve injury, or central nervous system (CNS) tracking of local anesthetic along the optic nerve sheath. A safer maneuver is to have the patient look straight ahead (neutral gaze position) and to avoid entering the cone. All injections should be performed slowly, to ensure patient comfort and to promote the even spread of local anesthetic within the orbit.

Use of an orbital compression balloon facilitates the block by lowering IOP and promoting the periorbital spread of local anesthetic to achieve akinesia of the periorbital muscles. In this way, the need for a separate and painful block of the facial nerve is avoided. Any complications that occur (vasovagal reactions, retrobulbar hemorrhage, spread of the local anesthetic to the CNS) are usually obvious within 10 to 15 minutes of injection.

This procedure is virtually painless because of use of the peribulbar approach, careful placement of fine needles, slow injection of local anesthetic, and avoidance of a separate block of the facial nerve. As a result, the elderly outpatient population usually needs minimal premedication with fewer drug side effects (e.g., somnolence, hypotension, emesis). The local anesthetic mixture advocated by Hamilton and colleagues [17] consists of equal portions of 2 percent lidocaine for rapid onset and penetration and 0.75 percent bupivacaine for prolonged duration and postoperative comfort. The addition of hyaluronidase (3 U/mL) promotes spread of local anesthetic, and the addition of epinephrine (in a final concentration of 1:400,000) reduces bleeding, promotes vasoconstriction, and prolongs orbital akinesia.

The peribulbar technique requires a total of approximately 6 mL of injectate. The total amount of epinephrine injected is small and should pose no problem to patients with angina, hypertension, or irritable myocardia.

Sub-Tenon Block

Direct injection of local anesthetic into the posterior sub-Tenon space using blunt dissection and a blunt probe avoids many of the complications of peribulbar or retrobulbar injections. [25] [26] [27] [28] Tenon capsule is a dense fibrous layer of connective tissue surrounding the globe and extraocular muscles. Local anesthetic in the posterior aspect of this space spreads along the extraocular muscles and diffuses into the retrobulbar space.

This technique uses a blunt probe (curved lacrimal cannula) to instill local anesthetic into the posterior sub-Tenon space, avoiding sharp needles blindly placed in the orbit or retrobulbar space. It is painless and provides reliable anesthesia with minimum risk of serious complications. [26]

Ripart et al [25] have shown computed tomographic (CT) confirmation that a sub-Tenon medial canthus injection is episcleral and allows the local anesthetic to spread over the extraocular muscles and to provide akinesia. A volume of 4 mL is sufficient to surround the globe and to produce analgesia. The sensitivity of the eye is provided by the ciliary nerves, which cross the episcleral space after they emerge from the globe. [25]

Complications

The complications associated with retrobulbar block techniques, although rare (approximately 1 in 500 blocks), usually occur within 15 minutes of injection and are the result of apprehension, pain, oversedation, local anesthetic toxicity, the method of needle placement, or injection of local anesthetic. Hypotension, bradycardia, cardiac arrest, diaphoresis, and nausea are usually responses to fear or pain of injection or to manipulation of the eyeball. Patients should have intravenous oxygen and full monitoring (e.g., ECG, blood pressure, oxygen saturation) during the block procedure.

The oculocardiac reflex (OCR), a vagal response manifested by cardiac arrhythmias and hypotension, may be elicited by pain, pressure, or manipulation of the eyeball. Treatment requires administration of oxygen, Trendelenburg positioning, intravenous administration of crystalloid, discontinuation of pressure or muscle traction at the eyeball (e.g., release of the Honan balloon), and, on occasion, intravenous administration of atropine.

Retrobulbar hemorrhage occurs in 1 of 700 retrobulbar blocks and is usually noted during injection as the eye tenses and pushes forward. Treatment includes the application of

gentle pressure for 20 to 30 minutes and, perhaps, a lateral canthotomy and rescheduling of surgery. This complication is less likely with peribulbar or sub-Tenon blocks.

Direct trauma to the eye (optic nerve damage, scleral perforation) occurs rarely (less than 1 in 1,000 retrobulbar injections). Possible needle penetration risk factors include increased axial length of the needle because of high myopia or previous scleral buckle procedure and poor patient cooperation during the injection. In one study, 70 percent of globe perforations involved sharp, full-beveled needles. Birch et al [29] used ultrasonic localization to show that 56 percent of retrobulbar needle shafts indent the globe. Optic nerve damage and retrobulbar hemorrhage may be minimized by having the patient look straight ahead and by avoiding deep penetration into the orbit. Shivering occurs in approximately 0.64 percent of patients, probably because of the absorption of local anesthetic into the CNS (Chs. 13 and 42 to 44).

Javitt et al [30] reported eight instances of brain-stem anesthesia after retrobulbar block, six of which progressed to apnea requiring mechanical ventilation. The clinical picture of brain-stem anesthesia can include amaurosis, gaze palsy (ductional defects), dysphagia, cardiac arrest, shivering, apnea, tachycardia, hypertension, loss of consciousness, and dilatation of the contralateral pupil. Full recovery from brain-stem anesthesia is the expectation, provided early detection and proper treatment occur. [31]

Nicoll et al [32] found that direct spread of local anesthetic to the CNS along the optic nerve sheath, although infrequent, caused severe, unpredictable, life-threatening complications within 2 to 40 minutes of injection in 1 of 750 retrobulbar blocks. If recognized early and treated promptly, patients usually recover within 60 to 90 minutes and do well. Access to the brain stem can be via direct injection of local anesthesia into the optic nerve sheath during deep retrobulbar approach, tracking retrograde to the midbrain and respiratory area of the brain stem. The effect may be delayed 5 to 15 minutes after injection and lasts for 20 to 90 minutes.

Another mechanism can be an intra-arterial injection with retrograde flow through the ophthalmic artery into the cerebral circulation and midbrain area. Onset is usually immediate and may be associated with seizure activity. Life-threatening complications associated with regional eye blocks can occur quickly and require the anesthesia care team to be prepared and vigilant. Treatment includes oxygen, intravenous fluids and pharmacologic circulatory support, suppression of convulsions, and, if necessary, intubation and cardiopulmonary resuscitation. [33] Javitt et al [30] noted that communication between the optic nerve sheath and subarachnoid space had been demonstrated and that contrast material is able to track along the optic nerve to the optic chiasm and into the subarachnoid space surrounding the pons and midbrain areas. Such an occurrence would be consistent with the signs and symptoms manifested by their patients. Javitt and coworkers also noted that a down-and-out gaze for retrobulbar block injection was safer than the traditional up-and-in gaze. Brain-stem anesthesia has not yet been reported for the peribulbar method of eye anesthesia. Javitt and colleagues concluded that careful monitoring and the presence of an anesthesiologist during administration of anesthesia for the eye are necessary to detect and treat these rare but serious complications.

Postoperative vertical diplopia resulting from muscle fiber degeneration in the inferior rectus muscle has been reported following regional local anesthetic injection for cataract surgery with an incidence of 1.4 percent. [20] Diplopia may be temporary or permanent. Possible causes include traumatic injection, myotoxicity of local anesthetic solution, bridle sutures, surgical trauma, ocular compression, and injectate volume pressure. Carlson and Raimin [22] found muscle degeneration following bupivacaine, mepivacaine, or lidocaine injected near extraocular muscles in rats. Damage reflected diffusion of the anesthetic into the muscle. General recommendations include the following: limiting the injected volume to 6 mL, slowly injected; avoiding injecting into the muscle body; injecting lateral to the inferior rectus muscle [21] ; and avoiding 4 percent xylocaine injectate and adding Wydase to the injection solution.

Postoperative ptosis following cataract surgery is reported with an incidence as high as 13 percent. This usually is associated with the levator palpebrae muscle. Feibel et al [34] found no significant difference in the incidence of ptosis between peribulbar or retrobulbar injections. Injection of a large volume of local anesthetic into the upper lid should be avoided when possible.

Intraocular Pressure

Management of anesthesia for ophthalmic surgery requires control of IOP before, during, and after the procedure. Control of IOP is often important to the success of the procedure. Therefore, the anesthesiologist must understand the physiologic effects of IOP and the implications of anesthetic drugs and maneuvers on IOP. Cunningham and Barry [35] and Murphy [36] thoroughly reviewed the physiologic determinants of IOP and its relation to management of anesthesia.

Physiologic Determinants

Normal IOP is approximately 12 to 20 mm Hg. The most important influences on IOP are movement of aqueous humor, changes in choroidal blood volume, central venous pressure, and extraocular muscle tone. The main physiologic determinant of IOP is the dynamic balance between the production of aqueous humor, a watery, clear fluid in the ciliary body of the posterior chamber, and its eventual elimination into the episcleral venous system via spaces of Fontana and the canal of Schlemm at the iridocorneal angle (Fig. 63-1) (Figure Not Available) .

Most of the aqueous humor is actively secreted at the ciliary process of the posterior chamber and circulates freely around the iris into the anterior chamber. Any increase in venous pressure or decrease in the cross-sectional area of the spaces of Fontana increases resistance to outflow of aqueous humor and increases IOP. Mydriatic drugs relax ciliary muscles, close the iridocorneal angle at Fontana spaces, and thereby increase IOP. Coughing, straining, and Valsalva maneuvers significantly increase central venous pressure, decrease the outflow of aqueous humor from the Schlemm canal into the episcleral venous system, and thus increase IOP.

Figure 63-1 (Figure Not Available) Circulation of the aqueous humor. *(From Aboul-Eish [221])*

Changes in choroidal blood volume (CBV) also affect IOP significantly. The choroid is a vascular meshwork of arterial anastomoses located in the posterior chamber. Choroidal blood flow is usually autoregulated over a range of perfusion pressures to keep IOP stable. Sudden increases in systolic arterial blood pressure cause a transient swelling of CBV; a subsequent temporary outflow adjusts IOP toward normal. Hypotension (systolic arterial blood pressure <90 mm Hg) may reduce IOP as CBV decreases. Sudden increases in CBV can force vitreous gel forward into the anterior chamber during open eye surgery or can increase IOP in the intact eye. Coughing, bucking, emesis, and the Valsalva maneuver increase CBV by increasing central venous pressure and thus increase IOP. Coughing can increase IOP to 30 or 40 mm Hg. CBV, and therefore IOP, will also increase in response to respiratory acidosis and hypercarbia. Choroidal circulation is also sensitive to changes in the partial pressure of oxygen. Hypoxia induces choroidal vasodilation and increases IOP.

When the eye is open during surgery, IOP may be somewhat lower than normal. The transluminal pressure on the choroidal vessels is greater, and a sudden increase in choroidal pressure caused by hypertension, increased venous pressure, or hypercarbia is likely to result in spontaneous bleeding of the choroidal vessels.

The CNS exerts some degree of control over IOP. Experiments with cat diencephalon indicate the areas that affect IOP. Some responses seem to be mediated neurovascularly, whereas others relate to increased extraocular muscle tone. These centers are usually depressed by barbiturates and volatile inhaled anesthetics.

Murphy [36] reviewed factors affecting intraocular blood volume and concluded that, although arterial blood pressure exerts some control over IOP, its effect over a physiologic range of blood pressures is small. A more definite, direct relationship exists between central venous pressure and IOP. A slight head-up tilt during intraocular surgery helps to counteract the effects of central venous pressure.

Intraocular vascular tone is predominantly affected by CO_2 and control areas in the diencephalon. A linear relationship exists between IOP and increasing CO_2 partial pressures. Hypocarbia decreases IOP through vasoconstriction of the choroidal blood vessels and decreases formation of aqueous humor through reduced carbonic anhydrase activity. The increased IOP associated with hypoventilation and hypercarbia occurs as a result of vasodilation of CBV and increases in central venous pressure.

Sudden external pressure on the eyeball initially increases IOP and may induce an oculocardiac vagal reflex. The increased IOP promotes outflow of aqueous humor, thus returning IOP toward normal. The effects of direct external compression of the eyeball on vitreous gel and CBV have not been documented.

Injecting a large volume (8-10 mL) of fluid into the orbit (e.g., peribulbar block [PBB]) may significantly increase IOP. [19] IOP reaching the level of retinal arterial pressure can cause retinal ischemia.

Anesthesia and Intraocular Pressure

Most anesthetics reduce IOP. In general, they relax extraocular muscle tone, depress the CNS (i.e., the diencephalon), improve outflow of aqueous humor, and lower venous and arterial blood pressures (Ch. 12) . Only succinylcholine and ketamine may increase IOP. Laryngoscopy and endotracheal intubation also elevate IOP.

Antisialogogues, such as atropine, scopolamine, and glycopyrrolate, given intramuscularly for premedication, have no significant effects on IOP. However, anticholinergic drugs applied topically to the eye may cause mydriasis and may increase IOP. Combinations using neostigmine and atropine to reverse the effects of nondepolarizing muscle relaxants do not seem to increase IOP. Orally administered diazepam (0.2 mg/kg) has no effect on IOP, whereas intravenously administered diazepam (0.15 mg/kg) and equipotent intravenous doses of midazolam (0.03 mg/kg) significantly lower IOP. Even in patients with glaucoma, narcotic premedication causes no change, or only a slight decrease, in IOP.

In general, CNS depressants lower IOP. Sleep doses of barbiturates such as thiopental and pentobarbital significantly decrease IOP by their central depressive effect on diencephalic control of IOP and by improved outflow of aqueous humor. Two drugs used to induce anesthesia, Althesin (the combination of alfadolone and alfaxalone) and etomidate, also lower IOP. The effect of propofol on IOP during induction of general anesthesia is similar to that of thiopental. [37] During controlled ventilation and normocapnia, volatile inhaled anesthetics reduce IOP in proportion to the depth of anesthesia. Reductions of 14 to 50 percent have been noted. Neuroleptanalgesia produced by mixtures of fentanyl and droperidol decreases IOP 12 percent in normocapnic patients.

The effect of ketamine on IOP varies. Early studies reported an increase in IOP after intramuscular or intravenous administration of ketamine. Ketamine given after premedication with diazepam and meperidine does not affect IOP, and intramuscularly administered ketamine may even lower IOP in children. [35]

The nondepolarizing muscle relaxants decrease IOP. By contrast, succinylcholine causes a transient (4-6 min) but significant increase in IOP of 10 to 20 mm Hg. Although the mechanism is unclear, the increase is not attributable simply to induced muscle fasciculations. Studies on the effects of succinylcholine on IOP were reviewed concisely and thoroughly by Cunningham and Barry. [35]

The increase in IOP after administration of succinylcholine may depend on timing and dose, on the special tonic response of extraocular muscles because of their unique morphologic structure (the Felderstruktur), or on a direct effect of succinylcholine on CBV or formation of aqueous humor. Sectioning the rectus eye muscle does not prevent the increase in IOP after succinylcholine. None of the many attempts at preventing an increase in IOP after succinylcholine has been consistently successful. On the other hand, there are no clinical case reports of further eye damage, loss of vitreous, or other complications in open eye surgery associated with these methods.

The effectiveness of giving a small pretreatment dose of *d*-tubocurarine, diazepam, beta-adrenergic receptor blocking drugs, acetazolamide, or even succinylcholine to attenuate the increase in IOP after succinylcholine has produced contradictory results. These studies have used different timing schedules, doses, anesthetics, and measurement tech-niques. Preventing fasciculations with a pretreatment of *d*- tubocurarine (0.05 mg/kg IV) does not necessarily prevent the increase in IOP following succinylcholine (Ch. 12).

Laryngoscopy and endotracheal intubation are the anesthesia-related practices most likely to increase IOP significantly, that is, at least 10 to 20 mm Hg. [2] [35] [36] The mechanism is not clear, but it probably relates to sympathetic cardiovascular responses to tracheal intubation.

Several pretreatment regimens have been advocated to control sympathetic responses to tracheal intubation; some have been successful in attenuating the IOP response to tracheal intubation. [2] [11] [36] These pretreatments include intravenous administration of lidocaine (1.5 mg/kg) or sufentanil [38] (0.05-0.15 mug/kg) given 3 to 5 minutes before induction. Oral administration of the centrally acting antihypertensive drug clonidine (5 mug/kg) 2 hours before induction of anesthesia blunts the IOP response to intubation. [39] Intranasal administration of nitroglycerin [40] or beta-adrenergic receptor blocking drugs may also be useful in this regard.

Specific Clinical Situations and Complications

Intravitreal Injection of Gas

Ophthalmologists sometimes inject a small bubble of gas into the vitreal cavity during surgical reattachment of the retina. Their goal is to have a long-acting bubble of stable size hold the retina in place. The gases commonly used, sulfur hexafluoride (SF6) and carbon octofluorine (C3F8), are inert, very insoluble in water, and poorly diffusible. Nitrous oxide (N_2O) is 117 times more diffusible than SF6 and rapidly enters the gas bubble. If administration of N_2O continues after injection of gas into the vitreal cavity, the size of the injected gas bubble rapidly increases to 3 times its original size. [41] Within 19 minutes, IOP increases from 14 to 30 mm Hg, and both bubble size and IOP decrease (from 29 to 12 mm Hg) within 18 minutes of discontinuation of N_2O. [42] These rapid and wide variations in bubble size during general anesthesia may adversely affect the outcome of surgery.

Because washout of N_2O from the lung is 90 percent complete within 10 minutes, administration of N_2O should be discontinued at least 20 minutes before an intravitreal injection of gas. Bubble size and IOP should then remain stable. Some anesthetists avoid N_2O altogether when in-travitreal injection gas is planned. Wolf et al [42] noted that SF6 gas bubbles remain for at least 10 days. Other intravitreal gases may remain for as long as 21 to 28 days. N_2O should be avoided in any patient returning for surgery within 3 to 4 weeks of undergoing intravitreal injection of gas. A second exposure to N_2O could cause reexpansion of the bubble and could elevate IOP, resulting in occlusion of the retinal artery and loss of vision. This event is more likely if hypotension occurs during general anesthesia. During experiments in monkeys having intraocular air volumes of only 0.25 mL that were then subjected to pressures simulating those of commercial air travel, IOP rose an average of 42 mm Hg and decreased to lower than normal after return to preflight pressures. Moreover, the retinal artery became temporarily occluded. Therefore, patients with intravitreal gas bubbles may risk ocular damage during air travel.

Penetrating Eye Injuries

Management of emergency anesthesia for a patient having a full stomach and an open eye injury requires balancing the need to prevent aspiration of gastric contents against prevention of sudden significant increases in IOP that may cause further eye damage and loss of vision. [2] [35] [36] [43] If possible, early administration of a histamine (H_2)-receptor antagonist such as cimetidine (2 mg/kg IM) with metoclopramide (0.15 mg/kg IM) decreases gastric acidity and volume, respectively, and provides some protection.

Prior to rapid-sequence induction of anesthesia, several precautions may be taken to blunt the cardiovascular and IOP responses to laryngoscopy and tracheal intubation. Intravenous administration of lidocaine (1.5 mg/kg) and of remifentanil (0.1 mug/kg IV), 3 to 5 minutes before induction, may help to attenuate the increase in IOP after tracheal intubation. A beta-adrenergic receptor blocking drug such as atenolol (0.1 mg/kg IV) or labetalol (0.03 mg/kg IV) may also be useful in blocking

the cardiovascular response to tracheal intubation, especially in patients with angina or hypertension.

A dose of thiopental (6 mg/kg IV) or propofol (2.5 mg/kg IV) ensures adequate depth of anesthesia during tracheal intubation. The effectiveness of using a pretreatmentsuccinylcholine technique in these cases is controversial. [43] Although IOP may increase with this method, no published reports have described further eye damage after rapidsequence induction of anesthesia with *d*-tubocurarine, thiopental, and succinylcholine. In their large clinical experience using this technique to manage open eye injuries, Libonati et al [44] did not encounter the problems of aspiration of gastric contents or extrusion of eye contents (Ch. 12).

Because nondepolarizing muscle relaxants reduce IOP, a modified rapid-sequence technique using preoxygenation, a large dose of nondepolarizing muscle relaxants, [43] thiopental, and application of cricoid pressure for 2 minutes has been advocated for open eye surgery. This technique still requires taking the aforementioned precautions to prevent

increased IOP after laryngoscopy and tracheal intubation. An intermediate-acting or short-acting nondepolarizing muscle relaxant such as vecuronium, mivacurium, or rocuronium can be given in sufficient dose to allow reasonably rapid onset (90-120 s) without prolonged duration of paralysis or excessive cardiovascular effect. Describing a rapid-sequence induction technique using vecuronium (0.2 mg/kg IV), Abbott [45] achieved adequate tracheal intubating conditions at 60 seconds without inducing coughing. If intubation is attempted too early, incomplete relaxation will make laryngoscopy difficult. Moreover, placement of the endotracheal tube may stimulate coughing or bucking, causing a sudden significant increase in IOP.

During general anesthesia for open eye surgery, depth of anesthesia must be adequate to ensure lack of movement [15] or coughing. It is advisable to use neuromuscular blockers and to document full neuromuscular blockade with a train-of-four response to prevent coughing caused by accidental carinal stimulation (Ch. 12).

When there is the possibility of a full stomach, the trachea should be extubated while the patient is awake, breathing spontaneously, and receiving oxygen; the patient's head is to the side. A smooth emergence from anesthesia can be aided by administering an antiemetic drug before or during surgery and by giving lidocaine (1.5 mg/kg IV) or remifentanil (0.5 mug/kg IV) approximately 5 minutes before the patient awakens.

Pediatric Eye Injuries

Management of eye anesthesia in children involves special considerations. [43] [46] [47] Children with eye injuries may also have cranial injuries. If administration of narcotics is necessary to control pain, an antiemetic drug also should be given. Regional anesthesia is not suitable because of the existence of eye trauma and because of the young age and lack of cooperation of the patient. Awake endotracheal intubation, which may increase IOP and is difficult in this age group, should be avoided in children with open eye injuries.

It is usually possible to start an intravenous line gently, using a topical anesthetic cream, and induction of anesthesia may proceed as described for adults. If no intravenous line is reasonably possible, then despite the patient's possibly full stomach, a rapid, gentle induction of anesthesia via mask (with 7-8% sevoflurane) must be performed, avoiding positive pressure and direct mask pressure on the injured eye. An intravenous line is secured as soon as possible.

If the patient has eaten recently, the risk of aspiration of gastric contents can be minimized by delaying these urgent cases a few hours. However, waiting is still no guarantee that the stomach will become empty. Further precautions include using an H_2-receptor antagonist and metoclopramide, as with adults.

The stomach should be decompressed during surgery, and the patient should be extubated awake, with protective airway reflexes intact. To facilitate tolerance of the endotracheal tube and to minimize bucking in the awakening patient, a narcotic may be given 10 to 20 minutes before the end of surgery, with lidocaine (1.5 mg/kg), administered intravenously 5 minutes before extubation of the trachea.

Retinopathy of Prematurity

As a result of improved neonatal care, more than 65 percent of premature infants (750-1,000 g) now survive. More than 50 percent of these survivors have retinopathy of prematurity; therefore, the incidence of this condition is increasing. Although usually associated with hyperoxic periods during neonatal care, retinopathy of prematurity has a complex cause with many origins. Full-term nonhyperoxic infants can also have this condition, as can premature infants who have not had oxygen therapy. The condition may also be associated with factors such as hypoxia, hypercarbia, hypocarbia, sepsis, and apnea. [48] Retinopathy of prematurity occurs despite efforts in neonatal nurseries to control and monitor oxygen delivery. Babies with this condition often have a history of general immaturity, apnea, bradycardia, jaundice, patent ductus arteriosus, intraventricular dysplasia, hypoxia, and developmental delays. [49]

Capillary oxygen tension should be kept at 35 to 40 mm Hg, and arterial oxygen tension should be maintained at 50 to 70 mm Hg in premature infants. The problem for the anesthesiologist giving general anesthesia to a premature infant is to balance the risk of hypoxic damage and respiratory problems frequently encountered in these sick, frail preterm infants [50] (Chs. 58 and 59).

The retina is not completely vascularized at birth. Even at 8 months of age, the temporal retina may remain avascular. Hypoxia causes immature vessels to constrict, leading to peripheral retinal hypoxia. This condition stimulates formation of vascular shunts, vasoproliferative factor, and vessel proliferation. Leaking fluid causes hemorrhages, fibrosis, and scarring. As scars contract, the retina becomes detached. Very early surgical intervention (i.e., at 1-4 wk) with cryotherapy has been advocated to ablate the avascular retina; such surgery eliminates the release of vasoproliferative factor.

Although there is no convincing evidence that retinopathy of prematurity has ever occurred solely because of oxygen given during anesthesia, [48] in addition to the usual anesthesia requirements and precautions for these young, immature patients, [48] [51] prolonged exposure to high intraoperative concentrations of oxygen is best avoided during the period of retinal immaturity (i.e.,
8 mo). Arterial oxygen tensions of 60 to 90 mm Hg may be achieved by giving mixtures of air and oxygen or N_2O and oxygen and by using finger-pulse oximetry to keep arterial oxygen saturations at 90 to 95 percent. [52]

Electroretinography

Halothane, isoflurane, and enflurane can affect visual evoked potentials (VEP). [53] [54] Halothane and isoflurane decrease the amplitude and increase the latency of VEP. A 0.9 percent or higher concentration of isoflurane can prolong the latencies of VEP. [54] Although some studies claim that this relationship is dose-dependent, at least two studies have failed to demonstrate significant differences for various concentrations of anesthetics. Neuroleptanalgesia seems to increase the latency of P2 slightly without changing the amplitude of EP. The effect of isoflurane on VEP may be

minimized by using low concentration, muscle relaxants, if necessary, and supplemental opioids.

Ketamine, a phencyclidine derivative, is a unique anesthetic agent because it increases the electrical activity of the brain. This increased activity could alter the amplitude of VEP and distort the conclusions of testing. Ketamine has been used for anesthesia in rabbits without affecting the electroretinographic response. [55]

Unlike the VEP, which is a complex cortical response, the electroretinographic response is a simple reflex occurring within the eye. Therefore, it is unlikely that such a response would be affected significantly by general anesthetics.

Strabismus

The treatment of poor alignment of the visual axis with amblyopia (strabismus) in children 1 to 6 years of age usually consists of surgery on the extraocular muscles. Surgical intervention must occur by 4 months of age if proper stereoscopic visual development is to proceed. [56] Strabismus repair in the older child is performed for cosmetic purposes. Three problems associated with strabismus are of particular interest for the anesthetist: the possible increased risk of malignant hyperthermia, the high incidence of postoperative nausea and vomiting (PONV), and the likelihood of an OCR.

Strabismus is considered by some to represent an underlying myopathy. These patients are assumed to be at increased risk of malignant hyperthermia. [57] For example, the incidence of isolated masseter spasm after halothane and succinylcholine administration was higher in children with strabismus compared with those without strabismus (2.8 versus 0.72%). [58] Patients with strabismus whose tracheas were intubated with the help of pancuronium did not have isolated masseter spasm. [59] In one study, approximately 50 percent of patients who had malignant hyperthermia had had isolated masseter spasm after induction of anesthesia. [60] Because the overall incidence of malignant hyperthermia in children is only 1 in 15,000, the high incidence of masseter spasm following succinylcholine administration in patients with strabismus suggests that such patients may be more likely to develop malignant hyperthermia.

The risk of malignant hyperthermia may be lessened by avoiding succinylcholine. In addition, because it increases extraocular muscle tone, succinylcholine interferes with the forced duction test (which evaluates muscle tone) for approximately 15 minutes. By contrast, vecuronium, rocuronium, cisatracurium, and mivacurium render the extraocular muscles flaccid, minimizing the afferent stimuli for nausea, vomiting, and OCR. To ensure that a malignant hyperthermia episode is detected promptly, body temperature, ECG, and end-tidal concentrations of CO_2 should be monitored carefully in patients with strabismus (Ch. 27).

The incidence of PONV in children after outpatient strabismus surgery varies from 48 to 85 percent. [61] Persistent PONV delay discharge and may even require overnight admission of the patient. Many regimens have tried to control PONV in these patients without also prolonging recovery time. Droperidol (75 mug/kg IV) successfully reduces PONV to 16 to 22 percent without increasing discharge time (4.6 h). [62] Lower doses of droperidol, usually effective as an antiemetic in adults, do not seem to be effective in children with strabismus. [63] Intravenous administration of lidocaine (1.5 mg/kg) prior to tracheal intubation also reduces the incidence of PONV to 16 to 22 percent. [64]

Wier et al [61] showed a significant decrease in the incidence and frequency (41%) of vomiting in the first 24 hours after strabismus surgery using a propofol infusion and N_2O technique. This incidence was further reduced (24%) when opioids were avoided. Discharge times averaged 2 hours, but postoperative restlessness was more common than in patients receiving an inhalational anesthetic. Splinter and Rhine [65] reduced the incidence of vomiting after strabismus surgery in children to 9 percent using a low-dose ondansetron (50 mug/kg IV) and dexamethasone (150 mug/kg IV) regimen. The emetic symptoms associated with strabismus surgery may be caused by eye muscle manipulation or pain that induces an OCR vagal response. Prophylactic treatment with atropine or glycopyrrolate, however, does not decrease the incidence of PONV. [63] The OCR, commonly elicited in response to traction of the extraocular muscles, is frequently associated with strabismus surgery. Previous studies have noted an increased incidence of OCR during strabismus surgery under propofol infusion. [64]

In addition to the usual practice regarding pediatric management, the following measures should be considered to decrease the incidence of PONV after strabismus surgery:

1. Minimal use of opioids for pain management.
2. The use of propofol to maintain general anesthesia without N_2O supplementing a potent volatile agent.
3. Administration of a serotonin ($5HT_3$) antagonist and metoclopramide (0.15 mg/kg IV) during anesthesia.
4. Insertion and removal of a gastric tube after induction of anesthesia to decompress the stomach.
5. Gentle surgical manipulation of the eye muscles.
6. Adequate hydration of the patient with intravenous crystalloids.
7. Placement of lidocaine near the extraocular muscle by the surgeon, to minimize afferent impulses and postoperative pain on awakening.

Selective $5HT_3$-receptor antagonists such as ondansetron or dolasetron are effective antiemetics as treatment for PONV. [65] [66] [67] [68]

Congenital Syndromes Involving Eye Pathology

The special problems of pediatric ophthalmic anesthesia make it almost a specialty in itself. [69] Congenital syndromes in which eye abnormalities are only one manifestation of a multisystem disorder present problems of overall general anesthesia management.

Patients with homocystinuria, a rare inborn error of amino acid metabolism, may present with subluxation of the lens or glaucoma. These patients are susceptible to thromboembolic complications during general anesthesia. Hyperinsulinemia and hypoglycemic convulsions are also common. Safe anesthesia management requires pretreatment with acetylsalicylic acid and dipyridamole, adequate hydration with glucose or low-molecular-weight dextran, and maintenance of good arterial blood pressure and peripheral

vasodilation. Moreover, to prevent venous stasis, the patient should wear elastic stockings and should walk as soon as possible.

Patients with Marfan syndrome, a disorder of connective tissues, have subluxed lenses and detached retinas. Anesthesia management should consider the possibility of heart valve defects, thoracic aneurysms, and kyphoscoliosis. Children with Down syndrome often have strabismus and cataracts. Of concern to the anesthesiologist are hypotonia, heart defects, hypothyroidism, macroglossia, and seizures, all of which are associated with this syndrome.

Patients with Sturge-Weber syndrome may have secondary glaucoma. This condition consists of cavernous cutaneous angiomas of the face, cerebral cortex, and lower airway. Seizures may occur.

Retinitis proliferans, vitreous hemorrhages, and retinal detachment may occur in patients with homozygous sickle cell disease or thalassemia. Anesthesia management involves the treatment of anemia and avoidance of conditions that trigger sickle cell crisis, such as dehydration, acidosis, hypoxia, infection, venous stasis, and hypothermia.

Patients with craniofacial abnormalities, as in Crouzon disease, Alport syndrome, or Kneist syndrome, may have myopia, detached retinas, exophthalmos, or glaucoma. The trachea can be difficult to intubate in these patients. Chapters 25 and 59 also discuss congenital syndromes involving eye disorders.

Complications

Stead [72] reviewed the mortality and morbidity from coexisting disease in patients having ophthalmic surgery. Wu and Schachat [73] reported that 0.7 percent of ophthalmic patients required transfer to medical service, usually for cardiacrelated conditions. Stead reviewed morbidity from the systemic effects of ophthalmic drugs and complications due to anesthetic techniques; monitored anesthesia care and the risks of regional eye blocks, including optic nerve trauma, ocular penetration, retrobulbar hemorrhage, corneal injury, oculocardiac reflex, and myotoxicity of local anesthetics on extraocular muscles; and discussed general anesthesia, the risk of nausea and vomiting, the results of ophthalmic surgery, and the effect of general anesthesia, intubation, and N_2O on IOP.

Oculocardiac Reflex

The OCR may be induced by pressure on the eyeball, traction on the extraocular muscle, orbital hematoma, ocular trauma, and eye pain. The OCR is a trigeminovagal reflex, manifested by cardiac arrhythmias such as bradycardia, nodal rhythm, ectopic beats, ventricular fibrillation, or asystole. The afferent pathway follows the long and short ciliary nerves to the ciliary ganglion and then to the gasserian ganglion along the ophthalmic division of the trigeminal nerve (the fifth cranial

nerve). These afferent pathways terminate in the main trigeminal sensory nucleus in the floor of the fourth ventricle. The efferent impulses start in the muscles of the vagal cardiac depressor nerve, causing negative inotropic and conduction effects.

The OCR occurs most often during strabismus surgery in children, but it also occurs occasionally during retinal surgery at the time of injection for retrobulbar block, and even during nonophthalmic surgery if pressure is placed on the eyeball. The reported incidence of OCR varies considerably (32-90%), depending on the intensity of observation and the definition of arrhythmias. Transient cardiac arrest may occur as frequently as in 1 in 2,200 cases of strabismus surgery.

The force and type of stimulus seem to influence the incidence of OCR. [70] The more acute the onset and the stronger and more sustained the traction, the more likely OCR is to occur. Although the medial rectus muscle is commonly believed to be the most sensitive in eliciting an OCR, Blanc et al [70] did not find this to be necessarily true. This misconception may result from two lines of reasoning. The medial rectus muscle is less accessible and therefore may require more pulling for exposure. Moreover, the medial rectus is the muscle manipulated most often in strabismus surgery and may therefore be more refractory to fatigue.

Hypoventilation and increased arterial CO_2 partial pressures significantly increase the incidence of bradycardia during strabismus surgery. Intramuscular administration of atropine, gentle manipulation of extraocular muscles, and control of ventilation to maintain normocarbia should reduce the incidence and severity of OCR. [70]

The intravenous administration of atropine to prevent or treat OCR is controversial. Atropine may cause bigeminy and increase ectopic beats, especially when halothane is the primary anesthetic. These arrhythmias are more persistent than the OCR response. Mirakhur et al [71] noted that intramuscular premedication with atropine reduced the incidence of OCR from 90 to 50 percent. However, intravenous administration of atropine or glycopyrrolate was even more effective in preventing OCR. Although the peak effect of glycopyrrolate did not occur for 3 to 4 minutes, glycopyrrolate did not produce as great a tachycardic response as did atropine.

Although bradycardia is the most common manifestation of OCR, other abnormal rhythms (nodal, junctional, ectopic atrial, or even serious ventricular arrhythmias) are possible. Therefore, the ECG should always be monitored continuously during ophthalmic surgery. Because the OCR ceases when stimulation (pressure or traction) ends, the surgeon and anesthesiologist should not hesitate to communicate during procedures involving the possibility of an OCR.

The first step in treating OCR is to stop stimulation by the surgeon before the arrhythmia progresses to sinus arrest. Fortunately, sustained and repeated stimulation usually causes the OCR to fatigue. If arrhythmias persist, treatment with atropine (0.007 mg/kg IV) and a local injection of lidocaine into the eye muscle may be necessary. If the patient still seems unusually sensitive to manipulation of the extraocular muscles, the anesthesiologist should ensure the adequacy of depth of general anesthesia, the existence of normocarbia, and the gentleness of surgical manipulation.

Systemic Effects of Eye Medications

Both the anesthesiologist and the ophthalmologist must be aware that eyedrops are readily absorbed through hyperemic incised conjunctivae. Although small in volume, these

drops contain highly concentrated medication that can produce systemic results. Infants and elderly patients are most susceptible. Systemic effects can be minimized by using lower concentrations, limiting instillation to only one or two drops, and promptly occluding the nasolacrimal duct at the time of instillation. [2] [74] Eye medications that cause systemic effects include phenylephrine, epinephrine, timolol, echothiophate iodide, acetylcholine, cyclopentolate, scopolamine, atropine, and cocaine (Chs. 13 and 14).

Phenylephrine

Phenylephrine eyedrops can cause severe hypertension, arrhythmias, headache, tremulousness, and myocardial ischemia. Because a single drop of 10 percent phenylephrine ophthalmologic solution contains 4 mg of phenylephrine, 2.5 percent solutions are recommended.

Epinephrine

Topical ocular epinephrine (a 2% solution contains 0.8 mg per drop) can cause tachyarrhythmia, premature ventricular beats,

Timolol

Timolol is a beta-adrenergic receptor blocking drug administered as eyedrops to treat glaucoma. Systemic effects include bradycardia, hypotension, congestive heart failure, and exacerbation of asthma and myasthenia gravis.

Echothiophate

Echothiophate iodide eyedrops act systematically to reduce plasma cholinesterase activity significantly. Four to 6 weeks are required for activity to recover after cessation of the drops. Patients treated with these eyedrops may have a prolonged response to succinylcholine or to mivacurium and ester-linked local anesthetics during this time (Chs. 13 and 14).

Acetylcholine

Acetylcholine may be used to produce miosis after cataract surgery. Systemic effects include bradycardia, hypotension, bronchospasm, and increased bronchial secretions and salivation. These undesirable effects may be prevented by the intravenous administration of atropine.

Cyclopentolate

Cyclopentolate eyedrops are used in a 2 percent concentration to dilate the pupils. CNS toxicity, resulting in effects such as disorientation, dysarthria, and seizures, has been reported. Less concentrated (0.5%) solutions are recommended for pediatric use.

Scopolamine

Scopolamine eyedrops can cause disorientation and hallucinations in elderly and very young patients.

Cocaine

Cocaine blocks reuptake of norepinephrine at the nerve terminal and usually produces sympathomimetic effects (Ch. 13) . However, after ocular instillation, very low plasma levels of cocaine can produce severe bradycardia. Topical application of cocaine is no longer recommended for ophthalmic surgery. However, during dacryocystorhinostomy, cocaine is used topically for vasoconstriction and topical anesthesia.

Postoperative Eye Pain

Postoperative eye pain is usually caused by corneal abrasion or acute glaucoma attack, the former being the more common source. During general anesthesia, the blinking reflex is lost, and basal and reflex tear production decreases. A dry, exposed cornea is at high risk for abrasion. Intraoperative measures such as using nonionic petroleum-based eye ointment, avoiding rubbing of the eye, and taping or suturing the eyelids closed are essential in preventing eye injury. Because eye

ointment can cause irritation, it should be used sparingly and only for procedures lasting longer than 60 minutes.

Corneal abrasion pain is a specific eye pain manifesting as the sensation of the presence of a foreign body in the eye, tearing, conjunctivitis, and photophobia. Corneal abrasion pain is made worse by blinking. The abraded section of cornea may be seen directly as a dull nonreflective patch or as a positive area on fluorescein staining. Treatment requires application of antibiotic eye ointment and covering of the eye with a patch for at least 48 hours. Topical application of anesthetic drops and steroids to the cornea is contraindicated because these drugs retard healing. If pain persists more than 24 hours, an ophthalmologist should be consulted.

Acute glaucoma occurs as severe, diffuse, periorbital pain in dry, pale eyes having dilated pupils. No photophobia, tearing, or conjunctivitis occurs. Vision may decrease, and IOP increases. Treatment to reduce IOP includes intravenous administration of either 20 percent mannitol (1 g/kg) over 30 minutes or 500 mg acetazolamide over 5 minutes.

ANESTHESIA FOR NOSE AND THROAT SURGERY

Functional Anatomy of the Larynx

The anesthesiologist confronted with decisions regarding airway management and difficult endotracheal intubations for patients with compromised airways must have a thorough knowledge of the physical and functional anatomy of the larynx. The larynx serves three functions: protection of

the airway, respiration, and vocalization. [75] [76] The protective function occurs primarily through reflex and involuntary processes. The glottic closure reflex activated by swallowing is a basic primitive reflex elicited by many different sensory stimuli that affect the superior laryngeal nerve. The false vocal cords (ventricular folds) can act as a muscular valve that closes because of pressure from below to prevent egress of air. The true vocal cords constitute a one-way entrance valve that resists pressure from above but not from below. [75] Thus, during spasm of the true vocal cords, sudden positive pressure from above may not in itself be sufficient to move air into the lungs.

The nerve supply to the larynx occurs through the vagus nerve (the tenth cranial nerve). Sensory innervation is provided primarily by the superior laryngeal nerve, which arises from the inferior ganglion of the vagus. The internal branch of the superior laryngeal nerve consists mostly of sensory fibers; a few motor fibers lead to the arytenoid muscles. This internal branch further divides into upper and lower branches. The upper branch provides sensory innervation to the mucosa of the lower pharynx, both surfaces of the epiglottis, the vallecula arytenoepiglottic folds, and the laryngeal vestibule. The lower branch passes close under the surface of the mucosa of the pyriform fossa and supplies sensory innervation to the arytenoepiglottic folds and posterior rima glottidis. Sensory innervation below the true vocal cords and into the upper trachea is provided by the recurrent laryngeal nerves. Sensory innervation is denser at the glottic inlet, and there are more touch receptors at the lower half of the true vocal cords; in addition, the epiglottic and supraglottic area contain chemical and thermal receptors. [77] The sensory components of the internal superior laryngeal nerve also include joint, pressure, and stretch receptors from the intrinsic laryngeal muscles. The afferent response impulses from these receptors track back to the tractus solitarius of the brain stem. [75] The recurrent laryngeal nerves provide motor innervation to all the intrinsic laryngeal muscles, except the cricothyroid and inferior pharyngeal constrictors, which receive motor innervation from the external branch of the superior laryngeal nerve.

The intrinsic laryngeal muscles consist of the following:

1. Posterior cricoarytenoids abduct the vocal cords and widen the glottic chink during respiration.
2. Thyroarytenoids and lateral cricoarytenoids adduct the vocal fold (false cords).
3. Interarytenoids close the posterior gap in the glottis (posterior commissure) by abduction.
4. Cricothyroids adduct and tense the true vocal cords.
5. The vocalis muscle also shortens the true vocal cords.
6. Arytenoepiglottis and oblique arytenoids narrow the glottic inlet by adduction of the arytenoepiglottic folds.

The recurrent laryngeal nerve can be injured by endotracheal intubation, neck surgery, or stretching of the neck during surgery. The resulting tone and position of the vocal cords depend on whether the injury is unilateral or bilateral and on whether the external branch of the superior laryngeal nerve (the motor innervation of the cricothyroid muscle, which shortens the vocal cords) is also involved.

Unilateral recurrent laryngeal nerve injury causes the cord on the injured side to assume a paramedian position because the unopposed action of the ipsilateral cricothyroid muscle adducts the cord toward the injured side. If the external branch of the superior laryngeal nerve is also involved, the true vocal cord will be more medial and less tense. The voice is weak and hoarse, and the risk of aspiration increases. Eventually, the muscles compensate somewhat, and the cord becomes positioned more medially.

Laryngospasm

Laryngospasm is an exaggerated prolonged response of the protective glottic closure reflex, mediated by the superior laryngeal nerve in response to irritating glottic or supraglottic stimuli such as the presence of blood, food, vomitus, or a foreign body; instrumentation or manipulation of the endolarynx can all induce laryngospasm.

This strong glottic closure reflex can persist even after irritation of the mucosa ceases. [77] During a fully formed laryngospasm, the false cords and epiglottic body come together firmly. There is no air flow, no vocal sound, and the true vocal cords cannot be seen. The extrinsic muscles of the larynx (especially the thyroid) may also be involved to help create a muscular ball-valve mechanism.

Intravenous administration of lidocaine, topical application of cocaine, and deep levels of anesthesia attenuate the effect of the stimulus and the activity of the superior laryngeal nerve, thereby decreasing the likelihood of prolonged glottic closure. Incremental doses of intravenous fentanyl up to 200 mug depressed the protective airway cough reflex, but not the laryngospasm reflex. [78] Hypoxia and hypercarbia decrease postsynaptic potentials and brain-stem output to the superior laryngeal nerve, resulting in less vigorous glottic closure. [75] Thus, laryngospasm eventually ceases spontaneously as hypoxia and hypercarbia develop. Stimulation of the superior laryngeal nerve may also inhibit medullary inspiratory motoneurons, thereby decreasing phrenic nerve activity and causing a reflex apnea.

Head and Neck Surgery

Major surgery for cancer of the head or neck includes laryngectomy, radical neck dissection, hemimandibulectomy, and radical sinus surgery. Anesthesia management for surgery of malignant tumors of the larynx or pharynx was reviewed in detail by Morrison et al [76] and Daugherty. [79] Joseph et al [80] reviewed the complications and anesthesia considerations for head and neck and reconstructive surgery.

These patients are frequently heavy drinkers and smokers who have bronchitis, pulmonary emphysema, and/or cardiovascular disease. If the tumor interferes with eating, then weight loss, malnutrition, anemia, dehydration, and electrolyte imbalance can be significant. These patients are evaluated and treated as representing difficult endotracheal intubation and potential problems in airway management, as discussed later and in Chapter 39 .

Generally, the use of an inhalation anesthetic dilates the bronchi, depresses airway reflexes, permits the use of high concentrations of oxygen, if necessary, and may produce moderate hypotension (systolic blood pressure 85-90 mm Hg). When a 10- to 15-degree head-up tilt is added, the resulting

moderate hypotension may be sufficient to diminish blood loss without resorting to deliberately inducing hypotension. [57] Induced hypotension is not without risk in debilitated patients and may be unnecessary and dangerous [76] [81] (Ch. 41).

During radical lymph node dissection of the neck for carcinoma, manipulation of the carotid sinus may elicit a vagal reflex that causes bradycardia, hypotension, or even cardiac arrest. Furthermore, trauma to the right stellate ganglion and cervical autonomic nervous system during right radical neck surgery can prolong the QT interval and may lower the threshold for ventricular fibrillation. [82] Severe tachyarrhythmia and cardiac arrest have been reported in these cases, especially in association with hypokalemia.

Although venous air emboli are usually associated with neurosurgical procedures, open neck veins create the possibility of air emboli during head and neck surgery (Ch. 52) . The incidence of air emboli during this type of surgery is low. An end-tidal CO_2 monitor indicates a sudden fall in CO_2 tension, and a precordial Doppler probe picks up the murmur characteristic of venous air embolism. Hypotension and arrhythmias are late signs of air emboli. [76] Treatment includes the following: increasing venous pressure (through the use of positive-pressure ventilation or jugular vein compression); slight Trendelenburg, left lateral positioning; discontinuation of N_2O; use of 100 percent oxygen; and, if possible, aspiration of the air through a central venous catheter.

Postoperative considerations consist of care of the tracheostomy, use of humidified oxygen, institution of chest physical therapy, and the obtaining of a chest radiograph to eliminate the possibility of pneumothorax. The position of the tracheostomy tube should be checked, and possible subcutaneous emphysema and hematoma formation should be sought.

Thyroid Surgery

Perioperative complications of thyroid surgery include airway obstruction secondary to compressing hematoma, hypocalcemic tetany, and recurrent or superior laryngeal nerve paralysis. [80] The recurrent laryngeal nerve (RLN) is at risk for injury during thyroid and parathyroid surgery, resulting in vocal cord paralysis and even airway obstruction. The incidence of permanent nerve injury is 0.2 to 1.0 percent. [80] Spontaneous and evoked electromyography are used to monitor RLN function during surgery. [83] Nerve action potentials can be monitored using a carefully placed special Nerve Integrity Monitor (Xomed-Treace, Jacksonville, Fla) endotracheal tube [84] [85] or surface RLN postcricoid laryngeal electrodes. [86]

Endoscopic Sinus Surgery

The complications of endoscopic sinus surgery are infrequent and are not usually related to the type of anesthesia. Venous air embolism, eye trauma, cerebrospinal fluid leak, excessive bleeding, [87] focal neurologic deficit, and death have been reported. [88]

Trauma

Open and Closed Injuries to the Neck and Larynx

There is no classic or standard presentation of laryngeal trauma (Ch. 62). [89] [90] [91] [92] Often, internal damage is extensive but external signs are absent or only minimal (e.g., mild redness, minor lacerations, hematoma, or subcutaneous emphysema). Stridor and cyanosis may not be present. These injuries most often result from high-speed blunt trauma (motor vehicle accidents, gunshot wounds, or falls). For example, velocity-deceleration accidents can produce severe closed neck injury to the trachea and larynx. [92] Inertia carries the body forward, hyperextends the neck, and forces these vulnerable anterior cervical structures against the fixed cervical vertebrae. Tracheal damage can also be caused by a burst injury that produces simple tears, dislocation of arytenoid cartilages, disruption of the cricothyroid joint (causing a floppy vocal cord), and bleeding (leading to hematoma or edema in the paratracheal/arytenoepiglottic fold space). [92] Unfortunately, more obvious injuries such as a fractured femur can divert the physician's attention from the more subtle signs of airway problems (e.g., hoarseness, weak voice, or tracheal tugging).

The following signs of airway problems may be delayed: increasing stridor, wheezing, coughing, hemoptysis, retractions of the airway, changes in voice (loss of voice, hoarseness, weak voice), and difficulty in speaking or swallowing. Loss of neck prominences and increasing crepitus indicate torn mucosa in the trachea, pharynx, larynx, or esophagus. However, the amount of crepitus does not always correlate with the size of the tear.

An air leak can dissect into the paratracheal space and produce a pneumothorax. Such leakage increases with straining and application of positive-pressure ventilation. Regardless of size, all open neck injuries should be explored, because mortality is as high as 5 percent. Moreover, the possibility of a cervical spine fracture should always be considered when head or neck trauma has occurred.

A review of airway management in a known or suspected cervical spine injury indicated that early neck immobilization followed by orotracheal intubation, while an assistant applied in-line stabilization, had the lowest incidence of adverse events. There is no evidence that nasotracheal intubation is necessarily safer. [93]

Certain age-related differences in anatomy may determine the type of injury and the ability to tolerate a compromised airway. The larynx of the infant and young child is positioned high in the neck and is shielded by the mandible. Cartilage is more elastic and flexible in the child, who is therefore less likely to sustain a fracture than is an adult. However, because of weaker connecting membranes, the child is more vulnerable to intercartilage rupture. [89] Moreover, because their airways have a small diameter at the subglottic region of the cricoid cartilage, young children do not tolerate edema or compromise of the airway as well as do adults.

There are many vital structures at risk in the neck (e.g., the recurrent laryngeal nerve, the carotid or inferior thyroid arteries, and major veins). Thus, mismanagement of neck

---

and laryngeal injuries has the potential for acute disaster. Airway problems are dynamic. Mild stridor can worsen an air leak, aggravating subcutaneous emphysema and, in turn, increasing airway obstruction and stridor. The onset of cyanosis may be followed in rapid succession by myocardial ischemia, hypotension, hypercarbia, and loss of consciousness. Therefore, the anesthesiologist needs as much information as possible when attending to the problem airway. Monitoring of these patients from the emergency department to the operating room should include an ECG, pulse oximeter, and observation of the state of consciousness.

Blind passage of an endotracheal tube can increase damage or obstruction, induce laryngospasm, or create a false passage through a tear in the mucosa. Whenever possible, when dealing with laryngeal trauma, the trachea should be intubated under direct vision using a laryngoscope, rigid bronchoscope, or fiberoptic laryngoscope. A careful mask induction of anesthesia with no application of positive pressure, followed by bronchoscopic examination, may be safe in selected cooperative patients (i.e., those with no full stomach or bleeding in the airway). Tracheostomy using local anesthesia is frequently a safe approach to laryngeal trauma and is the only guarantee of establishing an airway when dealing with a possible laryngotracheal disruption.

Facial Injuries

The evaluation and anesthetic management [92] [94] [95] of maxillofacial injuries have been discussed extensively. The most common fractures involve the mandible and midface (Le Fort I, II, and III fractures of the maxilla). Because of the presence of loose teeth, blood, and displaced fragments, all these fractures may be accompanied by some degree of compromised airway. A first priority is to secure the airway by placing the patient in the lateral position, pulling the mandible or maxilla forward, and clearing the oropharynx of blood or loose teeth. If this action is not successful, endotracheal intubation or emergency tracheostomy should be considered. These patients may also have head trauma or fractures of the cervical spine.

Mandible fractures, if unilateral, remain stable. Bilateral mandibular fractures are unstable. The posterior fragment may be pulled medially and upward, causing the base of the tongue to obstruct the pharynx. Trismus and lingual hematoma or edema may contribute to respiratory obstruction. [92] If no trismus or mechanical problem

exists, a routine rapid-sequence induction of anesthesia and tracheal intubation may proceed. Otherwise, induction of anesthesia with an inhaled anesthetic, or awake endotracheal intubation, is indicated. Although the possibility of interdental fixation may seem to make use of a nasotracheal tube preferable, the easiest route of intubation should be chosen. Later, during surgery, the oral tube can be removed and a nasal tube inserted. Patients undergoing interdental fixation should be given an antiemetic drug, undergo awake tracheal extubation, and be placed on their side with scissors/wire cutter at the bedside.

Midface fractures (Le Fort fractures of the maxilla) [92] often present difficult clinical problems. A Le Fort I fracture is a simple horizontal fracture of the lower maxilla that produces only a mobile palate. A Le Fort II fracture, a triangular extension of the Le Fort I fracture, involves two oblique fracture lines along the malarmaxillary suture to the floor of the orbit and the base of the tongue. The maxillae are displaced backward and may be free floating. The Le Fort III fracture is a high-level transverse fracture above the malar bone and through the orbits. It is characterized by complete separation of the maxilla from the craniofacial skeleton, epistaxis, and a flat dish-face deformity. Tears in the dura occur in 25 percent of all Le Fort II and III fractures, as evidenced by leakage of cerebrospinal fluid. Orotracheal intubation is necessary when intranasal damage is a possibility. Attempted passage of a nasogastric or nasotracheal tube may cause bleeding, mucosal dissections, and further damage. The course of these tubes is uncertain; they can enter the maxillary antrum, the orbit, the base of the skull, or even the cranium.

Special Clinical Problems Involving the Airway

Microlaryngoscopy

Many different anesthesia techniques have been advocated for microlaryngeal endoscopic surgery (Ch. 39) . The common goal of these techniques is to provide the surgeon with a clear view, immobile field, and sufficient room in which to work. The anesthesiologist's objectives are to protect the trachea, to ensure good ventilation and oxygenation, to minimize secretions and reflexes, and to promote rapid awakening and return of protective airway reflexes. Morrison et al [76] described the advantages and disadvantages of these techniques.

Because of the varying degrees of upper airway disorder and the need for rapid awakening in these brief (30-40 min) procedures, routine premedication should be avoided. An antisialogogue, such as glycopyrrolate, which facilitates drying of oral secretions, may be helpful. If sedation is necessary to decrease anxiety, intravenous titration of 1-mg increments of a benzodiazepine such as midazolam may be given with monitoring in the preinduction area.

Special attention must be devoted to understanding the extent of the upper airway disorder that brings these patients to surgery. For example, preoperative decisions about tracheal intubation and anesthesia management depend on whether the abnormality is a small lesion (e.g., a vocal cord polyp or carcinoma *in situ*), a large and potentially obstructing lesion such as a papillomatosis, or a large and friable supraglottic tumor that will completely obstruct the glottic opening. If there is any question about the airway, direct laryngoscopic examination should be performed (after topical laryngeal block) [96] [97] in the awake patient to assess the difficulty of intubation.

In only approximately 5 percent of microsurgical procedures on the larynx do the pathologic conditions involve the lower third of the vocal cords or the posterior commissure area. Therefore, for 95 percent of these procedures, a small, long (5 mm × 31 cm) endotracheal tube having a highvolume low-pressure cuff can be used without obscuring

the surgeon's view. [76] [98] The posterior commissure area may then be inspected at extubation or by moving the tube aside. Adequate oxygenation and ventilation can be monitored in adults by controlled ventilation through a small (4.5-5.0-mm ID) endotracheal tube. [99] The use of a small endotracheal tube allows for application of positive-pressure ventilation, ensures the absence of gastric distention, facilitates control of oxygenation and elimination of CO_2, protects the trachea, and allows for a variety of general anesthesia regimens and an indefinite time period for the surgeon.

Another method of providing anesthesia for microlaryngoscopy places a small catheter between the vocal cords for insufflation of anesthetic gases at high flows. This technique does not protect the trachea or allow for use of positive-pressure ventilation. High concentrations of the inhaled anesthetic must be used to overcome atmospheric dilution, and, unfortunately, exhaled gas is blown back at the surgeon and into the operating room. There may also be motion of the vocal cords.

Jet ventilation using the Venturi entrainment effect provides anesthesia and ventilation without the use of an endotracheal tube. [76] [100] The surgeon has an unobstructed view of the larynx. Keeping the tip of the jet within the laryngoscope avoids airway barotrauma and provides a clear view. Alignment of the laryngoscope with the tracheal axis is essential. The vocal cords need to be relaxed fully, and pathologic conditions in the airway must not be so large as to obstruct airflow into the trachea. The jetted gas must have free egress, and motion of the chest wall must be monitored at all times. Ventilation begins at low pressures (30-50 psi). Inspiration is 1.5 seconds, passive expiration is 6 seconds, and ventilatory rate is 6 to 7 breaths/min. [76] The jet Venturi technique is contraindicated in children, obese patients, and patients with bullous emphysema. When large tumors are present in the upper airway, debulking of the tumor using general anesthesia and a tracheal tube should be accomplished first, [76] because the jet technique may force blood or tumor tissue into the lungs and gas into the stomach.

An apneic technique using alternate tracheal intubation and no tube during endoscopic removal of papillomas in children has been used successfully by Weisberger and Miner. [101] Moreover, Babinski et al [102] described the use of high-frequency positive-pressure ventilation during anesthesia for laryngoscopy. Small tidal volumes provide good gas exchange at low airway pressures. Respiratory rates of 60 breaths/min at 60 to 100 psi are used by means of a stiff 3.5-4.0-mm catheter placed through the vocal cords. The risk of barotrauma and pneumothorax is lower, especially in patients with obstructive airway disease.

Good muscle relaxation is an essential part of anesthesia management for microsurgery of the larynx. A succinylcholine drip infusion may be considered for very brief cases. If the procedure is expected to last at least 30 minutes, use of a neuromuscular blocking drug such as vecuronium, rocuronium, or mivacurium for tracheal intubation allows return of muscle strength and spontaneous respiration for safe extubation.

Stimulation of the larynx can induce many reflex responses that produce hypertension, tachycardia, and arrhythmias. Intravenous administration or topical application of lidocaine and small doses of fentanyl (1-2 mug/kg IV) will help to moderate the sympathetic response. beta-Adrenergic receptor blocking drugs may also be helpful.

Propofol induction (2 mg/kg IV) and infusion (10 mg/kg/h) combined with fentanyl (1-2 mug/kg IV) supplementation, topical anesthesia of the larynx, and appropriate muscle relaxation have been used for microlaryngoscopy procedures. [103] Monitoring (pulse oximeter, ECG, blood pressure, and end-tidal concentrations of CO_2) is especially important, because the incidence of myocardial infarction or ischemia after microlaryngoscopic procedures has been reported to be 1.5 to 4.0 percent. [104]

Laser Surgery of the Upper Airway

CO_2 and neodymium-yttrium aluminum garnet (Nd:YAG) lasers are frequently used for microsurgery of the upper airway and trachea (Ch. 64). The surgical advantages of using lasers include less bleeding, the ability to coagulate small vessels, maintenance of sterile conditions, less tissue reaction, increased precision of dissection, preservation of normal tissue, and, in the case of Nd:YAG lasers, the ability to transmit the beam by fiberoptics. Excellent articles by Van der Spek et al [105] and Hermens et al [106] reviewed the physics and medical uses of lasers, including safety and implications for anesthesia management.

The American Society for Testing and Material (ASTM) Subcommittee F29.02.10 of the Anesthesia Patient Safety Foundation developed guidelines for the provision of safe anesthesia during laser surgery for the upper airway. These guidelines compare and comment on the advantages and disadvantages of several anesthetic techniques and laserresistant endotracheal tubes. [107]

Light amplification by stimulated emission of radiation (LASER) produces a beam of light that is monochromatic (of the same wavelength) and "coherent" (all the photons are moving in the same direction). Lasers exist in the infrared, visible, and ultraviolet regions of the electromagnetic spectrum. Depending on the emission medium used, such light can be focused into an extremely small point, thereby achieving a very high-power density. This beam of high-power density is capable of vaporizing biologic tissue. Each laser medium emits radiation of a specific wavelength, which determines how the beam will interact with biologic tissue. Lasers are operated in short pulses, long pulses, or continuously. The continuous-wave CO_2 laser, which produces radiation having a wavelength of 10 mm, is strongly absorbed by water, damaging tissue surfaces to a depth of 200 mm. For this reason, the CO_2 laser is suitable for removing lesions on the vocal cords and in the larynx.

The Nd:YAG laser, a short-pulsed, high-powered glass laser producing light with a wavelength of 1.06 m, can be transmitted by fiberoptics. Energy from Nd:YAG or

argon (wavelength of 0.5 mm) lasers is absorbed preferentially by hemoglobin and pigmented tissue, has deep, penetrating effects, and is useful in treating detached retinas.

Reflection and scatter of laser beams can cause immediate or delayed injury (perforation, hemorrhage, pneumothorax) to normal tissue. The CO_2 laser reacts at the surface, causing corneal damage, whereas lasers of shorter wavelength (argon, Nd:YAG) can pass through the cornea and damage the retina. Therefore, the patient's eyes must be

taped closed and covered with moist gauze. Nontarget tissue should be protected by moist gauze covering; in addition, alignment of the laser should be checked, and immobility of the patient should be ensured. Operating room personnel should wear appropriately colored glasses or goggles to absorb the wavelength emitted by the laser in use. Laser hits on the skin cause a pinpoint burn. Instruments used with lasers should have a dull matte finish, to decrease reflection. The energy density of reflected beams decreases greatly as the distance from the focal point increases.

Fire is a major hazard. As a source of intense heat, lasers can ignite various materials used in anesthesia practice (endotracheal tubes). The CO_2 laser beam can penetrate an endotracheal tube and ignite a fire, which would then be supported by oxygen and N_2O. [108] [109] The subglottic, epiglottic, and oropharyngeal areas are the regions usually involved. Furthermore, inhalation of smoke can cause chemical injury, bronchospasm, edema, and respiratory failure. Red rubber tubes char, melt, and then burn, producing carbon monoxide gas. Polyvinyl chloride tubes burn more vigorously, producing hydrogen chloride, a pulmonary toxin.

In 1979, the reported incidence of airway fires during CO_2 laser surgery was 0.4 percent. [106] [110] However, with the use of modern equipment, techniques, and gas mixtures according to the Anesthesia Patient Safety Foundation guidelines for anesthesia for laser surgery, [107] the incidence of airway fires during laser surgery should be negligible.

To reduce the hazard of fire during laser surgery on the airway, not more than 30 percent oxygen in nitrogen or helium should be used in the gas mixture. N_2O supports combustion, as does oxygen. Sixty percent helium is an effective fire quencher if the CO_2 laser is used at an energy level of 10 watts or less. [111] The use of selected, protected endotracheal tubes reduces the risk of fire. [112] Commercially available laser-safe endotracheal tubes should be used. These may be metal, aluminum, or copper foil [113] -wrapped, laser-resistant materials [114] or double-cuffed silicone-coated metal tubes. These tubes may be recommended as resistant to the CO_2 laser but not to the Nd:YAG laser. [115]

An alternative is to use a Venturi ventilation technique with no endotracheal tube. [100] However, fire in the airway can still be a risk, because tissue may dry up, carbonize, and ignite in the high jet flow of oxygen.

Treatment of airway fires requires temporary discontinuation of oxygen, removal of the burning endotracheal tube, reintubation of the trachea, and flushing of the pharynx with cold saline. Later, a rigid bronchoscope should be used to check for damage and the presence of foreign bodies (e.g., pieces of burned tube). Administration of humidified gas, steroids, and antibiotics, the use of controlled ventilation, and even tracheostomy may be necessary. Monitoring includes the use of chest radiographs, pulse oximetry, ECG, and analysis of arterial blood gases (Ch. 64).

Laser surgery of the tracheobronchial tree is performed with CO_2 or Nd:YAG lasers by means of a rigid bronchoscope. This instrument allows better visualization, access, control of bleeding, suctioning, and irrigation. [116] The literature on ventilation and anesthesia technique for bronchoscopic laser surgery is not consistent. Reviewing many techniques, Van der Spek et al [105] discussed advantages and disadvantages and described their own successful clinical practices.

The management of subglottic laser surgery presents challenges for the anesthesiologist. Bargainner et al [117] analyzed these challenges and outlined safe methods using a ventilating laryngoscope and jet ventilation, as well as discussing potential complications (Ch. 68).

Either a CO_2 laser or an Nd:YAG laser is used in subglottic laser surgery. The Nd:YAG laser penetrates tissue (4-5 mm), has hemostatic properties, and can be conducted by a single optic fiber. Even foil-wrapped and special laser-shielded endotracheal tubes have been perforated and ignited within 12 seconds during continuous Nd:YAG laser exposure. [118]

Postoperative considerations include head-up positioning to decrease edema, careful observation for bleeding and edema, and administration of humidified oxygen. If a Venturi jet technique has been used, complications such as pneumothorax or respiratory failure (from the forcing of blood or tissue particles into air passages) may occur within the first 2 hours. Steroids and racemic epinephrine mist may be helpful in controlling laryngeal edema.

Tonsillectomy

Improved monitoring and postanesthesia care have reduced mortality from tonsillectomy to almost zero (Ch. 59) . However, management of the airway during this procedure can still present a challenge to the anesthesiologist. The goal of anesthesia for elective tonsillectomy is to provide deep general anesthesia that prevents reflex-induced hypertension, tachycardia, or arrhythmias. Muscle relaxation is required to allow easy placement of the mouth gag and to prevent bucking, coughing, or straining. Rapid recovery to consciousness and the return of protective airway reflexes are also desirable. The safest practice is probably to extubate the trachea when the patient is awake. The use of the reinforced, flexible laryngeal mask airway for tonsillectomies, [119] [120] [121] adenoidectomies, [122] and nasal surgery [123] provides excellent airway protection and good field exposure with less eventful recovery, cough, or airway obstruction on emergence.

Postextubation stridor and laryngospasm following adenotonsillectomy can be minimized by applying topical 2 percent lidocaine (maximum 3 mg/kg) to the glottic and supraglottic areas before intubation. This proved as effective as giving intravenous lidocaine (1 mg/kg) just prior to extubation, but without higher sedation scores. [124]

Preoperative evaluation includes checking for loose teeth (especially in the 4- to 7-year-old patient), ensuring there has been no recent ingestion of aspirin, and determining coagulation variables. Premedication is usually not necessary. Barbiturates are of little use in brief upper airway surgical procedures, which require rapid return of protective airway reflexes and may render the larynx more susceptible to laryngospasm during a slow awakening from the effects of barbiturates.

A technique using fentanyl and a short-acting muscle relaxant with a volatile inhaled anesthetic is satisfactory. A topical spray of 4 percent lidocaine on the tonsil area will help to decrease the anesthetic requirement, the incidence of arrhythmias, and postoperative stridor and laryngospasm. [124] [125] These patients should be well hydrated with a solution of balanced crystalloid (3-5 mL/kg/h). Blood loss during tonsillectomy is difficult to estimate and may reach

5 percent of estimated blood volume. Blood loss should be replaced if it exceeds 10 to 15 percent of blood volume.

Patients with sickle cell disease are at a higher risk for postoperative complications such as pneumonia, atelectasis, and vaso-occlusive crises. Children with sickle cell disease presenting for elective tonsillectomy should be given a transfusion to reduce the hemoglobin S ratio to less than 40 percent. [126] Children with chronic adenotonsillar hypertrophy may also have associated undiagnosed obstructive sleep apnea syndrome and are at increased risk for respiratory complication in the immediate recovery period. [127] Patients with Down syndrome may have large tongues and unstable atlanto-occipital joints and require more careful perioperative airway management for tonsillectomy. [128]

Tracheal extubation usually occurs in the operating room when the patient is awake and protective airway reflexes are present. Some coughing should not interfere with surgical closure of the tonsillar bed. Intravenous administration of lidocaine (1.5 mg/kg) has been used to decrease laryngospasm after extubation.

Pediatric tonsil patients are placed in the "tonsil position" (i.e., on one side, with the head slightly down) in the recovery area to allow blood or secretions to drain out

rather than flow back onto the vocal cords and are observed closely for bleeding or airway obstruction. One hundred percent oxygen mist is given by facemask; pulse oximeter, arterial blood pressure, and ECG are monitored routinely. Patients should be kept in the recovery room for at least 60 minutes; the pharynx should be rechecked directly for bleeding before discharge from the recovery room.

Intraoperative complications from tonsillectomy consist of arrhythmias caused by increased levels of endogenous epinephrine from light general anesthesia, sensitization of the myocardium to catecholamines by halothane, and perhaps hypercarbia. Postoperative complications consist of poor respiratory function and continued bleeding. Patients with a history of obstructive sleep apnea must be extubated awake and observed closely in the recovery room for depressed respiratory function or apneic periods. [129] [130]

Increasingly, tonsillectomy is being performed as an outpatient procedure. Although postoperative bleeding is the most serious complication, persistent vomiting and poor oral intake are the most common reasons for unscheduled overnight admission after ambulatory surgery. The incidence of PONV can be as high as 70 percent during the first 24 hours after tonsillectomy. [131] Many different antiemetic regimens have been advocated to minimize PONV following tonsillectomy surgery. [132] [133] [134] Pappas et al [135] noted that a single, large (1 mg/kg, maximum 25 mg) preoperative dose of dexamethasone significantly decreased the incidence of PONV after tonsillectomy in children.

Although metoclopramide may help to empty the stomach, it does not seem to have specific antiemetic properties compared with ondansetron in preventing PONV after tonsillectomy. [136] Withholding oral fluids postoperatively from children undergoing day surgery reduces the incidence of vomiting. [137]

It is important to develop anesthetic techniques and to use appropriate antiemetics and recovery protocol to minimize vomiting after tonsillectomy (e.g., avoid meperidine, decompress stomach of air and blood, discontinue N_2O, [138] administer an antiemetic regimen prophylactically, keep patient well hydrated intravenously, and do not force oral food or fluid intake). [137]

Bleeding Tonsil Management

The incidence of post-tonsillectomy bleeding that requires surgery is 0.3 to 0.6 percent. This complication usually occurs within 6 hours of surgery [139] and can be a difficult anesthesia problem. Management of anesthesia for these patients should include the following considerations. The extent of blood loss may not be obvious and is usually underestimated. Before the patient is transported to the operating room, no premedication should be given, and coagulation variables should be checked, if possible. Moreover, blood should be typed and crossmatched for blood replacement, and the patient should be well hydrated via a reliable intravenous line. Most problems before induction of anesthesia for bleeding tonsil are caused by unsuspected hypo-volemia, full stomach, and airway obstruction.

At induction of anesthesia, an additional person should be available to provide good suctioning of blood. A rapid-sequence induction of anesthesia with application of cricoid pressure and slight head-down positioning of the patient will protect the trachea and glottis from aspiration of blood. After induction, a nasogastric tube may be placed and removed. As with elective tonsillectomy, extubation is safest with the patient awake.

Abscesses

A peritonsillar abscess extending to the soft palate can cause severe pain, trismus, dysphagia, and respiratory obstruction. Often, the abscess can be drained or decompressed by incision or needle aspiration using local anesthesia. The risks of general anesthesia include further respiratory obstruction, difficult endotracheal intubation because of continued trismus and distorted anatomy, and spontaneous rupture of the abscess, with subsequent spilling of pus into an unprotected airway.

Planning general anesthesia for a peritonsillar abscess may include preoperative decompression of the abscess by needle aspiration to minimize the risk of rupture. A difficult intubation should be expected because of distorted anatomy, edema, and incomplete resolution of trismus. Although difficult, endotracheal intubation must be performed slowly, carefully, and gently. If the abscess is right-sided, a left-sided approach for laryngoscopy may be indicated. If airway obstruction is expected, one of three options should be selected: careful intubation of the trachea under direct vision, with the patient awake; induction of anesthesia by mask, with the patient breathing spontaneously; or elective tracheostomy.

Ludwig angina is a cellulitis of the submandibular and sublingual spaces that may include the floor of the mouth and anterior compartments of the neck. Visualization of the glottic opening is frequently impossible because of trismus, edema, and distorted anatomy. General anesthesia is contraindicated if stridor occurs at rest. Therefore, tracheostomy using local anesthesia through the cellulitis, although not ideal, may be the safest way to secure the airway.

Adult Epiglottitis

Adult epiglottitis occurs in 1 per 100,000 adults per year. [140] Causes include infection, trauma, and radiation. Symptoms are typically sore throat, dysphagia, a muffled "hot potato" voice and respiratory distress. This respiratory distress can be immediate, severe, and progress rapidly, requiring airway management in the operating room. A careful inhalation induction and titrated intravenous sedation prior to a rigid bronchoscopy or endotracheal intubation are the recommended techniques. [141] [142] The use of steroids is controversial, but it may help in cases of angioedema. [143] Racemic epinephrine is not necessarily useful.

Foreign Body in the Airway

Aspiration of a foreign body into the trachea is a common cause of sudden onset of obstructive breathing, croupy cough, hoarseness, or wheezing in young children. Several reviews have described in detail the problems and precautions of managing anesthesia during retrieval of a foreign body from air passages. [76] [95] Care must be taken not to convert partial obstruction into total obstruction by dislodging the foreign body into the upper trachea.

During severe airway obstruction, the anesthesiologist should consider either direct laryngoscopy in an awake patient or a rigid bronchoscopic examination without application of positive pressure. Most of these cases occur in children. Usually, a gentle mask induction without cricoid pressure or positive-pressure ventilation is the preferred induction technique, [144] [145] although Kosloske [146] routinely used muscle paralysis and controlled ventilation. Removal of foreign bodies from the trachea and larynx is a hazardous procedure. The surgeon must be prepared to perform an emergency tracheostomy or cricothyrotomy if partial obstruction suddenly becomes complete.

Laryngeal and subglottic edema may last for 24 hours after removal of a foreign body. Close observation and use of humidified oxygen are suggested during this recovery period.

Difficult Airways: Causes and Classification

Difficult airways include both difficult intubations and compromised airways (Ch. 39) . Difficult intubations are usually caused by anatomic abnormalities such as micrognathia, limited jaw motion, or congenital syndromes (cra-niofacial dysostoses). Other causes of difficult intubations include obesity, acromegaly, cervical spine problems, rheumatoid arthritis, and even gastric reflux. [147] These patients usually have intact, clear airways, but abnormal anatomy prevents adequate visualization of the glottis and may inhibit easy passage of an endotracheal tube.

A preoperative evaluation of the head, neck, mandible, tongue, teeth, and oropharynx using specific assessment techniques may help to predict a potentially difficult intuba-tion. Various strategies have been devised and modified to assess the airway. [148] [149] [150] [151] [152] They often have a high sensitivity, but low predictive value, and may fail to predict difficult intubations accurately. Compromised airway implies partial obstruction to air flow and the risk of total obstruction if tumor, infection, or disease further narrows the airway. Pathologic conditions above the glottis may prevent a clear view of the glottic opening, whereas subglottic lesions permit a good view of the vocal cords, but they require careful placement of a small endotracheal tube or bronchoscope. All compromised airways are difficult intubations, but not all difficult intubations are in patients with compromised airways. A large percentage of serious anesthesia accidents involves some aspect of airway mismanagement. Caplan et al [153] reported that the majority of respiratory complications involve inability to intubate, unrecognized esophageal intubation, or inadequate ventilation. The American Society of Anesthesiologists (ASA) developed a specific practice algorithm for safe management of the difficult airway. [154] Several reviews of the causes,

techniques, necessary equipment, and problems associated with difficult airways are available. [155] Benumof [154] [158] reviewed the specific management of the difficult adult airway with emphasis on awake tracheal intubation techniques [96] and the use of transtracheal jet ventilation (TTJV). [159] The intubating laryngeal mask airway [160] [161] [162] is a recent development. Benumof noted that the incidence of "cannot ventilate-cannot intubate" situations may be as high as 1 per 5,000 anesthesics. [158] Proper responses to these emergency situations involve use of the intubating laryngeal mask airway, Combitube (Kendall-Sheridan, Argyle, NY), TTJV, or immediate surgical tracheostomy. [154] Sofferman et al [163] discussed alternatives for management of lost airway during anesthesia inductions in head and neck surgery, including use of the laryngeal mask airway and Combitube. A combined technique using an anterior commissure laryngoscope and gum elastic bougie is preferred for the special circumstances of patients requiring otolaryngologic surgery.

Laryngeal Block

Topical and regional nerve blocks of the nasal oropharynx, larynx, and glottis may be used to facilitate awake endotracheal intubation (Chs. 39 and 43) . Sanchez et al [96] and Donlon [97] reviewed in detail the preparation of patients for awake intubation, including premedication, topicalization techniques, and specific nerve blocks from nasal cavity to trachea. These include sphenopalatine nerve and blocks of the glossopharyngeal and superior laryngeal nerves. [96] [156] [164] [165] The glossopharyngeal nerve (the ninth cranial nerve) supplies sensory innervation for the posterior third of the tongue, the oropharynx, the tonsillar area, and the gag reflex. This nerve can be blocked by infiltration of 3 mL of 2 percent lidocaine posterior to the palatopharyngeal fold at its midpoint, 1 cm deep to the mucosa of the lateral pharyngeal wall. Paralysis of the pharyngeal muscles and relaxation of the base of the tongue may cause some respiratory obstruction. [166] [167] Therefore, if a glossopharyngeal nerve block is used with blockade of the superior laryngeal nerve for awake intubation, the latter procedure should be performed first to avoid respiratory obstruction.

The internal branch of the superior laryngeal nerve lies just below the mucosa in the depth of the pyriform fossa. A topical block of this nerve can be performed by applying local

anesthetic for 3 to 5 minutes onto the pyriform fossa mucosa. [96]

In the absence of neck tumor or infection, an external approach to block the superior laryngeal nerve may be used. A 23-gauge needle is placed 1 cm medial to the superior cornu of the hyoid bone and is directed caudad to pierce the thyrohyoid membrane. After aspiration, 2 mL of local anesthetic is injected. Block of the superior laryngeal nerve anesthetizes all laryngeal mucous membranes above the rima glottidis, including epiglottic and arytenoepiglottic folds. Because it removes some protective reflexes, this block should be used with caution in patients with a full stomach. A maxillary nerve block can interrupt sensory innervation to the nasal cavity in preparation for nasotracheal intubation. The mandibular nerve can be blocked from an external approach. This block eliminates masseter muscle tone, relaxes the jaw, and minimizes biting by an awake but uncooperative patient. The loss of masseter tone may cause partial upper airway obstruction.

The trachea and vocal cord area can be anesthetized either by atomizer from above or by transtracheal injection. The sensory innervation is supplied by the vagus nerve via the RLN. These nerves run along the tracheoesophageal groove and supply both sensory fibers and motor fibers (intrinsic muscles of larynx). Bilateral, specific RLN blocks could result in bilateral vocal cord paralysis and airway obstruction.

A combination of these regional blocks used in conjunction with topical anesthesia of the pharynx and larynx is simple and often very effective in dealing with difficult tracheal intubations or compromised airways. [51] Direct laryngoscopy, bronchoscopy, or tracheal intubation can be performed in the awake patient with minimal discomfort or risk after a topical laryngeal block. Lidocaine is absorbed rapidly into the systemic circulation from the trachea; therefore, the maximum safe dose of topical lidocaine in the trachea is 4 mg/kg.

Management Techniques: Difficult Intubations

These situations can occur unexpectedly in otherwise healthy patients, despite preoperative airway evaluation, and they usually involve the inability to visualize the glottic opening or even the epiglottis. Crosby et al [155] reviewed the literature and made recommendations for the safe management of unexpected difficult airways. Parmet et al [168] found that, over a 2-year period, the laryngeal mask airway provided rescue ventilation without complications in 94 percent of cases of unanticipated difficult intubation and ventilation. Difficult direct laryngoscopy occurs in 1.5 to 8.5 percent of general anesthetics. Failed intubation occurs in 0.13 to 0.3 percent of general anesthetics. [155] Current techniques for predicting difficult intubations have a low predictive value. Simple initial methods for dealing with these unexpected situations include the following: manipulation of the cricoid cartilage by the optimal external laryngeal manipulation [169] or backward, upward, rightward laryngeal displacement [170] maneuver to bring the glottis into view; use of a stylet in the endotracheal tube; repositioning of the head in a more-or-less flexed position; change (in size or shape) of the laryngoscope blade; and use of special blades. [171] A flexion-flexion (chin to chest) position of the head and neck may be ideally suited to achieve optimal glottal exposure in cases of difficult direct laryngoscopic intubations. The flexion-flexion position aligns the oral and pharyngeal cavities to facilitate direct view of the vocal cords. Extension of the head at the atlanto-occipital joint leads to backward displacement of the tongue base into the airway. If these actions are ineffective, further options include the intubating laryngeal mask airway, [154] [160] [162] [172] use of a flexible fiberoptic scope, various rigid fiberoptic laryngoscopes, [173] [174] or nasotracheal intubation with general anesthesia, spontaneous respiration, and as much visualization of the mouth as possible. Fewer than 50 percent of blind nasotracheal intubations succeed on the first attempt. Furthermore, bleeding and trauma often occur after several attempts.

Other methods use a light wand, [175] [176] a rigid bronchoscope, Combitube, [177] or a retrograde catheter technique. [171] [175] The Combitube has been associated with esophageal rupture and should be inserted carefully, under direct vision whenever possible. [178] Practice and skill should be attained in routine cases before relying on these methods for a difficult intubation. Fiberoptic equipment must be used often enough in routine situations to be reliable during intubation of abnormal airways. [179] [180] The fiberoptic scope has been useful during nasotracheal intubations in rheumatoid arthritis patients who have trismus or spondylosis. Fiberoptic visualization may also be difficult when the larynx has pathologic conditions or abnormal supraglottic anatomy. Chapter 39 also discusses difficult endotracheal intubations.

Compromised Airway

Several investigators have provided guidelines for the safe evaluation and management of patients with compromised airways. [92] [154] [155] [156] [157] [158] [171] [172] [181] [182] Often, the extent of the limitation of airflow is not obvious. Although clinical signs and symptoms (stridor, tachypnea, cyanosis, anxiety, sternal retractions, diaphoresis, and tachycardia) are usually present, patients with chronically abnormal airways learn to adapt their breathing and vocalization to limited airflow. Before attempting any method of intubating the compromised airway, as much information as possible should be gathered concerning the airway problem. Such information consists of radiographs, CT, or magnetic resonance imaging (MRI) scans, old records, history, and physical examinations.

Unlike difficult intubations in normal airways, patients with compromised airways must not be given general anesthesia or muscle relaxants unless control of the airway is ensured. Attempts at awake intubation should not be done "blindly" in patients with uncertain pathologic processes. Safe techniques for managing compromised airways include awake direct laryngoscopy after careful topical laryngeal block [96] [97] ; spontaneous breathing using an inhaled anesthetic; awake fiberoptic evaluation of the airway [183] ; tracheostomy under local anesthesia; and, if necessary, lifesaving TTJV through a cricothyroid puncture with a large-caliber (14-gauge) needle, or an emergency cricothyrotomy. [184]

The efficacy and importance of TTJV in the management of the difficult airway were reviewed by Benumof. [159] [185] Inadequate oxygenation and ventilation were reported to be responsible for as many as 75 percent of cardiac arrests following the administration of anesthesia. TTJV is a quick, easy, safe solution to the problem of "cannot ventilate/ intubate." Various methods of providing TTJV are possible, and it is recommended that TTJV be available for every anesthetizing location. The incidence of serious complications resulting from elective use of TTJV is relatively low and is usually related to tissue emphysema or pneumothorax. The risk of barotrauma, gas trapping, and lung hyperexpansion from TTJV is greatly increased in cases in which total upper airway obstruction limits the ability to expel TTJV gas from the lungs. [159]

Emergency Tracheostomy

Tracheostomy may be necessary for upper airway obstruction caused by marked edema, large supraglottic tumors, laryngeal trauma, or impacted foreign bodies, as well as for loss of protective airway reflexes owing to muscle weakness, unconsciousness, or chronic aspiration caused by vocal cord paralysis (Chs. 62 and 72). [186] Other reasons for tracheostomy are that endotracheal intubation is not feasible, stridor is present at rest, patency of the airway is lost on attempts to induce anesthesia by mask, or an unstable foreign body is present in the airway. Moreover, a tracheostomy after major head and neck surgery sometimes ensures a smoother postoperative recovery.

Ideally, a tracheostomy performed using general anesthesia provides the surgeon with an immobile, cooperative patient and allows a less-hurried procedure. When possible, general anesthesia may be provided by means of a small endotracheal tube, a rigid bronchoscope, a facemask, a glottic aperture seal airway, or a laryngeal mask airway. [187] Intubation may be accomplished with the aid of a fiberoptic bronchoscope or an intubating laryngeal mask airway. An expectation of airway obstruction warrants consideration of avoidance of muscle relaxants. Careful direct laryngoscopy with the patient awake may be possible to evaluate the airway fully before deciding a safe course of action.

Tracheostomy using local anesthesia is safe but requires some patient cooperation. Infiltration of local anesthetic may be supplemented with a bilateral superficial cervical plexus block. Patient cooperation is best achieved through the anesthetist's confident demeanor and verbal reassurance, and not through heavy sedation of the patient. During the procedure, the anesthesiologist must attend to airway management, giving 100 percent oxygen and following vital signs with full monitoring (i.e., ECG, blood pressure, end-tidal concentrations of CO_2, and pulse oximeter).

Coughing may be decreased by giving lidocaine (1.5 mg/kg IV) approximately 2 minutes before placement of the tracheostomy tube. Often, the sudden reestablishment of a good airway results in rapid correction of hypercarbia, resolution of stress, a decrease in endogenous catecholamines, and subsequent hypotension. Postobstructive pulmonary edema can also occur and has been reported in a young adult with coronary artery disease subsequent to relief of airway obstruction (intubated for epiglottitis). [188] A major early complication of tracheostomy, especially in children, is malpositioning of the tube. As soon as a tracheostomy tube is placed, end-tidal concentrations of CO_2, breath sounds, and oxygen saturation must be checked. As soon as feasible, a chest radiograph should be obtained to verify correct tube placement and the absence of pneumothorax. Other early complications of tracheostomy include bleeding and local emphysema, which are usually exacerbated if the patient coughs and struggles.

The most important of the late complications of long-term tracheostomy is tracheal stenosis at the cuff site or stoma. [189] The use of high-volume low-pressure (15-20 mm Hg) cuffs inflated only when necessary and checked every 4 hours sometimes minimizes this complication. During general anesthesia, N_2O diffuses into tracheal cuffs within 60 to 90 minutes, causing increased cuff pressure.

A Montgomery T-tube [190] or Olympic tracheal button must be carefully placed without tension. These devices have the advantages of having no cuff, producing less tracheal irritation and airway resistance, and allowing air to pass through the mouth for speech. On the other hand, they provide no protection from aspiration for the area above the device, and application of positive-pressure ventilation is difficult. In an emergency, the button is easily removed and replaced with a small endotracheal tube, which can then seal the airway and allow for use of positive-pressure ventilation, if necessary.

Postoperative care after tracheostomy requires administration of humidified oxygen, careful intermittent suctioning of secretions, attention to sterile precautions, and adjustment of cuff pressure to maintain 15 to 20 mm Hg. Prolonged tracheal suctioning not preceded or followed by oxygenation can result in arrhythmias secondary to hypoxia. Moreover, the tract from stoma to trachea is not fully established for 5 days. Therefore, changing the tube within 5 days of tracheostomy runs the risk of losing this tract. Under these circumstances, a pediatric laryngoscope may be helpful in holding the tissue apart and facilitating visualization of the trachea. For emergency airway management, a laryngoscope and small endotracheal tube should be at the bedside of all patients who have recently undergone tracheostomy.

Cricothyrotomy is another method of establishing an airway quickly (within 1-2 min) in an emergency, life-threatening situation. The complication rate of 8.6 percent is less than that for emergency tracheostomy. [191] The trachea is entered directly through an incision in the cricothyroid membrane at the third tracheal ring, just below the vocal cords. Disadvantages include damage to the cricoid cartilage that leads to tracheal collapse or stenosis, bleeding, and the need for insertion of a small tube. Emergency cricothyrotomy is a temporary procedure that secures an airway until a definitive tracheostomy can be established.

No patient should undergo injury or death because of upper airway obstruction. At the very least, the cricothyroid membrane can be punctured using a 12- to 14-gauge needle to provide temporary oxygenation until a proper airway can be established. This method of transtracheal ventilation through a large needle has been effective in preventing hypoxia and respiratory acidosis. [159] [192] Oxygen is provided by flushing oxygen at the rate of 15 L/min or by jet ventilation (40 psi) at a slow, intermittent rate of 6 breaths/min and an inspiratory, expiratory respiratory cycle of 14. This ratio allows

time for passive expiration through a narrow channel. Otherwise, high airway pressure results, thereby decreasing venous return and arterial blood pressure and increasing the risk of pneumothorax.

Complications of Endotracheal Intubation

The perioperative complications of endotracheal intubation have been reviewed by many investigators [193] [194] [195] [196] (Chs. 39 and 72) . Fortunately, the more common complications are minor; however, some of the less frequent complications can be serious.

Injury during intubation is more likely in children, female patients, patients with poor dentition, and those undergoing difficult tracheal intubation. Blanc and Tremblay [194] listed more than 30 possible acute problems associated with intubation and extubation of the trachea, such as broken teeth, lacerations and perforations of the pharynx, subluxation of arytenoid cartilage, hoarseness, sore throat, paralysis of the vocal cords, and nerve damage. The overall incidence of laryngeal injury after short-term intubation is 6.2 percent, [197] the most common injury being hematoma of the vocal cord (4.5%). Mucosal lacerations occur in approximately 1 in 1,000 intubations.

Perforations of the trachea usually occur during difficult intubations using a stylet. If subcutaneous emphysema is noted after a difficult intubation, the patient must be evaluated for mediastinitis and pneumothorax.

Reflex responses to laryngoscopy and tracheal intubation are frequently minor, but they may be serious. Sympathetic responses are hypertension, tachycardia, and tachyarrhythmias. Vagal responses are laryngospasm, bradycardia, hypotension, cardiac arrest, and apnea. These responses are most likely during light levels of anesthesia and, in association with hypoxia, during periods of hypercarbia and acidosis. These reflexes may be diminished by pretreatment with lidocaine (intravenous or topical administration), narcotics, or beta-adrenergic receptor blocking drugs and by ensuring an adequate depth of anesthesia at the time of laryngoscopy.

Pharyngitis and sore throat after tracheal intubation are not uncommon. Even patients undergoing only anesthesia by mask may complain of postoperative sore throat. This complication usually resolves within 72 hours. Causes include the use of dry gases, reaction to the lubricant, increased cuff size and pressure, patient motion (coughing, bucking) while the tube is in place, difficult intubation requiring repeated attempts, and excessive tube size. Hoarseness, indicating vocal cord injury, is another postintubation problem associated with tube size. Usually, mild postoperative hoarseness resolves within 5 to 7 days. Hoarseness that worsens or persists beyond 7 days requires evaluation by an otolaryngologist.

Vocal cord paralysis secondary to damage to the recurrent laryngeal nerve is a rare but more serious cause of hoarseness. This complication may occur because the endotracheal tube cuff presses the recurrent laryngeal nerve between the thyroid lamina and the arytenoid cartilage [193] or because of direct injury during head and neck surgery. Unilateral injury causes some change in voice and mild aspiration, but no respiratory obstruction. Bilateral recurrent nerve injury is more serious and may result in respiratory distress, stridor, and complete obstruction, as both true vocal cords become motionless and adducted. A tracheostomy may be required

during the 6-week recovery period.

The use of the laryngeal mask airway does not necessarily avoid complications. Sore throats and even unilateral right hypoglossal nerve paralysis have been reported. [198] Inadvertent intubation of the esophagus or bronchi can be avoided by the following practices: observation of the tube as it passes through the vocal cords; checking the distance indicator at the teeth (21 cm for female patients and 23 cm for male patients); listening for equal bilateral breath sounds and for the absence of gastric sounds; checking for symmetric chest motion synchronous with squeezing of the ventilator bag; and noting the sustained presence of exhaled CO_2 on a capnometer. CO_2 may temporarily effuse from the stomach, having been forced there during the application of positive-pressure ventilation by mask. Adequate oxygenation, as evidenced by monitoring of the pulse oximeter, does not necessarily indicate proper endotracheal intubation. If the patient has breathed 100 percent oxygen for 4 to 5 minutes, oxygen desaturation following intubation of the esophagus may not occur for at least 2 to 3 minutes. Moreover, the presence of breath sounds does not always indicate a successful endotracheal intubation. A spontaneously breathing patient whose esophagus has been intubated can still produce valid breath sounds.

Cocaine

Cocaine is a naturally occurring alkaloid of the *Erythroxylon coca* plant. It is an ester of benzoic acid and the methylated base ecgonine. In addition to its local anesthetic effects on mucous membranes, cocaine is an excellent vasoconstrictive agent. For these reasons, it is used in intranasal surgery to provide anesthesia, to decrease bleeding, and to shrink congested mucous membranes. [199] Cocaine also has sympathomimetic effects, sensitizing organs to epinephrine and blocking the reuptake of released epinephrine at peripheral nerve terminals. [200] Therefore, cocaine should be avoided in hypertensive patients, especially those taking monoamine oxidase inhibitors.

In one study, intranasally applied cocaine (1.5 mg/kg) was absorbed rapidly, reaching peak levels in 30 to 45 minutes; these levels remained elevated for at least 120 minutes. [201] No important cardiovascular effects occurred during general anesthesia with halothane. Smaller intranasal doses (0.5-1 mg/kg) have been found to increase heart rate 10 beats/min and to raise both systolic and diastolic blood pressures approximately 10 mm Hg. [202] Higher doses (2 mg/kg) sensitize the myocardium to the arrhythmogenic effect of epinephrine, whereas even higher doses (5-10 mg/kg) depress the heart.

The response to cocaine varies. In some patients, even small doses of 0.4 mg/kg may cause ventricular fibrillation, cardiac arrest, hypertension, tachycardia, respiratory depression, or restlessness. The median lethal dose (LD_{50}) for orally administered cocaine is approximately 500 mg. [203] For intranasal administration of a 4 percent solution, the safe recommended maximum dose is approximately 1.5 mg/kg.

Each drop of a 4 percent solution contains about 3 mg of cocaine.

Cocaine is absorbed from the laryngeal tracheal mucosa as rapidly as if it were injected intravenously. It is metabolized primarily through ester hydrolysis by plasma pseudocholinesterase and is also slowly detoxified in the liver and excreted unchanged by the kidney. Patients with pseudocholinesterase deficiency may be sensitive to cocaine. The practice of adding epinephrine to cocaine is hazardous, and there is no evidence that this addition produces less bleeding at the site of surgery.

ANESTHESIA FOR EAR SURGERY

Safe, comfortable operating conditions can be provided for ear surgery by infiltration of local anesthetic or by administration of general anesthesia. [204]

Local Anesthesia

Surgical otologic procedures such as premeatal operations, stapedectomy, and uncomplicated middle ear surgery of less than 2 hours' duration can be performed on selected patients using infiltration of local anesthetic and carefully titrated sedation. Patients should be able to understand, communicate, and be cooperative (i.e., remain still, especially during microscopic surgery of the middle ear). During the preoperative visit, the anesthesiologist should perform the same thorough medical evaluation as for general anesthesia. The goal of preoperative sedation is to render the patient calm, cooperative, and comfortable but not overmedicated (i.e., with obtunded reflexes) or out of touch with surroundings. Light sedation can be achieved by titrating intravenous propofol (0.5-0.7 mg/kg) during the injection of local anesthetic and, if necessary, by adding midazolam (0.02-0.04 mg/kg IV) during the procedure.

Nerve Block

Four nerves provide sensory innervation of the ear. The auriculotemporal nerve (the mandibular division of the trigeminal nerve) supplies the outer auditory meatus and can be blocked by injection of 2 mL of local anesthetic into the anterior wall of the external auditory meatus. The great auricular nerve (the cervical plexus nerve) supplies the medial-lower aspect of the auricle and part of the external auditory meatus. The auricular branch of the vagus runs between the mastoid process and the external auditory meatus to supply the concha and external auditory meatus. The great auricular and auricular (vagus) nerves can be blocked by injection of 2 to 3 mL of local anesthetic posterior to the ear canal (great auricular nerve). The tympanic nerve (the glossopharyngeal nerve) supplies the tympanic cavity and can be blocked topically by instillation of sterile 4 percent lidocaine. When a large perforation of the tympanic membrane has occurred, care must be taken not to place toxic substances into the auditory canal, lest they enter and damage the middle ear cavity.

Addition of epinephrine to the local anesthetic increases the intensity and duration of the effect and provides some local vasoconstriction, thereby decreasing bleeding. A safe dose of epinephrine is 0.1 mg (10 mL of 1:100,000 concentration) and may be repeated after 20 minutes, if necessary.

General Anesthesia

General anesthesia for ear surgery requires attention to preservation of the facial nerve, the effect of N_2O in the middle ear, extremes of head positioning, the possibility of air emboli, blood loss, and, during microsurgery of the ear, control of bleeding, and prevention of nausea and vomiting.

Positioning of the Patient During Ear Surgery

When positioning the patient's head for surgery under general anesthesia, one must avoid extremes of neck extension or head torsion. Injuries can occur to the brachial plexus (stretch injuries) or cervical spine (Ch. 26) . Patients with limited carotid artery blood flow are especially vulnerable to further decreases in blood flow from exaggerated neck positions.

Preservation of the Facial Nerve

Surgical identification and preservation of the facial nerve are essential during many ear operations. The goal is more easily accomplished and confirmed if the patient is not totally paralyzed. If a narcotic muscle relaxant technique must be used, the effects of the muscle relaxant should be monitored to ensure that at least 10 to 20 percent of muscle response remains. Otologic surgical procedures are associated with a 0.6 to 3.0 percent incidence of facial nerve paralysis. Intraoperative monitoring of evoked facial electromyographic activity may assist in functional preservation of the facial nerve during surgery in the mastoid/temporal bone area. [205]

Nitrous Oxide and Middle Ear Pressure

The middle ear and paranasal sinuses are normal body air cavities that consist of open, nonventilated spaces (Ch. 4) . The middle ear space is vented intermittently when the eustachian tube is opened. Expansion of these air spaces by replacing nitrogen with N_2O reflects the 34-fold difference between the blood/gas coefficients of the two gases (0.013 for nitrogen versus 0.46 for N_2O). Specifically, when inhaled in high concentrations, N_2O enters the air cavities faster than nitrogen can leave. In a fixed cavity such as the middle ear, the result is an increase in pressure. [206] Normally, passive venting by the eustachian tube occurs at a pressure of approximately 200 to 300 mm H_2O. If eustachian tube function decreases because of surgical trauma, disease, or acute inflammation and edema, middle ear pressure can reach 375 mm H_2O within 30 minutes of the start of N_2O.

In addition, after discontinuation of N_2O, the gas is rapidly reabsorbed, and sustained, marked, negative middle ear pressure may develop. When eustachian tube function is abnormal, negative ear pressure of -285 mm H_2O can occur within 75 minutes of discontinuation of N_2O. Such pressure may contribute to the development of serous otitis, disarticulation of the stapes, and impaired hearing. [196] Demonstrating these marked changes in middle ear pressure associated with N_2O, Patterson and Bartlett [207] also noted hearing impairment caused by hematotympanum and disarticulation of stapes struts. These investigators believe that N_2O anesthesia may be hazardous to hearing in patients who have had previous reconstructive middle ear surgery.

Transient worsening of middle ear function, rapid increases in middle ear pressures proportional to the inhaled concentration of N_2O, nausea and vomiting, and rupture of the tympanic membrane have all been associated with elevated middle ear pressure and abnormal eustachian tube function during N_2O anesthesia in susceptible patients. Susceptible patients include those with previous otologic surgery, acute or chronic otitis media, sinusitis, upper respiratory tract infection, enlarged adenoids, and pathologic conditions of the nasopharynx. Decreased compliance, increased resistance, and conductive hearing loss have also been observed in patients given N_2O anesthesia for adenotonsillectomy.

A bulging eardrum and "lifting off" of the tympanic membrane graft can occur during tympanoplasty surgery. There is no evidence that using N_2O (50%) for general anesthesia for type 1 tympanoplasties will interfere with the graft placement or outcome of the surgical procedure. [208] To avoid complications, however, the anesthetist should limit the concentration of N_2O to 50 percent and should discontinue administration 15 minutes before closure of the middle ear. The

subsequent decrease in subatmospheric pressure can be avoided by flushing the middle ear cavity with air prior to closure of the tympanic membrane.

Microsurgery of the Ear

During microsurgery of the ear, the technique selected for anesthesia should help to provide good operative conditions for the surgeon. A 10- to 15-degree head-up tilt increases venous drainage, keeps venous pressure low, and decreases venous bleeding. The use of a volatile anesthetic agent helps to control arterial blood pressure. Microsurgery of the ear may require additional local vasoconstriction to control bleeding. Local infiltration of 0.1 mg of epinephrine (10 mL of a 1:100,000 concentration), repeated within 20 minutes, is a safe practice in a well-ventilated patient given halothane anesthesia. Isoflurane does not sensitize the myocardium to catecholamines to the same extent as does halothane. Topical application of epinephrine in the ear usually requires only a few drops. Concentrations higher than 150,000 do not provide any additional vasoconstrictive effects.

The need for deliberately induced hypotension during microsurgery of the ear is questionable [81] [209] (Ch. 41) . The goal should be diminished bleeding, rather than an absolutely bloodless field. Inducing hypotension for ear, nose, or throat procedures, Condon [81] concluded that, even when precautions were taken, controlled hypotension was not free of complications. These complications, however uncommon, are usually major problems involving the heart or CNS. Furthermore, in a blind study on the use of controlled hypotension for ear surgery, Eltringham et al [210] found no correlations between blood pressure and quality (i.e., dryness) of the operative field. Modified hypotensive techniques based on controlled ventilation with halothane have been reported to provide successful general anesthesia for ear surgery. Multidrug combinations of nitroglycerin, hydralazine, propranolol, droperidol, and others can lead to excessive hypotension in which rapid reversal is not possible. In this author's experience, satisfactory conditions for microsurgery of the ear can be provided by placing the patient in a 15-degree head-up position, maintaining systolic blood pressure at approximately 85 mm Hg, using controlled ventilation with a volatile agent, and adding narcotic and local infiltration of topical application of epinephrine, if necessary.

In summary, general anesthesia using a volatile agent is the first choice for microsurgery of the ear. No muscle relaxation is required. Moreover, if the administration of N_2O must be discontinued, the effects of the potent anesthetic agent remain, identification of the facial nerve is not impeded, and relative hypotension (systolic blood pressure 80-85 mm Hg) can easily be maintained.

Middle Ear Surgery: Nausea and Vomiting

Procedures on the middle ear are likely to cause postoperative emesis (Ch. 65) . PONV can undo the results of the delicate middle ear reconstruction. The anesthetic management of middle ear surgery should include a plan to minimize PONV. Many regimens have been shown effective, including propofol infusion, [211] granisetron, [212] transdermal scopolamine, [213] ondansetron, [214] droperidol, and eliminating N_2O. [138] [215] Splinter et al [216] were unable to demonstrate that N_2O induces vomiting in children after the brief general anesthetic for myringotomy. PONV may be controlled with intravenous doses of a potent antiemetic drug (e.g., droperidol, 0.01/kg; ondansetron, 0.05 mg/kg; or dolasetron, 0.20 mg/kg) given during surgery.

Myringotomy

Bilateral myringotomy with tube placement is the second most frequently performed pediatric surgical procedure. [216] [217] Some form of analgesia is required in most children after this brief outpatient procedure. [218] Derkay et al [217] found that when intraoperative ear drops mixed with 4 percent lidocaine were used, the preoperative oral analgesics were of little added benefit. Preoperative oral acetaminophen, [219] or acetaminophen with codeine, [218] and even intranasal butorphanol [220] have been recommended as effective.

Chapter 64 - Anesthesia for Laser Surgery

Ira J. Rampil

INTRODUCTION

The word *laser* is an acronym for light amplification by stimulated emission of radiation, and laser technology is one consequence of Nobel prize-winning developments in quantum mechanics, which are among the most important in 20th century physical sciences. In essence, lasers provide the ability to transfer large quantities of energy rapidly to remote locations. Applications in medicine have been sought since the laser's creation. Now, some 30 years later, lasers are an accepted, often preferred member of the surgical armamentarium. The rapid proliferation of this technology has, however, been accompanied by occasionally severe complications, making it imperative that anesthesiologists understand the potential threat to their patients and themselves and be prepared to respond properly. This chapter reviews relevant highlights of the fundamental physics of lasers and laser light, rationales for the variety of lasers in clinical use, and important anesthesia-related concerns during laser surgery. A glossary of terms relevant to this topic is presented in Table 64-1 .

PHYSICS OF LASER LIGHT

Visual light is electromagnetic radiation, as are radio waves, x-rays, and gamma rays. These different classes of electromagnetic radiation are similar phenomena that occur at very different wavelengths. In 1864, Maxwell [1] explained that light is an electromagnetic wave with combined electrical and magnetic oscillations that propagates at 299,792,458 m/s. Max Planck [2] subsequently discovered the photoelectric effect: that is, light of a certain color (e.g., blue) causes metal to eject electrons at a rate proportional to the brightness of the light, whereas intense light at other wavelengths (e.g., red, orange, or yellow) cannot. Planck's discovery was the first step toward laser physics, because explaining it required a new conceptual framework. Einstein [3] developed this framework, quantum mechanics, in 1905, establishing the theoretical basis for laser action. He explained that all electromagnetic radiation (e.g., light, radio, x-ray) consists of photons, which may be described as follows:

1. Their properties are consistent with both particles and waves.
2. They propagate in a vacuum without diminishing, at a constant speed of 299,792,458 m/s.
3. Their energy is proportional to their vibrational frequency:

   v

   where h is the Planck constant, 6.63×10^{-34} (jouleseconds) and v is the frequency of the photon in hertz.
4. Their wavelength (lambda) can be calculated as follows:

Wavelengths of visible light range from 385 to 760 nm (nanometers, 10^{-9} m); shorter wavelengths are ultraviolet, and longer wavelengths are infrared.

Einstein also explained that the photoelectric effect is independent of the number of photons present, occurring even if only one photon at a time struck the metal surface. Energy is the key; that is, only photons of high enough energy

TABLE 64-1 -- Glossary of Laser Terminology

Ablation: Removal of tissue by vaporization

Absorption: The transformation, by interaction with matter, of radiant energy to a different form of energy.

Active medium: A material that acts as a laser with the proper excitation

Aiming beam: A very low-powered laser beam that is collimated with the high-powered, often invisible therapeutic beam to illuminate the target site

A **ngstrom unit** (A) **:** 10^{-10} m

Anode: The positive terminal in a gas discharge laser

Attenuation: The reduction in beam energy by absorption or scattering as it passes through matter

Brewster windows: Transparent windows at the ends of a gas laser discharge tube set at such an angle to the optical axis of the tube (Brewster angle) as to provide maximum light transmission

Coherent light: Light in which the photons all have the same wavelength and maintain a constant in-phase relationship with each other

Collimation: The property of a light beam that describes the degree to which the constituent photons move in a single direction; highly collimated beams do not spread in diameter as they move away from the source

Continuous wave (CW) mode: A mode of operation in which the laser discharge is continuous

Diffraction: The modulation in intensity and apparent bending exhibited by photons as they pass through an opaque body

Dopant: A chemical added to a crystal matrix to serve as an active laser constituent

Energy density: The amount of energy per unit area arriving at a surface, usually expressed in joules per square centimeter

Excimer: Excited dimer; a type of laser based on the transition states of a diatomic molecule (e.g., ArF, KrF, or XeCl); these lasers produce photons of very high energy

Extinction length: The thickness of a specified medium that absorbs 98 percent of the incident beam intensity (expressed as wave number in cm^{-1})

Infrared: Electromagnetic radiation whose wavelengths lie in the band 0.7 mum to 1.0 mm (i.e., longer than visible light, but shorter than microwave or radio waves)

Interference: The phenomenon in which photons of like wavelength but different phase combine constructively and destructively to modulate the resulting intensity

Joule (J): A unit of energy (1 joule = 1 watt-second)

Micrometer (mu **m):** 10^{-6} m

Mode: A description of the intensity cross-section of a laser beam

Monochromatic light: Light of a single wavelength or color

Nanometer (nm): 10^{-9} m

Neodymium (Nd): A rare earth metal, frequently chosen as a laser material within a substrate of glass or yttrium aluminum garnet (YAG)

Output power: Rate of energy discharge, usually measured in watts or joules per second

Photon: A quantum of electromagnetic energy possessing both wave-like and particle-like properties; photons travel at a constant speed of approximately 300,000,000 m/s

Power density: The amount of power (energy per second) per unit area arriving at a surface, usually expressed in watts per square centimeter

Pulsed mode: A mode of operation in which the laser delivers discrete (usually quite brief) bursts of photons

Pump: The means of inducing an electron population inversion so that stimulated emission might occur

Resonator: The combination of laser material and mirrors necessary to support laser activity

Spontaneous emission: The emission of a photon when an excited orbital electron decays back to its ground-state energy

Stimulated absorption: The process by which an orbital electron captures the energy of a colliding photon and is boosted to a higher energy orbital

Stimulated emission: The process by which an electron in a high-energy orbital will, if struck by an appropriate photon, emit a new photon of wavelength, phase, and direction equal to that of the original, colliding photon

Tunable laser: A laser that can be adjusted so as to provide a selected output wavelength from a range of possibilities

Ultraviolet: Electromagnetic radiation having wavelengths shorter than visible light, in the range between 0.01 and 0.38 mum

YAG: A synthetic crystalline matrix composed of yttrium, aluminum, and garnet, with the chemical formula $Y_3 Al_5 O_{12}$

Wavelength: The distance from peak to peak of a photon wave, the usual units for light waves are nanometers (nm) or micrometers (mum)

(high enough frequency) can provide the energy necessary to stimulate electron emission; lower-energy photons, even arriving in large numbers at a given time (brightness), cannot. These findings precipitated the development of laser light.

Some additional aspects of quantum physics provide greater insight into the origin and nature of laser light. For example, electrons circling the nuclei of atoms are constrained to a few specific orbital patterns and radii (Fig. 64-1) . Each orbital is associated with a specific energy level; the only way an electron can move from one orbital to another of higher or lower energy is to absorb or emit, respectively, an amount of energy exactly equal to the difference in energy between the two orbitals. The process by which a photon's energy is captured by an electron, thereby vaulting the electron into a higher energy orbital, is called *stimulated absorption* (Fig. 64-2) ; the converse process by which an electron drops to a lower orbital, in the process, sending out a photon to carry away the excess energy, is called *spontaneous emission.* In 1917, Einstein predicted that *stimulated emission,* the key to laser action, [4] also could occur. For this process, a photon of a particular wavelength (energy) must collide with an atom ready for spontaneous emission at that wavelength (i.e., having an electron already in the higher energy orbital), stimulating immediate photon emission and electron descent to a lower orbital. The colliding photon leaves the electron with the emitted photon, both photons having the identical wavelength, phase, and direction.

The energy differences between electron orbitals are specific to different atoms and are responsible for the fingerprint-like emission or absorption spectra used in chemical identification. Under normal circumstances of thermodynamic equilibrium, most of a substance's electrons are in the lowest available (ground-state) energy orbitals. Normally, an electron is much more likely to engage in spontaneous than in stimulated emission (by a factor of 10^{33}:1). The key to the creation of the laser was the achievement of a *population inversion,* in which many electrons are "pumped up" to the higher orbital, waiting for a photon to come along and start a chain reaction (or amplification) of stimulated emission. In 1958, the technology for pumping up electrons to achieve stimulated emission was introduced. [4] A method was found

---

Figure 64-1 Electronic orbitals and energy levels are shown in this schematic diagram of the Bohr model of the hydrogen atom. The circular electron orbitals are a simplification of the probabilistic electron cloud structure. Superimposed on the electron orbitals are the energy transitions responsible for two of the line series in the emission spectrogram of hydrogen. The Lyman series of spectral lines occurs when electrons release photons as they jump down to the lowest energy orbital; the Balmer series of lines represents jumps to an orbital just above the lowest. The wavelength of the resulting photons are inversely proportional to the size of the jump: for example, in the Balmer series the jump from the n = 3 orbital to the n = 2 orbital releases a photon of wavelength 656.3 nm, whereas the jump from n = 5 to n = 2 is more energetic, releasing a 434-nm photon.

for enclosing the laser medium between parallel mirrors, so that laser frequency photons could traverse the medium repeatedly and maximize the number of stimulated emissions. If one of the mirrors is partly transparent, a beam of laser light will eventually exit through that mirror.

Laser light differs from ordinary light in three ways. First, it is highly monochromatic; that is, it consists of photons that have a well-defined, very narrow band of wavelengths, whereas ordinary light contains a wide spectrum of wavelengths. Second, laser light is coherent, a property that implies that the electromagnetic fields of all photons in the laser beam oscillate synchronously, in identical phase. In ordinary light, the electromagnetic fields are phased randomly even at the same wavelength. Third, directed beams of laser light are collimated (i.e., have minimal dispersion). The light remains in a narrow, collimated beam, whereas ordinary light beams spread out in all directions from a point source. These three characteristics allow lasers to generate intense light beams, to send such beams efficiently and accurately through lenses, and to deliver intense energy to small target sites.

LASER SYSTEM HARDWARE

The essential components of a laser system include a laser medium containing the atoms whose electrons create the laser light, resonating mirrors to boost laser efficiency, and an energy source to excite or (pump) the atoms of the laser medium into producing laser light (Fig. 64-3) .

Figure 64-2 Absorption, emission, and stimulated emission. Photons may interact with orbital electrons in three ways. (A) A photon striking an electron may transfer its energy to the electron, pushing the electron into a higher energy orbit. This interaction is known as absorption. (B) An electron in an orbit higher than the ground (minimal energy) state may spontaneously lose energy in the form of an emitted photon. (C) An incoming photon may interact with an electron that is already in a high-energy orbit, with the result that two perfectly coherent, collimated photons leave the electron; this is known as stimulated emission.

The different types of lasers applied in clinical practice use a variety of laser media and energy pumps. Some clinical lasers use a gaseous medium such as CO_2, argon, krypton, or helium-neon and are pumped by electric discharge through the gas. Gas lasers may produce either a continuous or an intermittently pulsed beam output. Other lasers use solid rods of laser-passive material containing small quantities of ionic impurities, known as *dopants,* which are the actual laser materials. Dopants commonly used for their laser potential include chromium (as in the ruby laser), neodymium (Nd), and holmium (Ho). A synthetic gem crystal known as YAG (yttrium aluminum garnet) is commonly used as a passive host matrix, but even glass has been used. Solid lasers usually are pumped by high-energy photons from a xenon flash lamp and therefore produce a pulsed beam. Lasers also can be made from liquid dyes and semiconductors, but these technologies have yet to appear to a significant extent in surgical practice. Some medically relevant laser media and their respective output wavelengths are listed in Table 64-2 .

Because lasers are not very efficient at converting electricity into light, they require a large power supply. For example, a laser with a 10-W output requires in excess of 1,000 W of alternating current from a wall socket; consequently, some laser systems may require special wiring for the high current load. This electrical energy is converted to very high voltages (5,000-30,000 V) to drive the gas discharge or a xenon flash lamp. Many laser systems also require running water for cooling. Some power supply units contain nonmedical compressed gas (e.g., argon, krypton, or CO_2) either as a laser medium or as a coolant.

Frequency doublers convert laser light to a different wavelength, enhancing therapeutic flexibility. A beam of laser light passed through a crystal of KTP (potassium titanium

Figure 64-3 Generic laser hardware. A laser system consists of several components, regardless of whether the laser is solid-, liquid-, or gas-based. The central component is the laser medium itself, which may, for example, be a solid crystal of YAG with a small concentration of neodymium as dopant or may be a tube containing CO_2. The energy pump provides the means of obtaining a population inversion (see text) of orbital electrons; it may consist of a xenon flash lamp or an electric spark generator. A pair of axial mirrors allows repeated passes of collimated photons through the medium, allowing maximum amplification by stimulated emission. The mirror on the right is not 100 percent reflective, allowing the beam to escape eventually. The optional Q switch increases the efficiency of pulsed lasers by allowing a small delay to increase the pumping.

phosphate) emerges with a mixture of light of the original wavelength and light of a wavelength that is half of the original (double the original frequency). In medical lasers, KTP is most often used with Nd:YAG. Truly "tunable" or frequency-adjustable lasers exist, but they are still relatively low-powered devices.

A *light guide* directs the laser beam to the surgical site, as illustrated in Figure 64-4 . Fiberoptic bundles provide a convenient, flexible conduit for visible and near-infrared wavelengths. Wavelengths outside this range, such as the long infrared from a CO_2 laser, require either an articulated arm containing front-surface mirrors at each joint or newly developed exotic materials in a fiberoptic bundle. Once the laser beam is delivered in proximity to the surgical site, either

TABLE 64-2 -- Laser Media Wavelengths

LASER MEDIUM	COLOR	WAVELENGTH (nm)	TYPICAL APPLICATION
CO_2	Far infrared	10,600	General, cutting
Erbium-YAG	Infrared	2,930	Dental, arthroscopy
Holmium-YAG	Infrared	2,060	Angioplasty
Neodymium-YAG	Near infrared	1,064	General, coagulation, via fiberoptics
Ruby	Red	694	Tattoos, nevi
Krypton	Red	647	
Helium-neon	Red	632	Aiming beam
Gold (vapor)	Red	632	
Organic dye (liquid)	Red	632	Phototherapy
Organic dye (liquid)	Yellow	585	Dermatology, ophthalmology
Copper (vapor)	Yellow	578	
Organic dye (liquid)	Yellow	577	
Krypton	Yellow	568	Retina
KTP:neodymium-YAG	Green	532	General, pigmented lesions
Krypton	Green	521	

Argon	Green	514	Vascular, pigmented lesions
Copper (vapor)	Green	510	
Organic dye (liquid)	Green	504	
Argon	Blue	488	Vascular, pigmented lesions
Xenon fluoride	Ultraviolet	351	Cornea, angioplasty
Xenon chloride	Ultraviolet	308	Cornea, angioplasty
Krypton fluoride	Ultraviolet	248	Cornea, angioplasty
Krypton chloride	Ultraviolet	222	Cornea, angioplasty
Argon fluoride	Ultraviolet	193	Cornea, angioplasty

KTP, potassium titanium phosphate; YAG, yttrium aluminum garnet

Figure 64-4 Light guides. (A) Schematic representation of a CO_2 laser guide such as may be found in either an operating microscope or a hand-held wand. The guide consists of rigid hollow tubes with hinged, aligned mirrors, which reflect the beam from its source through the focusing lens. (B) Schematic of a flexible fiberoptic guide with a sapphire contact scalpel and a coaxial cooling system.

ther it is focused to the site by the lens of an operating microscope or the shape of the beam is intentionally altered by passing it through a contact probe directly on the tissue to be ablated.

An operating microscope accurately aims a laser by directing a low-powered (about 1-mW) visible beam (usually from a low-powered helium-neon gas laser) through the same optical path as the surgical laser. Some surgical lasers can be focused to a spot size of 30 mum (0.030 mm), creating very high-power densities.

For surgical procedures that do not require a "no-touch" technique, there are special heat-resistant (sapphire) direct-contact probes [5] (see Fig. 64-4) that are interchangeable and whose shapes can be designed for sharp cutting or diffuse coagulation, as needed. However, these probes require active cooling in the form of a compressed gas or liquid jet, a feature that has become responsible for a significant contribution to laser-related morbidity and mortality. [6] The mechanism of action of the contact probe is probably a combination of thermal conversion of most of the laser energy within the sapphire (heating the surface to >800°C) and transmission of perhaps 20 percent of the near-infrared energy to the surrounding tissue. [7]

CLINICAL APPLICATIONS

Lasers are now used as scalpels and electrocoagulators with some unique advantages. For example, lasers allow highly precise microsurgery, even in confined or difficult-to-reach sites. Two examples of a laser system's ability to reach remote sites effectively include percutaneous diskectomy [8] and endovascular angioplasty. [9]

The ability to focus laser beams on small target areas concentrates the intensity or power per area enormously. For example, a 10-W beam, originally 1 cm^{-2} in area, would have a power density of 10,000 W/cm^{2} when focused on a target area of 0.001 cm^{-2} . This power density delivers approximately 2,500 cal/s to the target site, producing heating at a rate of many thousand degrees per second, depending on the volume of energy absorption. This allows precise, rapid vaporization of tissue or indeed most materials except metals and ceramics. Lasers do not increase the energy of a particular photon, but simply place more photons at a given place and time than do other light sources. Laser surgery is relatively "dry," providing near-instantaneous sealing of small blood vessels and lymphatics, even in the presence of clotting abnormalities. However, early claims for faster than normal healing and lower infection rates have not yet been convincingly validated. [10]

BIOLOGIC EFFECTS OF LASER LIGHT

Living tissue is a complex aqueous solution containing a variety of molecules that absorb light. When an atom interacts with a photon whose energy does not exactly match a possible electron transition, the photon's energy may be translated into atomic vibrations we recognize as heat. The degree to which a particular wavelength of light is absorbed and converted to heat in the target tissue determines its effect on that tissue.

Long infrared wavelengths are absorbed with great efficiency by water, the main constituent of tissue. Long-wavelength laser light, like that from CO_2 (operating at 10,600 nm), is therefore completely absorbed by water in the first few layers of cells. With powerful, focused CO_2 beams, this results in explosive vaporization of the surface tissue of the target with surprisingly little damage to underlying cells.

Excimer lasers have an extremely precise effect because they produce ultraviolet light that is absorbed more intensely by water and other molecules. Near-infrared light from an Nd:YAG laser at 1,064 nm is less absorbed by water, and the beam diffuses through several millimeters, scattering through a volume of tissue perhaps 100 to 1,000 times the volume through which a CO_2 beam diffuses. Consequently, the energy of an Nd:YAG beam is more widely disseminated (Fig. 64-5) , producing less vaporization and more thermal coagulation (i.e., a cooking effect). Some of the effects of this bulk coagulation may not be apparent for hours or days following exposure. The red light produced by a ruby laser (694 nm) is poorly absorbed, except by cells containing dark pigment. The green and blue light produced by argon (514, 488 nm) or krypton (476, 521, 568 nm) gas lasers is transmitted by water but is intensely absorbed by hemoglobin, providing the ability to penetrate skin or ocular structures and selectively coagulate vascular or pigmented regions. Although lasers that produce infrared or

Figure 64-5 Different wavelength laser light causes different patterns of tissue destruction. The actual destructive effect of laser light on tissue depends on both laser parameters and tissue factors.

visible light have exclusively thermal effects on tissue, the photons produced by ultraviolet excimer lasers are energetic enough to disrupt chemical bonds directly and cause ionization, which can result in mutation and carcinogenesis.

RISKS OF LASER USE

Standards and Regulations

Because lasers are potentially dangerous technologic devices, their clinical use is subject to some degree of federal regulation and to voluntary consensus standards to minimize possible risks. The U.S. Food and Drug Administration (FDA) controls the manufacture and marketing of medical laser equipment. Currently, however, there are no mandatory federal safety precautions or regulations governing the clinical use of lasers. Institutions using lasers clinically should subscribe to the standards published in the *American National Standard for the Safe Use of Lasers in Health Care Facilities* (Z136.3-1988) by the American National Standards Institute (ANSI). [*] These standards reflect a consensus of governmental, industrial, and professional opinions on the methods used to define and control the risks of laser use, define and standardize training, and assess and ensure safety. The FDA also has suggested a set of regulations that have been adopted and modified by several states. [11] The safety guidelines proposed by both ANSI and the FDA should be followed to the maximal extent possible. Although it is patients who are at most risk from the surgical use of lasers, injuries to staff have not been rare. Accordingly, the U.S. Occupational Safety and Health Administration (OSHA) is empowered to intervene if the medical use of lasers threatens the health of employees.

Data regarding the true incidence of laser-related injury are limited. Manufacturers are required to report unusual incidents or injury as they become aware of them. However, clinical reporting has, until recently, been voluntary, except when complications of laser use occur in the course of a premarketing testing protocol. The passage by Congress of the Safe Medical Devices Act of 1990 now requires reporting by clinicians of all serious injuries and should provide more accurate data regarding the prevalence of such injuries.

LASER HAZARDS

The hazards associated with laser use can be divided into 4 major categories: atmospheric contamination, perforation of a vessel or structure, embolism, and inappropriate energy transfer. There were 21 injuries reported to the FDA between January 1989 and June 1990: 2 minor, 12 serious, and 7 fatal. [12] The distribution by type of injury is illustrated in Figure 64-6 .

Atmospheric Contamination: Laser Plume

Vaporization of tissue, whether by electrosurgery or laser radiation, produces a plume of smoke and fine particulates (mean size, 0.31 mum; range of sizes, 0.1-0.8 mum[13]), sized within the range that is efficiently transported and deposited in the alveoli. Many individuals find the odor of this plume objectionable, and sensitive individuals have described headaches, tearing, and nausea as a consequence of inhalation. Deposition of laser plume particulates in rat lung appears capable of producing interstitial pneumonia, bronchiolitis, reduced mucociliary clearance, inflammation, and emphysema. [14] [15]

Potentially, laser plume also may be mutagenic, [16] [17] teratogenic, or a vector for viral infection. *In vitro,* the mutagenic

Figure 64-6 Distribution of laser injury type reported to the U.S. Food and Drug Administration, from January 1989 to June 1990. *(Data from U.S. Food and Drug Administration [12])*

*ANSI Z136.3-1988 is available from the American National Standards Institute, Inc., 1430 Broadway, New York, NY 10018, or from the Laser Institute of America, 5151 Monroe St., 102W, Toledo, Ohio 43623

potential of laser condensate is half that of electrocautery, [17] and the total mutagenic potential from 1 g of tissue is comparable with that from smoking three to six cigarettes. The role of the smoke plume as a viral vector is controversial: viral DNA has been detected in plume from condylomas [18] [19] and skin warts, [20] but not from laryngeal papillomas. [21] Human immunodeficiency virus (HIV) was not detected in electrosurgical smoke plume [22] in one study, and only noninfectious DNA fragments were found in a CO_2 laser plume from HIV-infected tissue pellets. [23] Competent transmission of any viral infection via smoke plume has yet to be demonstrated. [24] Laser plume does not appear to contain viable eukaryotic cells (i.e., tumor cells [25] [26]) but it may contain viable bacterial spores. [27] [28]

CO_2 lasers seem to produce the most smoke due to the vaporization of tissue, and Nd:YAG contact probes produce much less. The most effective means of preventing dissemination of the plume is to use an efficient smoke evacuator at the surgical site. [29] [30] Ordinary surgical masks efficiently filter particles only down to 3.0 mum, and therefore, special high-efficiency masks (e.g., The Protector II, Anago, Fort Worth, Tex) are required to catch laser plume particulates. However, the high-efficiency masks are less effective when wet and may need to be changed periodically.

Tissue/Vessel Perforation

Misdirected laser energy may perforate a viscus [31] [32] [33] [34] or a large blood vessel (vessels >5 mm are not coagulable by laser). Laser-induced pneumothorax has been reported following a laryngeal procedure. [35] With an Nd:YAG system, the depth of damage is impossible to assess accurately or immediately, and perforation and bleeding may not occur until edema and necrosis have become maximal several days postoperatively.

Embolism

The Nd:YAG laser system has been associated with venous gas embolism. Embolization has been a particular problem during hysteroscopic surgery with Nd:YAG contact probes when the gas coolant for the sapphire probe tip has accidentally inflated the uterine cavity. In 1989, this technique was reported to have resulted in five widely publicized cases involving four deaths. [6] In another report, uterine insertion of a sheathed quartz fiber (with coaxial coolant gas running) produced an immediate massive and fatal gas embolism. [36] The laser and its contact probe per se were not directly responsible for the injury. Therefore, a liquid (saline) coolant is strongly preferred during hysteroscopy. If a coolant gas must be used, CO_2 will produce less damage following embolization than either nitrogen or air. If uterine distention is achieved with saline rather than with gas, a fluid overload similar to that seen during transurethral prostate surgery is possible. [37]

Venous gas embolization also has been reported during Nd:YAG resection of tumor in the trachea [38] [39] and during various types of laparoscopic and endoscopic procedures. [40] [41] A laser coolant malfunction during laparoscopic ablation of endometriosis lesions at the University of California, San Francisco resulted in complete subcutaneous air emphysema, from which the patient recovered following a benign course. During laparoscopic surgery with CO_2 insufflation, mechanical hyperventilation should be instituted and adjusted to compensate for intra-abdominal CO_2 absorption and cephalad displacement of the diaphragm. Continuous airway CO_2 monitoring is highly recommended for detection of either embolization or hypercapnia.

Energy Transfer to an Inappropriate Location

All currently available medical laser wavelengths are transmitted transparently through air and are well reflected by smooth metal surfaces. Pressing the laser control trigger at the wrong time can deliver damaging laser light across the wound to sites at which surgical ablation was not desired or across the operating room into colleagues' eyes. Potentially tragic situations include laser ignition of surgical drapes [42] [43] and, of special concern for anesthesiologists, accidental irradiation of an endotracheal tube during airway surgery.

EYE PROTECTION

The ANSI standards as well as common sense dictate that the eyes of the operating room staff and the patient be protected during the conduct of laser surgery. Errant infrared energy from a CO_2 laser can quickly cause a serious corneal injury, [44] whereas argon, (KTP) Nd:YAG, or ruby lasers may burn the retina. [45] The lids of patients' (nonoperated) eyes should be taped closed, then covered with an opaque, saline-soaked knit or metal shield. [46] [47] [48] Operating room personnel must wear safety goggles or lenses specific for the laser wavelength in use. Safety goggles should provide wraparound protection from reflected light. For CO_2 lasers, any clear glass or plastic lenses will suffice because they are opaque to far infrared. Regular eyeglasses may be sufficient, but contact lenses are not. Other lasers require color filters whose wavelength specificity and optical density are regulated. Nd:YAG lasers require either special green-tinted goggles, which make assessment of patient skin color difficult, or clear lenses (Nd:YAG Protection Glass, Surgical Laser Technologies, Malvern, Pa), which have a special coating opaque to near infrared. Argon or krypton lasers require an amber-orange lens filter, and KTP:Nd:YAG lasers require a red filter. Because lasers other than the far-infrared CO_2 produce beams that pass through glass, all windows into the operating room should be covered during laser procedures and specific, specially designed warning signs should be posted as described in ANSI Z136.3.

ENDOTRACHEAL TUBE FIRES

A feared complication of laser use during airway surgery is endotracheal tube fire. The estimated incidence of this complication during such operations is 0.5 to 1.5 percent. [49] [50] Although a survey of otolaryngologists did not provide an incidence for fires, it did demonstrate that laser-induced ignition of endotracheal tube, cuff, or cottonoids

Figure 64-7 (Figure Not Available) Blowtorch ignition of an endotracheal tube. *(From Emergency Care Research Institute [107])*

was responsible for most (41%) perioperative complications, followed by postoperative laryngeal web (19%) and laser-related or laser-induced facial burn (11%). [51] The largest published (retrospective) series of CO_2 laser airway procedures documented 6 airway fires in 4,416 cases (0.14% incidence), [52] confirming it as the most frequent laser-related complication in patients undergoing this type of procedure. Given the proximity of the endotracheal tube to surgical sites around the larynx, the potential for fire or other airway complications is clear. Many of these fires, when appropriately handled, result in minimal or no harm to the patient, [49] [53] [54] , 54 but catastrophic consequences are possible. [55] [56]

With the energy delivery rates described earlier, any hydrocarbon material, including tissue, plastic, or rubber, can ignite and burn, particularly in an oxygen-enriched atmosphere. Fires can result from direct laser illumination, reflected laser light, or incandescent particles of tissue blown from the surgical site. [57] Initially, most fires are located solely on the external surface of the endotracheal tube, where they can cause local thermal destruction. If a fire is unrecognized and burns through to the interior of the tube, the oxygen-enriched gas combined with the to-and-fro gas flow due to ventilation will produce a blowtorch-like flame, blowing heat and toxic products of combustion down to the pulmonary parenchyma (Fig. 64-7) (Figure Not Available) . Puncture and unrecognized deflation of the tube cuff may also permit oxygen-enriched gas to flood the operative site and increase the chance of a devastating fire following a subsequent laser burst.

Two strategies have been developed to reduce the incidence of airway fire: (1) reduce the flammability of the endotracheal tube, and (2) remove flammable materials from the airway by using a metallic venturi jet ventilation cannula or intermittent extubation with or without apnea. Each of these is discussed later.

Relative Flammability: Effect of Tube Composition

Given that all common endotracheal tubes are potentially flammable, the relative risks of the various types of construction material have been well studied. For many years, reusable red rubber tubes were commonplace, but these were supplanted by clear polyvinylchloride (PVC) plastic tubes. Modern PVC strongly absorbs far-infrared light and is thus very sensitive to CO_2 laser energy. PVC tubes appear to be much more easily ignited by CO_2 lasers than red rubber tubes [52] [58] [59] and to produce more toxic combustion products. *In vitro,* PVC is transparent and thus is immune to Nd:YAG and visible laser light; however, a thin coating of mucus or blood *in vivo* will absorb energy and restore the hazard. [60] Commercially available tubes fabricated of PVC without opaque lettering or barium stripe make claims of laser resistance based on the *in vitro* tests--however, caveat emptor ("let the buyer beware").

Two studies of the effects of Nd:YAG laser energy on common types of tubes, including those designed to be resistant to laser irradiation, revealed that endotracheal tubes of all materials are, in fact, quite vulnerable. [61] [62] Ossoff et al [58] compared the extent of acute damage to the trachea from blowtorch-type ignitions in dogs ventilated with 1 percent halothane and 70 percent nitrous oxide (balance oxygen) through PVC, rubber, or silicone endotracheal tubes. PVC ignited and developed intense flame the soonest, resulting in widespread deposit of carbonaceous debris and significant ulceration and inflammation of the trachea on postmortem analysis. Red rubber tubes were more resistant to ignition and produced less debris and inflammation. Silicone tubes were the most resistant to ignition, but they produced copious white silica ash, suggesting the potential for late development of silicosis. Ossoff [63] subsequently measured the time to intraluminal ignition during exposure to CO_2 laser energy to determine resistance to ignition and reversed the ranking of silicone and red rubber, PVC remaining the most vulnerable. He also found that addition of 2 percent halothane vapor retarded ignition. Once ignition occurs, the index of flammability is the minimum inspired oxygen fraction (F_{IO_2}) necessary to maintain combustion. Wolf and Simpson [64] reported that PVC is actually less flammable than silicone or red rubber, having a flammability index of 0.26 versus 0.19 for silicone and 0.19 for red rubber. When nitrous oxide was used as the oxidant, PVC retained the highest index (0.46), followed by silicone (0.41) and red rubber (0.37).

Despite the conflicting data, many authors recommend the use of red rubber endotracheal tubes during laser surgery of the aerodigestive tract and base this suggestion on criteria of resistance to ignition and least toxic combustion products. However, at the University of California, San Francisco, one surgeon has performed more than 4,000 microdirect laryngoscopies using a CO_2 laser, incurring only 2 fires (0.005%) and no significant fire-related morbidity (H.H. Dedo, personal communication, 1992), with aluminum-taped PVC endotracheal tubes and moistened pledgets (see later). Regardless of the tube substrate, there are additional safety considerations and maneuvers to consider, as outlined later.

Effect of Respiratory Gas Mixture

The mixture of airway gases becomes an important issue when any type of potentially flammable endotracheal tube is

used. Combustion is more vigorous when excess oxidizer is present, and most clinicians recognize the need to reduce the F_{IO_2} to less than 0.40 or to the minimum concentration consistent with patient oxygenation. That nitrous oxide also is a powerful oxidizer is less well recognized, but adding nitrous oxide as a diluent for oxygen is just as dangerous as having a high F_{IO_2} . [64] Use of an air-oxygen mixture appears to be acceptable. Some investigators prefer helium as a diluent to nitrogen because helium has a higher thermal conductivity and may delay the ignition of an endotracheal tube for a few seconds. [63] [65] However, the index of flammability is reduced by only 1 to 2 percent when oxygen-helium is substituted for oxygen-nitrogen. [66] Helium also has a lower density and allows the use of a smaller endotracheal tube without turbulence and high flow resistance. [67] [68] [69]

The volatile anesthetics currently used in clinical practice are nonflammable and nonexplosive in clinically relevant concentrations. [70] [71] During an airway fire, however, they may undergo pyrolysis to potentially toxic compounds. [72] Thus, the ANSI Z136.3 standard recommends not using volatile anesthetics during airway laser surgery. This is an extremely conservative stance given the low concentration of anesthetic gas as compared with the products of combustion from an endotracheal tube and the lack of evidence of toxicity due to the pyrolytic products. When venturi ventilation is used, administration of volatile agents usually is not

practical.

Protection of the Endotracheal Tube

Once the possibility of endotracheal tube ignition was raised, extrinsic protection of the tubes was suggested. [73] Patil and colleagues [74] suggested wrapping tubes with moistened muslin. However, if allowed to dry, muslin becomes flammable. Kumar and Frost [75] suggested coating the vulnerable portion of the exterior of the tube with dental acrylic. This approach, however, renders the tube rigid with a rough surface, which may traumatize the mucosal surfaces. The most popular approach to the problem has been wrapping the tube with metallized foil tape. [50] [59] [61] [63] [73] [76] [77]

Three types of tape have been used: aluminum foil with adhesive backing, copper foil with adhesive backing, and plastic tape thinly coated with metal on one side and adhesive on the other. These tape products are widely available from electronics, arts and crafts, and building supply shops. Lead foil (commonly used on windows for burglar alarms) is similar in appearance but is toxic and should never be used in the airway.

The aluminum and copper tapes have been evaluated for protection of different types of endotracheal tubes with various lasers. Although taping does not provide protection of the inflatable cuff portion of an endotracheal tube, these metal tapes do offer a measure of protection against inadvertent, brief, or unfocused far-infrared CO_2 laser hits to the taped portion of the tube shaft. Metallic tapes, however, are a less certain shield against the near-infrared beam from Nd:YAG. The solid copper (1-mil foil from Venture Tape Corp., Rockland, Mass) or aluminum (No. 425 or 433 from 3M Corp., Industrial Tape Division, St. Paul, Minn) tapes were able to withstand at least 60 seconds of direct Nd:YAG laser exposure without penetration or ignition. [77] An Emergency Care Research Institute (ECRI) study [78] found that the 3M aluminum tape provided protection against CO_2 and KTP:Nd:YAG, but it did allow ignition of a PVC tube at the highest power setting of an Nd:YAG laser. Copper tape (No. 1181, 3M Corp., Electrical Products Division, St. Paul, Minn) provided ignition protection from all three lasers. Sosis and Dillon [77] found that metallized plastic tape (Radio Shack No. 44-1155) was actually more easily ignited by Nd:YAG than an unwrapped red rubber tube, with a time to ignition of 6 seconds versus 13 seconds for the unwrapped control. ECRI [78] also found that although the metallized plastic tape was most pliant and least likely to abrade the larynx, it provided protection only against CO_2 lasers, not against Nd:YAG or KTP:Nd:YAG.

Applying a protective metal foil wrap to an endotracheal tube requires some care. A clean tube should be wiped with alcohol to remove residue that could interfere with adhesion, then optionally wiped lightly with Mastisol or tincture of benzoin. The end of the tape should be cut at an angle of about 60 degrees and the cut edge aligned with the proximal end of the cuff junction (Fig. 64-8) . Tape should be wrapped in a spiral, with about 30 percent overlap, to the exit point of the cuff pilot tube. Wrinkles should be eliminated to avoid abrading the tracheal mucosa. The result should eliminate bare tubing or areas of exposed tape adhesive (which is quite flammable). Rewiping the wrapped tube with alcohol will provide a degree of cleanliness prior to tracheal intubation.

Figure 64-8 Cuff wrapping technique. If a wrapped endotracheal tube is the chosen method for laser protection, the technique for wrapping is critical in ensuring protection from both ignition and foil-induced mucosal abrasions. It is often helpful first to paint the tube sparingly with a medical adhesive such as benzoin or Mastisol. The end of the tape should be cut with a scalpel to approximately 60 degrees. Wrapping is begun by aligning the cut end of the tape with the junction of the tube and the proximal end of the cuff and is done in a spiral with a 30 to 50 percent overlap between layers. Wrapping should include the inflation tube for the cuff and should be continued until just short of the pilot balloon, with care taken not to wrinkle the tape at any point.

Although this use is well supported in the medical literature, none of these metal foils currently has FDA approval because their manufacturers have not sought it. Thus, physicians who devise a wrapped endotracheal tube using such tapes incur some product liability risk as a noncertified "manufacturer" should injury occur, especially because there now are FDA-approved commercial products.

The Merocel Laser Guard (Merocel Corp., Mystic, Conn) is a commercial, FDA-approved endotracheal wrap consisting of an adhesive metal foil laminated to a synthetic sponge surface. Properly placed on an endotracheal tube and kept moist, the Merocel product provides protection against CO_2, argon, and KTP:Nd:YAG but not YAG lasers. [79] However, it adds almost 2 mm to the diameter of the endotracheal tube. Like the nonapproved tapes, Laser Guard can be applied only to the shaft of the tube and provides no protection for the cuff.

The FDA also has approved the use of an integral laser-resistant coating in the manufacture of endotracheal tubes. The commercially available Xomed Laser Shield tube (Xomed-Treace, Jacksonville, Fla.) is fabricated from silicone with an outer layer of finely divided aluminum powder in silicone; the aluminized layer extends over the inflatable cuff. However, this tube is specified for use only with CO_2 lasers, a beam power density of less than 4,900 W/cm_2, and an F_{IO_2} of less than 25 percent. Although more resistant to far-infrared radiation than either PVC or red rubber tubing, [79] [80] the Laser Shield nonetheless burns vigorously once ignited *in vitro,* [63] producing friable silica dust. It also may ignite under typical surgical conditions (thus failing the ECRI flammability test). [78] In at least one case, an airway fire involving this tube occurred, [56] resulting in serious injury attributed to an intraluminal fire secondary to laser penetration of the cuff; the laser power settings were within specified limits, but the respiratory gas mixture included an excessive F_{IO_2} and nitrous oxide. A newer version, the Laser Shield II, is approved for use with either CO_2 or KTP lasers. The construction of this version includes a silicone-based tube, which is smoothly wrapped by a coated aluminum tape. The cuff is made of unshielded silicone elastomer, designed to be expanded with saline, and includes methylene blue dye to tint the saline. The tube wrap is specified to withstand *(in vitro)* 35,000 W/cm_2 of CO_2 laser energy or 11,000 W/cm_2 of KTP energy for up to 3 minutes. Blood or mucus on the tube can be expected to reduce its tolerance to laser irradiation by approximately 60 percent.

Protection of the Endotracheal Tube Cuff

The thin plastic envelope of a standard high-volume, low-pressure endotracheal cuff is extremely susceptible to misdirected laser energy. Although combustion is possible, simple puncture may be more common. Unrecognized cuff punctures lead to oxygen enrichment of the gas surrounding the surgical site and endotracheal tube and increase the likelihood of a catastrophic airway fire. Cuffs with significant laser resistance that maintain the mechanical properties necessary to minimize tracheal trauma are not available. Many authors recommend filling the standard Hi-Lo cuff with colored saline both to signal a puncture more clearly and potentially to quench a small cuff fire. The cuff should be placed as far distal in the trachea as possible, and the surgeon should completely cover the visible cuff with moistened cotton pledgets. The cotton strings attached to the pledgets should be replaced by uninsulated wire, and the pledgets should be remoistened as needed. The utility of moistened pledgets in preventing or delaying cuff ignition from CO_2 laser exposure has been confirmed. [81]

Metal Endotracheal Tubes

In 1978, Norton and De Vos [82] introduced a nonflammable endotracheal tube constructed as an interlocking stainless steel spiral coil, resembling electrical cable armor (Baxter Healthcare Corp., Niles, Ill). The manufacture of this endotracheal tube has been discontinued. Its walls were not airtight, and although this property allowed a cooling gas flow to the exterior surface, it could make ventilation difficult in patients with relatively noncompliant lungs, particularly because the tube had no inflatable cuff. Jet ventilation with a modified Sanders venturi coupler was suggested as a means to overcome this problem, [83] as was the use of a separate, slide-on cuff, but these are all flammable and thus pose an ignition risk.

Two other metal endotracheal tubes are commercially available and are approved for use with specific lasers. The Laser Flex tube (Mallinckrodt Inc., St. Louis, Mo) is an airtight stainless steel spiral with two distal, saline-inflatable PVC cuffs (redundant in case of puncture of the proximal cuff). This tube is resistant to CO_2 and KTP laser energy, [84] but not to the Nd-YAG laser. [78] The Bivona Fome-Cuf (Bivona Inc., Gary, Ind) is an aluminum spiral tube with an outer covering of silicone and a unique, self-inflating foam sponge-filled cuff, which prevents deflation following puncture. This feature allows continued positive-pressure ventilation and segregation of airway gases from the operative site, but it may lead to injury if a puncture of the cuff or of the filling tube prevents deflation prior to removal. The Fome-Cuf is approved for use only with pulsed CO_2 lasers.

The use of laser-resistant endotracheal tubes requires particular care to prevent mucosal abrasions, because these tubes tend to be bulkier and more rigid than conventional tubes. Surgeons must ensure that laser energy is not reflected from smooth metal surfaces and directed at sensitive structures. Finally, use of a metal

endotracheal tube does not imply absolute protection from ignition; 50 W of an Nd:YAG beam focused to 0.68 mm has been reported to ignite a Laser Flex tube in 6 seconds. [85]

Jet Ventilation

Some authors contend that optimal surgical conditions and patient safety can be obtained with "jet" ventilation. This technique takes advantage of Bernoulli's venturi principle to augment the ventilation produced by a narrow, high-speed gas stream. In practice, jet ventilation uses an intermittent high-pressure oxygen supply, directed at the glottis through a small metal tube, such as a ventilating bronchoscope, or even a 12-gauge blunt needle. [86] [87] [88] [89] [90] [91] A retrospective review of 942 cases of microdirect laryngoscopy using endolaryngeal jet

---

Figure 64-9 Complications of laser airway surgery. Pneumothorax was relatively common with jet ventilation, but potentially lethal airway fires occurred with endotracheal intubation. *(Based on data by Cozine et al [97])*

ventilation found only four complications. [92] Jet ventilation with air also has been used via a bronchoscope when resecting distal tracheal and bronchial tumors. [93] [94] [95] [96] It has been suggested that patients undergoing laser resections of airway tumors during jet ventilation may absorb carbon monoxide from entrained laser smoke in the pharynx. The carbon monoxide, in turn, can result in an overestimate of arterial oxygen saturation by pulse oximetry. Goldhill and colleagues [95] found neither a significant increase in carboxyhemoglobin during Nd:YAG bronchoscopy nor a difference in pulse oximetry reading versus *in vitro* co-oximeter measurement of arterial oxygen saturation. Although jet ventilation generally provides adequate ventilation without introducing flammable material or a large obstacle to the surgical field, potential disadvantages include the following: the risk of barotrauma, pneumothorax, or crepitus; the restriction to intravenous agents; gastric distention; and the relative requirement for compliant lungs. In the presence of papillomas, a common indication for laryngeal laser surgery, jet ventilation could cause distal bronchial seeding with active virus. However, Shikowitz and colleagues [92] found no evidence of this phenomenon in 96 patients who had multiple laser procedures and were followed over time. Cozine et al, [97] in a survey of 58 institutions (15,701 cases) performing CO_2 laser airway surgery, found a higher rate of ventilatory complications with jet ventilation than with a standard endotracheal tube (Fig. 64-9) , but the only fatality was due to an endotracheal tube fire. [97] The authors concluded that no single mode of ventilation proved superior during laser surgery.

To reduce obstruction of the surgical field by ventilatory instrumentation even further, several authors have advocated complete removal of such instrumentation combined with the technique of spontaneous ventilation or intermittent apnea, with general anesthesia provided by nasal insufflation or bronchoscopic delivery of a potent inhaled anesthetic [47] [72] [98] [99] or use of an intravenous anesthetic. [100] Cohen et al [101] and Hawkins and Joseph [102] have advocated modest hyperventilation followed by intermittent tracheal extubation by the surgeon for periods of 90 to 120 seconds, during which the laser is used. Pulse oximetry adds a measure of safety by confirming adequate oxygenation from a denitrogenated pulmonary residual capacity during apnea.

Other Considerations

Although not specifically related to laser procedures in the airway, vagal hyperactivity often occurs during instrumentation of the trachea. Immediate recognition and treatment are important. In addition, the paraneoplastic syndrome occasionally observed in small cell and other types of endobronchial tumors may lead to prolonged weakness after administration of neuromuscular relaxants. [103]

AIRWAY FIRE PROTOCOL

Should an airway fire or explosion occur, the surgeon and anesthesiologist must act quickly, decisively, and in coordinated fashion. This may not be easy following an explosion, because the event may be so traumatic as to incapacitate the operating room staff temporarily. Clear communication and emergency practice (at least a mental drill of the emergency procedure) are key to managing such a crisis. Schramm and colleagues [104] have provided a useful review of the ensuing pathologic features and have suggested emergency management.

A surgeon who detects an endotracheal or other source of airway fire should as quickly as possible remove the source and simultaneously inform the anesthesiologist, who should immediately, despite reflexive training to the contrary, stop ventilation. Temporarily disconnecting the breathing circuit from the anesthesia machine may be useful. These maneuvers remove the flame and the retained heat in the tube and stop the flow of oxygen-enriched gas. The flaming material should be extinguished in a bucket of water, which should always be available during laser surgery. Ventilation with 100 percent oxygen should then be provided by mask, and anesthesia should be continued.

Direct laryngoscopy and rigid (venturi-ventilating) bronchoscopy should then be performed to survey damage and to remove debris. If the fire was of the "interior blowtorch" type, gentle bronchial lavage may be indicated, followed by fiberoptic assessment of the more distal airways. If any airway damage is apparent, the patient should be reintubated. Fortunately, small fires involving only the exterior of the tube may not cause appreciable damage. If the damage is severe, a low tracheotomy may be indicated.

The pattern of damage in interior fires tends to be worst in the upper airway and diminishes as one approaches and passes the carina. The patient's oropharynx and face should be assessed, and a chest radiograph should be obtained. Pulmonary damage due to heat and/or smoke inhalation may necessitate prolonged intubation and mechanical ventilation. A brief course of high-dose steroids may be helpful. [105] [106]

Lasers provide a useful tool in the surgical armamentarium, one for which anesthesiologists must, with increasing frequency, prepare their patients and themselves. Although some of the potential threats posed by clinical lasers are unique, most are simply extensions of the risks posed by the previous generation of surgical tools. As with most potentially dangerous procedures, the risks of laser use can be minimized by common sense and preconsidered contingency plans.

Chapter 65 - Outpatient Anesthesia *

Janet M. van Vlymen
Paul F. White

INTRODUCTION

In the early 1900s, a legendary American anesthesiologist, Ralph Waters, opened his Downtown Anesthesia Clinic in Sioux City, Iowa. [1] This facility, which provided care for dental and minor surgery cases, is generally regarded as the prototype for the modern freestanding ambulatory unit. However, there was little further interest in ambulatory surgical care until the 1960s, when the first hospital-based ambulatory surgery units were developed. Over the past 3 decades, outpatient surgery has grown at an exponential rate, progressing from the practice of performing simple procedures on healthy patients in a physician's office to encompass a broad spectrum of patient care in freestanding ambulatory surgery centers and offices. The formal development of ambulatory anesthesia as a subspecialty occurred with the establishment of the Society for Ambulatory Anesthesia (SAMBA) in 1984 and with the evolution of postgraduate subspecialty training programs.

By 1985, 7.3 million elective operations in the United States (34% of all elective surgical procedures) were performed on an ambulatory basis. Today, more than 60 percent of all elective surgery is performed in the outpatient surgical setting, and by the end of the century, it is expected that this number will increase to more than 70 percent. [2] This rapid growth in ambulatory surgery would have not been possible without the changing role of the anesthesiologist and the development of more highly titratable anesthetic drugs and less invasive surgical techniques. [3] The availability of rapid, shorter-acting anesthetic, analgesic, and muscle-relaxant drugs has facilitated the recovery process, allowing more extensive procedures to be performed on a wide variety of outpatients. [4] Future studies of new drugs need to focus not only on subjective improvement during the immediate perioperative period, but also on the overall cost-effectiveness and quality of care being provided. These studies should emphasize meaningful outcomes such as time to resume normal activities or return to work. [5]

The range of acceptable ambulatory surgical patients and procedures continues to expand. Because patients presenting for outpatient surgery may have increasingly complex medical conditions, the anesthesiologist must play an active role in their preoperative assessment and preparation in order to avoid costly delays and cancellations. [6] In modern outpatient facilities, surgical procedures may be safely performed without sacrificing quality while minimizing hospital resources. [7] In this era of cost containment, the savings inherent in providing ambulatory services ensure that the number of outpatient procedures will continue to grow into the 21st century.

BENEFITS OF AMBULATORY SURGERY

Ambulatory surgery can offer a number of advantages for patients, health-care providers, third-party payers, and even hospitals (Table 65-1) . Many patients, especially children and the elderly, prefer to have their surgical procedures performed as outpatients because it decreases separation from

* *See Appendix 1, Practice Guidelines for Sedation and Analgesia by Non-Anesthesiologists*

TABLE 65-1 -- Benefits of Ambulatory Surgery

Patient preference, especially children and elderly
Lack of dependence on availability of hospital beds
Greater flexibility in scheduling operations
Low morbidity and mortality
Lower incidence of infection
Lower incidence of respiratory complications
Higher volume of patients (greater efficiency)
Shorter surgical waiting lists
Lower overall procedural costs
Less preoperative testing and postoperative medication

their familiar home environment. One survey of patient satisfaction reported that 97 percent of respondents would choose day surgery again. [8] Unlike inpatient surgery, ambulatory surgery does not depend on the availability of a hospital bed, and thus there is a greater degree of flexibility for patients to schedule the timing of their operation. Outpatient surgery may be performed very safely with a low incidence of both minor and major morbidity. [9] Studies have shown that unanticipated admission to the hospital occurs in only 1 percent of patients, and return visits to the hospital occur in only 3 percent of patients following ambulatory surgical procedures. [10] [11] [12] The lower infection rate associated with outpatient surgery is particularly beneficial to pediatric and immunocompromised patients. [13] Finally, there is evidence that the incidence of respiratory complications (i.e., pulmonary embolus and pneumonia) may also be decreased. [14]

There are economic benefits associated with ambulatory surgery. The efficiency of ambulatory centers appears to be significantly increased, with shorter operating room times and faster turnaround times. [7] The ability to care for high volumes of patients may considerably reduce surgical waiting lists. Compared with similar procedures in hospitalized patients, there is less preoperative laboratory testing and a reduced demand for postoperative medications after ambulatory surgical procedures. These factors all contribute to the 25 to 75 percent reduction in overall costs for most operations performed in the outpatient setting. [15] However, procedures requiring specialized postoperative care (e.g., extensive physical therapy or pain management) may actually be more costly when performed on an outpatient basis. [16] Patients requiring blood transfusions or intravenous antibiotics may best be handled as same-day (23-hour) admissions, although modern home nursing and physical therapy may soon enable most of these services to be performed in the patient's home. Assuming that the number of available hospital beds declines in the future, the continued growth of ambulatory surgery should increase the return on increasingly limited health-care dollars.

FACILITY DESIGN AND SAFETY

Ambulatory surgical facilities need to be well designed in order to ensure optimal delivery of surgical services at reduced cost. In the late 1960s, it was proposed that a facility for performance of general anesthesia and minor surgical procedures did not need to be affiliated with a hospital. The first freestanding outpatient surgical facility was built and managed by a group of anesthesiologists in Phoenix, Arizona to provide surgical care to patients whose operations were too demanding for a surgeon's office yet did not require overnight hospitalization. [17] Since that time, outpatient surgical facilities have continued to grow and evolve. [18] Today, these facilities are found in a wide variety of different environments that reflect their association with other health-care facilities. There are four basic designs of a prototypical ambulatory surgical unit [19] :

1. *Hospital-integrated:* Ambulatory surgical patients are managed through the same surgery facility as inpatients. The outpatients may have separate preoperative preparation and second-stage recovery areas.
2. *Hospital-based:* There is a separate ambulatory surgical facility located within a hospital that handles only outpatients.
3. *Freestanding:* These facilities may be associated with hospitals but are housed in separate buildings that share no space or patient care functions. The preoperative evaluation, surgical care, and recovery occur within this unit.
4. *Office-based:* The operating suites are managed in conjunction with physicians' offices for the convenience of the surgeons.

There are many specific requirements to consider when planning an ambulatory surgical facility. The patient volume, types of patients and procedures, organizational structure, and radiologic and laboratory testing must all be considered during the initial planning of a new facility. To be optimally efficient, it is necessary to assemble all the outpatient services in one dedicated area. Designs that place the waiting room, preanesthesia room, operating suites, and recovery areas in proximity have many advantages. [20] Surgeons are able to visit the patient and family before and after the operation without losing time in transit. Patient transportation time is reduced to a minimum, and extra personnel are unnecessary because the circulating nurse or anesthesiologist can transport the patient to the operating room (Fig. 65-1) (Figure Not Available) .

Quality assurance and total quality improvement are necessary to maintain high standards for outpatient care and to ensure safety. Quality standards are set and enforced either by government regulation, through a licensing process, or by accreditation by private organizations such as the Accreditation Association for Ambulatory Health Care, Inc (AAAHC). [21] The AAAHC is an independent accreditation organization whose principal activities are the development of standards, the conduct of surveys, and the conferring of accreditation on ambulatory health-care providers. In the United States and Canada, hospital-based ambulatory surgical facilities receive accreditation through the Joint Commission on Accreditation of Health Care Organizations (JCAHO), which is the primary accreditation agency for hospitals.

The American Society of Anesthesiologists (ASA) also provides guidelines for ambulatory surgical facilities (Appendix 1). The availability of personnel and equipment for unexpected emergencies or a delayed return to the operating room is essential. In-service training of all staff regarding skills that are infrequently required should be given regularly, including advanced cardiac life support, drills for airway complications, emergency tracheotomy, and treatment of malignant hyperthermia (MH). [19] Depending on the size and range of surgical services, a formal cardiac arrest team

Figure 65-1 (Figure Not Available) Essential components related to patient flow in an ambulatory surgery facility. *(Modified from Snyder and Pasternak [15])*

may be needed, and all facilities require a portable crash cart and suction device. General support services for routine laboratory tests, a portable electrocardiography (ECG) machine, and access to a blood supply should be available. A permanent on-site MH kit is required for any location where general anesthesia is performed.

As ambulatory surgery continues to expand, dedicated outpatient facilities will be developed in a variety of settings (e.g., medical centers, surgical clinics, and physicians' offices). Anesthesiologists need to be involved in the initial planning and organization of these facilities to ensure safe, efficient, and economic patient care.

PATIENT SELECTION

Selection of Procedures

Surgical procedures suitable for ambulatory surgery should be accompanied by minimal postoperative physiologic impairment and uncomplicated recovery. [22] [23] With advances in surgical technologies and the rapid growth of minimally invasive surgery, a wide variety of operations may now be performed on an outpatient basis (Table 65-2) . Consequently, published reports have begun to appear regarding the advantages of minimally invasive outpatient thyroidectomy, vaginal hysterectomy, ectopic tubal pregnancy removal, ovarian cystectomy, and laparoscopic cholecystectomy. A report in the *New England Journal of Medicine* suggested that laparoscopic-assisted herniorrhaphy offered significant advantages over conventional open repair with respect to late recovery. [3]

Patients undergoing procedures that are likely to have postoperative surgical complications should be admitted to hospital. Although autologous blood transfusions are used for more extensive outpatient plastic surgery (e.g., reduction mammoplasty, liposuction), procedures associated with excessive fluid shifts are more appropriately handled in an overnight recovery facility. Similarly, operative procedures requiring prolonged immobilization or parenteral analgesic therapy are not ideally suited to ambulatory care. The availability of newer analgesic therapies (e.g., nonopioid, nonpharmacologic) and ambulatory patient-controlled analgesia (e.g., subcutaneous, transcutaneous) may alter the latter recommendation in the near future. [24] [25] [26]

Duration of Surgery

The duration of ambulatory surgery was originally limited to procedures lasting less than 90 minutes. A retrospective review by Meridy [27] showed no correlation between the duration of anesthesia and recovery time, and he concluded that an arbitrary upper limit on the duration of anesthesia was not warranted. More recently, other investigators have demonstrated that surgical time longer than 60 minutes is an independent predictor of unanticipated admission to the hospital [10] [28] and is associated with a higher perioperative complication rate. [14] Nevertheless, longer surgical procedures are regularly performed on outpatients, and with careful preoperative selection and postoperative management (e.g., home health care), hospital admission may be avoidable.

Patient Characteristics

In successful ambulatory surgical facilities, patients are properly selected and prepared for surgery. Most patients

TABLE 65-2 -- Operative Procedures Suitable for Ambulatory Surgery

SPECIALTY	TYPES OF PROCEDURES
Dental	Extraction, restoration, facial fractures
Dermatology	Excision of skin lesions
General	Biopsy, endoscopy, excision of masses, hemorrhoidectomy, herniorrhaphy, laparoscopic procedures, varicose vein surgery
Gynecology	Cone biopsy, dilatation and curettage, hysteroscopy, laparoscopy, polypectomy, tubal ligation, vaginal hysterectomy
Ophthalmology	Cataract extraction, chalazion excision, nasolacrimal duct probing, strabismus repair, tonometry
Orthopedic	Anterior cruciate repair, arthroscopy, bunionectomy, carpal tunnel release, closed reduction, hardware removal, manipulation under anesthesia
Otolaryngology	Adenoidectomy, laryngoscopy, mastoidectomy, myringotomy, polypectomy, rhinoplasty, tonsillectomy, tympanoplasty
Pain Clinic	Chemical sympathectomy, epidural injection, nerve blocks
Plastic	Basal cell cancer excision, cleft lip repair, liposuction, mammoplasty, otoplasty, scar revision, septorhinoplasty, skin graft
Urology	Bladder surgery, circumcision, cystoscopy, lithotripsy, orchiectomy, prostate biopsy, vasovasotomy

TABLE 65-3 -- Relationship Between American Society of Anesthesiologists Physical Status Classification and Morbidity and Mortality

(Not Available)

From Warner et al, [9] copyright 1993 American Medical Association

seen in ambulatory surgical facilities are classified as ASA physical status I or II. However, because of improved anesthesia care, increasing numbers of medically stable patients of ASA status III are able to undergo operations away from conventional medical centers. [2] In a large, prospective outcome study by Warner et al, [9] 24 percent of ambulatory surgical patients were ASA physical status III, and these patients had a similarly low incidence of morbidity when compared with ASA I and II patients (Table 65-3) (Table Not Available) . Other studies showed that patients with preexisting medical conditions do not have an increased incidence of perioperative complications. [29] This was attributed to prudent patient selection involving thorough preoperative evaluation and close communication among surgeon, anesthesiologist, and primary care physician. However, a multicenter study found an increased risk of perioperative complications in patients who had preexisting cardiovascular disease. [14] The risk of complications was reduced when symptoms were under good control for at least 3 months before the operation. Therefore, ASA physical status should not be considered in isolation because the type of surgical procedure, anesthetic technique, and a multitude of social factors can also influence decisions regarding patient suitability. [30]

Malignant Hyperthermia Susceptibility

MH-susceptible patients can be successfully managed with nontriggering anesthetics in the outpatient setting (Ch. 27) . The decision to admit a patient postoperatively should be based on clinical criteria, because admission solely on the basis of MH susceptibility is no longer warranted. [31] If anesthesia and surgery have been uneventful, MH-susceptible patients should be observed for at least 4 hours postoperatively and may then be safely discharged. [32] Patients and their families should be advised about the signs and symptoms of MH in addition to the usual postoperative instructions.

Extremes of Age

Although acceptability of patients at the extremes of age (i.e., <6 months and >70 years) has been questioned by some ambulatory centers, age alone should not be considered a deterrent in the selection of patients for ambulatory surgery (Chs. 59 and 61) . Most studies have failed to demonstrate an age-related increase in recovery time or incidence of complications following outpatient anesthesia. [27] However, recovery of fine motor skills and cognitive function is slowed with increasing age. Therefore, elderly outpatients may require a greater degree of supervision after discharge than their younger counterparts. Social factors, including lack of transportation, a responsible escort, or caretaker at home may make it difficult for some elderly patients to undergo ambulatory procedures.

By contrast, ex-premature infants (gestational age <37 wk) recovering from minor surgical procedures after general anesthesia have an increased risk of developing postoperative apnea. [33] Controversy exists regarding the postconceptual age after which no further risk remains. [34] Most studies suggest that the risk is greatest in premature infants younger than 46 weeks' postconceptual age. [35] [36] However, some authors have reported that the risk of apnea may persist until as late as 60 postconceptual weeks. [37] Anemia, with a hematocrit level less than 30 percent, independently increases the risk of postoperative apnea in former preterm infants less than 60 weeks' postconceptual age. [38] Treatment with high-dose caffeine may prevent prolonged apnea and desaturation in these patients, but postoperative monitoring is still recommended. [39] A combined analysis determined the following: (1) apnea was strongly and inversely related to both gestational and postconceptual age; (2) an associated risk factor was continuing apnea at home; (3) infants who were small for gestational age seemed to be somewhat protected from apnea; (4) anemia was a significant independent risk factor, particularly for patients less than 43 weeks' postconceptual age; and (5) no relationship between apnea and a history of necrotizing enterocolitis, respiratory distress syndrome, bronchopulmonary dysplasia, or intraoperative use of opioid analgesics or muscle relaxants could be demonstrated. [40]

Contraindications to Outpatient Surgery

With ever improving anesthetic and surgical techniques, the types of surgical procedures and patient populations undergoing ambulatory surgery continue to grow. Patients with more complex medical conditions are having longer and more complicated surgical procedures on an ambulatory basis. However, patients with the following conditions appear to be at increased risk for postoperative complications and should be offered the option of overnight hospitalization [23] :

1. Serious, potentially life-threatening diseases that are not optimally managed (ASA III and IV): brittle diabetes, unstable angina, symptomatic asthma
2. Morbid obesity complicated by hemodynamic or respiratory problems
3. Drug therapy: monoamine oxidase inhibitors (e.g., pargyline, tranylcypromine); acute substance abuse (active cocaine abuse increases the risk of intraoperative cardiorespiratory complications)
4. Ex-premature infants less than 60 weeks' postconceptual age
5. Lack of a responsible adult at home to care for the patient on the evening after surgery

PREOPERATIVE VISIT

The preoperative assessment of outpatients has become increasingly important because patients are presenting for ambulatory surgery with more complex medical conditions (Ch. 23) . It is essential to develop a method of screening these patients preoperatively in order to avoid costly delays and last-minute cancellations. [6] This may be accomplished by means of a telephone screening interview [41] or through a visit to a preoperative evaluation clinic. [42] [43] The use of computerized questionnaires before preoperative evaluation by the anesthesiologist can be timesaving and efficient. Modern computerized questionnaires are more accurate in listing positive and negative historical information than a physician interview and can be used to predict the need for preoperative laboratory testing. [44] A laptop computer-type device (HealthQuiz, Nellcor, Hayward, Calif), has been developed that asks patients yes/no questions. The answers are then printed out with the suggested laboratory tests. Clinical trials suggest that this computerized device is readily usable and is accepted by a wide range of patients, thus allowing for more appropriate and cost-effective use of preoperative laboratory testing in the future.

Preoperative Assessment

The preoperative assessment attempts to identify patients who have concurrent medical problems requiring further diagnostic evaluation or treatment. Patients requiring specific anesthetic techniques (e.g., difficult airway, MH susceptibility) or those with a high risk for anesthetic and surgical complications are also identified. Of the three key components of a preoperative assessment (history, physical examination, and laboratory testing), the medical history is clearly the most valuable. [45] Studies of medical ambulatory consultations showed that 86 percent of diagnoses depend entirely on information obtained from patients' histories. A further 6 percent of diagnoses were discovered by physical examination, and only 8 percent were determined by laboratory investigations or radiographs. [46] Routine preoperative testing of all patients prior to elective surgery is unjustified and expensive. [47]

Studies have suggested that 60 percent of routinely ordered preoperative screening tests could be eliminated if testing were based solely on recognizable indications, and only 0.2 percent of the abnormalities reported would have

TABLE 65-4 -- Laboratory Test Recommendations for Asymptomatic Healthy Patients Scheduled to Undergo Non-Blood Loss Peripheral Procedures Under General Anesthesia

(Not Available)

From Roizen [294]

influenced perioperative care. [48] Inappropriate tests may even be harmful to patients because of unnecessary follow-up of false-positive test results or lack of appropriate follow-up from false-negative results. The commonly used guidelines for ordering screening laboratory tests were developed by Roizen (Table 65-4) (Table Not Available) , and further specific testing should be governed by information obtained from the patient's history and physical examination. [49]

For healthy, active outpatients undergoing superficial surgical procedures (e.g., biopsy, dilatation and curettage, herniorrhraphy, vein stripping), no laboratory tests appear to be indicated in males, and only a hemoglobin (or hematocrit) test may be necessary for females. Obviously, patients with chronic diseases (e.g., hypertension, diabetes) require additional laboratory studies (e.g., electrolytes, glucose). Patients with an unexplained hemoglobin concentration of less than 10 g/dL should undergo further evaluation prior to elective outpatient surgery because a low hemoglobin level may be associated with many diseases that could influence perioperative mortality and morbidity.

In addition to the anesthesiologist's evaluation, the preoperative visit should be used by the nursing staff to assess, prepare, and teach the patient and by the hospital business office to perform a financial interview and to familiarize the patient and family with the center. To avoid unexpected delays resulting from incomplete assessment, all paperwork, including the consent form, history and physical examination, and laboratory test results should be reviewed before arrival for surgery. A well-planned and smooth-functioning ambulatory surgery program can yield many benefits to patients and their families, as well as to surgeons. In summary, thorough patient preparation prior to the day of surgery can

prevent unnecessary delays, absences, last-minute cancellations, and inadequate patient management.

Preoperative Preparation

Optimal preoperative preparation of outpatients makes ambulatory surgery both safer and more acceptable for patients and hospital staff (Ch. 23) . The preparation process is aimed at reducing the risks inherent in ambulatory surgery, improving patient outcome, and making the surgical experience pleasant for the patient and family. Preparation should minimize patient anxiety through pharmacologic and nonpharmacologic means and should reduce potential postoperative problems by use of appropriate premedication.

Nonpharmacologic Preparation

The anticipation of undergoing anesthesia can cause psychologic stress, which is manifested as anxiety. Preoperative anxiety has been shown to rise at least 1 week before surgery and return to normal levels in the postoperative period only after the patient is assured of uneventful recovery. [50] The cause of patients' preoperative anxiety is multifactorial, but most commonly it is related to concerns about intraoperative awareness, not awaking after surgery, or postoperative pain and nausea. High levels of stress preoperatively, which are associated with slower recovery and greater analgesic and antiemetic requirements, can be effectively reduced with preoperative preparation (Fig. 65-2) (Figure Not Available) . [51] Overall, well-informed patients tend to recover faster and experience less pain.

Nonpharmacologic preparation has many desirable characteristics. These methods are economical, lack undesirable side effects, and are associated with high patient acceptance and motivation. More than 30 years ago, Egbert et al [52]

Figure 65-2 (Figure Not Available) Preoperative psychologic preparation reduces stress prior to and up to 1 week after surgery, as measured by the Spielberger state anxiety score. * $P < .05$. *(Modified from Wallace. [51] Reprinted with permission of the Helen Dwight Reid Educational Foundation. Published by Heldref Publications, 1319 Eighteenth St., Washington, D.C. 20036-1802. Copyright 1984.)*

demonstrated that the anesthetist's visit was more effective than a sedative premedicant in relieving preoperative anxiety. Postoperative pain has been similarly reduced by preoperative instruction. [52] The timing of the preoperative interview is also important, because anxiety is only significantly decreased when the interview

takes place outside the operating room immediately prior to surgery. [53] Many centers have shown encouraging results using instructional preoperative videotapes that offer a complete explanation of the events surrounding surgery. [54]

The use of play-oriented preoperative teaching, books, pamphlets, and video programs may be particularly beneficial for pediatric patients. [55] Separation anxiety and postoperative behavioral changes, prominent with children 1 to 4 years of age, may be diminished with such preparation programs. [56] In the modern ambulatory surgery center, both psychologic and pharmacologic means should be used to alleviate patients' anxiety and to decrease postoperative morbidity. Proper preoperative preparation should also include written and verbal instructions regarding arrival time and place, fasting instructions, and information concerning the postoperative course, limitations in driving abilities, and the need for a responsible adult to escort and accompany the patient during the postoperative period.

Pharmacologic Preparation

The use of premedication in the outpatient setting has been a subject of considerable interest and debate. The primary indications for preoperative medications in the outpatient setting are similar to those for patients undergoing inpatient procedures. These indications include anxiolysis, sedation, analgesia, amnesia, vagolysis, and prophylaxis against postoperative emesis and aspiration pneumonia. [57] Despite these well-recognized indications, premedication is not routinely used in most ambulatory surgery facilities in the United States. [2] An important concern in outpatient anesthesia is prompt recovery, and many anesthesiologists avoid using centrally active depressant premedicants because of concerns that these drugs will prolong the recovery period. Interestingly, most prospective studies have not found a prolonged recovery following the use of premedication in the outpatient setting. [58] [59] Proper choice of the premedication may actually facilitate the discharge of outpatients because the anesthetic and analgesic requirements, as well as the degree of postoperative emesis, are decreased.

Anxiolysis and Sedation

When administered for premedication, sedative-hypnotic drugs can allay anxiety and can reduce the overall anesthetic requirements, thereby improving recovery. Traditionally, the most widely used anxiolytic-sedative-hypnotic premedications have been barbiturate and benzodiazepine drugs. With increased dose, these drugs produce anxiolysis, sedation, and even unconsciousness. Barbiturates are not commonly used as premedicants in the outpatient setting because of their adverse effects on postoperative recovery, effects that make them less cost-effective than the newer sedative drugs. [60]

TABLE 65-5 -- Use of Anxiolytic-Sedative Drugs as Premedication of Adult Outpatients

(Not Available)

Modified from Shafer [66]

Benzodiazepines.

The use of benzodiazepines for premedication is a well-established practice. Not surprisingly, the amnesic and anxiolytic properties of these drugs are also useful in the outpatient setting (Table 65-5) (Table Not Available) . Although diazepam was the most commonly used benzodiazepine, midazolam has become the drug of choice because its relatively short elimination half-life and lack of significant side effects contribute to a rapid recovery after ambulatory surgery. [61] [62] One study showed that midazolam, administered immediately before anesthetic induction with propofol, did not decrease the dose of propofol necessary for hypnosis or the maintenance of surgical anesthesia in patients undergoing diagnostic dilatation and curettage. [63] To achieve the benefit of administering midazolam for premedication, it should be administered at least 5 minutes before induction. Although larger doses of midazolam are required because of first-pass metabolism, oral midazolam has been reported to be highly effective in both adults and children. [56] [64] When given in doses of 0.5 mg/kg, oral midazolam allowed children to be separated from their parents as early as 15 minutes after ingestion, without prolonging recovery even after brief surgical procedures. [64] [65] Temazepam has also been reported to be an effective oral premedicant for outpatient surgery. [64] Although oral triazolam can produce effective sedation and amnesia, it may be less effective than diazepam or midazolam in decreasing anxiety. Lorazepam, because of its long duration of action, is not routinely used in ambulatory surgery. If a patient expresses significant anxiety during the preoperative interview, diazepam may be prescribed to be taken at home in the evening and in the morning 60 to 90 minutes before surgery. However, a responsible adult must accompany the patient to the surgery center. If significant anxiety becomes apparent after admission to the day surgery center, intravenous midazolam (1-3 mg IV) is the drug most often administered.

alpha$_2$ -Adrenergic Agonists

alpha$_2$ -Adrenergic agonist drugs reduce dose requirements for anesthesia and analgesia, produce sedation, and decrease heart rate and blood pressure under anesthesia. Oral clonidine, the prototypic alpha $_2$ -agonist, has been utilized for ambulatory premedication; however, residual postoperative sedation may be a problem for elderly outpatients. Dexmedetomidine, however, is a more highly selective alpha $_2$ -agonist with a shorter duration of action compared with clonidine. [66] Because of its high potency and selective agonist action on alpha $_2$ -receptors, dexmedetomidine may gain more widespread acceptance in outpatient anesthesia. Although the profound hemodynamic effects of these drugs may limit their use as premedicants, they may prove to be valuable adjuncts during surgery because of their anesthetic and analgesic-sparing effects. The adverse clinical effects of clonidine and dexmedetomidine can be readily reversed with the antagonist atipamezole.

Analgesics

Opioid Analgesics.

The routine use of narcotic analgesics for premedication has been criticized unless the patient is experiencing acute or chronic pain (Ch. 10) . Use of opioid premedicant combinations can increase the incidence of postoperative nausea and vomiting (PONV) and may result in a delayed discharge after ambulatory surgery. Opioid analgesics may be beneficial if given intravenously prior to induction because they provide acute control of preoperative anxiety, decrease anesthetic drug requirements at induction, and provide postoperative pain relief. [67] When sufentanil was given intravenously 15 to 30 minutes before induction of general anesthesia, anxiety was decreased without prolonging recovery times or increasing postanesthetic morbidity. [68] However, if reduction of anxiety is the primary goal, it is better achieved with sedative-hypnotic drugs. Oral transmucosal fentanyl can provide for effective preoperative sedation and analgesia, but it is also associated with a high incidence of pruritus and emetic sequelae. [69] The use of agonist-antagonists such as butorphanol and nalbuphine as premedicants increases sedation and is associated with an increased incidence of postoperative anxiety, confusion, and dreaming. [70]

Nonopioid Analgesics.

The use of nonsteroidal anti-inflammatory drugs (NSAIDs) during the perioperative period has been extensively studied. These drugs are clearly less efficacious than opioid compounds at controlling acute postoperative pain. [71] However, NSAIDs have proven to be valuable adjuvants because of their long-lasting opioid-sparing actions. [72] When administered as part of a balanced analgesia technique in combination with narcotic analgesics and

local anesthetics, NSAIDs can facilitate early recovery, decrease side effects, and result in faster discharge times. [4] For many minor outpatient procedures, NSAIDs can eliminate the need for opioid analgesics postoperatively. [73]

Prevention of Nausea and Vomiting

PONV are common problems after general anesthesia. They are particularly disturbing in outpatients, because they can delay discharge and may result in unplanned

overnight hospital admissions. [10] [27] [74] [75] As early as 1916, it had been suggested that the anesthetic agent, the type of surgery, and opioid analgesics can all influence PONV. More recently, additional factors have been identified that influence the incidence of PONV. These include the patient's body habitus and medical condition, gender, pregnancy, phase of menstrual cycle, type of surgery, anesthetic and analgesic medications, postoperative hypotension, and age (Table 65-6) (Table Not Available) . [76] [77] [78] The incidence of emesis is very low in infants and gradually increases toward adulthood (Fig. 65-3) (Figure Not Available) . [79] [80] [81] The phase of the menstrual cycle influences the incidence of PONV most prominently during the ovulatory and luteal phases of the cycle (Fig. 65-4) (Figure Not Available) . This information should be considered when scheduling a patient for surgery who has a significant history of PONV. It is doubtful whether a single drug will ever be effective in treating emesis in all conditions. Thus, a combination of medications may be required to treat some patients successfully. [82] [83] Because of the low

TABLE 65-6 -- Risk Factors for Postoperative Nausea and Vomiting

(Not Available)

From Kallar, [295] copyright 1992, with permission from Elsevier Science

Figure 65-3 (Figure Not Available) Incidence (percentage) of postoperative nausea and vomiting as a function of age. *(From Lerman [76])*

incidence of PONV and the cost, potential side effects, and variable efficacy of antiemetic medications, routine prophylactic use of these drugs is recommended only in susceptible (high-risk) patients who have a previous history of postoperative vomiting and in patients with other significant risk factors for postoperative nausea.

Butyrophenones.

Droperidol is a butyrophenone neuroleptic drug with antiemetic properties as a result of its antagonistic effects at dopamine receptors. It is used predominantly for the treatment and prevention of PONV. Outpatient studies involving both children and adults indicate that droperidol is a highly effective antiemetic. [74] [84] Large doses of droperidol, greater than 20 mug/kg, enhance postoperative sedation and may significantly prolong recovery and discharge in ambulatory surgical patients. [85] Low doses of droperidol, less than 10 mug/kg, may be as effective as higher doses without delaying recovery. [86] One study showed that low-dose droperidol in combination with metoclopramide was more effective than ondansetron in preventing postoperative nausea after laparoscopic cholecystectomy. [87] Larger doses of droperidol (>1 mg) may result in unwanted side effects, including dyskinesia, restlessness, and dysphoric reactions, which may last up to 24 hours after surgery. This morbidity limits the use of droperidol as a routine premedication for outpatients. To limit these side effects, the lowest effective doses are recommended.

Phenothiazines.

The antiemetic action of phenothiazines also results from their ability to block dopamine receptors in the chemoreceptor trigger zone. Chlorpromazine and promethazine have been used for many years to treat nausea and vomiting, particularly caused by opioid use. [77] Phenothiazines can produce hypotension along with significant sedation during recovery, thus delaying discharge, and

Figure 65-4 (Figure Not Available) Incidence of postoperative nausea and vomiting correlated to the day of menstrual cycle. *(From Beattie and Buckley [81])*

may produce extrapyramidal effects ranging from restlessness to oculogyric crisis. [88]

Gastrokinetic Drugs.

Metoclopramide and domperidone are gastrokinetic agents that facilitate gastric and small bowel motility and increase lower esophageal sphincter tone. Metoclopramide (20 mg IV or 0.2 mg/kg IV) seems to be effective in the prevention of PONV. Because of its short half-life, metoclopramide should be given near the end of surgery to ensure efficacy in the early postoperative period. [77] The combination of metoclopramide, 10 to 20 mg IV, and low-dose droperidol, 0.5 to 1.0 mg IV, appears to be more effective than droperidol (1 mg) alone. [83]

Anticholinergics.

Anticholinergic drugs (e.g., atropine, glycopyrrolate, and scopolamine) have traditionally been used because of their antisialagogic and vagolytic actions. Transdermal scopolamine, a centrally acting anticholinergic, is effective in controlling motion sickness. Preoperative placement of a patch can reduce the incidence of severe PONV but it must be in place at least 8 hours before surgery and is associated with an unacceptably high incidence of adverse effects. Side effects, including dry mouth, somnolence, mydriasis, and dizziness, limit its usefulness in the outpatient setting. [66]

Antihistamines.

Dimenhydrinate and hydroxyzine are antihistamines that act on the vomiting center and vestibular pathways to prevent PONV. They are particularly useful in the prophylaxis and treatment of motion sickness and for outpatients undergoing middle-ear surgery. Dimenhydrinate has been shown to be successful in decreasing vomiting after strabismus surgery. When given in doses of 0.5 mg/kg at induction of anesthesia, dimenhydrinate significantly reduced vomiting for up to 24 hours postoperatively and did not delay discharge from the ambulatory facility. [89]

Serotonin Antagonists.

The discovery of the role of 5-hydroxytryptamine (5-HT) in the pathophysiology of cytoxic drug-induced emesis, as well as the discovery of the 5-HT antagonists, has generated considerable interest in the use of these compounds in the treatment and prevention of PONV. Ondansetron, granisetron, dolasetron, and tropisetron are all highly selective 5-HT_3 -receptor antagonists that lack the sedative, dysphoric, and extrapyramidal effects of other commonly used antiemetics. [90] [91] Ondansetron, by blocking both central and peripheral 5-HT_3 receptors, is effective in preventing PONV after ambulatory surgery. [90] [91] [92] [93] [94] [95] It has also been shown to be effective in the treatment of established postoperative emesis. [96] Because ondansetron has a short elimination half-life, it is more effective in reducing the need for rescue antiemetics in the recovery room when it is administered at the end of longer surgical procedures. [97] The use of small, 1- to 2-mg doses of ondansetron has not been found to be as effective as 4- and 8-mg doses in preventing PONV after discharge. [92] This is important to consider when treating patients with ondansetron, because the cost of the drug is substantial. In comparison, droperidol, 0.625 mg, and ondansetron, 4 mg, had equal antiemetic prophylaxis and discharge times, but droperidol was more cost-effective. [84] [98] Thus, the cost of these agents prohibits their routine use in the prevention of PONV in the outpatient setting.

Nonpharmacologic Techniques.

Acupuncture and acupressure have been used for the prevention of PONV with varying degrees of success. [77] [99] [100] In a study of minor gynecologic procedures with opioid premedication, P-6 acupuncture point stimulation with a needle resulted in a significant reduction in emesis postoperatively. [100] More recent reports comparing the use of P-6 acupressure to placebo or sham (non-P-6 location) treatment have also shown beneficial effects. [101] [102] Future studies comparing acupressure to traditional antiemetic drugs should include a pharmacoeconomic analysis. [103]

Prevention of Aspiration Pneumonitis

A controversial aspect of premedication in outpatients relates to the need for prophylactic medication to decrease the risk of pulmonary injury from aspiration of gastric contents. Early studies suggested that outpatients may be at a theoretically increased risk for aspiration based on the finding that a larger percentage of patients had a residual gastric volume greater than 25 mL with a pH less than 2.5. [104] However, more recent work showed no difference in the risk of aspiration in outpatients compared with inpatients. Several studies suggested that 40 to 60 percent of outpatients meet the criteria to be at risk for aspiration. [105] [106] [107] Despite this finding,

the incidence of pulmonary aspiration is very low (<1/35,000) in elective surgical patients with no specific risk factors. [108] Therefore, routine prophylaxis for acid aspiration is not recommended.

Using medications prophylactically in all patients to decrease the risk of pulmonary aspiration is costly and may be associated with unwanted side effects. Unfortunately, many practicing anesthesiologists feel compelled to use these drugs as routine premedicants because of the prevailing environment for malpractice litigation. Nevertheless, in outpatients with predisposing factors for pulmonary aspiration (i.e., pregnancy, scleroderma, hiatal hernia, nasogastric tubes, morbid obesity), use of the H_2 -receptor blocking drugs for premedication may be appropriate.

[a] Mean values
[b] Average duration of fasting 12 to 14 hours

H_2 -Receptor Antagonists.

The H_2 -receptor antagonists are effective in increasing gastric pH and in decreasing gastric volume by reducing gastric acid secretion (Table 65-7) . Ranitidine offers the advantages of a prolonged period of protection and fewer side effects than cimetidine. [106] [107] [109] If given intravenously, ranitidine has a faster onset of action and better protection than cimetidine. [110] Cimetidine is more cost-effective, but it may cause sedation or confusion and may interfere with drugs metabolized by cytochrome P-450. Compared with fasted patients who did not receive ranitidine, patients who received fluids plus oral ranitidine 2 to 3 hours before induction of anesthesia had lower residual gastric volumes, higher pH values, and a decreased incidence of thirst. [111] [112]

Antacids.

Sodium citrate is a nonparticulate antacid, which rapidly increases gastric fluid pH. It is commonly used in obstetric and emergency anesthesia because it reduces the consequences of aspiration of gastric contents in these high-risk patients. Because ingestion of this antacid increases gastric volume, the addition of a gastrokinetic agent is necessary when it is administered in the outpatient setting. [113] Disadvantages include the potential for emesis resulting from unpleasant taste, variable duration of effect, and decreased efficacy compared with H_2 -receptor antagonists. [114] Its use should be restricted to a select outpatient population (e.g., diabetic or morbidly obese patients) at the highest risk for complications from aspiration of acidic gastric contents.

Gastrokinetic Agents.

Metoclopramide, a dopamine antagonist, reduces gastric volume by stimulating gastric emptying time without altering pH. The use of effective doses of metoclopramide in combination with an H_2 -receptor blocking drug has been advocated to decrease postoperative emesis and further reduce the potential risk of aspiration pneumonitis. [115] Other studies failed to demonstrate a significant advantage of this drug combination over an H_2 -receptor antagonist alone. [106] However, metoclopramide may offer an additional protective effect as a result of its ability to increase lower esophageal sphincter tone.

Nothing-by-Mouth Guidelines

Because prolonged fasting does not guarantee an empty stomach at the time of induction, several investigators have questioned the value of even a 4- to 5-hour fast prior to elective surgery. [109] [116] [117] [118] This is logical, because the half-life of clear fluids in the stomach is 10 to 20 minutes, and residual gastric volume after 2 hours is less in patients ingesting small amounts of clear fluids than in fasted patients. [119] After an overnight fast, 50 and 44 percent of outpatients complained of moderate-to-severe hunger and thirst, respectively. [107] It was postulated that these symptoms contributed significantly to preoperative anxiety. More important, 14 percent of young female outpatients presenting to the operating room in the afternoon after an overnight fast had a serum glucose concentration of less than 45 mg/dL. [120] Ingestion of

150 mL of water as late as 2 hours before surgery significantly decreased the severity of thirst without increasing gastric volume in fasted outpatients. [109] Furthermore, ingestion of 150 mL of either coffee or orange juice 2 to 3 hours before induction of anesthesia had no significant effect on residual gastric volume or pH in adults. [121] Similarly, preoperative ingestion of apple juice, 3 mL/kg, decreased gastric volume, thirst, and hunger in children and had no adverse effect on gastric contents. [122] Thus, arbitrary restrictions (e.g., nothing by mouth [NPO] after midnight) dictating when outpatients may drink fluids before an elective operation appear to be unwarranted. A national survey in the United States demonstrated that 69 percent of anesthesiologists had changed their NPO guidelines to allow ingestion of clear fluids for children, and 41 percent had changed their guidelines for adults. [123] Unless outpatients scheduled for late morning or early afternoon surgery have

delayed gastric emptying or receive a narcotic premedicant, the requirement for a 10- to 16-hour fast is not justified. Prolonged fasting causes discomfort to outpatients without any apparent benefit.

ANESTHETIC TECHNIQUES

Quality, safety, efficiency, and the cost of drugs and equipment are important considerations in choosing an anesthetic technique for outpatient surgery. The ideal outpatient anesthetic should have a rapid and smooth onset of action and it should produce intraoperative amnesia and analgesia, good surgical conditions with a short recovery period, and no side effects. Outpatient surgery requires the same basic equipment as inpatient surgery for delivery of anesthetic drugs, monitoring, and resuscitation. Standard intraoperative monitoring equipment for outpatient operations includes a precordial stethoscope, ECG, blood pressure cuff, pulse oximeter, and capnograph.

The choice of anesthetic technique depends on both surgical and patient factors. For many ambulatory procedures, general anesthesia remains the most popular technique with both patients and staff. Although central neuroaxis blockade has been traditionally popular for peripheral procedures, its use in ambulatory anesthesia can delay discharge because of residual sympathetic blockade. Peripheral nerve blocks, however, may facilitate the recovery process by minimizing the use of opioid analgesics, which can produce nausea or sedation. There are an increasing number of cases now being performed with a combination of local nerve blocks and intravenous sedation as part of a so-called monitored anesthesia care technique. Although there is no ideal anesthetic agent or technique for outpatients, there is a vast array of pharmacologically active drugs that, when combined in a rational manner and carefully titrated, can produce the desired anesthetic conditions with an acceptable recovery profile and cost.

General Anesthesia

The ability to deliver a safe and cost-effective general anesthetic with minimal side effects and rapid recovery is critical in a busy outpatient surgery unit. General anesthesia remains the most widely used anesthetic technique for managing ambulatory surgery patients because of its popularity with patients, surgeons, and anesthesiologists. In addition to intraoperative anesthetic conditions, the anesthesiologist must consider the recovery characteristics of the anesthetic as well as the management of postoperative pain and PONV when making the anesthesia care plan.

The question whether to start an intravenous line in outpatients arises in pediatric patients undergoing brief surgical procedures. For procedures lasting less than 15 minutes that do not require intravenous administration of drugs or fluid (e.g., myringotomies and eye examinations under anesthesia), an intravenous line is not essential. Preoperative fasting for periods of 10 to 15 hours does not result in hypoglycemia in healthy 5-year-old outpatients. However, for longer cases or situations in which the patient has been without oral intake for longer than 15 hours, an intravenous line is useful for the maintenance of fluid balance and glucose homeostasis, as well as for facilitating the administration of drugs during the perioperative period. [120] In addition, postoperative morbidity, such as drowsiness, dizziness, and thirst, may be associated with poor hydration status. Outpatients who received 20 versus 2 mL/kg of intravenous hydration had less minor postoperative morbidity, including PONV (Fig. 65-5) (Figure Not Available) . [124] Use of heated humidifiers, as well as passive heat and moisture exchangers, will further decrease fluid losses and conserve heat during longer outpatient procedures. [125] However, in procedures lasting less than 2 hours, these devices are unlikely to be cost-effective in adult ambulatory surgery.

Airway Management

Endotracheal intubation causes a high incidence of postoperative airway-related complaints including sore throat, croup, and hoarseness (Ch. 39) . Many outpatients undergoing

Figure 65-5 (Figure Not Available) Preoperative hydration of 20 versus 2 mL/kg decreases postoperative morbidity in outpatients. *(Modified from Yogendran et al [124])*

peripheral procedures under general anesthesia do not require endotracheal intubation unless they are at high risk for aspiration. The laryngeal mask airway (LMA) was first described by Brain in 1983 as an alternative to endotracheal intubation or a facemask. Its use has grown rapidly for outpatient surgery since that time. [126] When compared with anesthesia with a mask and oral airway, patients with an LMA had fewer desaturation episodes, fewer intraoperative airway manipulations, and fewer difficulties in maintaining an airway. [127] The LMA frees the anesthesiologist's hands for record-keeping, monitoring, and drug administration. Fatigue from maintaining the airway with mask is also eliminated.

The LMA can be positioned easily without direct visualization or neuromuscular blocking agents, and the patient can be allowed to ventilate spontaneously throughout the procedure. Compared with endotracheal intubation, insertion of the LMA causes minimal cardiovascular response and is better tolerated at lighter levels of anesthesia. [128] The incidence of sore throat is markedly reduced when the LMA is used. In a large survey, 47 percent of intubated patients complained of sore throat postoperatively versus only 7 percent with patients having the LMA. [129] [130]

The LMA does not protect the airway from foreign material and should not be used in patients at high risk of regurgitation, aspiration, or upper airway bleeding. Furthermore, if a high positive airway pressure is required for maintaining the airway or ventilation, the risk of gastric dilatation and subsequent aspiration may be increased. [131] An alternative to the LMA is the cuffed oropharyngeal airway (COPA) device. [132] Although the COPA is easy to insert after induction without muscle relaxants, its ability to maintain an obstruction-free airway must compared with the currently used airway devices. Furthermore, the ability to assist ventilation with the COPA must be further evaluated.

Intravenous Anesthetic Drugs

Induction of general anesthesia is usually accomplished with a rapid-acting intravenous anesthetic (Chs. 8 and 9) . The increased availability of intravenous, inhaled, analgesic, and muscle-relaxant drugs with a rapid onset and short duration of action has made brief surgical procedures safer and more pleasant for outpatients (Table 65-8) (Table Not Available) . Propofol has virtually replaced barbiturates and benzodiazepines for induction of anesthesia because of its favorable recovery profile. [133] The most popular technique for maintenance of anesthesia is the combination of a volatile anesthetic agent with nitrous oxide. The extremely low solubility of nitrous oxide and the newer less soluble volatile agents contribute to a more rapid onset and recovery from general anesthesia. Although some investigators have suggested that there is an association between nitrous oxide and PONV, more recent studies question the clinical importance of nitrous oxide in producing this side effect. [134] [135] [136] [137]

Barbiturates

Thiopental (3-6 mg/kg) is the prototypic intravenous induction agent with a rapid onset and a short duration of action resulting from redistribution of the drug (Ch. 8) . However, thiopental impairs fine motor skills for several hours after surgery and produces a "hangover" sensation. Methohexital appears to be associated with slightly

shorter awakening time, but recovery of fine motor skills may still require 6 to 8 hours after an induction dose. [138] [139] Compared with thiopental, methohexital is associated with a higher incidence of pain on injection, involuntary muscle movements, and hiccoughing. The use of small doses of a rapid-acting opioid analgesic (e.g., sufentanil 5-10 mug IV) can minimize side effects during the induction period. Furthermore, methohexital compared favorably with propofol when used for induction only in outpatient procedures lasting longer than 2 hours. [140]

Benzodiazepines

Studies with the water-soluble benzodiazepine, midazolam (0.2-0.4 mg/kg IV) indicate that it is also an adequate induction agent in outpatients (Ch. 9) . However, its onset of action is slower and recovery is prolonged compared with the barbiturate compounds and propofol. [141] If combined with nitrous oxide and sufentanil or alfentanil, midazolam, in doses of 0.1 to 0.15 mg/kg, will induce general anesthesia. When midazolam was used for induction and flumazenil, a specific benzodiazepine antagonist, was administered at the end of surgery, prompt recovery was achieved after outpatient arthroscopy. However, compared with propofol, recovery after flumazenil antagonism of midazolam anesthesia was still significantly slower. [142]

TABLE 65-8 -- Comparison of Currently Available Intravenous Anesthetics for Use During Ambulatory Anesthesia

(Not Available)

From White [163]

Etomidate

Etomidate (0.2-0.3 mg/kg) has also been used for induction and maintenance (1-3 mg/min) of general anesthesia during short outpatient procedures (Ch. 9) . Recovery tends to be faster than after thiopental administration and compares favorably with methohexital. Disadvantages of etomidate include pain on injection, high incidence of PONV, myoclonic movements, and transient suppression of adrenal steroidogenesis. [143] Because of its side-effect profile, the use of etomidate is best restricted to those clinical situations in which its hemodynamic stability offers an advantage over other available induction agents (e.g., elderly outpatients with coronary artery or cerebrovascular disease).

Ketamine

Ketamine compares unfavorably with barbiturates and opioid compounds for minor gynecologic procedures because of its prominent psychomimetic effects and high incidence of PONV during the early postoperative period (Ch. 9) . Premedication with a benzodiazepine (e.g., midazolam 0.05-0.1 mg/kg IV) decreases the incidence of ketamineinduced emergence reactions. [144] Investigators have reported that low doses of ketamine (10-20 mg IV) may be a useful alternative to opioid analgesics during induction of anesthesia.

Propofol

Propofol is an intravenous anesthetic agent that has a metabolic clearance ten times faster than that of thiopental (Ch. 9) . [145] Recovery after propofol anesthesia compares favorably with that of most other anesthetics in the outpatient setting. This is particularly important because the cost of propofol is higher than that of many other commonly used anesthetics. [146] [147] [148] However, when the total patient costs are calculated, the use of propofol may contribute to significant savings. [60] For example, compared with an isoflurane-based anesthetic, patients who had a propofol-based anesthetic were discharged earlier from the hospital and returned to work significantly sooner. [149] Recovery following induction of anesthesia with propofol is faster than with the commonly used barbiturate compounds, irrespective of the maintenance agent used (Fig. 65-6) (Figure Not Available) . [133] [139] [150] Compared with methohexital, the use of propofol was associated with fewer side effects (hiccoughing, nausea, and vomiting) intraoperatively and postoperatively and faster recovery times. [139] Faster intermediate recovery with propofol-based anesthetics may also yield significant savings in nursing hours. For example, a 15-minute reduction in phase I recovery room stay could save 1,000 nursing hours in a 4,000-case per year ambulatory surgical facility. [149] Early experience with propofol in the United Kingdom suggested a reduction in the need for overtime nursing personnel.

Propofol is associated with less PONV and decreased use of antiemetic medications. [146] [151] [152] [153] [154] There is evidence that propofol may possess inherent antiemetic activity, and it has been successfully used to treat refractory nausea and vomiting in patients undergoing chemotherapy. [155] When propofol

Figure 65-6 (Figure Not Available) Comparison of mean changes in choice reaction time (CRT) postoperatively in untreated controls and outpatients who received thiopental, methohexital, or propofol for induction of anesthesia. * $P < .05$. *(From MacKenzie and Grant [150])*

was administered in subhypnotic doses (10-20 mg IV) to treat PONV, 81 percent of patients showed improvement versus 35 percent of the lipid emulsion control group. [156] Unfortunately, 28 percent of patients experienced a relapse of their symptoms within 30 minutes. For propofol to be clinically useful as an antiemetic, it would need to be given as a continuous infusion because of its rapid clearance. Subhypnotic concentrations of propofol have also shown other central effects, including perioperative mood alterations. Patients emerging from propofol anesthesia were more likely to exhibit sensation-seeking tendencies (e.g., adventurous, daring, energetic) and to report feeling elated and euphoric. [157] Intravenous administration of propofol is associated with a high incidence of venous pain and discomfort. Lidocaine (40 mg IV) immediately before propofol injection reduces the incidence and severity of pain when it is injected into small hand veins, whereas thiopental (50 mg IV) has also been shown to reduce only the severity of the pain. [158]

Inhaled Anesthetic Drugs

Volatile anesthetics are convenient to use in ambulatory anesthesia (Chs. 4 and 5) . Changes in the depth of anesthesia can be made readily because of the rapid uptake and elimination of these anesthetics. [159] [160] The rapid elimination of anesthetic vapors provides for a fast patient recovery and potentially earlier discharge from the outpatient facility. Although a similar spectrum of pharmacologic activity is produced by the three traditionally used volatile agents (halothane, enflurane, and isoflurane), isoflurane has been the most commonly used for maintenance of general anesthesia. Studies involving outpatients undergoing brief procedures have shown no significant clinical differences in recovery

TABLE 65-9 -- Comparison of Currently Available Inhaled Anesthetics for Use During Ambulatory Anesthesia

(Not Available)

From White [163]

TABLE 65-10 -- Recovery Times After Discontinuation of Isoflurane or Desflurane

(Not Available)

From Ghouri et al [169]

times among the three potent inhaled anesthetics. For procedures lasting longer than 90 minutes, recovery times after isoflurane seem to be faster when compared with enflurane. [161] Despite its lower solubility, isoflurane may not offer any significant advantages over enflurane for short ambulatory procedures. Interestingly, adult outpatients receiving isoflurane during minor gynecologic surgery had a higher incidence of postoperative complications than those receiving enflurane. [160]

Most studies of pediatric patients have reported that halothane is associated with the lowest incidence of perioperative complications. [162] Isoflurane is associated with

several disadvantages when it is used for induction of anesthesia in children (e.g., coughing, laryngospasm). However, ventricular arrhythmias are more likely to occur during halothane anesthesia.

The newer volatile anesthetics, sevoflurane and desflurane, are proving to be extremely useful in the outpatient setting because of their more favorable pharmacokinetic profiles (Table 65-9) (Table Not Available) . [163] [164] [165] [166] [167] [168] In outpatients, the immediate recovery (emergence) after desflurane was significantly faster compared with isoflurane (Table 65-10) (Table Not Available) . [169] However, intermediate and late recovery after desflurane is similar to that after isoflurane and propofol (Fig. 65-7) (Figure Not Available) . [170] [171] In fact, propofol anesthesia may offer some advantages because the incidence of nausea and vomiting is less than with desflurane (Fig. 65-8). (Figure Not Available) The solubility of desflurane (0.42) is lower than that of nitrous oxide (0.46), and clinical studies suggest that recovery of cognitive and psychomotor function occurs very rapidly following discontinuation of this agent. [170] [172] [173] [174] [175] [176] [177] [178] Despite its shorter elimination kinetics and recovery characteristics, the introduction of desflurane in one center did not result in faster operating room exit times. [179] Other studies have showed a greater incidence of postoperative agitation and excitement in patients recovering from desflurane and significant autonomic stimulation may result from rapid adjustments in inspired concentration. [174] [175] [180] [181] The pungency of desflurane results in respiratory tract irritation and coughing, breath-holding, and laryngospasm when administered at high concentrations for induction of anesthesia. [182] Thus, desflurane's usefulness as a drug to induce anesthesia in children and adults is limited.

Sevoflurane has a relatively low solubility and an impressive lack of airway irritation that makes it very useful for inhalation induction of anesthesia. [183] [184] [185] [186] Even at high concentrations, inhalational induction is well tolerated because of its lack of pungent odor, and it is more pleasant for rapid inhalational

Figure 65-7 (Figure Not Available) Intermediate recovery after propofol, desflurane (±N_2O), or propofol-desflurane anesthesia. *(From Van Hemelrijck et al [171])*

Figure 65-8 (Figure Not Available) Postoperative nausea after propofol, desflurane (±N_2O), or propofol-desflurane anesthesia. *(From Van Hemelrijck et al [171])*

induction than halothane. [187] These features make sevoflurane popular for pediatric outpatient anesthesia. [188] [189] [190] [191] [192] [193] Controversy still exists regarding the significance of the breakdown products of sevoflurane. [194] Sevoflurane can be degraded in carbon dioxide absorbents to compound A, which can produce renal toxicity in rats. [195] [196] [197] The production of compound A is related to the concentration of sevoflurane, the temperature of the absorbent, the fresh gas flow rate, and the duration of administration. Although the U.S. Food and Drug Administration has recommended that sevoflurane not be used at total gas flow rates less than 2 L/min, studies have failed to demonstrate any change in renal or hepatic function when sevoflurane was used at total gas flows of 1 L/min or during closed-circuit anesthesia. [194] [197]

Use of nitrous oxide as an adjuvant to the anesthetic management of outpatients significantly reduces the requirements for the volatile agents during the maintenance period. Therefore, recovery is rapid and the cost of the anesthesia less when nitrous oxide is used. Nitrous oxide can increase postoperative nausea by increasing the pressure in the middle ear, thereby stimulating the vestibular system, and by increasing gastrointestinal pressure. Nevertheless, the role of nitrous oxide in causing PONV remains controversial and is not clinically significant when considering the overall ratio of cost to benefit to the health-care system. [135] [137] [198] [199]

Analgesics

Opioid and nonopioid analgesics are frequently administered in the immediate preinduction period to suppress the autonomic responses to endotracheal intubation and during maintenance of general anesthesia to prevent autonomic responses to painful stimuli (Ch. 10) . Opioids can reduce the requirement for sedative-hypnotic drugs, thereby decreasing recovery times. In addition, opioids have been shown to decrease the incidence of pain on injection and involuntary motor activity associated with methohexital, etomidate, and propofol.

Although morphine (and its more lipid-soluble derivatives) and meperidine can be used in outpatient anesthesia, they are not as popular as the more potent, rapid, and shorter-acting opioid analgesics (e.g., fentanyl, sufentanil, and alfentanil). A recent study comparing morphine and fentanyl in ambulatory surgical patients found higher pain scores and more oral analgesic use in the fentanyl group. Morphine produced better quality analgesia, but it was associated with increased nausea and vomiting especially after discharge. There was no difference in recovery times or discharge times despite the shorter duration of action of fentanyl. [200]

Use of small doses of potent opioids (e.g., fentanyl, 1-2 mug/kg; alfentanil, 15-30 mug/kg; sufentanil, 0.15-0.3 mug/kg) can effectively attenuate the cardiostimulatory response to laryngoscopy and intubation, and these drugs are useful supplements to inhaled anesthetics during the maintenance period. Compared with a standard inhaled anesthetic, most investigators have demonstrated improved intraoperative conditions and a more rapid emergence from anesthesia when fentanyl or one of its newer analogues was administered as part of a balanced anesthetic technique. [201] [202] When a sufentanil infusion was compared with fentanyl for maintenance of general anesthesia with nitrous oxide, its use was associated with less nausea and postoperative pain. [203] Alfentanil has a rapid onset and a short duration of action. These characteristics make it particularly useful in the outpatient setting. Although one study found no significant difference in awakening times after anesthesia maintained with alfentanil compared with fentanyl, most investigators have reported a faster emergence and recovery of psychomotor function after an alfentanil-based anesthetic technique. [202]

Remifentanil is an ultrashort-acting opioid analgesic with an analgesic potency similar to that of fentanyl. It is metabolized by nonspecific esterases, a process that allows for rapid systemic elimination. [204] [205] Remifentanil has a half-life of 8 to 10 minutes and a context-sensitive half-life (the time for a 50% decrease in its effect-site concentration after the infusion is stopped) of 4 minutes regardless of the duration of infusion (Fig. 65-9) (Figure Not Available) . [206] This is in contrast to alfentanil, which has a context-sensitive half-life of 58 minutes and depends on its small volume of distribution for rapid termination of its clinical effect. [207] When remifentanil was compared with alfentanil as part of a total intravenous anesthesia technique, remifentanil provided more effective suppression of intraoperative responses but prolonged awakening and recovery room stay. [208] There was an earlier need for analgesics postoperatively with remifentanil, and both groups had similar discharge times. Studies involving the use of remifentanil in

Figure 65-9 (Figure Not Available) Computer simulation of the "context-sensitive" half-life time (CSHT) for remifentanil (3.65 min), alfentanil (58.5 min), sufentanil (240 min), and fentanyl (262.5 min). Note that remifentanil's CSHT is independent of the duration of infusion. *(Modified from Egan et al [206])*

combination with the less-soluble volatile anesthetics suggest that a low-dose infusion (0.05-0.2 mug/kg/min) can produce a significant anesthetic-sparing effect. [209] Furthermore, a 1-mug/kg bolus dose of remifentanil was more effective than a similar dose of fentanyl in suppressing the acute hemodynamic responses to laryngoscopy and tracheal intubation in patients undergoing outpatient laparoscopy. [210]

The semisynthetic opioid agonist-antagonist compounds (i.e., butorphanol, nalbuphine, dezocine) may offer advantages as adjuvants to general anesthesia over the potent opioid compounds in the outpatient setting because of their more limited potential to produce ventilatory depression. Unfortunately, there is a "ceiling effect" with respect to analgesic efficacy. Dezocine is a short-acting opioid with high mu-receptor activity. Compared with alfentanil, intraoperative dezocine provided significantly longer postoperative analgesia. However, dezocine increased postoperative nausea and delayed discharge from the hospital compared with fentanyl and ketorolac. [211] When nalbuphine (0.3-0.5 mg/kg) was compared with fentanyl (1.5 mug/kg) during outpatient anesthesia, it was found to produce more unpleasant dreaming during surgery and greater postoperative anxiety, drowsiness, and PONV. [70]

Muscle Relaxants

Many outpatient surgical procedures require no neuromuscular relaxation (Ch. 12) . Muscle relaxants are required in outpatient anesthesia to facilitate tracheal intubation and to optimize the surgical conditions during intra-abdominal procedures. In addition, their use can decrease anesthetic requirements and recovery time. Although it has been suggested that controlled ventilation with muscle relaxants may decrease postoperative emesis, this was not verified when controlled ventilation (versus spontaneous) was compared in outpatients undergoing strabismus repair. [212]

Before the introduction of intermediate-acting nondepolarizing muscle relaxants, an infusion of succinylcholine was the most frequently used muscle relaxant technique during outpatient anesthesia. Unfortunately, the administration of succinylcholine may be associated with hyperkalemia, arrhythmias, MH, and muscle pains lasting up to 4 days after surgery. Nevertheless, succinylcholine is indicated when a rapid onset of neuromuscular block is required. Factors other than succinylcholine may also contribute to the occurrence of myalgias following outpatient surgery. For example, the use of vecuronium (versus succinylcholine) did not lower the incidence or severity of muscle pain after laparoscopy. [213]

With the availability of intermediate-acting nondepolarizing muscle relaxants (e.g., atracurium, vecuronium, and mivacurium), reversal of neuromuscular blockade can be achieved even after brief surgical procedures. [214] Atracu- rium, vecuronium, and mivacurium are each metabolized through distinctly different pathways. [215] Intubating doses of atracurium and mivacurium cause histamine release, which may prove to be disadvantageous in certain situations. In outpatients, the primary consideration in choosing one of these agents is the duration of surgery and the costeffectiveness of the drug. After the recommended intubating doses of atracurium and vecuronium, the duration of action (time to 95% spontaneous recovery) is approximately 1 hour. An intubating dose of mivacurium (0.15-0.20 mg/kg) has approximately twice the duration of succinylcholine (20-30 min) and a significantly more rapid spontaneous recovery profile than atracurium, vecuronium, or rocuronium. [216] [217] [218] A continuous infusion of mivacurium or small (4-8-mg) bolus doses can further improve titration and thereby can ensure a prompt spontaneous recovery, decreasing the need for muscle relaxant reversal agents.

Reversal of Drug Effects

Pharmacologic antagonists, drugs that compete with agonists at the receptor site, may be useful in outpatient anesthesia by facilitating the recovery process. However, antagonists may also have unwanted side effects that should be considered before using these agents. Because their duration of action is sometimes shorter than that of the agonists, (e.g., naloxone, flumazenil, and edrophonium), a rebound of the agonist effect may follow their use.

Although severe opioid side effects, such as rigidity and respiratory depression, can be treated with incremental boluses of naloxone (20-40 mug), this drug is not recommended for routine reversal of opioid effect because of its own intrinsic side effects (nausea and vomiting, pulmonary edema, and arrhythmias). [219] It is preferable to titrate the opioid carefully to achieve the desired effect during surgery. Butorphanol, nalbuphine, and dezocine combine the properties of opioid agonists and antagonists such as naloxone. These drugs can be used to treat such opioid-related side effects as pruritus without adversely affecting the analgesia.

The central effects of benzodiazepines (excessive sedation, amnesia, and dysphoria) can be promptly reversed with flumazenil (0.1-0.2-mg increments). Although flumazenil is a specific benzodiazepine antagonist with few side effects, it is too costly for routine use. As with opioids, it may be more

cost-effective to titrate the benzodiazepines to the desired clinical effect, rather than relying on flumazenil to reverse residual effect. Relapses of sedation (rebound) can occur, because the half-life of flumazenil is shorter than that of most benzodiazepine agonists.

Intermediate-acting neuromuscular agents usually require reversal of their action, and neostigmine and edrophonium are the two most widely used anticholinesterase drugs. The choice of the reversal agent may influence the frequency of PONV. When compared with patients receiving no reversal agents or reversal with edrophonium, patients receiving neostigmine have an increased frequency of PONV. [220] [221] [222] Mivacurium may be advantageous in this regard because reversal is seldom required if the drug is carefully titrated during the maintenance period. The ability to avoid reversal drugs may prove cost-effective because of a reduction of the costly treatment of PONV.

Special Pediatric Considerations

In unruly, frightened, or mentally retarded children, preoperative sedation is often required prior to taking the patient into the operating room (Ch. 59) . In general, sedative premedication is not offered for patients less than 9 to 12 months old and is most often used for toddlers or preschool-aged children. Because of the aversion of these patients to intramuscular injections, oral or rectal premedicants are more popular with children. Midazolam is the most common anxiolytic premedication used at present. After receiving 0.5 mg/kg of midazolam orally, children can be easily separated from their parents within 10 to 20 minutes without prolonging discharge time. [65] [223] When rectal methohexital is administered (20-30 mg/kg) prior to halothane anesthesia, the recovery time may be prolonged significantly compared with halothane alone. Rectal etomidate (6 mg/kg) or ketamine (5-10 mg/kg) can also produce a rapid onset of hypnosis without cardiorespiratory depression in children undergoing minor outpatient procedures. [224] Intramuscular ketamine (2-4 mg/kg) can also be an extremely useful drug for induction of the uncooperative child; however, home-readiness may be delayed when larger doses of ketamine (>5 mg/kg) are combined with a volatile anesthetic. [225] In addition, recurrent illusions and flashbacks have been reported several weeks after ketamine administration to children. [226]

Although controversial, the practice of allowing parents to be present during the induction of anesthesia is becoming more common. An informal survey indicated that 50 percent of pediatric anesthesiologists allow parents to be present during induction. [227] Studies have shown that most parents are calm and supportive, and the number of very upset or turbulent children during preinduction and induction is significantly decreased. [228] Appropriate selection and education of parents is essential. Parents must be told exactly what to expect and must agree to leave immediately if asked to do so by the anesthesiologist. Unduly anxious or hysterical parents should not be encouraged to be present for induction because they may increase the child's anxiety. [229] With proper preparation, parents can help to decrease the need for sedative premedication and can avoid a traumatic separation.

Regional Anesthesia

Regional anesthesia can offer many advantages for the ambulatory patient (Chs. 42 to 44) . In addition to limiting the anesthetized area to the surgical site, common side effects of general anesthesia (e.g., nausea, vomiting, dizziness, lethargy) can be avoided. [230] Furthermore, the risks of aspiration pneumonitis and the side effects of tracheal intubation are minimized, postanesthesia nursing care and patient recovery time may be decreased, and effective analgesia is provided in the early postoperative period. [231] [232] A large retrospective study by Meridy [27] showed a shorter recovery room stay and a lower unanticipated hospital admission rate in patients with local or regional anesthesia compared with general anesthesia. Proper patient selection along with the skill and enthusiasm of the surgical and anesthesia teams will allow a wider variety of procedures to be performed with regional anesthetic techniques.

Epidural and Spinal Anesthesia

There is renewed interest in the use of regional anesthesia in the outpatient setting because of the lower incidence of side effects and improved recovery compared with general anesthesia. [233] Spinal anesthesia is the simplest and most reliable regional anesthetic technique; however, the incidence of side effects is surprisingly high. [234] The most troublesome complications of outpatient spinal anesthesia are postdural puncture headache (PDPH) and backache. Although the incidence of PDPH can be minimized by the use of small-bore, 25-gauge, pencil-point needles, the incidence of failed blocks is higher. [235] The use of these needles results in a low incidence of PDPH (1-2%), few failed blocks, low incidence of backache, and high patient acceptance. [233]

Short-acting local anesthetics, such as lidocaine, are preferable for use in outpatients to ensure predictable recovery. However, the use of 5 percent hyperbaric lidocaine has become controversial because of numerous reports of transient radicular irritation. [236] [237] As a result, investigators are recommending the use of isobaric lidocaine (2% lidocaine) as well as combinations of low-dose hypobaric lidocaine and fentanyl. The addition of fentanyl (10-20 mug) prolongs sensory but not motor block and appears to decrease the time to voiding and full recovery. In a study involving outpatients undergoing laparoscopy, a small-dose hypobaric solution of 1 percent lidocaine (25 mg) with 25 mug of fentanyl caused significantly faster recovery and less intraoperative hypotension compared with 75 mg of hyperbaric lidocaine alone. [238] [239] [240] However, the addition of the opioid analgesic increased the incidence of pruritus. Intrathecal bupivacaine has been used in ambulatory surgical patients, but it should be reserved for procedures of anticipated long duration (2-3 hours) because of the prolonged recovery times. [238] [241] [242] Outpatients should be allowed to recover motor function fully prior to discharge. Following complete recovery of motor function, residual sympathetic blockade and orthostatic hypotension are rarely a problem on ambulation. [243] [244]

Epidural anesthesia is technically more difficult, has a slower onset time and a risk of potential intravascular or intrathecal

injection, and a greater chance of an incomplete sensory block compared with spinal anesthesia. The main advantage of epidural anesthesia is the ability to extend the duration of anesthesia for procedures with a variable surgical time. Some studies have shown a faster recovery time with epidural versus spinal anesthesia, whereas the incidence of PDPH and patient satisfaction were similar. [233] The use of chloroprocaine for outpatient epidural anesthesia is associated with a high incidence of back pain resulting from muscle spasm thought to be related to the preservative ethylenediaminetetra-acetic acid (EDTA). [233]

The use of combined spinal-epidural anesthesia has also been studied in ambulatory surgical patients. [245] [246] [247] The combined technique allows for the reliability of spinal anesthesia with the flexibility of continuous epidural anesthesia. [233] Patients receive an initial small dose of intrathecal local anesthetic via a needle-through-needle technique, and then an epidural catheter is placed. The small initial dose of intrathecal drug results in lower sensory levels, reduced side effects, and faster recovery from the sensory-motor blockade. If necessary, the epidural catheter could be used to extend the block beyond the duration of the spinal anesthetic.

Intravenous Regional Anesthesia

For short superficial surgical procedures (<60 min) limited to a single extremity, the intravenous regional (Bier) block with lidocaine, 0.5 percent, is a simple and reliable technique (Ch. 43). [233] This procedure, which can be used for either upper or lower extremity surgery, uses a double tourniquet to decrease tourniquet pain. Intravenous regional anesthesia also facilitates the outpatient treatment of upper extremity injuries in children.

Peripheral Nerve Blocks

If more profound and prolonged anesthesia of the upper extremity and shoulder is required, a regional block of the brachial plexus can be used (e.g., axillary block or interscalene block) (Ch. 43) . [248] Peripheral nerve blocks are also useful for surgery on the leg. The "three-in-one block" (femoral, obturator, and lateral femoral cutaneous nerves) using a perivascular technique is useful for outpatient knee arthroscopy and anterior cruciate ligament repairs, providing excellent postoperative analgesia with a high degree of patient acceptance. Ankle blocks are also simple and effective techniques for surgery on the foot. Popliteal sciatic nerve blocks have been shown to provide excellent postoperative analgesia after foot surgery. [249]

Pediatric Patients

In pediatric patients, regional blocks can be performed immediately after induction of general anesthesia to reduce the anesthetic requirement, to provide profound postoperative analgesia, and to facilitate early recovery after surgery (Ch. 44) . [243] Historically, caudal anesthesia has been the most popular technique to reduce postoperative pain in children undergoing lower abdominal, perineal, and lower extremity procedures. Other useful techniques include blockade of the ilioinguinal and iliohypogastric nerves to minimize postherniorrhaphy pain and the use of caudal, dorsal nerve block, subcutaneous ring block, or topical lidocaine ointment for postcircumcision pain. [250] Interestingly, simple wound infiltration with local anesthetics may be as effective as a caudal or ilioinguinal nerve block in reducing pain after inguinal hernia repair. [251] Studies suggest that systemic ketorolac (1 mg/kg) is as efficacious as caudal blockade, with a lower incidence of side effects. [252]

Local Infiltration Techniques

Of all the anesthetic techniques suitable for outpatients, local infiltration of the operative site with dilute solutions of local anesthetics may be the simplest and safest. Outpatient urologic procedures (e.g., vasovasostomy, orchiopexy, and hydrocele and spermatocele repairs) performed using local anesthesia can significantly decrease the overall cost compared with inpatient procedures. [15] Outpatient knee arthroscopy is commonly performed using local anesthesia (e.g., bupivacaine 0.5%, 30 mL). [253] Inguinal herniorrhaphy has also been performed using local anesthesia, with excellent patient acceptance and minimal postoperative complications. [254] A combination of local infiltration and intercostal nerve blocks can be used for lithotripsy. [255] Careful patient selection is required for operations performed with local infiltration or a field block because patient cooperation is necessary. Local anesthetic supplementation (e.g., infiltration with bupivacaine 0.25-0.5%) may decrease incisional pain in the recovery room, and the use of topical local anesthetics (e.g., lidocaine creams and aerosols, Emla cream) may be beneficial for analgesia after selected procedures.

Monitored Anesthesia Care

The combination of local anesthetics with intravenous analgesic and sedative drugs is gaining popularity, particularly for ambulatory procedures (Ch. 40) . This technique was introduced by the American Dental Association to describe the care of patients requiring sedative or analgesic drugs during dental procedures and was called "conscious sedation." [256] As the term implies, conscious sedation is a minimally depressed level of consciousness that retains the patient's ability to maintain an airway independently and continuously and to respond appropriately to physical stimulation and verbal commands. The ASA avoids this term in their *Practice Guidelines of Sedation and Analgesia by Non-anesthesiologists* because it is imprecise. [257]

Monitored anesthesia care is the term used when an anesthesiologist monitors a patient receiving local anesthesia and/or administers anesthetic drugs to patients undergoing diagnostic or therapeutic procedures. [258] The standard of care of patients receiving monitored anesthesia care should be the same as for patients undergoing general or regional anesthesia and should include a complete preoperative assessment, intraoperative monitoring, and postoperative recovery. Vigilant monitoring is required because patients may rapidly progress from a light level of sedation to deeper sedation or unconsciousness and thus may be at risk for airway

---

(Not Available)

From Federated Ambulatory Surgery Association [14]

obstruction, oxygen desaturation, and aspiration. In fact, a Federated Ambulatory Surgery Association survey found a higher overall complication rate after ambulatory surgery with combined local anesthesia and intravenous sedation compared with general, regional, or local anesthesia alone (Table 65-11) (Table Not Available) . [14]

Anesthetic drugs administered during monitored anesthesia care procedures should provide analgesia, sedation, and anxiolysis, which is easily titratable and provides for a rapid recovery with few side effects. Systemic analgesics are used to reduce discomfort during injection of local anesthesia and from prolonged immobilization or where effective local anesthesia is difficult to achieve (e.g., endoscopy). [259] However, the primary method of treating pain should be supplemental local or regional infiltration with local anesthetics. Sedative drugs make procedures more tolerable for patients by reducing anxiety and by providing a degree of intraoperative amnesia. During longer surgical procedures, patients may become restless, bored, or uncomfortable from remaining immobile, and sedative-hypnotic drugs may be beneficial in allowing patients to rest. [260] Patients' anxiety may also be substantially reduced by simple measures, including good preoperative communication, keeping the patient warm and covered, and allowing the patient to listen to music during the procedure. [261] Many different sedative drugs have been used during monitored anesthesia care procedures (including barbiturates, benzodiazepines, ketamine, and propofol) using different delivery systems (e.g., intermittent boluses, variable-rate infusion, target-controlled infusion, patient-controlled sedation). [262] [263] The most commonly used sedative drugs are midazolam and propofol, either alone or in combination. [264] [265] [266] However, the careful titration of these agents to achieve the desired level of sedation and to ensure prompt recovery is more important than the choice of the drug. [258]

SPECIAL CONSIDERATIONS

Office-Based Anesthesia

Office-based anesthesia is a variant of ambulatory anesthesia, which has attracted growing interest for short surgical procedures. It is currently estimated that 3 to 5 percent of outpatient surgical procedures are performed in the office setting, and this number is anticipated to be at least 15 percent by the year 2000. [267] As efforts to reduce the overall cost of surgical procedures continue to increase, surgeons and anesthesiologists are moving cases to facilities where they have more direct control over costs. Because office-based facilities have lower overhead than hospital or freestanding ambulatory surgical centers and are comfortable and convenient for patients, interest in office-based surgery centers continues to grow. It is important to select patients appropriately and to adhere to the usual guidelines for safe anesthetic care (Appendix 1). The optimal anesthetic techniques for office-based surgical procedures are not known. The effect of nitrous oxide with propofol anesthesia was studied in outpatients having short procedures in an office setting. [268] Nitrous oxide was shown to decrease the propofol requirements and to allow patients to be discharged within 30 minutes after the procedure without increasing the incidence of PONV. The availability of newer anesthetics associated with a faster emergence as well as improved surgical technology should facilitate the growth of office-based anesthesia in the future.

Although the practice of office-based anesthesia is relatively new in the United States, a similar practice of office-based dental anesthesia has been in place for several decades in the United Kingdom. Following a review of several anesthetic deaths in dental offices, it was recommended that all anesthetics be administered by an accredited anesthesiologist whose training included specific experience in dental anesthesia. [269] There were also recommendations regarding resuscitation equipment and the availability of drugs needed for emergency use. In the years following publication the Poswillo report, the number of dental offices offering general anesthesia for office-based procedures significantly decreased. [270] The high cost required to equip and maintain such locations was the main reason for this change of practice in the United Kingdom. Based on the British experience, it is obvious that if office-based anesthesia is going to be successful in North America, issues other than cost must be considered.

Anesthesia for Procedures Outside the Operating Room

Anesthesiologists are being called upon to provide anesthetic care for an increasing number of procedures in remote locations (Ch. 66) . The most common of these are electroconvulsive therapy (ECT), extracorpeal shock wave lithotripsy (ESWL), and neuroradiologic procedures including magnetic resonance imaging (MRI) and computed tomography (CT). The anesthetic machines and monitors used in these locations are frequently old or unfamiliar models, and the monitoring equipment and supplies are often limited. Experienced assistants may be unavailable, and nursing staff members in these locations are frequently unaccustomed

to the anesthetic equipment or procedures. Consequently, the anesthesiologist must be vigilant when checking the anesthetic machine and must know where to locate emergency resuscitation drugs and equipment.

As with any ambulatory surgical procedure, patients must be carefully selected and evaluated prior to the procedure. The anesthetic techniques used for these procedures should provide for a prompt recovery with minimal side effects. Patients undergoing general anesthesia, regional anesthesia, or monitored anesthesia care must fulfill the same discharge criteria as patients having procedures in an operating room facility.

Many of these procedures have specific anesthetic considerations and potential complications, which may require careful management. The anesthetic techniques used for ESWL have changed dramatically over the past several years. With the development of new-generation lithotriptors, a water bath may no longer be required, and the targeting is more precise so fewer shocks are required. These improvements have essentially eliminated the routine use of general or regional anesthesia, and most of these procedures can be performed with intravenous sedation and analgesia techniques. [271] [272] Intercostal nerve blocks may improve patient comfort during ESWL. [255] However, the topical use of eutectic mixture of local anesthetics (Emla cream) did not have a significant opioid-sparing effect during immersion lithotripsy. [273]

The use of ECT is expanding, particularly in the elderly population, in whom antipsychotic drug therapy is poorly tolerated because of side effects. Because the clinical efficacy of ECT depends on the duration of the seizure, the anesthetic drug that allows for the longest seizure is preferred. The effects of methohexital, propofol, and etomidate on seizure duration have been compared. [274] Both methohexital and propofol produce dose-dependent decreases in motor and electroencephalographic seizure duration compared with etomidate. The awakening times and recovery profiles were similar in all groups. The administration of adjuvant medications may be necessary to blunt the hypertensive response to electrical stimulation. The use of beta-blockers (e.g., labetalol, esmolol) is usually adequate to control the acute hyperdynamic response following the electrical stimulus. In hypertensive patients, nicardipine (1.25-2.5 mg IV) may be a useful adjunct to the beta-blocking drugs. [275]

DISCHARGE CRITERIA

There are three stages of recovery following ambulatory surgery, namely, early, intermediate, and late (Ch. 68) . Early and intermediate recovery stages occur in the ambulatory surgical facility, whereas late recovery refers to the resumption of normal daily activities and occurs after discharge. Early recovery is the time interval during which patients emerge from anesthesia, recover their protective reflexes, and resume motor activity. During this phase of recovery, patients are cared for in a phase I postanesthesia care unit (PACU), where their vital signs and oxygen saturation are carefully monitored and supplemental oxygen, analgesics, or antiemetics may be administered. The Aldrete score is commonly used to assess the fitness of patients to be transferred to the phase II recovery area (or to a hospital bed in the case of hospital inpatients). [276]

During the intermediate recovery period, patients are cared for in a reclining chair and progressively begin to ambulate, drink fluids, void, and prepare for discharge. Most ambulatory surgical facilities have a separate phase II recovery area for the intermediate recovery of outpatients to a home-ready state (see Fig. 65-1) (Figure Not Available) . The choice of anesthetic technique as well as postoperative analgesic and antiemetic drugs may have an impact on the duration of the intermediate recovery period. A prolonged early and intermediate recovery will significantly increase the cost of the patient's operation. [277] The late recovery period starts when the patient is discharged home and continues until full, functional recovery is achieved and the patient is able to return to work. The anesthetics, analgesics, and antiemetics may have an effect on the patient's recovery during the first 24 to 48 hours. However, the surgical procedure itself has the highest impact on the patient's full functional recovery.

"Fast Tracking" After Ambulatory Surgery

The availability of rapid and short-acting anesthetic drugs for the maintenance of general anesthesia (e.g., propofol, desflurane, and sevoflurane) has facilitated the early recovery of outpatients after ambulatory surgical procedures. [278] Patients may be completely awake and oriented, breathing comfortably, with stable vital signs at the time they leave the operating room after brief ambulatory surgical procedures performed using general anesthesia. A faster early recovery may not necessarily correlate with a reduction of overall costs because the major determinant of PACU costs is personnel. [279] [280] However, significant cost savings may be achieved by bypassing the PACU and transferring patients directly to a more economical phase II (step-down) recovery area. There is a growing interest in this process known as "fast tracking" after ambulatory surgery. [281]

A newer study examined the effects of three maintenance anesthetics (propofol, desflurane, and sevoflurane) on the fast-track eligibility of outpatients after laparoscopic tubal ligation. [282] Compared with propofol, desflurane and sevoflurane caused a higher percentage of outpatients to be judged fast-track eligible (89 and 75% versus 26%). There was no evidence of respiratory depression with any of the anesthetic techniques. Further outcome studies are needed to ensure patient safety before widespread implementation of fast tracking after ambulatory surgery can be recommended.

Assessment of Home-Readiness

Guidelines for safe discharge from an ambulatory surgical facility include stable vital signs, return to baseline orientation, ambulation without dizziness, minimal pain and PONV, and minimal bleeding at the surgical site. [31] The major accreditation bodies in the United States and Canada require that all ambulatory surgical patients have an escort to transport them home, and they must receive written postoperative instructions including advice on whom to contact in case

a problem develops. A discharge scoring system has been developed to evaluate and document patient's readiness for discharge objectively. [283] [284] The Post-Anesthetic Discharge Scoring System (PADSS) is a simple cumulative index that measures patient's home-readiness and is based on five major criteria: (1) vital signs, including blood pressure, heart rate, respiratory rate, and temperature; (2) ambulation and mental status; (3) pain and PONV; (4) surgical bleeding; (5) fluid intake/output. [283] Patients achieving a score of 9 or greater and have an adult escort are considered fit for discharge. The requirement for patients to drink and to void prior to discharge may not be necessary. A modified PADSS score was developed that eliminated input and output as discharge criteria and resulted in earlier discharge for 20 percent of patients (Table 65-12) (Table Not Available) . [31]

Delays in discharge are typically related to persistent symptoms such as pain, PONV, hypotension, dizziness, unsteady gait, or, frequently, the lack of an escort. [285] Excessive postoperative pain is a common surgery-related cause of delayed discharge from ambulatory surgical facilities and of unexpected hospital admission of outpatients. [286] One prospective study of 10,008 ambulatory surgical patients found a 5.3 percent incidence of severe pain in the PACU after ambulatory surgery. [287] Outpatients with severe postoperative pain often had more prolonged surgical procedures, a longer stay in the PACU and step-down unit, and a longer time to discharge compared with patients without severe pain. Outpatients undergoing orthopedic surgery had the highest incidence of pain (16.1%) followed by urologic (13.4%) and general surgical procedures (11.5%). The ability to identify outpatients at risk for severe postoperative pain allows the anesthesiologist to formulate an appropriate prophylactic analgesic plan.

Discharge After Regional Anesthesia

Patients recovering from regional anesthesia must meet the same discharge criteria as patients recovering from general

TABLE 65-12 -- Modified Postanesthesia Discharge Scoring System

(Not Available)

From Chung, [31] copyright 1993, with permission of Elsevier Science

anesthesia. However, these outpatients must also fulfill additional criteria to ensure safe ambulation after central neuroaxis blockade. With spinal or epidural anesthesia, it is generally accepted that motor and sensory function return before sympathetic nerve function. [243] Residual blockade of the sympathetic nerve supply to the bladder and urethra may cause urinary retention. Because it is necessary after ambulatory regional anesthesia for patients to be able to void, long-acting local anesthetics (e.g., bupivacaine, tetracaine) should be avoided. [238] The use of shorter-acting local anesthetics (e.g., lidocaine) with the addition of fentanyl can provide adequate anesthesia without prolonging recovery. [239] [240] Prior to ambulation, patients should have normal perianal (S4-S5) sensation, the ability to plantarflex the foot, and proprioception of the big toe. [243] Thus, discharge criteria after spinal and epidural anesthesia should include the return of normal sensation, muscle strength, and proprioception, as well as the return of sympathetic nervous function.

Controversies Related to Discharge Criteria

There is considerable controversy surrounding the requirement for all outpatients to drink fluids and void prior to discharge from an ambulatory surgical facility. It is clearly unacceptable to discharge a patient who is actively vomiting and unable to tolerate oral fluids. However, Schreiner and Nicolson [119] found that requiring children to drink prior to discharge increased the rate of vomiting by more than 50 percent and delayed discharge. Children are more likely to vomit after discharge than during their stay at the surgical facility, and, therefore, tolerating clear fluids prior to discharge does prevent vomiting and dehydration at home. At the Children's Hospital of Philadelphia, more than 20,000 day-surgery patients have been discharged without requiring intake of oral fluids with no readmissions for dehydration. [119] All patients (except those having myringotomy tubes placed) received the equivalent of 8 hours of intravenous maintenance fluids during their hospital stay. Thus, wellhydrated outpatients have been discharged home safely without necessarily demonstrating an ability to tolerate oral fluids.

The requirement to void prior to discharge is also controversial. The inability to void and urinary retention may be caused by pain (which inhibits normal bladder detrusor function), administration of drugs with anticholinergic effects, or prolonged blockade of the autonomic innervation to the bladder. [31] Patients may be discharged earlier if voiding is not a discharge requirement; however, there must be appropriate measures in place if the inability to void persists after discharge. [284]

Prior to leaving the outpatient facility, patients should have their dressings checked and should be given both verbal and written instructions regarding their postoperative care. Most postoperative symptoms (e.g., pain, PONV, dizziness, headache, and myalgias) resolve within 24 hours. However, if these symptoms persist, the patient should be encouraged to contact the facility regarding appropriate follow-up care. All patients must leave in the company of a responsible adult and must be aware of the recommendations

regarding appropriate activities after discharge. Patients should be warned not to operate machinery, drive a car, or make important decisions for at least 24 hours following outpatient anesthesia. [288]

It is important to have an efficient mechanism in place for admitting outpatients to the hospital. Most well-organized outpatient facilities have an overall hospital admission rate of less than 1 percent. [10] [14] However, transfer rates are higher in ambulatory centers with a larger proportion of neonates, the elderly, and ASA physical status III outpatients. The Federated Ambulatory Surgery Association multicenter study showed that 69 percent of all perioperative complications occurred after discharge from the ambulatory surgery center. [14] This finding emphasizes the importance of providing clear, written discharge instructions and the availability of a responsible adult to monitor the patient at home. Most practitioners recommend that out-of-town patients spend their first postoperative night within a reasonable distance from the outpatient facility. All outpatient facilities should have a mechanism in place for collecting follow-up information regarding patient well-being after discharge. For example, nurses at many outpatient facilities telephone the patient the day after discharge to determine the progress of recovery from surgery and anesthesia, whereas other facilities use postcard questionnaires for postoperative follow-up.

OUTCOME MEASURES AFTER OUTPATIENT SURGERY

As outpatient surgery continues to grow and the types of surgical procedures become more complex, ambulatory surgical centers must develop methods to evaluate patient outcome during both early and late recovery periods (Chs. 21 and 22) . [289] The overall risk of major morbidity and mortality is very low following ambulatory surgery. A large, retrospective study of more than 45,000 ASA I to III outpatients found that only 31 patients (1:1455) experienced major morbidity. [9] Four patients died, 2 as passengers in automobile accidents within the first 48 hours and 2 of myocardial infarctions more than 48 hours after surgery. The Federated Ambulatory Surgery Association performed a multicenter study in 1987 that found an increased risk of perioperative complications in patients who had preexisting cardiovascular diseases and after procedures with a duration longer than 1 hour (Table 65-13) (Table Not Available) . [14] A similar Canadian 4-center prospective study of 6,914 outpatients showed that patients with underlying medical conditions (e.g., hypertension, diabetes, and gastrointestinal disorders) were at higher risk for adverse events in the perioperative period, even if they were optimally managed preoperatively. [290] There were no deaths during the study period, and major morbid events were rare.

Although there is a low incidence of major morbidity, minor complications remain problematic after ambulatory surgery. PONV remains a "big little problem." [291] One study showed that 35 percent of outpatients discharged from ambulatory surgical centers experienced PONV severe enough to prevent their return to normal daily activities. [292] Most of these patients had not experienced PONV in the recovery room and only became symptomatic several hours after discharge.

TABLE 65-13 -- Predisposing Factors to Complications During and After Outpatient Anesthesia

(Not Available)

From Federated Ambulatory Surgery Association [14]

Other postoperative symptoms may persist for more than 24 hours after outpatient surgery. Incisional pain, PONV, drowsiness, dizziness, headache, and fever are the most frequent minor symptoms that occur after patients are discharged home. [293] The type of surgical procedure also influences the incidence of symptoms, with laparoscopic, general, and orthopedic surgical procedures having a high incidence and dilatation and curettage and ophthalmologic procedures having a low incidence of postoperative symptoms. As with PONV, patients experiencing other postoperative symptoms had a delay in returning to their usual daily activities compared with a similar population not experiencing postoperative symptoms. Despite the frequent occurrence of minor sequelae of ambulatory surgery, there is remarkably high patient satisfaction, and most would choose to have their surgery on an outpatient basis in the future. [8]

Unexpected hospital admission following outpatient surgery is an easily identifiable and important outcome measure in ambulatory anesthesia. Not only does hospital admission add to the expense of the procedure, but also it is disruptive for the patient and the surgical facility. Most facilities have admission rates of less than 1 percent. [10] [11] However, freestanding and office-based units tend to have lower transfer rates compared with hospital-based units. This may reflect the relative ease of admission of the latter or possibly a difference in the criteria for patient and procedure selection. [11] The most common causes for unexpected admission are pain, bleeding, intractable vomiting, surgical misadventure (e.g., bowel or uterine perforation), more extensive surgery, urinary retention, or lack of an escort. [10]

The likelihood of admission is related more to the type of anesthesia and surgical procedure than to specific patient characteristics. The frequency of return hospital visits after discharge from ambulatory units is another useful outcome measure. One published study found that 3 percent of patients returned to the same hospital after discharge following ambulatory surgery. [12] Bleeding at the surgical site was

the most common reason (41.5%) for patients to seek medical attention and occurred with greatest frequency after dilatation and curettage. Patients undergoing varicocelectomy and hydrocelectomy were eight times more likely to return to hospital and most commonly were diagnosed with an infection at the surgical site. Most outpatients (76.5%) who sought medical attention in the emergency room were treated and discharged, a finding indicating that better preoperative and postoperative education may have prevented an unnecessary hospital visit.

SUMMARY

Ambulatory anesthesia is continuing to evolve and has now become a recognized anesthesia subspecialty with formal postgraduate training programs. It is clear that the number of operations performed on an outpatient basis will continue to expand in the 21st century. Increasing evidence suggests that arbitrary limits placed on the type of surgery, the age of the patient, the duration of the operation, and the preoperative fasting period may be unwarranted. The ability to provide adequate pain management following outpatient surgery has become a major limiting factor in determining the types of operative procedures that can be performed in this setting. The expansion of home health-care services creates the potential for newer analgesic modalities to be used in the home (e.g., ambulatory patient-controlled analgesia, nonpharmacologic techniques).

Many controversies remain unresolved. [163] Questions regarding the optimal anesthetic technique, airway management device, need for prophylactic antiemetics, and type of postoperative pain management remain to be answered. With growing limitations on health-care resources, anesthesiologists must carefully reevaluate clinical practice. The focus in future studies of new anesthetic drugs should emphasize overall cost-effectiveness, as well as quality of patient care and improvement in outcome.

In conclusion, the rational use of combinations of anesthetic drugs will provide for rapid and smooth induction, excellent intraoperative conditions, and fast recovery with minimal adverse effects. The incidence of anesthetic-related side effects may be altered depending on the premedication, the anesthetic technique, and the skill of the anesthesiologist. Further studies are needed to determine the origin of the adverse effects caused by anesthesia and surgery, as well as the optimal therapeutic modalities. With the availability of more rapid-acting and shorter-acting anesthetic, analgesic, and muscle relaxant drugs as well as improved administration and monitoring techniques, and highly specific intravenous adjunctive drugs, anesthetic care will continue to improve into the next century.

Chapter 66 - Anesthesia at Remote Locations *

Ronald A. Mackenzie
Peter A. Southorn
Paul E. Stensrud

INTRODUCTION

When called on to provide care to patients undergoing diagnostic or therapeutic procedures outside the surgical or obstetric suites, anesthesiologists should strive to maintain their high standards of anesthesia care. [1] The anesthetic implications of the patient's medical condition do not vary with anesthetizing location, but the logistics in providing anesthesia services frequently differ. Physical constraints imposed by the environment, different paramedical personnel, and often a lack of the full array of monitoring and equipment available in the surgical suite challenge the anesthesiologist to tailor provision of anesthesia services to the special requirements posed by the situation.

Standards have been developed by the Harvard Medical School for anesthetizing in locations outside the operating rooms. [2] The American Society of Anesthesiologists (ASA) 1994 Guidelines For Nonoperating Room Anesthetizing Locations include recommendations for (1) oxygen source, (2) suction, (3) scavenging, (4) necessary equipment, drugs, and monitors, (5) electrical outlets, (6) illumination, (7) space, (8) emergency equipment, (9) communications, and (10) building and safety codes. [3]

Monitoring

Appropriate patient monitoring is a universal requirement (Chs. 28 to 37) . The ASA standards for basic anesthetic monitoring (originally published in 1986 and updated in 1996) [4] require the following: (1) the continuous presence of qualified anesthesia personnel in an anesthetizing location throughout the conduct of all anesthetic regimens; and (2) during all anesthetic regimens, patients' oxygenation, ventilation, circulation, and temperature must be continually evaluated. Oxygenation should be measured by monitoring inspired oxygen and pulse oximetry. [5] Adequacy of ventilation should be evaluated by clinical examination and expired gas analysis, endotracheal tube positioning must be verified, and disconnection alarms must be used with mechanical ventilators. Circulation should be evaluated by continuous display of the electrocardiogram (ECG) and by frequent determination of arterial blood pressure and heart rate and other measurements (e.g., auscultation of heart sounds). In addition, there should be readily available a means to measure the patient's temperature continuously.

---

* *See Appendix 1, Practice Guidelines for Sedation and Analgesia by Non-Anesthesiologists*

Facilities and Equipment

Potential problems for the anesthesiologist providing care for patients in remote locations can be due to the physical layout of the facility, to unfamiliar or outdated anesthesia equipment, to the anesthetic implications of the procedure performed, to working with personnel who are less familiar with the anesthetic aspects of patient care in these settings, and to the remoteness from available help. [6] [7] [8]

Delivery of anesthetic care for diagnostic or therapeutic procedures in a room not originally designed for such work frequently means that access to the patient may be compromised by diagnostic or therapeutic equipment (e.g., x-ray tubes, C-arms, angiographic equipment, extracorporeal lithotripter) (Figs. 66-1 and 66-2) . Achieving and maintaining adequate access to the patient, anesthesia equipment, and monitors often require advance planning.

Piped-in gases, suction, and isolated power or grounded plugs are not always available. Electrical equipment posing an increased risk to the patient or electrical interference with monitors frequently is present. Lack of an isolated power system mandates proper grounding of electrical equipment. Since 1962, the National Electrical Code requires installation of three-contact grounding-type electrical receptacles in new construction. Retrofitting of outlets in existing buildings, however, was not required. Patient and personnel safety dictates that grounding of electrical equipment via three-wire cords, three-pronged plugs, and grounded three-contact outlets be a minimum requirement in anesthetizing locations.

Anesthesia personnel used to working with anesthesia machines supplied by piped-in gases need to maintain familiarity with gas cylinder-supplied machines. Proper function of the anesthetic machine and the availability of an adequate supply of gas cylinders must be confirmed prior to beginning the anesthetic administration. Older anesthesia machines with features that do not meet recent standards for new machines may have been relegated to the remote area; anesthesia personnel need to be familiar with all equipment prior to its use. A mechanism to prevent contamination of one calibrated vaporizer by the output from another vaporizer

Figure 66-1 The surgeon and radiotherapist align the operative site and accelerator port prior to treatment. Bulky equipment and the sterile field restrict the anesthesiologist's access to the patient.

Figure 66-2 Anesthetized patient undergoing magnetic resonance imaging. Another example of limited accessibility to the patient.

is required. An oxygen analyzer is required by Joint Commission on Accreditation of Healthcare Organizations (JCAHO) standards. The oxygen flush valve must have only one function and cannot be integrated with a vaporizer on/off valve. The practice of using obsolete equipment in remote locations is to be condemned. [9]

Personnel

Nonanesthesia personnel involved in the care of patients in areas remote from the operating suite may be less familiar with the overall management of anesthetized patients than are their counterparts who work in surgical or obstetric suites. This lack of familiarity, combined with geographic remoteness from the surgical suite, may mean that less ancillary help will be available to the anesthesiologist. Education programs for these nonanesthesia personnel regarding care of anesthetized patients are both beneficial and appreciated. The presence of an adequate number of fully trained anesthesia personnel is vital.

Medications

Monitored anesthesia care (MAC) (incorporating the usual noninvasive hemodynamic and respiratory monitoring, oxygen administration as indicated, intravenous sedation/analgesia in adults, and oral, intramuscular, intravenous, or rectal administration of sedatives/analgesics in children) or general anesthesia may be required. [10] Benzodiazepines and opioids frequently are used for intravenous sedation and analgesia in patients receiving MAC for diagnostic or therapeutic procedures. Midazolam's advantages of water solubility, minimal discomfort on intravenous injection, comparable effects on cerebral metabolism and blood flow, shorter half-life, and lack of active metabolites have rendered it preferable to diazepam. In doses generally used, midazolam usually does not produce significant cardiovascular

depression. Midazolam dosage requirements are reduced

in older patients. [11] Midazolam is associated with a depression of the central respiratory drive that is related to both dose and rate of administration. [12] In analgesic doses, fentanyl has minimal cardiovascular effects, even in patients with compromised left ventricular function. [13] The combination of fentanyl and a benzodiazepine, however, can produce cardiovascular depression. [14]

Opioids that stimulate mu receptors cause a dose-dependent depression of the ventilatory response to CO_2 by a direct effect on medullary respiratory centers. [15] Analgesic doses of fentanyl (e.g., 2 mug/kg) can result in respiratory depression that peaks at approximately 5 to 10 minutes after injection and can last longer than the analgesic effect. Higher doses of fentanyl can result in chest wall rigidity.

Evaluation of the patient's respiratory status throughout the procedure and during the recovery period is essential. A methodology for this evaluation was described in the ASA practice guidelines for sedation and analgesia by nonanesthesiologists (Table 66-1) (Table Not Available) . [16] Both during the procedure and in the recovery period, patients are asked to respond verbally to a series of questions, are encouraged to take a deep breath periodically, and are monitored with a pulse oximeter. Respiratory depression usually can be avoided by following these guidelines.

The assistance of the anesthesiologist frequently is sought when verbal reassurance and sedation administered by the radiology team have failed. [17] Midazolam (0.5 mg/kg), in concentrated grape-flavored Kool-Aid (with sugar added to counter the bitter taste) given orally 30 minutes prior to the procedure, can be an effective sedative for small children. Ketamine can be administered by a variety of routes: intramuscular, intravenous, rectal, [18] or oral. [19] [20] Propofol has become a popular intravenous anesthetic for use in remote areas. [21] [22] [23] Tachyphylaxis to propofol [24] and ketamine [25] has been reported.

Rectal administration of thiopental or methohexital can be used to sedate children [7] [26] (Ch. 59) . Prolonged sedation for up to 2 to 3 hours can follow rectal administration of barbiturates. Rectal mucosal injury can occur with this technique, and proctitis and colitis have been reported following repeated use of rectal thiopental in some children [27] (e.g., children who require repeated therapeutic radiation sessions). General anesthesia may be preferable to sedation in certain patients (e.g., infants and mentally impaired adults.)

Modified from the American Society of Anesthesiologists [16]

[a] This is a summary of the guidelines. The body of the document should be consulted for complete details.

Patient Transport and Postanesthesia Care

The patient's medical condition should be stable before initiating transport (Ch. 68) . In some situations, it may be preferable to keep the patient sedated or anesthetized during transport and then recover him or her in the postanesthesia care unit (PACU) or other recovery area. The anesthesiologist responsible for the patient's welfare during transport should be accompanied by an assistant responsible for moving the transport cart.

During transportation to the PACU following the procedure, appropriate monitoring related to the patient's anesthetic management and medical condition should be continued. Following general anesthesia, such monitoring includes arterial blood pressure, heart rate, ECG, and pulse oximetry. A transport stretcher that has facilities for supplying supplemental oxygen and appropriate resuscitative drugs and equipment for airway management is useful (Fig. 66-3) . For patients with significant cardiovascular disease who are being transported to or from remote anesthetizing areas, the transport stretcher also should include a portable defibrillator. Following monitored anesthesia care, a transport stretcher with those components appropriate for the patient's medical condition is used. The importance of monitoring oxygen saturation and providing supplemental oxygen

Figure 66-3 A transport stretcher with oxygen tanks, a self-inflating bag with valve for ventilating the patient, an electrocardiographic/hemodynamic monitor, a pulse oximeter, an intravenous pole, and brackets for strain gauges and flush bag. To this type of cart can be added infusion pumps, a defibrillator, equipment for chest compression, medication storage, and other essential equipment and supplies.

as indicated in both children and adults has been well documented. [28] [29] [30] [31] [32]

RADIOLOGY SUITE

Technical advances in radiologic imaging in the last few years and, in particular, the realization of the full potential of ultrasound, computed tomography (CT), and magnetic resonance imaging (MRI) have both dramatically improved the ability to detect and diagnose disease and increased the demand for this expertise. These developments go hand in hand with the greater use of minimally invasive surgery and demands to control health-care costs. They have also opened new diagnostic and therapeutic options. For example, it has become possible for radiologists, using their imaging techniques, to place biopsy needles precisely in various organs to obtain tissue for pathologic diagnosis. Even more recently, two other important types of interventional radiology have evolved. Cancer treatment may be revolutionized by one of these techniques, percutaneous ultrasound-guided tissue ablation. [33] In the other field, interventional neuroradiology, high-speed digital subtraction angiography is used to guide endovascular treatment of various life-threatening, sometimes inoperable, cerebrovascular lesions. [34] This realization of the potential for radiology, together with these advances, has increased the need for the anesthesiologist's involvement in the radiology suite, both to provide general anesthesia and to advise and assist management of patients who need to be sedated during examinations.

General Considerations

In both diagnostic and therapeutic radiology procedures, patients must often remain immobile for long periods. For many studies, radiologists ideally require patient cooperation, but in numerous instances this may not be possible, such as when studies are performed in obtunded individuals, in those with seizures or tremors, and in children too young to understand. Patients also may not be able to tolerate the procedure by virtue of anxiety, claustrophobia, or confused mental status. Certain aspects of these procedures, for example, inserting needles, urinary catheterization, and the discomfort associated with injection of contrast dye also can affect the patient's ability to cooperate and to lie still.

The anesthesia provider called on to sedate or anesthetize patients in the radiology suite confronts several problems in addition to those found when managing patients in other locations outside the operating room. It is unfortunate that, to date, many radiology studies have been regarded as minor procedures in which anesthesia and sedation, if required, can be given with little risk. This clearly is not the case, particularly in those patients who are a poor anesthetic risk because of their age or coexisting medical conditions such as coronary artery disease, respiratory disease, diabetes, and obesity. In addition to the patient's comorbid conditions, often he or she has already been sedated by the radiologist, but this has not produced the desired effect of immobilizing the patient. These patients also may have received oral contrast media that places them at risk of aspiration when their

airway reflexes are impaired. The work environment in the radiology suite confronting the anesthesiologist often is ill adapted to safe care of patients, particularly in older facilities. Radiology rooms tend to be crowded, the presence of bulky radiology equipment impedes patient access, and poor lighting combined with other impediments to monitoring the patient such as are found in the MRI suite can all potentially adversely affect the delivery of anesthesia care. The patient is often deliberately moved during the radiologic examination, a factor that can, unless carefully guarded against, cause dislodgement or obstruction of airway devices and loss of monitoring capability or vascular access. Given the use of high-voltage equipment, there is a risk that leakage current will be conducted down electrically conductive leads used for monitoring the patient. Finally, it is also worth noting that many radiology suites have poor air circulation, and effective scavenging of waste anesthetic gases in them is difficult.

A unique hazard encountered in the radiology suite is radiation exposure. This is potentially harmful, both in terms of its somatic effects during a person's lifetime (e.g., producing leukemia) and in causing genetic injury resulting in fetal abnormality due to damage to the gonadal cells. Although it has been found that anesthesia personnel working in the operating room do not face a significant radiation danger, [35] this may not be the case when working in the cardiac catheterization, CT, and interventional radiology suites. In these latter environments, anesthesia personnel should take precautions to avoid such exposure from the radiation source and that scattered from the patient and should monitor this exposure by wearing dosimeters. The maximum permissible radiation dose for occupationally exposed persons is 50 milliSieverts (mSv) annually, 10 mSv × age lifetime cumulative dose, and 0.5 mSv monthly exposure for pregnant women. [36] Radiation exposure can be reduced by wearing appropriate lead aprons and thyroid shields, employing movable lead-lined glass screens, and innovative techniques to allow patient monitoring to be conducted remote from the patient's immediate contact, for example, with the use of microphones and closed-circuit television.

Administering safe anesthesia care in this environment is not to be undertaken lightly. Ideally, the anesthesiology department should be involved in planning for such care with the building of each new radiology suite. The safe delivery of anesthesia care requires not only employing trained and experienced anesthesia personnel, but also ensuring that the equipment for administering anesthesia and for monitoring and resuscitating the patient, if needed, are up to the standard used in the operating room.

Sedation Practices Used in the Radiology Suite

Sedation is frequently employed in various radiologic examinations to improve patient comfort, to allay anxiety, and to permit theprocedure to be performed while the patient remains immobile (Chs. 40 and 65) . Traditionally, anesthesiologists have rarely been involved in the provision of such sedation and have acted only in an advisory capacity. The altruistic goal of ensuring the maximum patient benefit without harm suggests that the special expertise of anesthesiologists should be employed in this activity. The JCAHO has mandated such involvement by our specialty. [37] [38]

Even though sedation during radiology procedures is a field of active ongoing study, with most modern potent intravenous anesthetics currently being evaluated, there is little consensus to date about the most appropriate sedation practice for a particular patient or procedure. Various gradations of sedation are described. The most common is "conscious sedation," a state in which a patient can respond appropriately to verbal command and other stimuli, can retain protective airway reflexes, and can independently maintain the airway. "Deep sedation" is a state in which the patient is not easily aroused, and airway reflexes and patency of the airway may be lost. Deep sedation appears to be more akin to general anesthesia. Currently, the most popular sedative used by radiologists for very young children remains chloral hydrate. Pentobarbital is commonly used for older children, and the benzodiazepines with or without fentanyl supplementation are first-line drugs used to sedate adults (Table 66-2) .

The American Academy of Pediatrics first published its comprehensive guidelines on the sedation and anesthesia of children in 1985. [39] Recommendations made included obtaining informed consent for sedation, employing NPO (nothing by mouth) standards prior to sedation, continuously observing the deeply sedated child, and monitoring and documenting vital signs. A large national study of sedation practices used for children undergoing CT examinations, however, revealed considerable variability in practice patterns among centers, with many of them not following these guidelines. [40] A survey of adults undergoing sedation for interventional radiologic procedures found similar variability in terms of the lack of universality in obtaining preoperative patient assessment and the lack of consistent availability of trained nursing staff to monitor the patient's welfare during sedation. [41]

Newer anesthetics, for example, propofol, are currently being examined for possible use in sedating patients undergoing

TABLE 66-2 -- Sedation Medication Guidelines

PATIENT AGE	DRUG	COMMENTS
<1 mo	--	Avoid sedation if possible
4 mo	Chloral hydrate PO	25-50 mg/kg
Older children/toddlers	Chloral hydrate PO	50-75 mg/kg (begin 50 mg/kg)
Children >12 mo	Pentobarbital IV	2-3 mg/kg over 1-2 min (repeat 10-15 min if needed, max 7 mg/kg)
Adults	Diazepam IV	2 mg/5 min (max 20 mg/max 10 mg with narcotics)
	Midazolam IV	1 mg (max 5 mg)
	Fentanyl	50-100 mug (max 200 mug)

As used in Radiology Department, Mayo Clinic, Rochester, Minn, 1997

radiologic procedures. [42] Such use was, however, criticized in a radiologic journal editorial because arterial oxyhemoglobin desaturation secondary to airway obstruction has been documented to occur occasionally in such studies. This situation is not necessarily managed optimally by the radiologist performing the imaging procedure, but rather it necessitates the presence of an individual trained in airway management. [43]

The Department of Anesthesia at Harvard Medical School has published its guidelines for sedation by nonanesthesiologists, [44] and recently, the American Society of Anesthesiologists Task Force on Sedation and Analgesia by Non-Anesthesiologists also published similar practice guidelines (see Table 66-1 (Table Not Available)). [16] These guidelines, together with the recommendations by the American Academy of Pediatrics, which were updated in 1992, [45] will be helpful to anesthesiologists seeking to counsel and assist their radiologic colleagues involved in the sedation of patients. Such involvement by anesthesiologists is now mandated by the JCAHO. This body considers sedation to be a component of anesthesia services and mandates that hospitals have training programs, policies and procedures, and monitoring systems for their safe provision, that there be collaboration between departments and services providing and supporting surgical and anesthesia services, and, finally, that the director of anesthesia has a specific responsibility to ensure the quality and appropriateness of anesthesia care provided by individuals in any department or service in the hospital. [37] [38]

Side Effects of Iodinated Contrast Media

The radiopacity of contrast media is based on their containing substances with a high atomic number to absorb x-rays. Soluble contrast media utilize iodine (atomic number 53) for this purpose. Side effects used to be common with the older, relatively toxic, ionized contrast media, in part because of their hyperosmolarity. [46] More recently, nonionized contrast media, which have a much lower osmolarity, have been increasingly utilized despite their higher cost. [47] [48] [49] [50] [51] The use of such agents is associated with a much lower incidence and severity of adverse side effects. Indeed, it has been suggested that their higher cost is offset by the reduced cost of managing the adverse reactions associated with the older agents. [47] Examples of the newer agents used in intravascular studies include iohexol, iopamidol, iopromide, and ioversol.

Adverse reactions encountered with these drugs comprise toxic, idiosyncratic, and allergic side effects. Their incidence and severity depend on which agent is used, the type of investigation performed, the total dose and speed of injection, and, importantly, patient susceptibility. Most organ systems can be affected, but cardiovascular and respiratory system adverse reactions are potentially of greatest risk (Table 66-3) . These reactions usually occur in the first 5 or 10 minutes following the injection of the contrast media. It is advisable, therefore, to keep the patient under close observation for 20 minutes following such an injection.

Minor cardiovascular complications include hypertension or hypotension, bradycardia, various arrhythmias, and serious life-threatening manifestations are hypotensive shock, ventricular fibrillation, and cardiac arrest. Disseminated intravascular coagulation can follow hypotensive shock. Most of these cardiotoxic adverse reactions respond to treatment if it is prompt. It has been suggested that such complications are more common in patients undergoing CT because these patients are inaccessible during this examination. [47] Respiratory complications include bronchospasm, which may be particularly induced in patients with preexisting asthma. Pulmonary edema has occurred, especially in patients with incipient cardiac failure. Adult respiratory distress syndrome is also reported. Hypotension induced by a contrast media reaction can render the patient unconscious, and convulsions have been reported in patients with a history of epilepsy. Nausea and vomiting are frequent antecedents of such severe complications. Diarrhea and various other manifestations affecting the gastrointestinal tract have also been reported. Renal failure is a well-documented association with the use of contrast media, particularly in patients with preexisting renal disease or other factors predisposing to renal failure; for example, diabetes, jaundice, severe cardiovascular disease associated with diminished renal blood flow, and multiple myeloma. [47] [52] In these particular patients, radiologic studies employing contrast media should, if possible, be avoided. If renal failure is induced in diabetic patients taking metformin, lactic acidosis could occur. It is recommended that this particular drug be withheld for 48 hours before performing a radiologic study employing contrast media. [53]

Patients who have experienced previous reactions to contrast material have a higher incidence of potentially severe repeat reactions if they are exposed to these agents again. This increased prevalence and severity can, in part, be reduced by pretreatment with prednisolone, 50 mg the night

TABLE 66-3 -- Reactions to Soluble Contrast Media

MILD	SEVERE	LIFE-THREATENING
Nausea, retching	Vomiting	Glottic edema/bronchospasm
Perception of warmth	Rigors	Pulmonary edema
Headache	Feeling faint	Life-threatening arrhythmias
Itchy skin rash	Chest pain	Cardiac arrest
Mild urticaria	Severe urticaria	Seizures/unconsciousness
	Bronchospasm, dyspnea	
	Chest pain	
	Abdominal pain/diarrhea	
	Arrhythmias	
	Renal failure	

before and the morning of the procedure, and diphenhydramine, 50 mg intravenously immediately before the procedure. [47] [54]

The mechanisms of these adverse drug reactions are often unclear. [47] [55] Some of the effects are immunologically based, but this is not universal. The treatments referred to earlier for patients who have previously experienced adverse reactions with these agents will reduce the frequency and severity of such reactions, but they will not necessarily eliminate the risk. When the reaction does occur, it is treated with intravenous steroids, oxygen as needed, and management directed at specific components of the patient's reaction. For example, shock and hypotension would be treated with fluid replacement and vasopressors. Clearly, all radiology suites

should have immediately available the medications and resuscitation equipment required to manage these reactions.

Magnetic Resonance Imaging

MRI can reveal subtle differences between areas of different anatomy, physiology, and pathology not possible with other imaging techniques. Other advantages include the following:

1. Unlike conventional x-rays and CT, MRI can obtain images in any plane (transverse, sagittal, coronal, or oblique).
2. It provides excellent soft tissue contrast (Fig. 66-4) .
3. It may provide intravascular contrast without the need for intravenous contrast media (Fig. 66-5) .
4. It requires very little patient preparation.
5. It does not produce ionizing radiation, is noninvasive, and does not in itself produce biologically deleterious effects.

Figure 66-4 Detailed soft tissue contrast of brain is possible with magnetic resonance imaging.

Figure 66-5 Cerebral angiogram obtained with magnetic resonance imaging.

Principles

Detailed discussions on the physics and technical aspects of MRI are addressed elsewhere. [56] [57] [58] Briefly, atomic nuclei with an odd number of protons or neutrons have the potential to act as magnetic dipoles. This property is possessed by all paramagnetic elements (^{1}H, ^{13}C, ^{19}F, ^{23}Na, and ^{31}P). In biologic tissues with their high water content, hydrogen, which contains a single proton, is the most important element in this context, and its detection is the basis of MRI. Outside a magnetic field, these hydrogen protons are oriented randomly and do not exhibit any net magnetic field. If, however, biologic tissue containing them is placed in a strong external magnetic field, some of the hydrogen protons will align themselves parallel or antiparallel to the applied magnetic field (like a compass), and the tissue itself will exhibit slight net magnetism. This tissue magnetism results from the nuclei that are aligned antiparallel to the external magnetic field, being in a slightly higher energy state than those aligned parallel to the field. This energy difference increases with the strength of the applied magnetic field. In MRI, tissue so magnetized by a powerful static magnetic field is suddenly also exposed transiently to a second magnetic field aligned perpendicular to this static field. This transient second magnetic field is generated by a pulse of radio frequency (RF) energy sent through an RF coil that

closely surrounds the patient. These events cause the tissue nuclei to flip away from their previous longitudinal alignment and into a higher energy state. When the transient RF pulse is subsequently terminated, the nuclei return to their original alignment and equilibrium in the static magnetic field and simultaneously induce a weak transient RF signal that is picked up by the RF coil, which now acts as a receiver. This energy release is related to the proton quantity, their chemical identity, and their relationship with surrounding tissue. The characteristics of the decay of the emergent signal, which is called "relaxation," provide most of the information for generating the MRI image. The latter is constructed with sophisticated computers that control the timing, strength, and sequencing of the RF pulse and also analyze the transmitted RF signal from the tissue.

The magnetic field strength employed in MRI scanners is measured in tesla units. One tesla unit equals 10,000 gauss, with the strength of the earth's magnetic field at its surface being between 0.5 and 1.0 gauss. Field strengths used in most clinically used MRI vary from 0.05 to 2.0 tesla, but the use of 3 tesla units is currently being studied. The advantage of weaker-field MRI scanners is that they allow better patient access, and the advantage of those with stronger fields is that they produce better image quality. Stronger-field MRI scanners usually employ cryogenic magnets with superconductivity coils operating in liquid helium (4° Kelvin).

Hydrogen proton density and relaxation dynamics as detected by MRI vary in different tissues, reflecting the tissue's physical and chemical properties. Because the differences in water content and proton environment in gray and white matter are greater than differences in electron densities as measured by CT, the MRI can produce better resolution between gray and white matter (see Fig. 66-4), and the same is also applicable to soft tissue examinations. MRI permits evaluation of blood flow (see Fig. 66-5), cerebral spinal fluid flow, contraction and relaxation of organs, and, because calcium does not emit a signal in the MRI, images of tissues surrounded by bone. This lack of a calcium signal, however, prevents MRI from detecting pathologic calcification in tumors of soft tissue and pathologic changes in cortical bone. [59]

The RF signal obtained during MRI scanning is of very low intensity and is subject to interference from stray high-frequency, electronic radiation (e.g., FM radio signals) and that arising from electronic equipment or monitoring devices. [56] For this reason, the scanning area is enclosed in the RF shield, which is incorporated usually into the fabric of the MRI imaging suite (Fig. 66-6) . Monitoring devices situated outside the monitoring field can conduct interference to the scanner unless appropriate filters are employed. Preventing interference from monitors situated within the RF field is often challenging, with attempts to overcome this problem made by using isolated power sources or battery power, filtering, and sometimes enclosing the monitor in its own small RF shield.

Limitations and Hazards

MRI scanning has a number of limitations and one major hazard. A relatively long time is required to obtain images; individual scans may take up to 20 minutes, and an entire examination may take more than 1 hour. Any patient movement

Figure 66-6 View of a magnetic resonance imaging scanner from control desk, showing the radio frequency shield in the window.

and that resulting from physiologic motion (e.g., cardiac and vascular flow pulsations, cerebrospinal fluid flow and pulsation, respiratory excursion, and peristalsis in the gastrointestinal tract) can produce artifacts. To optimize information when imaging the cardiovascular system, the signal acquisition is synchronized or "gated" with phases of the cardiac cycle (ECG R wave) in order to freeze cardiac motion. Anxiety and claustrophobia are experienced by some patients when they have to lie in the small-diameter, hollow bore of the magnet (typically 50-65 cm in diameter) and are exposed to the loud pulsing noises, caused by the switching on and off of the RF coils. Obese patients cannot be examined in this small magnetic bore. Heating due to RF energy of nonferromagnetic prosthetic devices has not proved to be a problem. [60] Body surfaces do absorb this RF energy, but it is unlikely that the patient's temperature will increase by more than 1°C.

The most significant risk posed to the patient and workers in the MRI scanning suite is the attraction of ferromagnetic objects to the magnet. [56] [59] [60] Such metallic objects (e.g., scissors, pens, keys, ferromagnetic stethoscopes, and oxygen cylinders) brought into the vicinity of the magnet can literally fly into it and may cause severe injury to the patient and bystanders. Dislodgement and malfunction of implanted biologic devices or other objects containing ferromagnetic material is also a real possibility. Such items include shrapnel, vascular clips and shunts, wire spiral endotracheal tubes, pacemakers, automatic implantable cardiac defibrillators, and implanted biologic pumps. Potential problems with cardiac pacemakers include possible reed switch closure or damage, pacemaker inhibition, or reversion to an asynchronous mode. Programming changes, torque on the pacemaker itself, or development of voltage across the pacemaker inhibiting its discharge may also occur. [57] Implanted automatic cardiac defibrillators may be deactivated. Patients with such devices should not undergo MRI examinations. Manufacturers of some biologic devices, for example, the clips used in vascular surgery and neurosurgery, are now trying to employ alloys that have low ferromagnetic properties and are safe in the MRI suite. Detailed lists of each manufacturer's implantable devices and their ferromagnetic properties

Figure 66-7 Patient screening form for magnetic resonance imaging.

have been published and should be consulted. [61] [62] A particular item from one manufacturer may be unsafe, whereas a similar product from another manufacturer may pose no danger to the patient in the MRI suite. Some eye makeup products and tattoos can cause artifacts in the scan, and some permanent eyeliners may produce eye irritation. Many departments have found it useful to develop a checklist to review with patients to ensure that they do not possess a potentially harmful metallic object that would make MRI scanning dangerous (Fig. 66-7) . [63]

Anesthetic Management

Patient acceptance is generally high. Most adults and small babies (if recently fed and well wrapped up) tolerate the procedure without sedation. Sedation may be required in older children and in adults who cannot cooperate. Such sedation is usually administered by the radiologists, nurses, and technical staff in the MRI suite. This generally works well, although, as previously discussed, concern has been expressed for the patient's safety in this situation. The likelihood that a child can undergo the examination successfully under such sedation is enhanced if he or she is sleep deprived for several hours the previous night. All patients receiving such sedation need supplemental oxygen and close monitoring. Anesthesia personnel become involved in these patients' care in the MRI suite when sedation fails, when it is impossible to control patient movement without general anesthesia, and when it is necessary to protect the patient's airway and to control ventilation, for example, in patients who are critically ill.

Several thoughtful reviews have been published regarding the anesthetic management of patients undergoing MRI. [64] [65] [66] [67] [68] [69] Anesthesia and monitoring in the MRI suite pose several unique problems. These include the following:

1. Limited patient access and visibility.
2. The need to exclude ferromagnetic components.
3. The interference/malfunction of monitoring equipment produced by the changing magnetic field and RF currents.
4. The potential degradation of the imaging caused by the stray RF currents produced by the monitoring equipment and leads.
5. The necessity to not move the anesthetic and monitoring equipment once the examination has started so as to prevent degradation of the magnetic field homogeneity.

To overcome these problems, ideally, anesthesiology departments called on to take care of patients in MRI suites should be involved in the suites' planning and construction. Satisfactory performance of the anesthetic and monitoring equipment and ensuring that this equipment does not interfere with the scanning need to be confirmed prior to clinical use. One solution adopted by some MRI units and their anesthesiologists is to keep the anesthetic and monitoring equipment outside the MRI suite. [69] The disadvantage of this approach includes the need for extralong monitoring leads, breathing tubing, and other connections to the patient with the risk of disconnection, and the need to have extra personnel resources simultaneously with the patient and with monitoring equipment. A more common approach is to induce anesthesia in the induction area adjacent to the MRI suite outside the magnetic field using conventional equipment with the patient on a stainless steel dedicated MRI transport table, which is nonferromagnetic (unlike the normal hospital cart). This transport table is used to bring the patient into the MRI suite, where anesthesia and monitoring are continued using MRI-compatible devices. This MRI transport table is also used to remove the patient rapidly from the scanner should an emergency arise. This is important because the ferromagnetic equipment employed for patient resuscitation by the code team and others cannot be brought into the MRI room.

Various techniques for modifying anesthesia machines, for identifying appropriate ventilators, using the Bain and other breathing circuits, and other measures to permit satisfactory equipment function and monitoring and avoid image degradation have been described. [64] [65] [66] [67] [68] [69] Locating this anesthetic and monitoring equipment beyond the 100-gauss line limits artifact and projectile risk. We have used custom-made, wall-mounted, and secured anesthetic machines equipped with pipe gases and suction located approximately 3 m from the scanner to anesthetize our patients (Fig. 66-8) . The fixed location of this machine permitted adjustment of the magnetic field when the magnet was brought on-line. Temperature-compensated specific-anesthetic vaporizers operate satisfactorily when exposed to a magnetic field. [70] We have also employed portable anesthetic machines that are constructed of nonmagnetic material, utilize aluminum gas cylinders, and have an MRI-compatible oxygen analyzer. Several manufacturers make these MRI-compatible anesthetic machines. Various breathing circuits have been used successfully in the MRI suite. They can be used to deliver breaths generated by a nonmagnetic pressure-generator mechanical ventilator or

Figure 66-8 Wall-mounted anesthesia machine, nonrebreathing bag and circuit, wall-mounted suction equipment, anesthesia storage cart with automatic blood-pressure measuring device, and pulse oximeter.

by manual inflation of an anesthesia bag. Because the patient's airway is not easily accessed during the MRI scan, many centers routinely intubate the anesthetized patient to control the airway. Other centers utilize a laryngeal mask for this purpose. Endotracheal tubes and laryngeal masks and the connections to the breathing circuit must contain no ferromagnetic material. Because conventional zinc batteries are strongly ferromagnetic, if a laryngoscope is needed in the MRI suite, it should be of plastic construction and equipped with lithium batteries and aluminum spacers.

Given the patient's inaccessibility in the MRI scanner and limitations of physical examination usually to only observing chest expansion and palpating the dorsalis pedis artery pulse, additional monitoring is essential (see Fig. 66-2) . In this environment, monitoring each physiologic parameter poses its own distinct unique problems, and in addition, there is a potential risk of patient burns resulting from current induction in the monitoring leads induced by oscillating RF fields. The latter risk can be minimized by removing any electrically conductive material from the magnetic core that is not required and by ensuring that leads are properly insulated, that they do not form loops within the magnetic core, and that they are separated from the patient's skin by thermal insulating padding. [64]

In general, cathode ray displays are distorted by magnetic fields, whereas those based on liquid crystal technology are

preserved. This is one modification employed by equipment manufacturers in designing monitoring equipment for use in the MRI environment.

Specific problems and solutions for monitoring each physiologic parameter in the MRI environment can be summarized as follows [64] :

1. ECG: Voltage induced by blood flow in the aorta when the patient is in a static magnetic field produces T- and ST-wave abnormalities. In addition, the rapid changing magnetic fields can induce artifacts in the ECG trace. Twisting the ECG leads and placing them as close as possible to the center of the magnetic field help to minimize the latter artifacts.
2. Pulse oximetry: This has proven very difficult to use. Technologies employed by manufacturers to address the problem include incorporating RF filters, ECG-locking facilities, and fiberoptic signal linking between the sensor and monitor.
3. Noninvasive blood pressure monitoring: This can be successfully accomplished, provided the metal connections of the blood pressure cuff and hoses are changed to plastic.
4. Precordial and esophageal stethoscopes: These do not function well because of the interference created by the noise of the scanner when it is in operation.
5. Capnography: This monitor usually functions satisfactorily, but the length of the sample tube may cause a significant time delay in signal transduction.
6. Temperature: This is not generally a problem if temperature probes employing RF filters are utilized.

It is prudent to test each monitoring device in the specific location and room where it is to be used to make sure that it functions appropriately. Magnetic field strength

and RF may vary between two supposedly identical MRI systems. It has been documented that one specific manufacturer's pulse oximeter functioned satisfactorily in one MRI room, whereas in another, supposedly identical adjacent room, it produced a significant artifact in the MRI image. This problem was subsequently shown to be due to differences in the RF employed by the two MRI systems. [71]

It is our practice to secure the patient's airway routinely with endotracheal intubation and to control ventilation mechanically. Although some centers permit the patient to breathe spontaneously, we believe that neuromuscular blockade and controlled ventilation are preferable, not only in terms of producing satisfactory gas exchange, but also in avoiding excessive head and neck movement that may interfere with the imaging process. Some patients benefit from sedative premedication prior to being anesthetized, but this may compromise seriously ill patients, including those who have increased intracranial pressure. Airway secretions cannot be removed during the examination, and when secretions are perceived to be a potential problem, glycopyrrolate can be administered to reduce the volume. The MRI examination is not painful, and we normally avoid nitrous oxide and excess opioids. Anesthesia is usually maintained with a volatile anesthetic, rather than an intravenous agent, given the potential problems associated with the use of drug infusion pumps in this environment. Following the procedure, the patient is transferred to an adjacent induction room and then is taken to the postoperative recovery room, where recovery from anesthesia can be closely monitored.

Computed Tomography

CT produces a two-dimensional, cross-sectional image by rotating an x-ray beam around the area of the patient's anatomy of interest. Each cross-section requires a few seconds of radiation exposure, and the typical scan comprises 20 such sections. Patient immobility is required during each exposure to produce a high-quality image, but the patient can move between sections, provided alignment with the imaging equipment is not changed. The x-ray tube and detectors are housed in a circular scanning tunnel in which the patient lies during the study. The scanning procedure is noisy, some heat is generated, and the patient can become claustrophobic and frightened. Although small children often sleep through an examination if they have been recently fed, older children commonly and some adults need to be sedated to tolerate this examination. As previously discussed, the administration of these sedatives and the care of the patient receiving them have not traditionally involved anesthesiologists.

CT is commonly used for diagnostic purposes, for example, to evaluate the status of a neoplastic process in the thorax or abdomen. It has proved valuable in studies of vascular malformations and tumors. Caregivers involved in imaging the patients undergoing this examination should be mindful that some patients have limited reserve because of their disease process, (e.g., compression of the upper airway or vena cava by a neoplastic process). The CT is occasionally also used for invasive therapeutic procedures instead of fluoroscopy, for example, for visualized drainage of a liver abscess. Contrast media are often used in conjunction with the CT to enhance the quality of the image. If contrast media are to be given into the gastrointestinal system in patients who are sedated or anesthetized, it is usually given via nasogastric tube. When the airway is not protected in this situation, there is a risk of aspiration. [40] It has also been suggested that there is a higher incidence of adverse sequelae associated with the use of contrast media in patients undergoing CT compared with other types of radiologic studies because of limited access to the patient and consequent compromised monitoring and treatment if reactions do occur. [47]

Many of the issues confronting anesthesiologists requested to anesthetize patients undergoing CT are similar to those previously identified as occurring in the MRI suite, such as inaccessibility of the patient and control of movement artifact. Monitoring interference is not a problem in CT, however. With anesthetized patients, care needs to be taken to ensure that the side walls of the scanning tunnel do not occlude or dislodge the breathing circuit or monitoring leads. Cautions need to be taken against ionizing radiation exposure that occurs during CT scans. The patient can be monitored visually through a lead glass window, supplemented if necessary by closed-circuit television.

Ultrasound-Guided Percutaneous Tissue Ablation

Percutaneous ethanol injection performed under ultrasound (or CT) guidance has become widely used in the treatment of early stages of hepatocellular carcinoma. [33] [72] [73] [74] For appropriate patients with this malignant disease, ablation by

injection of absolute alcohol into the tumor is associated with lower morbidity and mortality compared with surgery, can be performed at significantly lower costs, and has high patient acceptance.

The ideal patient has good liver function and a single neoplasm smaller than 3 cm in diameter. Now that experience has been gained, patients with multiple neoplasms or larger ones are also being treated. The procedure is usually performed on an outpatient basis with the patient fasted. Total calculated dose of absolute alcohol required to ablate the tumor is given in divided doses in two to three sessions over a 1-week period. This alcohol is injected into the tumor using 21- or 22-gauge spinal needles, which are sometimes modified to have multiple holes at their distal end. The procedure takes 20 minutes to perform, and the patient is kept under observation for 3 hours afterward. Injection of alcohol is associated with mild to moderate pain, probably because the alcohol tracks back into the peritoneum through the hole created by the needle. This discomfort can be effectively treated with sedation and analgesics. Some centers have started giving the total ablating dose of alcohol in one treatment session. [75] [76] Patients undergoing such single-session treatments are usually anesthetized because the larger ethanol injection is associated with significant pain. A conventional anesthetic regimen employing muscle relaxants, control of the airway, and mechanical ventilation has been found to be successful in this situation. During injection of the ethanol, periods of controlled apnea and respiratory standstill with partial pulmonary inflation are required.

Complications associated with this procedure are uncommon and are usually minor. They include the pain already mentioned, a fever lasting several days associated with destruction of the tumor, and acute alcohol intoxication. A severe persistent fall in blood pressure requiring vasopressor therapy has been occasionally documented with ethanol injection. [77] This is presumed usually due to systemic vasodilation induced by the alcohol metabolite, acetaldehyde acetate, and possibly direct alcohol-induced pulmonary vasoconstriction and negative inotropic effect. Intraperitoneal hemorrhage must also be considered in the differential diagnosis. Rarely, when the lesion is subdiaphragmatic, the pleural cavity has been entered and has resulted in pneumothorax, pleural hemorrhage, and pleural effusion.

Liver metastases are more common than hepatocellular carcinoma in the United States. Ethanol injection ablation is usually ineffective with such liver metastases because their firm texture prevents adequate perfusion of the ethanol in the neoplasm. [78] [79] Cryoablation has been used when patients cannot undergo surgical resection or receive adequate chemotherapy to treat such a metastasis. The relatively large size of the liquid nitrogen cryoprobes has limited this technique to the operating room. An alternative to cryoablation now being employed to treat these metastases in the radiology suite is RF ablation. In this technique, high-frequency alternating current is sent through an insulated electrode inserted through a percutaneously placed needle into the tumor. Patients need to be anesthetized for this treatment. A 5- to 10-minute electrocautery burn is employed that usually needs to be repeated once to complete the patient's treatment. The results of RF tissue ablation appear to be comparable to those of surgery, but it has the advantage of minimal side effects and easy repeatability if tumor recurs. [33] Percutaneously inserted ultrasound-guided laser therapy is another related technique that holds great promise for the future. In it, optical fibers are inserted through percutaneously placed needles to deliver lasers that cause photocoagulation by heating the tissue. Finally, ultrasound can also be used to guide the injection of substances, such as chemotherapeutic and immunochemical therapeutic agents, into the tumor. It is indeed possible that ultrasound-guided tissue ablation techniques will revolutionize cancer treatment in the future.

Because of its success in treating liver tumors, percutaneous ultrasound-guided ethanol injection has also been used to ablate hepatic and renal cysts, parathyroid adenomas, thyroid nodules, and ovarian cysts. [33] This imaging technology has been used to facilitate percutaneous neurolysis of the celiac plexus via the anterior approach in patients with malignancy or chronic pancreatitis. [80] [81]

Interventional Neuroradiology

Neuroradiologists and neurosurgeons are currently making rapid strides in employing an endovascular approach to treat various cerebrovascular disorders. [34] [82] [83] [84] [85] [86] [87] [88] [89] This advance has been made possible by the simultaneous development of new imaging technology, catheter systems that can gain access to the distal cerebral and spinal cord vasculatures through use of this imaging, [90] and the use of a variety of detachable balloons, coils, and other vascular embolic agents, therapeutic materials, and drugs that can be placed through these catheters. Many conditions for which there were formerly no effective therapies can now be managed using these techniques, either by themselves or as adjuncts to planned neurosurgery. This field has proven to be particularly useful in the management of unclippable cerebral aneurysms, [34] [91] [92] complex arteriovenous malformations and fistulas, [93] [94] and the vasospasm that can follow aneurysmal subarachnoid hemorrhage, [95] [96] in applying superselective thrombolysis for acute strokes, [97] [98] [99] and as an alternative to carotid endarterectomy. Reducing the vascularity of central nervous system tumors prior to surgery is another application. In the future, there will undoubtedly be other conditions that benefit from this rapidly evolving

therapeutic modality.

This complex field, by its very nature, can be associated with significant morbidity and benefits from expert anesthesiology involvement. [100] [101] [102] Relieving any patient stress and discomfort is essential because patients have to remain immobile for extended periods, often for several hours. Successful treatment of some lesions requires monitoring the patient's neurologic status, particularly at certain critical junctures and, for this, the patient's level of consciousness often needs to be modified on demand. Elevating or lowering the blood pressure is also often needed at certain critical times, both as part of the treatment of the lesion and to treat any complication that arises.

Methods

High-resolution fluoroscopy and high-speed digital subtraction angiography are combined to obtain a real-time

---

"road map" of the patient's vascular anatomy through which the catheter can be manipulated. [103] [104] This map is made by initially injecting contrast through the catheter and then superimposing the resulting angiogram onto a live fluoroscopy image in which the interference produced by bone and other overlying structures has been simultaneously subtracted. The vascular system is usually accessed via the femoral vessels, and then, following anticoagulation with heparin, a catheter system is advanced under fluoroscopic control into the carotid or vertebral arteries, where, finally, a microcatheter is superselectively advanced into the vessels supplying the lesion or the lesion itself (Fig. 66-9) (Figure Not Available) . This superselective microcatheter is used to deliver the therapeutic device, embolic material, or drug therapy required to treat the lesion. The rapidly expanding variety of embolic agents includes detachable balloons, silk suture material, polyvinyl alcohol particles, thrombogenic platinum coils (Fig. 66-10) (Figure Not Available) , and cyanoacrylate, a monomer that polymerizes to a solid form on contact with blood. [105] [106] [107] The use of

balloons allows neurologic testing before permanent occlusion.

Neurologic assessment of the awake patient remains the most sensitive measure used to assess the effects of distal ischemia induced by the embolization procedure. Once the superselective catheter is believed to be correctly placed, to ensure further that such embolization will not impair the function of critical brain areas adjoining the lesion, provocative testing of the cerebral circulation may be performed. [108] [109] [110] [111] This testing entails injecting 30 mg of sodium amylbarbital through the superselective catheter and then assessing its effect on involved or adjacent brain by observing the patient's awake neurologic status. This test is generally reliable, but it does have false-positive and false-negative results. Lidocaine, 15 mg, has been similarly used to assess cranial nerve function and the integrity of white matter tracts, especially in the spinal cord. [112]

The interventional neuroradiology angiography suite in which these procedures are performed should be equipped similarly to the neurosurgical operating room. This includes having an anesthetic machine with piped gases and suction, a refrigerator for drugs, cardiopulmonary resuscitation equipment, and adequate lighting. Caution needs to be followed to prevent undue radiation exposure. The ability to summon help immediately, including that of a neurosurgeon, is vital.

Anesthetic Management

Patients undergoing aneurysm ablation usually do not require awake neurologic assessment during the procedure and can be managed with general anesthesia given in a fashion similar to that used to treat these lesions surgically. Awake intraprocedure assessment is more commonly employed during the embolization of arteriovenous malformations, fistulas, and tumors. Such patients must remain immobile, usually for several hours, yet they must be rapidly arousable for neurologic assessment. This state is usually achieved by reversible intravenous sedation aiming to alleviate anxiety, pain, and discomfort. Small children and uncooperative adults who cannot tolerate such sedation need to have a general anesthetic. With these latter patients, the neurologic status may be monitored by using the electroencephalogram, somatosensory and motor-evoked potentials, transcranial Doppler ultrasound, or cerebral blood flow monitoring.

When awake neurologic assessments during the procedure are planned, it is useful, during the preoperative preparation, to train patients in what to expect. In evaluating such patients preoperatively, one should also make sure that they can lie supine for extended periods and that they are not prone to airway obstruction when sedated in this position. A history of past reactions to contrast media needs to be solicited in all patients. Likewise, because management of patients' blood pressure is often an important part of the procedure, one should ensure that patients are normotensive or that their preexisting hypertension is well controlled.

Because the procedure lasts many hours, and multiple treatments often are needed, it is important to position the patient comfortably. Air and foam mattresses are employed, and a pillow is placed under the knees. Two intravenous

(B) A microcatheter has been placed inside the aneurysm, and the first coil has been delivered inside the aneurysm but not yet detached. The arrow depicts the junction between the guide wire and the coil. (C) The coil has been detached, and the guide wire has been withdrawn proximally into microcatheter (arrow). (D) Appearance of the aneurysm after completion of treatment. The aneurysm is filled and is excluded from intracranial circulation by a combination of thrombus and multiple coils. The microcatheter is being withdrawn from the basilar artery (arrow). *(From Nichols et al [34])*

lines are placed, one for drug infusions and the other for administering fluids and drug boluses. Invasive arterial pressure monitoring is essential, accessed via the side port of the femoral artery catheter inserted by the neuroradiologist. Because contrast media are osmotic diuretics and significant quantities are utilized in these procedures, it is essential to catheterize the patient's bladder. The patient's respiratory rate is monitored with a capnograph sampling tube connected to the nasal cannula through which oxygen is given to the patient. The ECG, pulse oximetry, and temperature are monitored. It is also useful to have a pulse oximeter on one of the toes of the patient's leg that has the femoral artery cannulated. This device gives an early warning of distal thromboembolism in that leg. Because it is essential for the patient to avoid shivering, which causes movement and image degradation, heating devices are employed.

Various analgesic and sedative combinations have been used to manage these patients. Currently, we titrate small intravenous doses of fentanyl and midazolam, aiming to produce an easily arousable, lightly sedated patient with a patient airway and adequate spontaneous ventilation. In addition to these medications, ondansetron is commonly administered to reduce the risk of postprocedure nausea and vomiting.

To prevent thromboembolic complications, most patients are heparinized throughout these procedures. Following determination of a baseline activated clotting time, the patient is given 60 U heparin/kg, and activated clotting times are repeated half-hourly, with subsequent heparin doses being adjusted to keep the activated clotting time two to two and one-half times its baseline value (Ch. 49) .

Deliberate hypotension may be employed to decrease blood flow through a feeding artery to the arteriovenous malformation prior to injection of cyanoacrylic glue, to prevent this material from being embolized distally beyond the malformation (Ch. 41) . Such hypotension is also useful to test the cerebrovascular reserve in patients undergoing trial balloon occlusion of the carotid artery. Esmolol with, if necessary,

---

labetalol works well for this purpose, and sodium nitroprusside has also been used. Deliberate hypertension is required when the patient experiences cerebral ischemia resulting from either a planned or an inadvertent vascular occlusion, with the goal of increased perfusion via collateral vessels to the area of ischemia on a temporary basis. For this situation, phenylephrine, 1 mug/kg bolus intravenously, followed by an infusion of this drug, is used to increase mean blood pressure 30 to 40 percent higher than baseline. With such therapeutic hypertension, it is important to monitor the ECG for signs of myocardial ischemia.

Interventional neuroradiology, by its nature, can be associated with significant morbidity. Complications, if they occur, tend to be rapid in onset, and to prevent them from producing permanent brain damage requires established prior planning and teamwork. [113] Emergency neurosurgical intervention may occasionally be required. The primary responsibility of anesthesia personnel in such emergencies is to secure the patient's airway and to ensure that the patient has good gas exchange. This situation usually necessitates rapid induction of general anesthesia with sodium thiopental and use of a muscle relaxant to facilitate endotracheal intubation. Temporizing measures employed to treat vascular occlusion-induced ischemia are to improve collateral blood flow to the ischemic area by elevating systemic vascular pressures using phenylephrine with or without direct thrombolysis. If the problem is hemorrhagic, immediate reversal of the heparin with protamine combined with induced hypotension is indicated. Rupture and perforation of blood vessels can sometimes be treated using balloons, coils, or glue.

NONSURGICAL CARDIOVASCULAR PROCEDURES

Nonsurgical cardiovascular procedures include arteriography, coronary angiography and cardiac catheterization, electrophysiologic studies, and cardioversion. These procedures, both diagnostic and therapeutic, can benefit from the involvement of anesthetic personnel, in terms of both procedural outcome and patient comfort. Anesthesiologists caring for these patients, in order to develop a coherent anesthetic plan, must be familiar with the patient's medical condition as well as with the planned procedure.

The environment of the cardiac catheterization laboratory is not optimized for anesthetic management (see Fig. 66-1) . The rooms are frequently darkened to allow better visualization of fluoroscopic images, and they are crowded with equipment and personnel. It is critical that the requirements for anesthetic equipment and monitoring discussed earlier are met and that the anesthesiologist remains vigilant for rapid changes in the patient's condition, which frequently occur in this distracting environment.

Arteriography

Arteriography permits radiologic visualization of blood vessels by injection of contrast media through a catheter inserted into proximal vasculature. The arteries of the viscera and lower extremities may be accessed via the femoral arteries, although arterial occlusive disease may require a translumbar approach to the aorta. The gaining of vascular access and the injection of contrast media may result in patient discomfort. Many patients benefit from judicious administration of analgesics and sedatives. Some patients requiring translumbar aortography may require general anesthesia and endotracheal intubation, because the procedure is performed in the prone position. Alternatively, transvenous aortography may be performed with a larger amount of contrast media injected via the venous circulation. This approach is much less invasive and requires only minimal, if any, sedation. Patients undergoing arteriography to determine the extent of vascular occlusive disease have a high incidence of serious comorbid conditions, including diabetes mellitus and coronary and cerebral vascular disease, and appropriate monitoring and precautions must be taken when caring for this group of patients.

Coronary Angiography

The coronary vasculature may be visualized using radiographic contrast media, allowing determination of coronary anatomy, precise determination of the presence and location of coronary artery stenoses, and detection of coronary vasospasm. [114] Although other procedures, such as rapid CT and MRI, may allow determination of the presence of coronary artery disease, coronary angiography remains the "gold standard" for this diagnosis. In addition, interventional procedures to improve coronary blood flow may be performed as part of the same procedure. [115] Some patients undergoing this procedure may be inpatients, but many are outpatients, and the anesthetic plan must take this possibility into account. Information obtained from coronary angiography is used to determine further treatment, which may range from medication to transvascular interventional procedures performed in the coronary catheterization laboratory to coronary artery bypass grafting (CABG). Increasingly, interventions are performed in the coronary catheterization laboratory.

Coronary angiography is performed by passing a catheter in retrograde fashion through the arterial tree to the aortic root for the selective injection of contrast media into the ostia of the coronary arteries. Usually, the catheter is inserted via the femoral artery, but arterial occlusive disease may necessitate access via the brachial or radial arteries. Local anesthesia is used at the catheter insertion site, to limit patient discomfort related to vascular access. Peripheral intravenous access is necessary for the administration of cardiac medications and analgesics and sedatives. Anesthetic agents used include fentanyl and midazolam, sometimes supplemented with propofol. Sedation and analgesia are helpful in reducing the discomfort of contrast injection and of remaining motionless and supine during long procedures. Supplemental oxygen is administered via nasal cannula. Sublingual and intravenous nitroglycerin should be readily available for administration, if the patient develops myocardial ischemia. Standard anesthetic monitoring [4] is used during the procedure. Arterial blood pressure can be directly transduced from the arterial introducer during femoral or brachial catheterization. The ECG must be scrutinized and the patient closely watched for the presence of angina or heart failure,

all while anesthetic personnel are shielded from exposure to radiation. Complications are more common in patients with severe coronary artery disease and include arrhythmias, heart failure, and stroke. [116] Finally, the patient must be observed closely following the procedure for bleeding or hematoma at the catheter site. Discharge criteria for outpatients are the same as for outpatient surgical procedures.

Interventional Transvascular Coronary Arterial Procedures

Once the presence and location of coronary artery stenosis are confirmed, interventional cardiologists can use a variety of methods to improve myocardial blood flow directly. Access to the coronary arteries is via the femoral, brachial, or radial arteries using local anesthesia, combined with intravenous analgesia and sedation. [117] Heparin is administered prior to the procedure. Percutaneous transluminal coronary angioplasty (PTCA) involves traversing the stenotic area with a balloon-tipped catheter and compressing the stenosis with the balloon, thus opening the coronary artery. [118] Transient coronary artery occlusion occurs during balloon inflation, and the patient's hemodynamic status must be closely monitored. Further analgesia may be necessary because angina may develop during this time. The obligate ischemia limits the stenosis sites that may be treated with this technique to the distal coronary vasculature and, usually, to one- or two-vessel coronary artery disease. These limitations are changing as technology of angioplasty, coronary stents, and extracorporeal circulation allows treatment of more severely affected patients in the catheterization laboratory, as discussed later. More recently, PTCA has been supplemented by various techniques that remove, rather than compress, the atheromatous plaques causing coronary arterial stenosis. Coronary atherectomy may be performed using either atherectomy catheters that "shave" the plaque or excimer laser. [119]

During ischemia, and frequently during reperfusion following dilation of the stenotic coronary artery, ventricular arrhythmias may develop and may require treatment. Hemodynamically significant premature ventricular contractions and nonsustained ventricular tachycardia should be initially treated with lidocaine. More severe arrhythmias may require cardioversion with the patient under general anesthesia. Rupture of the coronary artery may result in hemopericardium and pericardial tamponade. Tamponade must be treated with emergency pericardiocentesis and may require operative intervention. Another rare complication of PTCA is coronary artery occlusion, which may result from coronary artery dissection, thrombus within the coronary artery, or vascular spasm due to dysfunctional coronary artery endothelium. Vascular spasm often may be relieved by the injection of 200 mug of nitroglycerin via the coronary artery. Thrombosis of the coronary artery may require multiple therapeutic approaches. [120] Thrombus formation is retarded by the prior administration of heparin. Once thrombus has formed, intracoronary injection of thrombolytic agents, such as urokinase, may dissolve the thrombus. Bleeding complications may result from thrombolytic therapy, especially if the patient requires an emergent surgical procedure. Abciximab, a platelet IIb/IIIa receptor antagonist, has been demonstrated to reduce the rate of acute ischemic complications associated with PTCA markedly. Abciximab is increasingly administered as an intravenous infusion during these procedures. [121] [122] Again, bleeding disorders may result, complicating postprocedural management and management during emergency operation. These patients may require relatively massive autologous platelet

transfusions. It should be anticipated that further developments will occur in regulation of the hemostatic system to reduce acute and chronic occlusion. [123]

Acute coronary occlusion may not respond to transluminal treatment in the catheterization laboratory and may require emergency CABG. The patient may have angina, hypotension, and arrhythmias and may benefit from the insertion of an intra-aortic balloon pump. In addition, the patient may require inotropic support and endotracheal intubation. Nitroglycerin is administered in an effort to improve collateral coronary flow and to reduce preload. Adequate preload must be ensured, and monitoring of central pressures may be helpful. If the stenotic or dissected area can be traversed with a guide wire, the cardiologist may be able to leave a perfusing catheter in place, allowing some coronary blood flow and limiting myocardial ischemia pending surgical revascularization. [124] Great care must be taken in transport in order not to dislodge this catheter.

Time is critical when the patient requires emergency CABG in this situation. The patient must be expeditiously transported to the operating suite and placed on cardiopulmonary bypass as soon as possible for maximal myocardial salvage. Multidisciplinary examination of institutional systems may result in streamlining of the procedure for rapid transport of the patient to the operating suite, thus improving patient outcomes. [125] Because these patients may be very hemodynamically unstable, their cardiovascular and respiratory status must be continuously monitored.

Results obtained from PTCA and atherectomy procedures are initially excellent. However, the rate of restenosis of the dilated coronary arteries is as high as 30 to 40 percent and is at least partially due to dysfunctional coronary endothelium. [126] Increasingly, expandable metallic stents are used to maintain coronary artery patency. The stents are placed across the area of stenosis following PTCA or atherectomy and remain in place following the procedure. [127] The anesthetic implications are similar to those for PTCA. The spectrum of treatment administered in the cardiac catheterization laboratory is constantly changing, and various combinations of the described procedures may be performed on each individual patient, depending on the severity and location of lesions and the practice at each individual institution. [128]

Patients with evolving myocardial infarction benefit from thrombolytic therapy and, possibly, from PTCA and/or coronary artery stenting to restore myocardial blood flow. [129] [130] Such treatment must be administered within 6 to 12 hours to maximize myocardial viability and to reduce morbidity and mortality. These patients may have full stomachs and may be hemodynamically unstable. General anesthesia has been successful in such patients who cannot tolerate the procedure because of pain, anxiety, or dyspnea. [131]

Developments in perfusion technology have increased the portability of the cardiopulmonary bypass machine. It is now

feasible to perform extracorporeal circulation in the cardiac catheterization laboratory. This procedure maintains hemodynamic stability during procedures that would otherwise result in unacceptable amounts of myocardial ischemia, such as PTCA and stenting of stenoses of the left main coronary artery. Currently, this is most frequently done on patients who are not otherwise candidates for CABG surgery, such as those with unacceptably poor ventricular function or distal coronary artery disease that would preclude CABG. [132] Extracorporeal circulation is established via the femoral artery and vein following induction of general anesthesia and systemic heparinization. Monitoring is as for CABG in the operating suite. Following the procedure, extubation is perform-ed as soon as the patient's condition allows. The anesthetic technique chosen must provide hemodynamic stability and the potential for early extubation. A balanced anesthetic regimen of fentanyl and a volatile agent, with neuromuscular blockade, provides these conditions. The patients must be closely monitored for bleeding complications because heparinization is frequently continued following the procedure. Abciximab and other medications affecting hemostasis are frequently administered. Should complications occur in these patients, who are supported by extracorporeal circulation but who are not surgical candidates, ethical dilemmas may occur. The possibility of complications and the potential treatment options, or lack thereof, must be clearly understood by the patient and by all medical personnel caring for the patient prior to undertaking such procedures. Clear and open communication is essential in this setting.

Cardiac Catheterization

Placement of transvenous and transarterial catheters into the heart and great vessels (cardiac catheterization) allows determination of cardiac anatomy, ventricular function, valvular anatomy, and pulmonary vascular anatomy (Ch. 49) . Pressure measurements in cardiac chambers and vascular structures may be made via these catheters. Injection of contrast media allows radiologic visualization of various structures, and indicator injection with distal sampling allows flow determination using the Fick principle. In addition, blood samples may be withdrawn from various areas for determination of oxygen saturation to detect the presence and location of shunts. Although much (but by no means all) of this information can be obtained with echocardiography, cardiac catheterization remains the gold standard for detailed diagnosis of complex cardiac anatomic anomalies. [133] It must be noted that, because multiple measurements and samples are necessary for the complete cardiac catheterization procedure, the measurements cannot be performed simultaneously. In order for the hemodynamic and shunt calculations to be valid, a relatively constant cardiovascular and respiratory state is necessary. [134] [135] Arterial pressures of oxygen (Pa $_{O_2}$) and of CO_2 (Pa $_{CO_2}$) must be "normal" for the patient being studied and must remain so during the measurement periods. The anesthetic techniques used in a given institution should be consistent in order that the cardiologist not have to account for differences in anesthetic techniques in interpreting diagnostic data. These constraints can make anesthetic management of these patients extremely difficult.

Adult Cardiac Catheterization

Cardiac catheterization in adults is frequently performed in conjunction with coronary angiography (Ch. 49) . Access to the right heart (pulmonary circulation) is via the venous system, usually involving catheter placement in the femoral vein. The left heart (systemic circulation) is accessed as the coronary arteries are accessed, via the brachial, radial, or, more commonly, femoral arteries. Complications related to vascular access are similar to those outlined for coronary angiography. Because catheters are placed within the cardiac chambers, supraventricular and ventricular arrhythmias are common during this procedure. The procedure is usually performed using local anesthesia, but patients benefit from systemic analgesia and sedation. Medications frequently used for this purpose include fentanyl and midazolam, sometimes supplemented with propofol. Oxygen is administered as needed, but care must be taken to maintain "normal" (for the patient) arterial blood gases if pulmonary hemodynamics are to be measured during the procedure. As with coronary angiography, the anesthesiologist must be prepared to deal with acute hemodynamic and respiratory instability in patients who may have severe valvular and myocardial dysfunction.

Pediatric Cardiac Catheterization

Anesthetic management for cardiac catheterization in pediatric patients can be uniquely challenging (Ch. 50) . These patients range in age from premature neonates to the upper limits of the pediatric age group. Cardiac anomalies vary from relatively simple atrial septal defects to complex congenital cardiac anomalies such as hypoplastic left heart syndrome. Shunts may be present at multiple levels, and the patients may be profoundly cyanotic. Ventricular dysfunction may be severe. Patients may also have coexisting noncardiac congenital abnormalities. In addition, these young patients may be uncooperative, and their parents may be severely stressed and thus of limited assistance. Neonatal studies are frequently performed on an emergency basis, and these patients are often deeply cyanotic and critically ill. The diagnosis of the cardiac anomaly is usually made prior to cardiac catheterization by echocardiography, but the determination of surgical treatment or possible catheter-based intervention is dependent on the results of the cardiac catheterization.

Anesthetic techniques used in these cases range from sedation and analgesia to general anesthesia. Again, it must be remembered that a "steady state" must be maintained for diagnostic accuracy. In general, older, cooperative patients are readily managed with intravenous sedation and analgesia. Even in cyanotic patients, supplemental oxygen is not administered unless oxygen saturation falls below baseline levels. Care must be taken to maintain ventilation and Pa $_{CO_2}$ within normal physiologic limits to avoid alterations in pulmonary vascular resistance. [136] Medications administered for sedation include fentanyl, midazolam, propofol, and ketamine. Premedication with midazolam, 0.5 mg/kg by mouth dissolved in grape Kool-Aid with sugar added for increased palatability, can be particularly helpful. There is some evidence that ketamine can increase oxygen consumption, and

care must be taken to ensure that this does not impair diagnostic accuracy. [137] Even small infants have been sedated in this manner for these procedures.

Infants and small children frequently cannot tolerate the procedure under intravenous sedation and are more readily managed with a general anesthetic regimen. As with intravenous sedation for these procedures, premedication with oral midazolam, 0.5 mg/kg, can be very helpful. If intravenous access is not present, an inhalation induction with nitrous oxide, oxygen, and a volatile anesthetic, such as sevoflurane, is performed, and intravenous access is obtained after the patient is anesthetized. Alternatively, intravenous induction using thiopental, ketamine, etomidate, or propofol is performed. A nondepolarizing neuromuscular relaxant is administered, and endotracheal intubation is performed when the patient is fully relaxed. Correct endotracheal tube position is confirmed by end-tidal CO_2 measurement, and position above the carina is readily confirmed using fluoroscopy. Anesthesia is maintained with volatile anesthesia and controlled ventilation using room air, as long as the oxygen saturation does not fall below baseline levels. Controlled ventilation avoids the increases in Pa $_{CO_2}$ frequently seen with levels of intravenous sedation adequate to allow performance of this invasive procedure in pediatric patients. Controlled ventilation has not been found to affect the diagnostic accuracy of cardiac catheterization. [134] Minute ventilation and respiratory rate are adjusted to maintain normal Pa $_{CO_2}$, based on analysis of arterial blood gases drawn by the cardiologist from the arterial catheter. The end-tidal CO_2 determination can be used to adjust ventilation subsequently, but it must be remembered that the physiologic dead space is highly variable in such patients. Infiltration of local anesthetic at vascular access sites limits postprocedural discomfort. Small amounts of an opioid such as fentanyl may be administered to provide for postprocedure sedation, thus allowing the patient to remain still and to avoid bleeding complications at the femoral vascular access sites. As an alternative to a volatile anesthesia-based technique, the patient can be managed with total intravenous anesthesia using various combinations of opioids, benzodiazepines, propofol, and ketamine. [138] [139] [140] [141] [142] [143] Again, steady-state conditions are essential, and the anesthetic plan at any institution should be consistent from patient to patient to provide reproducible patient conditions for the cardiologists who must interpret the diagnostic data.

Close monitoring of these patients is required. Especially in neonates, deterioration can be rapid. These patients may be very sensitive to anesthetics, and hemodynamic instability may ensue. Repeated blood gas analysis is necessary, because metabolic acidosis may be the initial sign of low cardiac output state. Even mild degrees of metabolic acidosis should be treated in critically ill patients, and inotropic therapy may be necessary. Hypocalcemia and hypoglycemia may develop in neonates and may require treatment. Hypothermia can be a problem in young patients, especially those under general anesthesia. The room may need to be warmed. In addition, inspired gases may need to be warmed and humidified, and a warming blanket or forced air warming system should be available. Rectal temperature may need to be monitored in small patients, because an esophageal or axillary probe may intrude into the cardiologist's imaging area. Blood loss during the procedure is less well tolerated than in larger patients, because the loss may represent a significant fraction of a smaller patient's blood volume. Hematocrit must be monitored carefully, and anemia must be treated appropriately. Deeply cyanotic patients tend toward polycythemia, and sufficient fluids must be administered to balance the osmotic effects of contrast media, which could result in hemoconcentration and microembolic events.

Complications of cardiac catheterization include arrhythmias, bleeding at vascular access sites, perforation of cardiac chambers or great vessels by catheters, vascular dissection or hematoma, and embolic phenomena. Arrhythmias are the most frequent complication. [144] Supraventricular tachycardias are most common, often related to catheter tip placement, in which case the arrhythmias usually resolve with withdrawal of the catheter. Occasionally, vagal maneuvers, intravenous medication, or cardioversion may be necessary to terminate the arrhythmia. Second- or third-degree heart block may also be seen. Sinus bradycardia may require treatment with atropine. Profound bradycardia may require temporary ventricular pacing if hemodynamic instability results.

Pericardial tamponade can be detected by characteristic hemodynamic alterations, as well as by a widened mediastinum and reduced cardiac motion on fluoroscopy. The definitive diagnosis of tamponade is best made by echocardiography, which should be readily available and can be used to guide emergency pericardiocentesis. The pericardiocentesis catheter can cause arrhythmias by mechanical irritation. These arrhythmias can be either supraventricular or ventricular, and they may be poorly tolerated in critically ill patients. As with coronary angiography, emergency surgical procedures may be necessary, and hospital systems must allow rapid, safe transport of these patients to the operating suite.

Interventions During Cardiac Catheterization

Balloon Atrial Septostomy

Balloon atrial septostomy (Rashkind procedure) is performed in infants requiring communication between the pulmonary and systemic circulations for survival (e.g., transposition of the great vessels) (Ch. 49) . A balloon-tipped catheter is placed across the atrial septum. The balloon is inflated to rupture the septum, thus creating an atrial septal defect and allowing shunting at the atrial level. In the case of transposition of the great vessels, oxygenated blood flowing from the lungs to the left atrium would mix in the right atrium with venous return blood and flow into the systemic circulation via the right ventricle. Neonates presenting for this procedure are usually receiving intravenous prostaglandin E_1 to maintain a patent ductus arteriosus. It is critical to maintain this infusion to keep the ductus patent until the atrial septostomy is complete and is determined to be of adequate size to maintain systemic oxygenation. Anesthesia for the procedure is otherwise as described earlier.

Balloon Valvuloplasty

Balloon-tipped catheters have been used to dilate stenotic heart valves and great vessels. The procedure has been used

to dilate congenital pulmonary valvular stenosis, [145] stenotic pulmonary arteries, and aortic coarctation. Balloon valvuloplasty has also been used to ameliorate acquired stenosis of the tricuspid, pulmonary, mitral, and aortic valves. [146] The procedure is usually reserved for patients regarded as very high-risk surgical candidates. [147] During balloon inflation, the circulation is blocked, and severe hypotension may result that, because of the tenuous condition of the patient, may not resolve immediately on deflation of the balloon. Inotropic and antiarrhythmic therapy may be necessary, and preload may need to be optimized with intravenous fluid administration. Complications of the procedure are similar to those of cardiac catheterization. In addition, valvular insufficiency may develop.

Older patients usually tolerate this procedure when local anesthetics are infiltrated at the site of catheter entry. Intravenous sedation with fentanyl, midazolam, and propofol attenuates discomfort related to the environment and to balloon inflation. When the aortic valve is to be dilated, two intravenous catheters are inserted. Valvuloplasty of other valves requires only a single intravenous catheter. If the patient becomes hemodynamically unstable, the balloon must be immediately deflated. Vagal stimulation can occur with balloon inflation and may require treatment with atropine. Should major complications ensue, prompt surgical intervention may be necessary.

Electrophysiologic Studies and Catheter Ablation of Abnormal Conduction Pathways

Electrophysiologic studies involve placement of special multipolar catheters within cardiac chambers to define the mechanism, origin, and pathways of arrhythmias and to determine the best therapeutic options. [148] Vascular access is usually via the femoral artery and vein, and frequently additional catheters are placed via the internal jugular vein. Programmed electrical stimulation is performed near the bundle of His, in the right ventricular apex, and sometimes in the left ventricular apex, using standard transvascular catheterization techniques. Using specifically timed electrical impulses, the arrhythmia is reproduced under controlled conditions and is monitored through both the catheters and the surface ECG leads. Electrical energy delivered through appropriately positioned catheters can then be used to ablate arrhythmogenic foci or accessory pathways. Another intervention that also may be employed in the laboratory is to place the electrodes precisely for subsequent connection to an implantable defibrillator.

Antiarrhythmic drugs are stopped prior to these studies and are avoided during the procedure, because they may prevent the detection of accessory conducting pathways and arrhythmogenic foci. These studies use multiple catheters and often take several hours to perform. To ensure patient comfort, adults and older children are usually sedated with midazolam and receive analgesics such as fentanyl. Total administered doses of these drugs may seem quite high at the end of the procedure, but the procedures are prolonged, and the pain resulting from the ablation current may be severe. Brief periods of general anesthesia using thiopental or propofol may be needed during ablation, [149] or if cardioversion is required for supraventricular arrhythmias that cannot be terminated by overdrive pacing via the catheters. Care must be taken during mask ventilation so that the internal jugular venous catheters are not moved and the operative site is not contaminated. Electrophysiologic studies in younger children are usually performed using general anesthesia, as outlined in the section on cardiac catheterization. Intravenous and volatile anesthetic techniques have both been used successfully in electrophysiologic testing, [150] [151] but, as for cardiac catheterization, consistent anesthetic techniques should be used in a given institution to ensure diagnostic accuracy.

Pacemaker and Implantable Cardioverter-Defibrillator Implantation

Permanent pacemakers and permanent cardioverter-defibrillators are increasingly placed in the cardiac catheterization laboratory. Implantation of both devices involves placement of transvenous leads into the cardiac chambers (usually right atrium and/or ventricle) with tunneling of the leads to a subcutaneous pocket in which the device is placed. Although the discomfort of the procedure can be reduced with local anesthesia, these procedures are most readily performed with the patient under general anesthesia, with endotracheal intubation or laryngeal mask airway. General anesthesia is necessary during testing of the permanent cardioverter-defibrillator. Patients with severely impaired ventricular function are best managed with direct arterial pressure monitoring.

Elective Cardioversion

Cardioversion is used to convert supraventricular and ventricular arrhythmias to sinus rhythm. When these arrhythmias are not causing hemodynamic instability or when the arrhythmia is of long standing and has not responded to drug therapy, the cardioversion can be performed on an elective, possibly outpatient, basis. The patient's cardiovascular status and medical therapy are optimized prior to elective cardioversion. In contrast, emergency cardioversion is often required when the arrhythmia causes hemodynamic instability and when time pressure and the patient's condition may not allow for full evaluation or administration of anesthesia.

Elective cardioversion is uncomfortable, and general anesthesia is required. Many medications, including barbiturates, propofol, etomidate, and benzodiazepines, have been used. [152] [153] [154] [155] The patient should be fasting. In the case of chronic atrial fibrillation, echocardiography is performed prior to cardioversion in order to rule out the presence of left atrial thrombus, which could cause stroke. Monitoring includes ECG, blood pressure cuff, and pulse oximetry. When all is in readiness for the cardioversion, the patient is preoxygenated and then is given small incremental doses of anesthetic agent until the eyelid reflex is abolished. Immediately prior to the countershock, the mask is removed, and it is confirmed that no person is touching the patient. More than one shock may be required to restore sinus rhythm, and it is important to keep the patient anesthetized until the

procedure is successful or the attempt is terminated. Following the countershocks, the patient is ventilated with 100 percent oxygen until he or she regains consciousness and is able to maintain the airway. It should be noted that muscle relaxants are not typically required for this procedure. If cardioversion is required on an urgent basis, it must be remembered that the patient may not have been fasting prior to the procedure. To prevent aspiration during anesthesia in this situation, it is appropriate to intubate the trachea using a rapid-sequence induction technique employing cricoid pressure.

THERAPEUTIC RADIATION

Intraoperative Radiation Therapy

Intraoperative radiation therapy (IORT) involves the delivery of radiation during exposure of a tumor or tumor bed at the time of a planned operative procedure. In its broadest sense, this includes brachytherapy with temporary or permanent implantation of radioactive seeds. [156] As discussed in this section, IORT refers to the intraoperative application of electron beams. Radiation therapy plays a major role in the management of many malignant diseases. The usual method by which radiation is delivered is external-beam treatment with high-energy photons. The external-beam doses required to achieve local tumor control can exceed the radiation tolerance of some normal organs and other structures of the body. [157] IORT with variable-energy electrons can effectively be used as a supplemental boost to external-beam treatments. By delivering the radiation therapy during surgery, it is possible to remove normal structures away from the radiation beam or to shield them with lead. [158]
