It seems intuitive to assume that the percentage of patients free of PONV correlates well with patient satisfaction. Several factors militate against this correlation. [9] First, antiemetics may induce adverse effects that diminish their utility. An example is the demonstration by Tramer et al [10] that, although ondansetron decreases the incidence of PONV, it increases the incidence of headache and abnormalities in liver enzymes. Second, an analysis in which the occurrence of vomiting is treated dichotomously fails to distinguish between a patient with a single minor episode of vomiting 10 minutes after arrival in the postanesthetic care unit (to whom this episode is of no consequence) and another with persistent vomiting that delays discharge by 2 hours. If the true motivation to decrease the incidence of PONV is to improve patient satisfaction or to decrease the incidence of prolonged in-hospital recovery (e.g., rather than to decrease the soiling of linen), then the adverse effects of treatment might be sufficient to overcome or even overwhelm any potential benefits. However, if the intent is to measure costs (including the soiling of linen or

nursing activities related to cleaning patients), then all episodes of vomiting might be of equal importance.

A commonly used and problematic surrogate marker is hospital charges instead of costs. One such study examined whether (nonrandomized) extubation in the operating room versus the intensive care unit (ICU) decreased hospital charges. [11] In that the hospital's policy was to charge separately for ventilatory support provided before and after midnight, a patient who arrived in the ICU 1 hour before midnight and who was extubated 1.5 hours later would be charged for 2 days of support, whereas another patient ventilated for 12 hours but extubated before midnight would be charged for only 1 day. Even though the second patient used far fewer resources, the peculiarities of the accounting system resulted in larger charges for that patient. In that hospitals charge in a manner inconsistent with costs (a practice that insurance companies now recognize and reimburse hospitals accordingly), it seems imprudent to perform any analysis using charges rather than costs.

Perhaps most problematic in the use of surrogate outcomes is the failure of investigators to identify them as such. Many studies of PONV claim that a decreased incidence of PONV "should" lead to a decreased incidence of unanticipated hospital admission, fewer prolonged recovery room stays, and improved patient satisfaction. Yet, many of these studies do not measure these outcomes, but instead count

the incidence of patients free of PONV, despite the lack of studies that demonstrate the association of surrogate and true outcomes.

Despite my criticism of the use of surrogate outcomes in anesthesia research, [9] there are instances in which their use is inevitable. The most obvious of these is when the incidence of the true outcome is so small in the treatment group that no reasonable sample size would attain statistical significance. However, whenever a surrogate outcome is used, the investigator should acknowledge its use and the resulting limitations. Although the expected more frequent occurrence of the surrogate outcome makes it more likely that the investigator will demonstrate statistical significance, the investigator must be cautious not to extrapolate a positive finding with the surrogate outcomes to one regarding the true outcome.

Randomized Clinical Trials

Traditionally, most clinical studies in anesthesia were randomized clinical trials (RCT). There were several advantages to this approach. First, the investigator could control the design precisely, thereby ensuring that the data obtained would permit examination of the question of interest. Second, the study could be both randomized and blinded, both of which are important to minimize bias. Third, the investigator could perform a power analysis before the study to determine how many subjects should be studied to ensure sufficient power.

Randomization and Blinding

The hallmark of an RCT is that, if possible, both the investigator and the patient are blinded to the treatment to which each patient is assigned. In addition, treatments are assigned using some type of randomization procedure. Use of both of these approaches minimizes the opportunity for bias. Although investigators may claim that their nonrandomized, nonblinded studies are not biased, it is often difficult for them to demonstrate this convincingly. Bias can be introduced to studies in many subtle ways. In a well-publicized violation of the design of a multicenter trial of therapy for breast cancer, one investigator violated certain enrollment criteria because of a personal belief that treatment was effective. [12] [13] Had this violation not been identified by the study's coordinators, the results of the study might have been compromised. During the enrollment interview for an anesthesia study, a patient may report himself or herself to be at higher-than-average risk for a postoperative complication under investigation. An investigator who is aware of the group assignment may provide subtle clues that may influence the patient's willingness to participate. Unless there are compelling reasons that a trial cannot be both randomized and blinded, both should be demanded from investigators.

Single Center Versus Multicenter Trials

Occasionally, the investigator planning a study might determine that an RCT in his or her institution could not enroll sufficient subjects to demonstrate statistical significance, even if the trial were conducted for years. Demonstrating an improvement in adverse outcomes from 1.0 to 0.5 percent requires more than 7,000 patients, certainly a daunting task. In response, the investigator might invite 9 or 99 other investigators to participate, thus decreasing the number of subjects per center from 7,362 to 736 or 74. The last number is certainly closer to the range of sample sizes that one could obtain in a reasonable time frame, making the multicenter approach desirable. Although the multicenter approach presumably ensures that the study will be conducted more rapidly, it also incurs risks. Perhaps most significant of these risks (because of its subtlety) is the possibility that individual centers will deviate from the protocol in ways that influence outcome, but are not identified by the investigators.

Once the decision is made to involve more than a single center in a trial, several problems appear. An obvious one is that the results may differ among institutions, a function of differences in patient population, surgical technique, surgical skills, or other "covariates." For example, a new therapy (that we "know" to be effective) may be designed to decrease the quantity of blood lost perioperatively in patients undergoing cardiac surgery. Figure 21-1 displays simulated data from three centers in which this therapy was compared to a placebo group. Note that within each center, the effect of the treatment is evident and statistical significance is attained, despite a small sample size. However, a pooled analysis (as would be the statistical approach used to analyze this multicenter trial) fails to demonstrate statistical significance, a result of large intercenter differences in blood loss in both control and treatment groups. Thus, although the multicenter approach speeds collection of the data, it compromises the results. Fortunately, statistical techniques (in this instance, a linear data transform) exist to address this particular problem. The average value for blood loss at each center can be subtracted from the value for each subject. This approach, termed "centering the data," improves the statistical power of the analysis. However, statistical "manipulations" of this sort should be adopted a priori, that is, before the study is conducted.

Tight Versus Loose Control of Studies

The implications of tight versus loose control of experimental conditions should be considered. For example, one might conduct a study in which vigorous attempts are made to control blood pressure in both treatment and control groups versus one in which a significantly broader (yet still clinically acceptable) range of blood pressures was allowed in both groups. The incidence of adverse outcomes (the focus of this study) might be markedly lower in both treatment and control groups in which blood pressure was well controlled. Although this finding might lead to the conclusion that tight control of blood pressure is desirable to minimize adverse outcomes, that is not the stated goal of this study. However, adverse events might be so infrequent in the groups with tight control that one might not be able to demonstrate a benefit to the treatment under investigation. If "tight" control is realistic only in a research setting, then application of the results of this trial to the clinical environment might be limited.

Figure 21-1 Simulated data from a three-center clinical trial is shown. Each panel displays measured blood loss in two groups of ten patients. The control group at each center received a placebo, and the treatment group received a therapeutic agent designed to decrease blood loss. When data for the three centers are pooled, statistical significance is not attained. However, within each center, the data demonstrate statistical significance. This example illustrates how increasing sample size by increasing the number of sites included in a study may not necessarily improve (and, in this simulated instance, may actually worsen) statistical power.

Large Databases

In many instances, the opportunity to perform an RCT is limited. For example, the projected sample size might be so large as to make the cost of a study prohibitive, or the interested investigator might be someone who is unable to conduct a clinical trial but who has the ability to analyze data. In these instances, another source of data for analysis might be observational databases. With the advent of electronic data collection, organizations such as hospitals, health care systems, regulatory bodies, and governmental agencies compile massive quantities of data regarding health care outcomes that might be relevant to clinical research. For example, hospital or blood bank information systems might track all the blood that is administered to all patients, or governmental agencies might track all deaths that occur in each hospital and the reported cause of death. Frequently, these databases are available for research purposes.

The magnitude of these databases is seen by some investigators as providing unparalleled opportunities for research. Advocates of this approach note that the quantity of data available through existing databases probably cannot be matched, even at astronomic cost. In addition, these databases include information on actual clinical practice, rather than on the potentially altered practice used in research protocols (e.g., "tight" control).

However, critics note numerous problems. Foremost of these is that the information in these databases was not obtained in a prospective randomized manner. One example of such research is a study that examines the differences among medical centers in the likelihood of death after cardiac surgery. [14] Those hospitals with poor outcomes argue that their complications resulted from caring for higher-risk patients. Investigators who perform these analyses frequently attempt to control for risk (e.g., results can be stratified by age, accounting for possible differences in outcome for patients of different ages). Although these risk adjustments are claimed to be sufficient, it is doubtful whether they are. In contrast, the RCT design, one hopes, protects the investigator from introducing this problem.

Another example of the influence of lack of randomization can be seen in the comparison of two surgical approaches to the repair of coronary artery disease. In this fictitious example, investigators are unaware that the clinicians were interested in this same issue and that they provided all high-risk patients procedure A and lower-risk patients procedure B. The investigator obtained data from a hospital database, and the outcome measure is incidence of MI in the year after surgery. Even though procedure A is better (by definition), outcome is no different in the two groups because of differences in selection.

A second problem involves blinding, although I use the term differently here from when I refer to the RCT. It might be that the team caring for the patients is more interested in the outcome of patients undergoing procedure A than in those undergoing procedure B. So all patients undergoing procedure A are strongly encouraged to return for follow-up care (possibly even provided gratis). In turn, the percentage follow-up in the two groups differs markedly. This factor undoubtedly influences the results. Although issues of surveys are quite different, the analogy to return rates for surveys is important--investigators are often satisfied that 50 percent of individuals who were sent questionnaires returned them, yet they are unable to comment on what distinguishes the 50 percent who did from those who did not.

A third problem involves an unidentified influence of time. In some instances, investigators examine the incidence of an outcome before and after the introduction of a new clinical practice. For example, a trial mentioned earlier examined whether a new policy of extubating children in the operating room after cardiac surgery saved money compared with extubation in the ICU. [11] The authors of this study assumed that the only factor that changed costs during the period was the new extubation practice. The validity of this assumption is certainly questionable, even based on the data presented by these authors. In addition to the two groups already described (those patients "studied" before the change in practice who were not extubated in the operating room and those patients "studied" after the change in practice who were extubated in the operating room), the authors

obtained data on a third group, patients "studied" after the change in practice who were *not* extubated in the operating room. Of note, hospital charges for this group were markedly less than those for the group studied in the earlier time period. Thus, the decreased charges in the early extubation group could, at least partially, be attributed to practice changes that occurred over time, independent of the change in extubation practice.

One study demonstrates a similar phenomenon. Macario et al [15] found that institution of practice guidelines decreased costs of knee replacement by 19 percent. However, costs for a second procedure, prostatectomy, decreased 12 percent during the same time interval, although no practice guidelines were instituted. Thus, only a portion of the "savings" can be attributed to the guidelines, a finding that could be identified only because the investigators selected an appropriate control group. Lack of such a control group markedly diminishes the validity of other similar studies. For example, Lubarsky et al [16] reported that a pharmaceutical practice guideline in their institution decreased the cost of drugs used during anesthesia by $24. These authors dismissed a 7-minute increase in anesthesia time as being of no consequence. This increase in anesthesia time might have resulted from changes in surgical practice, such as a larger number of laparoscopies and a decrease in open procedures, and it might not have been a detrimental outcome from their pharmaceutical practice guidelines. However, the results of the practice guideline study of Macario et al and changes in practice in other university hospitals (e.g., the increased likelihood that an attending surgeon, rather than an undersupervised medical student, will perform skin closure) suggest that anesthesia time should have *decreased* rather than *increased* during the period of the study. Thus, the 7-minute increase in anesthesia time may represent the "tip of the iceberg." Lack of a control group prevents either the investigators or their critics from determining the answer.

A fourth problem with the use of retrospective databases involves the handling of missing data. When data are collected prospectively, investigators can define a priori how missing data will be handled in the ensuing analysis. In addition, investigators can make appropriate efforts to minimize the quantity of data that are missing. In contrast, databases often lack large quantities of critical information. Excluding these missing data from a retrospective analysis may lead to a bias. For example, if investigators are examining survival with different anesthetic techniques, it is possible that data missing at a 3-month follow-up visit might reflect either patients lost to follow-up (e.g., having moved to a new community or health care plan) or those who have died.

A fifth problem involves the quality of data. When investigators obtain data prospectively, they generally define criteria explicitly. For example, a study examining the influence of anesthetic technique on time to recovery room discharge might use strict criteria to define the time at which a patient is ready for discharge. In contrast, an existing database such as a recovery room log would provide information on when the patient was actually discharged, rather than when the patient attained the criteria for discharge. Thus, potentially irrelevant factors such as the availability of transportation might confound the results. In addition, the accuracy of the values entered for routine clinical purposes is often questionable.

Finally, the question of interest is probably not exactly answered by the database. For example, it is likely that the investigator has specific focused questions of interest, yet the people who created and implemented the database did not ask these specific questions. When this situation occurs, investigators might choose to use other measures such as surrogate outcomes. Compromise might be small or it might be large. Despite the marked cost savings associated with retrospective studies involving databases, few, in any, of these studies have been accepted into the anesthesia literature, presumably a result of these serious limitations.

Meta-Analysis: A Solution or a Problem

Frequently, as a clinical issue emerges, small clinical trials are conducted independently at a number of institutions. For example, numerous trials have examined the influence of antiemetics on the incidence of PONV. Some of these trials demonstrate statistical significance, whereas others suggest a trend, but their sample size is insufficient to demonstrate statistical significance. With the latter, investigators might conclude that the therapy was not beneficial. One prominent example in the anesthesia literature regards the influence of regional versus general anesthesia on outcomes in high-risk patients, an issue that has been examined in many small studies. The conflicting results of these multiple publications frustrates the clinician from applying the results of these analyses. Although the optimal solution might be to perform a large RCT that is sufficiently powered to demonstrate statistical significance, several factors militate against the likelihood of this new trial. First, the expense of such a trial might be prohibitive. Second, investigators may be concerned that efforts expended in the earlier trials will have been wasted. Finally, funding agencies may believe that the earlier trials provided sufficient evidence that the new trial is not warranted.

Under these circumstances, one approach that is currently popular is termed meta-analysis. With this technique, the investigator (henceforth identified as the meta-analyst) does not obtain data himself or herself. Rather, the metaanalyst carefully searches bibliographic databases to obtain a comprehensive list of relevant publications. Each study is then examined to determine its "quality" and suitability for inclusion in a pooled analysis. For example, studies in which the randomization procedure was not stated explicitly might be rejected. Statistical techniques specifically created for meta-analysis are then applied to the results of these studies, accounting for the different sample size in each study, to yield a pooled result, for example, an odds ratio. For example, a meta-analysis of the effects of regional versus general anesthesia for surgical repair of femoral neck fracture reported that general anesthesia was associated with a 4-fold higher incidence of deep vein thrombosis. [17]

Meta-analysis has polarized the medical research community. Its advocates claim that it is a legitimate means to resolve questions for which multiple inadequately powered studies have been performed, and its efficiency is appealing in that existing studies are used, and no additional patients need to be subjected to the "less desirable" therapy. In contrast, its critics claim that it is flawed.

First, meta-analysts typically do not have access to the original data, so that the published data become their new database. Unfortunately, editorial limitations often prevent publication of large quantities of data, so that the information available to the meta-analyst may be inadequate. In addition, issues that were well established and handled appropriately by the investigator may not be well defined in the manuscript, thus preventing the meta-analyst from using the information correctly. The meta-analyst typically deals with these issues by assigning a quality score to each study and using only those studies that meet certain criteria. However, the procedure by which studies are judged as acceptable or unacceptable for inclusion is questionable--well-designed studies might be rejected simply because the authors failed to specify certain criteria demanded by the meta-analyst (and such criteria might have been standard practice at the time the study was conducted but not routinely reported).

Second, the database from which the trials are identified may be incomplete and, possibly, biased. This "publication bias" (or "file drawer" problem) occurs because an underpowered study that fails to demonstrate statistical significance is likely not to be published, whereas a similarly sized study that attains statistical significance will be. Assuming that the former set of studies is inaccessible to the metaanalyst (and there are virtually no registries that collect these data), the meta-analysis will be biased toward studies with positive results. This problem is typically discounted by meta-analysts as unimportant, despite their inability to assess its prevalence. Finally, meta-analysis may include studies with different designs.

Ultimately, the test of meta-analysis is whether it yields the same results as a sufficiently powered, large RCT. Le Lorier et al [18] examined 40 primary and secondary outcomes for which such a comparison could be performed. In numerous instances, the large RCT yielded results different from those of the meta-analysis, despite effect size estimates that differed minimally (i.e., the magnitude of effect detected by the meta-analysis was similar to that detected by the large RCT, yet the results of the meta-analysis yielded a different conclusion than the RCT). In this case, one might question whether the meta-analysis or the large RCT yielded the more meaningful result. Of course, the design of each of the many small RCT and the large RCT must be compared. If there is no obvious difference between them, my bias would be toward the large RCT. In this context, many researchers are critical of meta-analysis.

Determining the Appropriate Sample Size

On some occasions, an investigator reports that the *P* value for a critical analysis was equal to .05. The implications of this *P* value should be considered. If one subject included in a study were replaced by another, it is likely that the results from these two subjects would differ. In turn, differences between the two groups would be either smaller or larger. If the difference were smaller, the *P* value would now be greater than .05, and the investigation would not attain statistical significance. In turn, the results of the study would diminish in importance.

To avert such problems, it is generally considered advisable for investigators to perform a power analysis before the study is initiated. This analysis permits the investigators to determine how many patients should be included to ensure the study's success. Unfortunately, many studies are performed without an appropriate power analysis, and investigators frequently submit manuscripts in which small sample sizes yield *P* values of .05 to .1 (5-10%). In some instances, the investigators claim that these results indicate a trend (i.e., they imply statistical significance); in others, they claim that this *P* value indicates no difference between groups. In either instance, the inadequate sample size prevents the reviewer and reader from arriving at a meaningful conclusion. In response, it is in vogue for reviewers to request a post hoc ("after the fact") power analysis, that is, to use the existing data to estimate how many patients *should* have been studied to attain statistical significance. If the *P* value is close to .05 (e.g., .06), then the results of this post hoc power analysis are obvious--the number of patients studied was inadequate, and a *small* increase in sample size (assuming the data from the new subjects followed a pattern identical to those of the patients already studied) would be sufficient to attain statistical significance. If the *P* value is much larger than .05, then a markedly larger sample size was needed. However, this post hoc power analysis does not provide any insights into the validity of the results or clinical implications of the present study. Thus, I remain skeptical of post hoc power analysis. Instead, power analyses should be performed *before* the study is initiated.

In planning an experiment, one presumably has some idea of the result. For example, the incidence of ECG changes consistent with ischemia might be 30 percent with a common anesthetic agent, and one might expect an incidence of only 12 percent with a new agent (therefore, an "effect size" of 18%). The number of eligible patients might be 100 per year, and the investigator might be constrained to performing the study within 1 year (e.g., during a fellowship). A statistical analysis (either a continuity-corrected chi^2 test or Fisher exact test) based on these expected results yields a *P* value lower than .05 (.049 and .048, respectively). So the investigator might embark on the experiment, confident that the results will turn out as expected and that statistical significance will be attained by the end of the experiment.

Luck may be with the investigator. After studying 100 patients, the incidence of adverse events may be exactly as planned, and statistical significance will have been attained. Or the situation may be even better--the incidence of ischemia may be only 10 percent in the treatment group and 30 percent in the control group (note that this results from only 1 less patient with ischemia in the treatment group), leading to a *P* value of .02. However, it is equally likely that the results could be unfavorable to the investigator's hypothesis. For example, the incidence of ischemia might be 14 percent in the treatment group and 30 percent in the control group (note again that this results from a change in outcome for only a single patient). Even though the effect size (16%) is still quite large, statistical significance is not attained (*P* = .09), and the investigator might conclude that the therapy was not efficacious (and might not even attempt to publicize the results). Conversely, the surgical team might vacation during the 12th month of the study, thus decreasing

the sample size to 46 per group, and a *P* value of .08. Thus, with an experiment designed to achieve a *P* value of .05, trivial changes in the samples size and/or results lead to either success or failure with nearly equal frequency.

This leads to the concept of the "power" of the trial. The trial described earlier, and any trial in which the expected results yield a *P* value of .05 exactly, has a power of 50 percent (meaning that 50 percent of the time, the "expected" variability leads to "success," and 50 percent of the time, it leads to "failure." Bettors might, or might not, consider 50 percent to be good odds, but most researchers would not consider them to be so. Therefore, before investing any resources (time, money, pride), an investigator should decide how much power a trial has. Typically, an investigator selects a sample size sufficient to ensure statistical significance with 80 percent power.

One of the more frustrating problems experienced by an investigator is to perform a study, then to determine that the anticipated trend in the data does not achieve statistical significance, such as *P* = .06. Although the investigator then may be tempted to increase the sample size slightly to achieve statistical significance, this approach is not considered appropriate. [19] This problem of inadequate sample size often can be eliminated by prospectively estimating the sample size necessary to achieve statistical significance. Many mathematic approaches exist to address this problem. However, a descriptive introduction to the techniques of *power analysis* is useful.

Two investigators (Dr. Goodluck and Dr. Badluck) are performing identical studies in identical populations. Both are examining whether the time to 100 percent twitch depression of a new muscle relaxant, "Faston," is faster than 4.0 minutes, the previous "gold standard" for a nondepolarizing muscle relaxant; both investigators plan to use a one-tailed, one-sample *t*-test to examine their results. Dr. Goodluck studies ten patients, finding a mean value of 3.0 minutes with a standard deviation (SD) of 1.6 minutes; his results achieve statistical significance (Table 21-2) . Dr. Badluck also studies ten patients, obtaining a mean value of 3.2 minutes with the same SD; however, although his mean value is minimally different from Goodluck's, Badluck's results yield a *P* of more than .05. How did this happen?

Unknown to these investigators is that their mentor previously determined the onset time for "Faston" in a large sample

TABLE 21-2 -- One-Sample *t*-Test for the Onset Time of "Faston," An Imaginary Anesthetic

[a]

[a] Read, "the one-tailed *t* value when alpha = 0.05 and degrees of freedom (df) = 9."

(*N* = 1,000); from that study, we know with reasonable assurance that the population mean is 3.0 minutes, with an SD of 1.6 minutes (and that the onset time is faster than that of the "gold standard"). Goodluck's sample mean is identical to the "true" value (merely a coincidence), and Badluck's value, although not identical, is close. Knowing that the population mean is 3.0 minutes, we can use the standard error (SE) to determine the distribution of sample means: with a sample size of ten, the SE is 0.5 minute (1.6/
10), and 95 percent of sample means lie between 2.1 and 3.9 minutes (mean ± *t* · SE). Thus, both Goodluck's and Badluck's mean values are likely estimates (i.e., not unusual events). Although Badluck's estimate is "correct," it lies in an unfortunate area (i.e., nonsignificant) of the distribution of possible mean values that he might have obtained (Fig. 21-2 , upper panel). Thus, Badluck's analysis succumbed to the laws of chance: in a large percentage of samples, by chance, differences between these groups would have achieved statistical significance with a sample size of ten, but his actual results did not. Had Badluck studied four times as many patients and obtained the same mean value and SD, his SE would have been smaller by a factor of two, and his results would have achieved statistical significance (Fig. 21-2 , lower panel): this larger sample size would have resulted in statistical significance in a larger percentage of studies.

Badluck could have avoided his misfortune by performing a power analysis. Prior to initiating the study, he might have realized (e.g., based on a pilot study or his impression from clinical use of "Faston") that the likely difference between groups was 1.0 minute and that the SD within a group was approximately 1.6 minutes. Assuming that the true (i.e., population) mean value for "Faston" is 3.0 minutes (and assuming that the distribution of possible sample means is symmetric), he would expect a 50 percent chance of obtaining a sample mean greater than 3.0 minutes and a 50 percent chance of obtaining one smaller than 3.0 minutes. With a sample size of ten and an expected SD of 1.6, his expected SE would be 1.6/
10 or 0.5 minute. Had he obtained a mean value greater than 3.1 minutes (determined as 4.0 min - *t* · SE, using the one-tailed *t* value for 9 *df* and alpha = 0.05), his *t* value would have been less than the critical value, and he would not have achieved statistical significance. Conversely, all experiments in which the mean value was less than 3.1 minutes would have resulted in statistical significance. Because the population mean for the onset of "Faston" is 3.0 minutes, * slightly more than half of all possible sample mean values would be equal to or less than 3.1 minutes. Thus, a statistician would conclude that this experiment had slightly better than a 50 percent power to detect a difference of 1.0 minute between groups. Once Badluck recognized that his experimental design had a power of only slightly greater than 50 percent, he likely would have increased the power of his analysis, most simply by increasing the sample size. An increased sample size accomplishes two goals. First, as the degrees of freedom increases, the critical value for *t* decreases (Table 21-3) ; this small decrease means that it is slightly more likely that his *t* value would exceed the critical value. Second, and of greater importance, is that an increase in the sample size decreases

*The population mean is rarely known; thus, power analyses are typically performed using the sample mean or an estimate of the sample mean.

Figure 21-2 Power analysis for onset time for subjects given the hypothetic muscle relaxant "Faston." The upper panel shows the distribution of possible sample mean values assuming a population mean value for "Faston" of 3.0 minutes, a standard deviation of 1.6 minutes, and a sample size of 10, resulting in a standard error of .51 minute. The population mean value for the standard is 4.0 minutes. Thus, any mean value for "Faston" greater than 3.1 minutes (determined as mean - *t* · SE = 4 - 1.833 · 0.51) will not result in statistical significance. In that 38 percent of sample means exceed 3.1 minutes, the likelihood of a type II error is 38 percent; conversely, 62 percent of sample mean values are less than 3.1 minutes, so the experiment has a power of 62 percent. The lower panel differs only by having a sample size of 40, resulting in a standard error of 0.25 minute. More than 98 percent of sample mean values are less than the new critical value (mean - *t* · SE = 4 - 1.685 · 0.25); thus, the power of this analysis exceeds 98 percent.

the SE of the sample (because the SE equals SD divided by the square root of the sample size). Had Badluck increased his sample size by a factor of four, his SE would have decreased by a factor of two, thereby increasing his value for *t* by a factor of two.

By estimating the expected difference between sample means and the expected SD within the groups, the investigator can prospectively determine the sample size necessary

TABLE 21-3 -- Critical Values of the *t* Distribution (Two-Tailed)

	alpha		
DEGREES OF FREEDOM	***0.05***	***0.01***	***0.001***
3	3.18	5.84	12.92
4	2.78	4.60	8.61
5	2.57	4.03	6.87
10	2.23	3.17	4.59
20	2.09	2.84	3.85
50	2.01	2.69	3.50
100	1.98	2.63	3.39
1,000	1.96	2.58	3.30
	1.96	2.58	3.29

for the analysis. Three approaches (the first two being mathematical, the third graphic) are commonly used, each of which requires the investigator to estimate the expected difference between mean values and the expected SD (or to perform a pilot study to obtain preliminary estimates). The first approach is to calculate Z_{beta}:

where $Z_{1-alpha}$ is the (1-alpha) percentile of the normal distribution (the area associated with the alpha tail of the normal distribution: 1.64 for the 5% tail or 1.96 for the 2.5% tail), mu_0 and mu_1 are the mean values for the null and alternate samples, and $sigma_0$ and $sigma_1$ are the SE of these respective samples (often assumed to be equal). The Z table is then consulted to determine the fractional area associated with this Z_{beta} value: this area represents the likelihood of a type II error. In turn, [1 - area(Z_{beta})] represents the power associated with the proposed analysis. For the Goodluck/Badluck analysis, a power of 62 percent is now demonstrated (Table 21-4) .

In the second approach, equation 1 is rewritten as

TABLE 21-4 -- Power Analysis for the Onset Time of "Faston," An Imaginary Muscle Relaxant

Using Equation 1 to determine the power of the analysis in Table 21-2 :
$mu_0 = 3.0$
$mu_1 = 4.0$
$sigma_0 = sigma_1 = 1.6$
Using the Z table, this value suggests a 38% likelihood of a type II error; alternately, this implies a 62% (100-38%) power to detect a 1.0-min difference with 10 subjects per group.

where $sigma_0$ and $sigma_1$ are the SD of the two samples. The investigator assumes that a power of 90 percent and a one-tailed type I error of 5 percent are desirable; the corresponding values of $Z_{1\text{ -beta}}$ (1.28) and $Z_{1\text{ -alpha}}$ (1.64) are used. Mean values and their SD are estimated (possibly based on a pilot study), usually assuming that SD for the groups are equal. Using this approach, a minimum sample size of 22 per group is now evident for the Goodluck/Badluck analysis (see Table 21-5) . Recognizing that the estimates for SD may be conservative, a prudent investigator might select a slightly larger sample size, such as 25 subjects per group. These two approaches to power analysis are explained in detail by Cohen. [20] The third approach to power analysis is graphic: the investigator examines a set of charts to estimate sample size. [21] [22]

If the data are nonparametric and require chi ^{2} analysis, other approaches are available to estimate sample size. For example, an investigator might be interested in whether a new anesthetic, "Nochuck," is associated with less PONV than the traditional anesthetic. Assume that the true incidence of vomiting is 10 percent in patients given "Nochuck" and 30 percent in patients given the traditional anesthetic. With a sample size of 40 patients in each group, these incidences would result in $P > .05$; a sample size of 50 patients in each group would achieve statistical significance ($P < .03$). With 50 patients in each group, the expected number of patients vomiting would be 5 with "Nochuck" and 15 with

TABLE 21-5 -- Estimating the Sample Size Necessary to Demonstrate that Onset of "Faston" (An Imaginary Muscle Relaxant) is Faster than that of the Gold Standard

Using Equation 2 to determine the sample size necessary to achieve 90% power for the experiment in Table 21-2 :
Using an alpha value of 0.05, $Z_{1\text{ -alpha}} = 1.645$
Using a beta value of 0.05, $Z_{1\text{ -beta}} = 1.282$
$mu_0 = 3.0$
$mu_1 = 4.0$
$sigma_0 = sigma_1 = 1.6$
Thus, 22 subjects per group are necessary to ensure a power of 90% of detecting a difference between groups.

the traditional anesthetic. However, as before, it is easy to imagine that 1 additional patient given "Nochuck" might vomit and 1 fewer given the traditional anesthetic might vomit, that is, 6 patients in the "Nochuck" group and 14 in the traditional anesthetic group. These new results would not achieve statistical significance ($P = .08$). Again, this problem can be addressed prospectively by a power analysis. For a 2 × 2 contingency table (also known as a two-sample test of proportions), the appropriate sample size in each group (n) can be determined as

where p_1 and p_2 are the expected proportions in the two groups, p equals ($p_1 + p_2$)/2, $Z_{1\text{ -alpha}}$ is the fractional area associated with a type I error of alpha (typically 5%), and $Z_{1\text{ -beta}}$ is the fractional area associated with a type II error of beta, or a power of (1 - beta), typically 90 percent. For example, if an investigator expected to find an incidence of perioperative ischemia of 10 percent for one anesthetic and 20 percent with a second, a total of 434 subjects (217 in each group) would be needed to ensure 90 percent power of detecting a difference. Without a prospective analysis, the investigator might well select a smaller sample size; conversely, the knowledge that such a large sample size is necessary might make the study prohibitive in expense.

A more serious problem occurs if the investigator attempts to extrapolate from a small sample size. For example, an investigator has developed a new technique to perform an axillary nerve block that he or she believes is less likely than the traditional technique to produce an intravascular injection. The nerve block is performed in 60 subjects in whom no intravascular injections occur. Can the investigator conclude that intravascular injections never occur? If the "true" incidence of intravascular injection in a large sample were 1 in 100, the likely incidence in 60 subjects would be 0.6. However, in that events occur in discrete individuals, the most likely value would be 1; however, 0 (or 2 or, possibly, 3) might be likely values. Hanley and Lippman-Hand [23] examined this issue in an interesting article entitled "If nothing goes wrong, is everything all right?" Briefly, an investigator who demonstrates no adverse events in N trials can conclude with 95 percent confidence that the "long run" rate is no higher than 3/ N. Thus, our investigator cannot claim that the experience of no adverse events in 60 subjects ensures no adverse events ever, but, rather, that adverse events are likely to occur in fewer than 5 percent of subjects (3/60). Finally, if sample size cannot be estimated prospectively, or if there may be a significant cost to prolonging the analysis once the earliest signs of statistical significance appear, the investigator may opt for the sequential analysis technique described later.

Statistical Errors

Many clinicians and investigators distrust statistical analysis. Sometimes this distrust is based, in part, on lack of

knowledge of the terms used by the investigator or on the inability of the investigator to communicate thoughts clearly. However, distrust also occurs when the data presented in a manuscript appear to contradict the statistical conclusions. For example, one study reported that theophylline's elimination half-life was 216 and 72 minutes in different groups, a 3-fold difference the authors claimed was not statistically significant. [24] In contrast, distribution half-lives for the same groups were 2.7 and 3.0 minutes, a 10 percent difference for which the authors claimed statistical significance ($P < .05$). Because neither individual data points nor SD were reported, the reader was unable to examine the data and draw his or her own conclusions; thus, the reader can only be suspicious regarding the conclusion.

Perhaps the most common error is presentation of descriptive data without indicating whether the values for variability represent the SD or the SE. Because there is no consensus or conventional practice regarding which of these should be reported, investigators may be tempted to report the smaller value (suggesting less variability in the data)--the SE--without identifying it as such. The reader may have insufficient information to determine which value is being reported. This problem occurs less frequently than in past years, probably because of the heightened interest in statistics in recent years. [25] [26] Another error is to use sample sizes that are

too small to detect expected differences. The denominator used in *t*-tests and analysis of variance is the variability within the groups, a value determined using sample size [see equation (19)]. If sample size is small, the denominator will be large, and the *t* or *F* will be smaller than they would be with a large sample size. Thus, the investigator may be unable to detect differences between groups. This problem might be prevented by the use of power analyses.

An additional reason for obtaining the wrong statistical conclusion is the use of the wrong statistical test. This error occurs most frequently when multiple *t*-tests are performed without applying the appropriate correction. The resulting type I errors can be avoided by using the appropriate statistical test, such as analysis of variance. Alternately, the investigator might select a test that is inappropriately strict. For example, if three or more measurements were obtained on the same subject, the investigator would be correct in avoiding multiple paired *t*-tests. Unless the investigator is knowledgeable of statistical techniques such as repeatedmeasures analysis of variance, he or she might erroneously use one-way analysis of variance, a test that ignores the information gained by obtaining repeated measurements on the same subject. Just as the two-sample *t*-test may be unable to find differences that can be detected with a paired *t*-test (assuming that paired measurements were obtained), a one-way analysis of variance may be unable to find differences that can be detected with the repeated-measures test. Frequently, investigators recognize the value of statistical tests that consider that paired measurements were obtained, but they are unaware that appropriate tests such as repeated-measures analysis of variance exist. In response, they analyze their data first with a one-way analysis of variance (a test that is inappropriately strict), then with paired *t*-tests with or without the Bonferroni correction. If the Bonferroni correction is applied, the analysis may be too strict; if it is not applied, the analysis is too lenient. Regardless, the analysis could have been performed more appropriately with a repeated-measures analysis of variance and one of the multiple comparison tests described later. Use of one-way analysis of variance instead of the more appropriate repeated-measures analysis of variance occurs frequently in the anesthesia literature. Using a statistical test with inadequate sensitivity often prevents investigators from detecting a difference when one really exists.

A final problem with statistical analyses results from collecting too much data. If the investigator fails to achieve statistical significance of the primary question, it is tempting to select a whole series of new questions, performing unintended statistical analyses, an approach known as "data torturing." [27] The legitimacy of this approach is certainly questionable.

Selecting the Appropriate Statistical Test

Most statistics courses focus their attention on the techniques necessary to perform statistical analysis and give the student examples of each statistical test. In contrast, when performing research, the investigator must decide which statistical test is appropriate for the data collected. Because statistics courses emphasize performance of the tests rather than study design and how to select the appropriate test, the investigator may have difficulty in selecting the appropriate test. Ironically, with the great availability of hand-held calculators, microcomputers, and even user-friendly mainframe computers, performing complicated statistical tests is now possible for almost all medical investigators. The greatest difficulty therefore lies in selecting the appropriate test.

The first question the investigator should ask is, "What type of data have I obtained?" If the data are on a nominal scale, the choice of analytic techniques is generally limited to chi^2 analysis. For data on an ordinal scale, the investigator is generally restricted to nonparametric analyses. For data on a ratio or interval scale, a large variety of tests, both parametric and nonparametric, is appropriate. To choose between parametric and nonparametric tests, the investigator should consider the sample size and whether the data are distributed normally. If the data are not distributed normally, a parametric test may not demonstrate statistical significance, because the distribution of critical values is based on the assumption of normality. Because of the small sample size frequently used in many medical studies, nonparametric techniques should probably be used more frequently. The major argument against their use is that, if the data are distributed normally, nonparametric tests are slightly less powerful and may not detect real differences. Typically, the advantage they yield with abnormal distributions significantly outweighs the minor lack of power compared with parametric analyses.

Once the investigator determines the type of data obtained, the data should be displayed in a readily understandable form, such as a histogram or scattergram. Appropriate visual presentation permits the investigator to learn whether the data are distributed normally and also to perform a quick and informal visual analysis. Many analyses can be terminated at this point--if no obvious difference exists between groups, statistical analysis will be fruitless, although an investigator might be able to find an obscure statistical test that suggests significance. For example, some statistical

packages perform the Bartlett test of equal variances with each analysis of variance. If mean values of each group do not differ but variances do, the Bartlett test (but not analysis of variance) will yield a statistically significant result.

The next step is to determine the descriptive statistics (including the mean, SD, and SE). These statistics describe the location and variability of the sample; in addition, they are prerequisites for subsequent analyses. Only after completing these preliminary steps should the investigator embark on inferential statistics. The choice of inferential test depends on the nature of the data. If the independent variable consists of only a single or paired measurement on one group, the one-sample *t*-test should be used. For two groups, the two-sample *t*-test should be used. For more than two groups, analysis of variance is the appropriate statistical test, although an investigator may choose the two-sample *t*-test with the Bonferroni correction. If measurements have been repeated on the same subject, repeated-measures analysis of variance should be used rather than the paired *t*-test. For each of these tests, the investigator may select the parametric or nonparametric version. Finally, if the independent variable is continuous and cannot be divided readily into discrete groups, analysis of linear regression is the appropriate test to apply.

For most of the research reported in the anesthesia literature, these statistical techniques are sufficient. As study design becomes more complicated, more sophisticated techniques may become necessary. Because a more detailed discussion of these tests is beyond the scope of this chapter, the investigator should turn to the resources described later. These resources permit the investigator to design a study for optimal data collection and analysis.

In some instances, the investigator performs a study for which a specific statistical approach has been developed and is appropriate. For example, an investigator may compare two techniques to estimate cardiac output, a noninvasive technique and the thermodilution technique. My previous experience suggests that the thermodilution technique is not a "gold standard," and therefore differences between the measured values do not necessarily indicate an error in the noninvasive technique (the error may be in the thermodilution technique); however, a linear regression comparing the two techniques would imply that all errors lay with one of the techniques, presumably the new technique. An alternate approach, suggested by Bland and Altman, [28] is to assume that the best estimate is the average of the values obtained by the two techniques; the investigator then examines the difference between the two techniques as a function of this best estimate. This scatterplot may permit the investigator to detect systematic errors in the new technique. Many other specific approaches for specific problems are available. Unfortunately, these approaches are not catalogued and are therefore not readily available to investigators. When these guidelines are used, the choice of statistical tests is often simple.

Statistical Resources

The techniques described in this chapter should permit the reader to examine a data set, to determine descriptive statistics, and to perform simple tests such as the onesample or two-sample *t*-test. More complicated tests such as analysis of variance or linear regression analysis, if done manually, are tedious and require mathematical precision beyond the ability and scope of many investigators. In addition, mathematical errors occur and, as the number of calculations increases, may be compounded. To avoid these problems, most investigators turn to a variety of resources. The simplest of these, a scientific calculator, permits accurate calculation of means, SD, and SE. More sophisticated programmable calculators can perform analysis of variance and linear regression analysis.

Microcomputers (e.g., PC and Macintosh) and minicomputers (e.g., Sun workstations) are commonplace in offices, laboratories, and homes. Various statistical packages that perform complicated analyses with minimal effort are available for these computers. Popular packages include Statvew (SAS Institute), BMDP (Biomedical Statistical Software, University of California Press), SPSS (Statistical Package for the Social Sciences), and SAS (SAS Institute). Regardless of the statistical package, the results must be examined by the investigator. I have found errors in several statistical software packages, one produced locally, and others, widely available. On occasion, errors are subtle and may escape notice; in some instances, the errors are obvious to even the casual user. Several steps are available to confirm the accuracy of the statistical package. First, the investigator can use a data set analyzed in a standard textbook; differences between the results offered in the textbook and those from the statistical package should alert the investigator to errors. Second, the investigator should always examine the entire output from the statistical package, not just the statistical results. If the mean values, SD, or other results differ from those predicted from the data, the investigator should be suspicious of the results.

Materials are readily available to guide the investigator toward more sophisticated statistical techniques. Glantz has written an excellent monograph, *Primer of Biostatistics*.[21] Textbooks by Zar, [29] Dixon and Massey, [30] and Colton [31] are also valuable resources, particularly if the investigator has selected a particular test and

needs guidance through the individual steps.

In addition, the number of statisticians who have biomedical expertise is increasing. These statisticians have knowledge of the particular problems associated with medical research, including small sample sizes and abnormal distri-butions. Biostatisticians can be valuable in directing the medical investigator toward the appropriate statistical test, in performing the analyses, and in interpreting the results.

Finally, a word of caution regarding study design is in order. Inexperienced investigators may accumulate a large amount of data before identifying the most appropriate statistical techniques to be used. When an attempt is made to select the appropriate statistical test, the investigator may learn that the data have been collected in a way that prohibits appropriate statistical analysis. This problem can usually be avoided if the investigator considers the issue of statistical analysis before data are collected, particularly if outside advice is necessary. With increasing awareness among anesthesia researchers, these problems should occur less frequently.

DESCRIPTIVE STATISTICS

The initial step in statistical analyses is to categorize and summarize the data, that is, to apply the techniques of descriptive statistics.

Types of Data

The most familiar type of data, data on a ratio scale, has two characteristics (Table 21-6) . First, the size interval between successive units on the measurement scale is constant. For example, the difference between cardiac outputs of 4 and 5 L/min is the same as the difference between cardiac outputs of 7 and 8 L/min. Second, the measurement scale must have a zero point, and this zero value must have physiologic significance. These characteristics permit statements about the ratio of different values on the measurement scale. For example, a drug effect lasting 30 minutes is twice as long as a drug effect lasting 15 minutes.

Data on an interval scale also have constant intervals but lack a true zero point. For example, most measurements of pressure are referenced to atmospheric pressure (
760 mm Hg) rather than to a true zero point. The pressure represented by 20 cm H_2O (14.7 mm Hg) is not twice as great as the pressure represented by 10 cm H_2O (7.4 mm Hg). To calculate the true ratio, we would have to convert the pressures to absolute measurements by adding the reference zero value, in this case 760 mm Hg. Similarly, the temperature represented by 36°C is not twice the temperature represented by 18°C.

For many physiologic variables, there are known numeric differences between subjects. However, the data may indicate only a relative, rather than a measurable, difference between subjects. For example, a patient whose American Society of Anesthesiologists (ASA) physical status is III is at greater risk of harm from undergoing anesthesia than is the patient having a physical status of I. However, the difference in terms of degree of illness between patients having a physical status of II and those having a status of III is not necessarily the same as the difference between patients having a status of I and those having a status of II. Similarly, an Apgar score of 8 is better than one of 5; however, the difference between these two scores, in terms of neurobehavioral well-being, is not necessarily the same as the difference between Apgar scores of 5 and 2. These scoring systems are examples of *data on an ordinal scale.* Ordinal scales have arbitrary intervals that describe relative, rather than absolute, relationships between the ranks. They convey less information than data on a ratio or interval scale, because only relative comparisons can be made (e.g., that an Apgar score of 10 is better than a score of 5). In medical literature, it is common to see data on an ordinal scale treated as if they were on a ratio or an interval scale. For example, the extent of sensory blockade produced by spinal or epidural anesthesia is often reported in units of dermatomes, although a segment in the sacral region may not be identical, in terms of the amount of anesthetic required to produce loss of sensation, to a segment in the thoracic region. The treatment of ordinal data with statistical techniques more appropriately applied to interval or ratio data is so common as to be widely accepted. [32] Nevertheless, special techniques are available that are often more appropriate for the analysis of these types of data.

On occasion, we choose to describe, that is, name, a variable in terms of a quality rather than a quantity. Variables described in this fashion are called *data on a nominal scale.* For example, genotypes of pseudocholinesterase are identified by names rather than by numeric measurements. [33] To permit mathematical comparisons, we can obtain ratio-scale measurements of pseudocholinesterase activity for each of the genotypes. Using these ratio-scale, rather than nominal-scale, measurements, we can compare the various groups. Finally, some variables have only two possible attributes. For example, after surgery, a patient is either alive or dead. The investigator must correctly identify the type of data collected. Only then can the appropriate statistical analysis be applied.

Significant Digits

For all measurements, there are limits to precision. For example, blood pressure is usually measured to the nearest millimeter of mercury, and arterial oxygen (Pa_{O_2}) and carbon dioxide (Pa_{CO_2}) partial pressures are measured to the nearest millimeter or, at best, to the nearest tenth of a millimeter of mercury. In neuromuscular studies, because the ulnar nerve is usually stimulated no more frequently than once every 10 seconds, onset times cannot be measured with a precision greater than that. Whenever data are reported, a greater degree of precision should not be suggested than really exists.

Populations and Samples

Inherent in statistical analysis of a measured variable is the desire to draw conclusions about that variable. To accomplish this goal, the investigator could measure the variable for the entire population. For example, if we were interested in knowing $P_{A}CO_2$ for all adult patients anesthetized with an end-tidal concentration of desflurane of 6.0 percent at the University of California, San Francisco, in 1998, we could measure that variable in all eligible subjects. The values for $P_{A}CO_2$ might then be presented in a histogram displaying the number of subjects having each value of $P_{A}CO_2$; the histogram might also display the percentage of subjects having each value of $P_{A}CO_2$ (Fig. 21-3) . Obtaining measurements for all eligible subjects would be cumbersome and expensive. To simplify the task, we might select a smaller sample of the original population and assume that

TABLE 21-6 -- Types of Data

TYPE OF DATA	CHARACTERISTIC	EXAMPLES
Data on a ratio scale	Measurement scale has constant intervals and a true zero point	Duration of drug effect, cardiac output
Data on an interval scale	Measurement scale has a constant interval, but no true zero point	Airway pressure, body temperature
Data on an ordinal scale	Data are ordered or ranked, not measured	ASA physical status, Apgar scores
Data on a nominal scale	Data are classified not by a numeric measurement but by some quality or attribute	Electroencephalographic patterns, survival, genotypes of pseudocholinesterase

Figure 21-3 Histogram showing hypothetic values for P $_{CO_2}$ for all patients undergoing desflurane anesthesia at the University of California, San Francisco during 1993. The X axis represents values for P $_{CO_2}$. There are two Y axes. The left-hand axis represents the actual number of patients with each value of P $_{CO_2}$; the right-hand axis shows these values as a percentage of the total population.

this sample represents the entire population. Values for P $_{ACO_2}$ for a hypothetic sample are shown in Figure 21-3 . Note that extreme values (>58 mm Hg and <36 mm Hg) are not represented, nor are certain intermediate values (e.g., 42, 44, 45 mm Hg). Using these data, we cannot conclude that P $_{A}CO_2$ is always somewhere between 36 and 58 mm Hg during light desflurane anesthesia, only that extreme values did not occur in this sample. The values obtained from this sample of 12 subjects suggest that during light desflurane anesthesia, P $_{A}CO_2$ is frequently between 40 and 52 mm Hg.

Although measurements have been made on 12 subjects, the purpose of our study was to make predictions about a larger group, the entire population of adults undergoing light desflurane anesthesia. In order for this prediction to be valid, we must assume that the sample represents the entire population. If this assumption is not true, the results may not apply to the entire population. For example, Stanley and Webster [34] found that fentanyl, in doses of 50 mug/kg, provided sufficient anesthesia for cardiac surgery; however, subsequent studies suggested that larger doses are necessary for most patients. The studies by Stanley and Webster were conducted in Salt Lake City, a community that is largely Mormon. Because Mormons abstain from alcohol and other drugs, the low dose requirement observed by Stanley and Webster may have resulted from the personal habits of the subjects; therefore, this sample may represent the population of Salt Lake City but not the population of the United States. Recognizing these types of bias is important. If possible, these biases should be avoided. If they cannot be avoided, they must be identified.

Central Tendency

After the investigator selects the sample population and obtains measurements, he or she must then describe the results. All the measured values could be displayed as in Figure 21-4 or in other formats, such as a table. Although these methods of data presentation permit the reader to make judgments about the individual data points, they limit communication about the general nature of the sample. To describe a variable for the entire population, the investigator would like to be able to select the single value from the sample

Figure 21-4 Histogram showing hypothetic values for P $_{CO_2}$ obtained from 12 patients undergoing desflurane anesthesia. These 12 values represent a sample taken from the values in Figure 21-3 .

that would represent the center of the entire population, a value known as the *index of central tendency.*[35] If all the values in the sample were identical, the investigator would report that single value. However, for most variables, the sample contains many different values for individual members.

Mean

The value most widely used to represent the population is the arithmetic mean, usually referred to as the mean. The mean is determined by adding all the values of the population and dividing by the number of values in the population. This is described mathematically as population mean equals the sum of observations/number of observations. When a large number of terms is being summed, a shorthand way of expressing the process, called *summation notation,* is used:

where mu is the *population mean,* X_i are the individual values, and upper case sigma (Sigma) means to sum these values. Therefore, this expression is read as follows: mu is equal to the sum of all individual values of X_i from X_1 to X_N , divided by *N.* Because we usually sum all the values of the population, it is conventional to omit several of these symbols and write

When the investigator is studying a sample rather than the entire population, another term, $\bar{X}$, is used to represent the *sample mean.* $\bar{X}$ is equal to the sum of all measurements in the sample divided by the number of measurements in the sample. The mean is expressed with the same units as the individual observations.

Median

Alternatively, central tendency might be expressed with the *median.* To determine the median, the individual values are ranked from smallest to largest (or from largest to smallest). The median is the middle measurement, that is, the value below which half the values lie and above which the

other half lie. Median values have rarely been reported in the anesthesia literature; however, the median, being less sensitive to extreme values than is the mean, is a sensitive indicator of central tendency and should probably be reported more frequently. In addition, most nonparametric analyses compare the median rather than the mean; therefore, when these analyses are performed, it is appropriate to report the median.

Mode

The *mode* is the value that occurs most frequently. With the small number of observations in many medical studies, there will be no mode if each observed value occurs only once.

The arithmetic mean is a valid description of the location of the population only when ratio or interval data are used; for ordinal data, the arithmetic mean has no meaning. For example, the arithmetic mean of 5 is not the appropriate value to describe a sample consisting of subjects having Apgar scores of 0 and 10. [36] Instead, the location of the sample is more accurately described with values such as the median or, in this case, with individual values.

For many sets of measurements, the arithmetic mean represents the population accurately. For the measurements of P $_{ACO_2}$ during desflurane anesthesia, the arithmetic mean is (37 + 38 + ... + 57)/12 or 47 mm Hg. Individual values range from 37 to 57 mm Hg, and most are between 40 and 52 mm Hg. Thus, the arithmetic mean of 47 mm Hg is close to each of the members of the sample and can be considered a fair representative of all the members of the sample. In contrast, two patients in this small sample (see Fig. 21-3) had values of 51 mm Hg, making this value the mode. Although the mode is theoretically a measure of central tendency, in this instance it lies near one extreme of the sample and therefore does not represent the population. Because the number of members of this sample is even, no value lies exactly in the middle. In such circumstances, the median is taken to be the average of the two values ranked nearest the middle of the population (47 and 48 mm Hg, respectively)--that is, 47.5 mm Hg. Therefore, of the three values describing the location of this population, the mean and median represent the population well, whereas the mode does not. In all statistical analyses, the investigator should examine the values in the sample to determine how the central tendency of the sample can best be described.

Finally, just because we have selected a value to represent the sample does not necessarily imply that this value represents the larger population from which the sample was drawn. For example, our sample might have been biased toward, or away from, certain members of the population; or by chance we might have selected highly unusual members of the population. We must always remember that the mean represents the sample, rather than the population. If we extrapolate conclusions to the population, we must also consider our sampling process and the ability of this sampling process to identify the mean of the population.

Data Transformation

Most samples can be well represented by one of these three indicators of central tendency, particularly the arithmetic mean or the median. However, some samples, particularly those that are not symmetrically distributed, are not well represented by the arithmetic mean. For example, Feinstein [37] determined that the arithmetic mean for four concentrations of hydrogen ion (0.03162, 0.0002512, 0.0000001995, 0.000000001259) was 0.00797. This value is close to the first member of the sample and far from the other three. Rather than using the arithmetic mean to locate the central tendency of the population, he suggested using another indicator, the geometric mean, which is equal to the *n*th root of the product of each of the observations.

Therefore, the geometric mean of these four concentrations would be $[(0.3162 \times 10^{-1}) \times (0.2512 \times 10^{-3}) \times (0.1995 \times 10^{-6}) \times (0.1259 \times 10^{-8})]^{1/4}$ or 0.6683×10^{-5}. In this instance, the geometric mean, being larger than two of the observations and smaller than the other two, is more representative than is the arithmetic mean. Alternatively, the hydrogen ion concentrations could be converted to pH values of 1.5, 3.6, 6.7, and 8.9, respectively. The arithmetic mean of these pH values is 5.2, which corresponds to a hydrogen ion concentration of 0.6683×10^{-5}. Thus, the central tendency of hydrogen ion concentration is best expressed using the geometric mean, whereas the central tendency for pH is best expressed using the arithmetic mean.

The foregoing example demonstrates how data might be converted to an easier-to-use form (transformed) by applying simple algebraic processes such as taking the logarithm or square root of each value. Data transformation permits easier manipulation of the data or changes the distribution, possibly making a skewed distribution normal (see next section). Before using a calculator or computer to determine the arithmetic mean, the investigator should examine the data to determine whether the arithmetic mean is representative of the sample and whether transformation may be necessary to improve statistical analysis.

Normal Distribution

The ability of the arithmetic mean to express the central tendency of the population is a function of the distribution of the values within the population. For many variables, such as P_{ACO_2} (shown earlier), values tend to cluster around a central value, with fewer values located toward the extremes. If one obtains a sufficiently large sample, for many biologic variables the histogram would assume the shape of a bell (Fig. 21-5 A). This distribution, known as the *normal distribution,* was first described by de Moivre, [29] but it is credited to Gauss, being called the gaussian distribution. Many statistical tests described in this chapter assume that the population under examination is distributed normally. Because medical studies often use a small sample size, the assumption that resulting data have a gaussian distribution frequently is not tested.

Populations that do not have a gaussian distribution may assume a number of different shapes (Fig. 21-5 B and C). For example, administration of an imaginary drug, histodrenaline, might result in the release of histamine in some individuals and in the release of catecholamines in others. Therefore, if we measured the change in blood pressure after administration of this drug, half the subjects might have

Figure 21-5 The distribution of values for a population may assume many shapes. One shape frequently encountered in biologic experiments is the normal distribution shown in A. On occasion, distributions may be bimodal (humped), as shown in B, or J-shaped, as shown in C.

an increase in blood pressure, whereas the other half could have an equal decrease (see Fig. 21-5 B). If the mean value were zero, we might be led to believe that histodrenaline had no cardiovascular effects. A more appropriate conclusion would be that the arithmetic mean did not represent the population. The importance of examining the distribution of the data points should now be readily apparent: on occasion, the investigator finds that the arithmetic mean should not be used to describe the population. In that case, alternate methods of describing the results of the study, such as a histogram or table, become essential.

Variability

Identifying the central location of the sample is necessary but not sufficient to describe the population. For example, had all P_{ACO_2} values during desflurane anesthesia ranged from 44 to 49 mm Hg, the mean might have been 47 mm Hg. Although the mean for this new sample would have been the same as that for the sample described earlier, these two samples probably describe different populations, one having a broad range of P_{ACO_2} values during desflurane anesthesia and the other having a narrow range. Thus, in addition to describing the central location of the sample, we need to describe how dispersed the data are, that is, the variability of the sample.

Range

The smallest and largest values within a sample define the *range* of the sample. Although a description of the range is often useful, it can also be misleading: outliers, whether they are small or large, may suggest a greater variability of the sample than is indicated by the remaining elements of the sample.

Mean Deviation, Mean Absolute Deviation

A second technique to describe variability might be to find the average deviation from the mean. However, because some deviations are positive and others are negative, their sum is always zero; hence, the average deviation has no value as an indicator of dispersion of the data. Alternatively, the investigator could sum the absolute values of these differences from the mean and divide by *n,* thus producing the *mean absolute deviation.* This technique is mathematically cumbersome and has not become popular.

Sum of Squares

Another approach to the problem of describing the dispersion of the data is to sum the square of the deviations from the mean, a method that eliminates the negative signs. Squaring the deviations has a second effect: it increases ("weights") the contribution of the values according to their distance from the mean. For example, if the deviations from the mean were -1, -5, +1, and +5, the sum of squared deviations would be 52. A sample containing deviations of -3, -3, +3, and +3 would produce a smaller sum of squared deviations, 36. Although the mean absolute deviation (3) is the same for both samples [(1 + 5 + 5 + 1)/4 or (3 + 3 + 3 + 3)/4], the sample containing values more distant from the mean has the larger sum of squares. This sum of the squared deviations from the mean, known as the *sum of squares* (SS), is a fundamental tool used repeatedly in statistics. It is expressed mathematically as

Calculating the value of this equation requires two passes through the data: the first pass, to sum the individual values to determine the mean value; and the second, to determine the difference between individual values and the mean. Calculators and computers reduce this to a single step, known as a *machine formula,* which is derived as follows:

This can be expanded to

The second part of this equation, 2Sigma X_i X, can be simplified to: 2 × X × Sigma X_i , which is equal to 2 × (Sigma X_i / n) × Sigma X_i , or [2 × (Sigma X_i)^2 / n]. Similarly, the third part of the equation, Sigma X^2 ,

can be simplified to n × X^2 , or [n × (Sigma X_i /n)^2] or (Sigma X_i)^2 / n. Equation (8) can then be simplified to

Using this machine formula, one can determine the sum of squares in a single pass through the data; this technique greatly simplifies data manipulation.

Variance

Dividing the sum of squares by the sample size yields the average squared deviation from the mean, also known as the *mean squared deviation* or *population variance,* sigma^2 :

This equation is read as follows: population variance is equal to the sum of the squared differences between individual values and the population mean, divided by the sample size. Usually we are dealing with samples rather than populations and, when we calculate the *sample variance,* we do not know the population (i.e., true) mean. Instead, we use the sample mean to estimate the population mean. If we represent the difference between the sample mean and the population mean as epsilon, equation 10 could be written as follows:

This can be rearranged to

The first term,

, is what we would obtain had we used the sample mean instead of the population mean to es- timate the sample variance. The second term,

always equals zero (it is equivalent to a sum of the average deviations from the mean). The third term,

, is equal to n × epsilon^2 / n, or epsilon^2 . Thus, when the sample mean (rather than population mean) is used to estimate sample variance, sample variance is underestimated by the amount epsilon^2 . We correct for this underestimate (bias) by decreasing the denominator by 1. This process produces a better estimate for sample variance (s^2):

If there are n values that are squared and summed to determine the sample variance (equation 13), after one determines the next-to-last [(n - 1)th] value, the last [n^{th}] difference has been predetermined [the sum of the individual deviations from the mean, Sigma(X_i - X), must equal zero]. Thus, the number of independent values used to calculate sample variance differs from the sample size and is known as the *degrees of freedom (df).* A more elaborate proof that using n - 1 as the denominator yields a less biased estimate is available elsewhere. [38]

Standard Deviation

Although it is possible to express variability of the sample or the population using the respective variances, this is impractical because the units for variance for a sample are different from those for the population. Because variance is determined by squaring the differences between individual values and the mean, the units for variance consist of the square of the original units. For example, for P $_A CO_2$ values, the units for variance would be (mm Hg)^2 . A more common approach is to obtain the square root of the variance, the *SD.* As before, the SD for the population (sigma) and the SD for the sample (s) differ depending on whether n or (n - 1) is used in the denominator. In most situations, the SD of the sample, rather than of the population, should be used, even though it is a larger number.

Now we have estimated the central tendency and the variability of the sample, two values that describe the location and dispersion of the entire sample. If the population has a gaussian distribution, approximately 68 percent of the values lie within the range from 1 SD above to 1 SD below the mean. Approximately 95 percent lie within 2 SD above or below the mean, and more than 99 percent of all values lie within 3 SD of the mean. [*] Returning to the values for P $_A CO_2$ during desflurane anesthesia, we find that the SD is 6.3 mm Hg. If we examine values ranging from 1 SD below the mean (approximately 47 - 6 = 41 mm Hg) to 1 SD above the mean (approximately 47 + 6 = 53 mm Hg), we find that two-thirds of the values in the sample lie in this range and that one-third lies outside this range. The range from 2 SD below the mean to 2 SD above the mean (
34 to 60 mm Hg) includes all the values in this sample. If P $_A CO_2$ for any subject had been higher than 65 mm Hg or lower than 29 mm Hg, 3 SD or more below or above the mean would have been necessary to include those values.

Coefficient of Variation

If the sole information communicated about a sample is that the SD is 6 mm Hg, we cannot assess whether variability is large or small. For a mean arterial pressure of

100 mm Hg, a SD of 6 mm Hg is small; however, for a pulmonary artery occlusion pressure of 12 mm Hg, an SD of 6 mm Hg suggests greater variability. The ratio of SD to the sample

*In a gaussian distribution, 95 percent of all values are actually found within 1.96 (rather than 2.0) SD of the mean, and the range of 2 SD from the mean actually includes 95.44 percent of all values. However, it is common practice to use 2.0, rather than 1.96, SD to describe the 95 percent variability of samples and populations.

mean is known as the *coefficient of variation* and is often expressed as a percentage. The coefficient of variation is valuable in describing the variability of the sample. The units of the numerator and denominator being the same, the coefficient of variation has no units.

Standard Error of the Mean

If we were to repeat our measurements of P_ACO_2 during desflurane anesthesia in another 12 subjects, we would probably obtain slightly different results. For example, P_ACO_2 values might be 34, 36, 40, 41, 44, 44, 47, 48, 48, 49, 54, and 55 mm Hg. The mean of this sample would be 45 mm Hg, and the SD 6.5 mm Hg. A third sample of 12 subjects might yield a mean of 44 mm Hg; additional samples might have mean values of 43, 44, 48, and 49 mm Hg. Which of these mean values best represents the population? Had we not divided these patients into 6 groups, we would have had a single sample containing 72 members. The mean value for such a sample would have been 46 mm Hg. This could be calculated by summing the values for all 72 subjects and dividing by 72 or by determining the weighted average of the means for the individual groups: [(12 × 43) + (12 × 44) + (12 × 45) + ... + (12 × 49)]/(12 + 12 + ... + 12) or 3,312/72 or 46 mm Hg. These different techniques yield identical results. Because this new mean value, the mean of mean values (also known as the *grand mean*), was obtained from a larger sample, it better represents the population than each of the other values. As sample size increases, so does the ability of the sample to represent the population from which it came.

Because the sample mean is only an estimate of the mean of the population, we would also like to describe how closely this value approximates the population mean. This is accomplished with the *SE of the mean* (SEM), more commonly called the SE. The SE is obtained by dividing the SD of the sample by the square root of the size of the sample. The term SEM is curious, because this value is neither standard nor an error. This phrase originated during the Industrial Revolution, at which time reproducibility of measurements was important. If one measured the length of an object repeatedly, successive measurements would differ slightly, and an individual measurement would be unlikely to represent the true length of the object. Repeating the measurement and determining the average of these measurements provides a better estimate. If we then calculate the SEM value, we determine the error with which our measurement was made or how far from the true length the measured values are.

Using our initial set of values for P_ACO_2 during desflurane anesthesia, we find that the SE is $6.3/12^{1/2}$, or 1.8 mm Hg. Just as approximately 68 percent of the sample lies within 1 SD deviation of the mean, there is a 68 percent likelihood that the population (i.e., true) mean lies within one SE of the sample mean. As before, increasing the range to 2 SE above and below the sample mean increases to approximately 95 percent the likelihood that the population mean is included. Expanding the range to 3 SE increases the likelihood to more than 99 percent. Note that doubling the sample size does not decrease the SE by a factor of two; to decrease the SE by half, one would have to increase the population by a factor of four.

Confidence Limits

These ranges, when used to describe the mean, are called confidence limits. The 68 percent confidence limits include all values from 1 SE below the mean to 1 SE above the mean (written as mean ± SEM or mean ± SE). More commonly reported are the 95 percent confidence limits, which include all values within 2 SE of the mean (mean ± 2 SEM). Because the likelihood is 95 percent that the population mean is included in these confidence limits, they are a valuable way to describe both the location and the variability of the mean.

What to Report: Standard Deviation or Standard Error?

When reporting data, investigators must decide whether to report the SD or SEM. This decision should follow from the purpose of the study, which is usually to describe the sample in order to predict values for the population. Because the SD describes the variability of the sample and, hence, is used to estimate values for the population, I contend that SD should usually be reported.

Why, then, are SE reported with such frequency? The answer to this question lies in the mathematical relationship between the two values, SE being SD divided by the square root of the sample size. Thus, the SE is always smaller than the SD (and the difference between the two increases as the sample size increases). When describing a sample, it is a too-frequent practice to provide the mean plus or minus a value describing variability without identifying whether that value is the SD or the SE. [39] Because the SE is the smaller of the two values, it suggests less variability than would the SD.

Two solutions may lessen the ambiguity. First, because it is usually more important to describe the variability of the population rather than the variability of the mean (and the SE can be calculated by the reader if sample size is reported), perhaps investigators should be required to report only SD rather than SE. A simpler solution would be to require that all values describing the sample be identified as SD or SE, a practice occurring with increasing frequency. Whenever SE is reported, the investigator should ensure that the reader can determine the sample size for that value and thus be able to calculate SD.

Z Transformations

If we select a single value from the population, it would be of value to know the location of that value within the population. For example, if we found that 30 minutes after administration of pancuronium, subject A had a serum drug concentration of 150 ng/mL, we might inquire how that subject compared in that regard with other subjects given the

same dose. If we knew that the average serum drug concentration for a number of other subjects was 200 ng/mL 30 minutes after drug administration, we could conclude that the value for subject A was lower than the mean. However, without knowing the distribution of data for the other subjects, we would not be able to conclude whether this subject had an unusual response. If we also knew the SD for the other subjects, we would be able to better estimate whether this subject differed from others. If the SD for the sample was 40 ng/mL, the value for subject A would be less than 2 SD from the mean. In contrast, if the SD were 5 ng/mL, the value for subject A would be 10 SD below the mean; such an occurrence would represent an unusual response.

The distance that a value lies from the mean can be expressed mathematically as the difference between that value and the mean divided by the SD (sigma). This statistic, known as the *Z transformation*, is calculated as

that is, how many SD the measured value is from the mean. If Z is large, the new value is far from the mean; if Z is small, the value is near to the mean.

Probability

If we measured P_ACO_2 in a single subject undergoing light desflurane anesthesia, we might obtain a value of 61 mm Hg, a value that occurred infrequently in our other subjects (see Fig. 21-3). If the population mean were 46 mm Hg and the SD 6 mm Hg, the Z score would be (61 - 46)/6 or 2.5, a value that indicates this subject had an unusual response to light desflurane anesthesia. Examining a table of Z scores reveals that values of 2.5 or greater occur less than 2 percent of the time. If we

established that this subject was healthy and that no other obvious reason existed for the greater degree of respiratory depression, we would be able to say that this response is unlikely. However, statistics does not permit us to conclude that the response is abnormal.

The concept of probability attaches a numeric likelihood to the occurrence of an event. Regarding the occurrence of a $P_{A}CO_2$ of 61 mm Hg during light desflurane anesthesia, we can conclude from our other measurements that this event occurs in fewer than 2 percent of all anesthetics; this degree of likelihood is expressed as $P < .02$. Is this a significant event? Instinct tells us that an event occurring less frequently than once in 50 times is unusual and therefore worthy of notice. Is an event occurring once in 10 times ($P = .10$) worthy of notice? By convention, statisticians accept as significant any event that occurs less frequently than once in 20 times ($P < .05$). However, no biologic or mathematical rationale exists for choosing 5 percent as the level of statistical significance. R.A. Fisher, a noted statistician, observed that "The value for which $P = .05$, or 1 in 20, is 1.96 or nearly 2 [SD]; it is convenient to take this point as a limit in judging whether a deviation is to be considered significant or not. Deviations exceeding twice the standard deviation are thus formally regarded as significant." [40] Later he wrote, "It is usual and convenient ... to take 5 per cent. as a standard level of significance ... [and] to ignore all results which fail to reach this standard ...." [41] Although a probability of 5 percent is the usual standard for statistical significance, one publication, the *Journal of Experimental Psychology,* has encouraged a significance level of 1 percent (i.e., $P < .01$). [42]

Type I and Type II Errors

The level of probability we select as representing significance, known as alpha, is also the frequency with which we erroneously conclude that a difference exists when there is no real difference. This is known as a *type I error,* or an a *error.* Alternatively, we could ask how often we can afford to be wrong. If an investigator repeats an experiment frequently, he or she will eventually select a sample whose mean differs significantly from the population mean. If we select a probability level of 5 percent (alpha = 0.05), we accept a 5 percent chance of being wrong. If the price for being wrong is very great, we may select a stricter criterion for statistical significance--for example, alpha = 0.01.

Thus far, we have focused on the issue of erroneously concluding that a difference exists when none exists in reality. A second issue involves whether we can truly state that no difference exists between 2 populations. For example, if we were to measure recovery of twitch tension 60 minutes after administration of a dose of pancuronium in a group of subjects and 90 minutes after administration of the same dose in another group, instinct would tell us that more recovery would have occurred in the group studied at 90 minutes. If the samples consisted of 3 patients each, the variability within each of the groups might be great enough to prevent us from detecting a difference; therefore, we might erroneously conclude that no recovery had occurred between 60 and 90 minutes. With samples of 20 subjects or more, we are more likely to detect a difference. The ability of a statistical test to detect a difference, known as its power, depends on the expected difference between groups, the variability within the groups, and the size of the samples. If the sample size is not sufficiently large, we will not be able to detect real differences between groups. This is known as a *type II* or beta *error.* Type II errors commonly occur when an investigator selects the sample size without considering the issues mentioned earlier. To avoid this type of error, the investigator should perform a *power analysis* prior to initiating any data collection. Several approaches to power analysis are described later in this chapter.

One-Tailed Versus Two-Tailed Comparisons

Thus far, we have considered the idea that a value located toward either extreme of the probability distribution is unlikely to occur. If alpha equals .05 and the distribution is symmetric, then the 5 percent of values considered unlikely to occur (and therefore worthy of note) would be found equally at both ends of the distribution; that is, the left-hand

tail of the curve would contain 2.5 percent of the values, and the right-hand tail of the curve would contain 2.5 percent of the values. An analysis that examines both tails of the curve is known as a *two-tailed comparison.*

An investigator often has a priori (i.e., "before the fact") assumptions that he or she is interested in testing. For example, in assessing the relationship between volume status and blood pressure, we would only be interested in assessing whether blood pressure was lower in hypovolemic patients, because we assume that hypovolemia would decrease, rather than increase, blood pressure. If we performed the two-tailed test, we would be able to answer two questions: First, does blood pressure differ between normovolemic and hypovolemic subjects? If so, is blood pressure higher or lower in hypovolemic patients? If we are interested in only one extreme, we can examine the 5 percent located at one end of the distribution, rather than the 2.5 percent located at each end of the distribution. This is known as a *one-tailed comparison.* If the investigator is able to make an a priori assessment as to the direction of the relationship between groups and is willing to limit statistical evaluation to that issue, a one-tailed test may be appropriate. The investigator must decide to perform a one-tailed comparison before the data are collected. It is inappropriate to examine the data, observe a difference between groups, and then test the significance of the difference using a one-tailed comparison.

Hypothesis Testing and Statistics

Statistics does not permit us to conclude whether or not an association is valid, only whether it is likely or unlikely to have occurred. For example, if we studied an adult with chronic lung disease whose P_{ACO_2} values were 59 mm Hg during desflurane anesthesia, we might ask whether this patient differed from the healthy adults mentioned previously whose $P_{A}CO_2$ was measured during desflurane anesthesia (i.e., does chronic lung disease affect ventilatory response during desflurane anesthesia?). A statistician would convert this question into a *null hypothesis;* that is, that there is no difference between this sample and the population. The likelihood of this hypothesis would then be tested. If the alpha were low, such as less than 5 percent, the statistician would reject the null hypothesis, stating that there is little probability that the sample was selected from the original population. In turn, we can conclude that there is likely to be a difference between these subjects and the original sample.

Before continuing to inferential statistics, we should define certain terms more specifically. The word *statistics* describes not only the name of the discipline that is the subject of this chapter, but also certain numeric entities calculated as part of that discipline. For example, mean, SD, and variance are all statistics. A statistic is an estimate, based on random sampling of the population, of parameters of the population. In addition, *t, F,* and a multitude of other symbols represent statistics. Tests employing these statistics are known as *parametric tests;* such tests are based on the actual magnitude of the values. In contrast, tests based on ranking of the values are known as *nonparametric tests.*

INFERENTIAL STATISTICS

After determining the descriptive statistics and noting differences between groups, the investigator would typically like to draw statistical conclusions regarding these differences. To draw these conclusions, the investigator employs a second area of statistics known as *inferential statistics.*

One- and Two-Sample t-Tests

The most widely used, and misused, statistical test is Student's *t*-test, a group of statistical tests designed for analysis of a single group or comparison of two groups. The name of this test refers to a pseudonym used by W.L. Gosset. Gosset's employer, the Guinness Brewing Company, did not permit its employees to publish their research under their own names; however, because of the importance of this work, Gosset was permitted to publish under the name Student. [43] Gosset's contribution was to develop the *t* distribution. The Z distribution (Z scores) described earlier is based on an infinite sample size. Gosset recognized that with smaller sample sizes (e.g., less than 30), the distributions differed from the exact bell-shape of the gaussian distribution. In particular, the presence of an extreme value (i.e., one far from the mean) was more likely to occur in a small sample. Gosset examined a variety of distributions of small samples and determined the frequency with which the more extreme values occurred.

Earlier we observed that in an infinitely large, normally distributed sample, 95 percent of all observations fell within 1.96 SD of the mean. Gosset found that with a sample size of 20, a slightly larger range, 2.09 SD, was necessary to include the same 95 percent of the observations. As the sample size decreased to 10, 2.26 SD were necessary; with a sample size of 5, an even larger range, 2.78 SD, was necessary to include 95 percent of all observations. These values (e.g., $t = 2.09$ for alpha = 0.05 and $N = 20$) comprise the *t* distribution. Every value in the *t* distribution is associated with a sample size and a value for alpha. As the sample size becomes large (e.g., >30), the values for the *t* distribution approach those for the Z distribution; with an infinite sample size, they are identical. Gosset's observations were then used to define three statistical tests: the one-sample, the twosample, and paired-sample *t*-tests.

Parametric t-Tests

One-Sample t-tests

If an investigator measures a variable in a single group of subjects, he or she may be interested in determining whether the mean for this sample differs from zero (or alternatively, from some other specific value). This analysis can be performed using the one-sample *t*-test. To examine the association between diuretic drugs and acid-base status, we might identify a group of patients taking diuretic drugs, obtain arterial blood samples, and determine base excess. A hypothetic set of values is shown in Table 21-7 . The mean of

TABLE 21-7 -- Hypothetic Set of Values for Base Excess for Subjects Given Diuretic Drugs

SUBJECT		BASE EXCESS (MEQ/L)
1		0
2		8
3		1
4		6
5		-3
6		7
7		9
8		2
9		1
10		0
11		-1
12		6
	N = 12	
	Mean = 3.0	
	Standard deviation = 3.98	
	Standard error = 1.15	
	Degrees of freedom = 11	

these values is 3.0, a fact that might suggest an association between diuretic drugs and alkalosis. However, two of the subjects have negative values and two have zero values. Because a quick and informal appraisal of the data (the "eye" test) cannot determine whether 3.0 differs significantly from zero, we must use statistical analysis--in this case, the one-sample *t*-test. If we assume that this sample represents the population and that the distribution of these values is normal, we can state with 95 percent confidence that the population mean lies between [mean - ($t \times SE$)] and [mean + ($t \times SE$)]. This statement is similar to an earlier one that the population mean lies between [mean - (1.96 × SE)] and [mean + (1.96 × SE)]. However, the value 1.96 (the Z value to include 95 percent of the population) must now be replaced by the value of *t* appropriate for the sample size, that is, 2.20. This value can be found on a table of *t* distribution by locating the row corresponding to the appropriate *df* (in this case, the value for *df* is one less than the sample size) and the desired value of alpha (typically, 0.05). Sample values for *t* distribution are shown in Table 21-3 ; a complete listing can be found in any statistical textbook. In this case, the 95 percent confidence limits for the mean are 0.47 and 5.53; these limits do not include the value zero. To determine the 99 percent confidence limits, we use the *t* value for alpha = 0.01 and 11 *df,* 3.11. This results in 99 percent confidence limits of -0.57 and 6.57, a range that does include zero. We can conclude with 95 percent, but not 99 percent, confidence that the use of diuretic drugs is associated with alkalosis. Note that our conclusion is limited to making an association between diuretic drugs and alkalosis rather than implying causality. Statistics

does not prove causality, only the likelihood of an association.

An alternate approach to this problem, more familiar to some readers, is shown in Table 21-8 . The division of the mean value by the SE produces a value for *t.* This value is compared with a value for *t* appropriate for the desired level of significance (usually, alpha = 0.05 or 5%) for the appropriate degrees of freedom. If the value for *t* exceeds the value from

TABLE 21-8 -- One-Sample Student's *t*-Test Applied to Hypothetic Data from Table 21-7

$t_{0.05(2),11}$ [a] = 2.20

$t_{0.01(2),11}$ [b] = 3.11

Therefore, .01 < *P* < .05

SE, standard error.

Notation from Zar [29]

[a] Read, "the two-tailed *t* value when alpha = 0.05 and degrees of freedom = 11."
[b] Read, "the two-tailed *t* value when alpha = 0.01 and degrees of freedom = 11."

the table (known as the *critical value*), the null hypothesis is rejected, and we would conclude that a difference exists (at the alpha level) between zero and the mean value for this population. In this instance, the value for *t* is 2.6. The critical value for *t* for alpha = 0.05 and 11 *df* is 2.20; the value for *t* for alpha = 0.01 and 11 *df* is 3.11. The value for *t* exceeds the critical value for alpha of 0.05, but not for alpha of 0.01. This fact also leads us to conclude (as we did earlier) that the mean for this sample differs from zero and that the likelihood is between 95 and 99 percent.

The one-sample *t*-test can also be applied to populations for which mean values are expected to be other than zero. For example, if we were interested in whether 90 mm Hg was the mean Pa_{O_2} of smokers, we would determine the difference between 90 mm Hg and the mean value for the sample population, divide this value by the SE of the sample to determine the *t* statistic, and then compare the resulting value with the critical value for *t.*

Two-Sample t-Tests

More commonly, we make measurements on two groups of subjects and compare the responses. Such a comparison requires use of the two-sample *t*-test. In this form of *t*-testing, two independent samples are being compared, that is, an individual datum in one sample is not associated with another datum in the second sample. For example, we might want to compare blood pressure in normovolemic and hypovolemic individuals. Hypothetic values are provided in Table 21-9 . In this instance, an informal appraisal of the data would establish that a significant difference exists between the mean values. This difference can be confirmed by using the two-sample *t*-test to evaluate the null hypothesis that there is no difference between these two samples; that is, they come from the same population.

Computation of the *t* statistic for the two-sample test is slightly more complicated than for the one-sample test. In the one-sample test, we divided the mean by its SE. With two samples, each sample has its own SE; we then determine the SE of the difference between the means. Although the derivation of the SE between the means is beyond the scope of this chapter, [44] the denominator of the equation is similar to that for the one-sample test:

TABLE 21-9 -- Application of the One-Tailed Two-Sample Student's *t*-Test to Hypothetic Sets of Mean Blood Pressure Values for Normovolemic and Hypovolemic Subjects

	NORMOVOLEMIC SUBJECTS	HYPOVOLEMIC SUBJECTS
	77	72
	91	62
	101	51
	81	81
	76	47
	68	74
	72	52
	82	65
N	8	8
Mean	81.0	63.0
SD	10.6	12.3
SE	3.76	4.33
$t_{0.05(1),14}$ [a] = 1.76		
$t_{0.01(1),14}$ [b] = 2.62		
Therefore, *P* < .01		

SD, standard deviation; SE, standard error.

[a] Read, "the one-tailed *t* value when alpha = 0.05 and degrees of freedom = 14."
[b] Read, "the one-tailed *t* value when alpha = 0.01 and degrees of freedom = 14."

Alternate methods are available to calculate the SE of the difference between means, one of which uses a pooled variance instead of the separate variances of equation (15). [44] Despite the different methods for calculation, the SE are similar.

Next, the difference between groups is divided by this SE; this process produces the now familiar *t* statistic, which is then compared with the critical value from the tables. If the value for *t* exceeds the critical value, the null hypothesis is rejected; if *t* is less than the critical value, the null hypothesis cannot be rejected. An instinctive approach to the comparison between the calculated value for *t* and the critical value is as follows: the numerator is the difference between the mean values, an estimate of the distance between the central location of the two samples. The denominator, shown in equation 15, is the SE of the difference between means, an estimate of the variability within the samples. The ratio of these values estimates how much of the difference between means can be explained by the variability within the samples. If the variability within each of the samples is small, only a small difference between mean values should be sufficient to suggest that a difference exists between the samples. In contrast, if the variability within one or both of the samples is great, the difference between the means of the samples must be larger if the investigator is to have confidence that a difference exists between groups.

Before using a table of *t* values to determine the critical value for this example, we should consider one special aspect. In our hypothetic situation, we have been comparing blood pressure in normovolemic and hypovolemic individuals. Our a priori assumption is that blood pressure will be lower, rather than higher, in the hypovolemic group. Therefore, rather than perform a two-tailed comparison that would permit us to assess all possible relationships among the data, it would be appropriate to perform a one-tailed test. Because the critical value for *t* (alpha = 0.05, *df* = 14) is lower for a one-tailed comparison (1.76) than for a two-tailed comparison (2.14), we have increased our chances of detecting a statistically significant difference by using the former.

In this example, the *t* statistic is markedly greater than the critical value; we conclude that it is unlikely (*P* < .05) that these two samples were selected from the same population. Therefore, the mean value for blood pressure is lower for these hypovolemic individuals than for normovolemic individuals. Because the *t* statistic is markedly greater than the critical value for alpha = 0.05, we can refer to the table to determine the critical values for higher levels of significance. With 14 *df,* the one-tailed *t* is 2.62 when alpha = 0.01 and 2.98 when alpha = 0.005. Because the *t* statistic exceeds both these values, we can conclude that the likelihood of these samples being from the same population is extremely small, less than 0.005 or 1 in 200.

Paired-Sample t-Tests

On occasion, an investigator obtains measurements before and after an intervention and then studies whether this intervention produced a significant effect. Under these circumstances, when the two samples being compared are paired, a *paired-sample* t- *test,* more commonly called a *paired* t *-test,* is used. For example, measuring cardiac output before and after the administration of pancuronium might produce the values shown in Table 21-10 . In this instance, an informal appraisal of the data suggests a strong difference between the "before" and "after" values, because five of six subjects had an increase in cardiac output. The paired *t*-test is used to confirm this observation. A new sample is created whose members are equal to the difference between the "before" and "after" values for each subject. This new sample is then analyzed by the one-sample *t*-test. The mean value for this sample is 0.80 L/min, and the SE is 0.30 L/min. Therefore, the *t* statistic is 2.69, a value that exceeds the critical value of 2.01 (again, we can use a one-tailed test because we assume that pancuronium will increase, not decrease, cardiac output). We would conclude that the "before" and "after" measurements are unlikely to be from the same population. This conclusion suggests that pancuronium increases cardiac output.

An alternate statistical approach to this hypothetic situation would be to use the two-sample *t*-test (Table 21-11) . This test produces a value for *t* of 1.69, which is less than the critical value of 1.81. Despite the greater degrees of freedom for the two-sample test (10) than for the one-sample test (5), the unpaired test does not support our belief that a difference exists between the "before" and "after" values. This lack of confirmation results because of the variability of the "before" and "after" values. The two-sample test assumes that the investigator obtained the "before" measurements in one group of subjects and the "after" measurements in another group. The paired test is more sensitive to small changes because it assumes that the "before" and "after"

TABLE 21-10 -- Application of the Paired *t*-Test to Hypothetic Values for Cardiac Output Before and After Administration of Pancuronium

SUBJECT	CARDIAC OUTPUT BEFORE PANCURONIUM (L/MIN)	CARDIAC OUTPUT AFTER PANCURONIUM (L/MIN)	CHANGE IN CARDIAC OUTPUT (L/MIN)
1	4.3	5.7	+1.4
2	5.6	5.4	-0.2
3	3.9	4.6	+0.7
4	5.7	7.3	+1.6
5	4.8	6.0	+1.2
6	5.2	5.3	+0.1
Mean	4.92	5.72	0.80
Standard deviation	0.72	0.91	0.73
Standard error	0.29	0.37	0.30
$t_{0.05(1),5}$ [a] = 2.01			
Therefore, *P* < .05

TABLE 21-11 -- Inappropriate Application of the Two-Sample *t*-Test to the Hypothetic Analysis of Data of Table 21-10

$t_{0.05(1),10}$ [a] = 1.81	
Therefore, *P* > .05	
SE, standard error.	

[a] Read, "the one-tailed *t* value when alpha = 0.05 and degrees of freedom = 10."

values were measured in the same subject. For example, a change in cardiac output from 4 to 6 L/min in one subject means something entirely different than would the measurement of 4 L/min in one subject before pancuronium and the measurement of 6 L/min in a different subject after pancuronium.

Nonparametric t-Tests: the Mann-Whitney U-Test

Data on an ordinal scale require special treatment, because determining means and variances for this kind of data is usually inappropriate. In order to make statistical

comparisons on ordinal data, nonparametric tests, which assess the relative ranks rather than the magnitude of the data, are applied. Most parametric tests have a corresponding nonparametric test.

Nonparametric tests are also valuable for analyzing samples that deviate strongly from the normal distribution. Although parametric tests are based on the assumption that distribution is normal, they are sufficiently powerful (statisticians use the term *robust*) to detect differences even when samples are not distributed normally. However, as the samples stray significantly from a normal distribution, parametric tests lose their ability to detect differences. Because nonparametric tests analyze only the ranks rather than the individual values, they may detect differences not detected by parametric tests.

The nonparametric test corresponding to the two-sample *t*-test is the Mann-Whitney *U*-test. With this test, the values in each of the two groups are assigned ranks. The smallest (or largest) value is assigned the rank of 1; the next smallest (or next largest), the rank of 2. This process continues until the largest (or smallest) value has been assigned the rank equal to the sum of the two sample sizes. If values are tied in rank, they are assigned a value equal to the average of the corresponding ranks. For example, if two samples are tied for ranks 4 and 5, both are assigned the rank of 4.5. The statistics R_1 and R_2 are equal to the sum of the ranks for groups 1 and 2, respectively. The test statistic, *U,* is determined by the following equation:

where n_1 and n_2 are the sizes of the first and second groups, respectively. The value for *U* is then compared with critical values for *U* obtained from a table. The data comparing the blood pressures of normovolemic and hypovolemic subjects (see Table 21-9) can be analyzed using the Mann-Whitney *U*-test, as shown in Table 21-12 . As with the two-sample *t*-test, the results of the Mann-Whitney *U*-test suggest a difference between the two groups ($P < .05$). Nonparametric tests such as the Mann-Whitney *U*-test rarely appeared in the anesthesia literature until recent years; however, with increased sophistication in research, these tests are being used more frequently. The nonparametric version of the paired *t*-test is the Wilcoxon paired-sample test.

Comparing Three or More Groups

The critical values for *t* are calculated with the assumption that comparisons are being made between only two

TABLE 21-12 -- Nonparametric Comparison of Hypothetic Data from Table 21-9 Using the Mann-Whitney *U*-Test

BLOOD PRESSURE		RANKS	
NORMOVOLEMIC	***HYPOVOLEMIC***	***NORMOVOLEMIC***	***HYPOVOLEMIC***
77	72	11	7.5
91	62	15	4
101	51	16	2
81	81	12.5	12.5
76	47	10	1
68	74	6	9
72	52	7.5	3
82	65	14	5
$n_1 = 8$			
$n_2 = 8$			
$R_1 = (11 + 15 + ... + 14) = 92$			
$R_2 = (7.5 + 4 + ... + 5) = 44$			
$U = n_1 \times n_2 + n_1 \times (n_1 + 1)/2 - R_1 = 8 \times 8 + 8 \times 9/2 - 92 = 8$			
or			
$U = n_1 \times n_2 + n_2 \times (n_2 + 1)/2 - R_2 = 8 \times 8 + 8 \times 9/2 - 44 = 56$			
$U_{0.05(2),8,8}$ [a] = 51			
$U_{0.01(2),8,8}$ [b] = 57			
Therefore, $0.01 < P < .05$			

[a] Read, "the two-tailed *U* value when alpha = 0.05, $n_1 = 8$, and $n_2 = 8$."

[b] Read, "the two-tailed *U* value when alpha = 0.01, $n_1 = 8$, and $n_2 = 8$."

groups. If the investigator collected data on three groups of subjects, three comparisons would be possible: A versus B, A versus C, and B versus C. If each of these comparisons was made using the two sample *t*-test and alpha = 0.05, we would be accepting a 5 percent risk of committing a type I error for each comparison. For three comparisons, the chance of committing a type I error increases to approximately 3 × 5 percent, or 15 percent (actually closer to 14 percent [*]), a level that is usually considered unacceptable. As the number of groups increases, the number of possible comparisons increases such that, with enough groups, the investigator will eventually uncover a nonexistent difference.

Thus, the *t*-test is properly used for comparing two groups (or a single group to a predetermined value). When more than two groups are being compared, other tests, particularly analysis of variance, are more appropriate. If the investigator chooses to use the *t*-test to compare more than two groups, a correction must be made to prevent type I errors. When one such correction, the *Bonferroni inequality* (or *Bonferroni correction*), is applied, the alpha level for each comparison is divided by the number of comparisons to be performed. For example, if the investigator chooses a value of 0.05 for alpha and three comparisons are possible, a value of 0.05/3 or 0.0167 for alpha should be used for each of the comparisons. Then, the investigator is able to state that, overall, the chance of committing a type I error is less than 5 percent.

If the Bonferroni inequality is used, the investigator must decide in advance which of the comparisons will be made. For example, if there are four groups, the investigator may choose to compare group I with each of the other groups (e.g., if subjects in group I were given the placebo and subjects in groups II to IV were given one of three different drugs). In this case, only three of the six possible comparisons will be made. However, it is inappropriate to examine the data and then decide a posteriori which comparisons to make.

Multisample Tests: Analysis of Variance

Parametric Analysis of Variance

The *t*-test enabled examination of a single group or comparison of two groups. For comparison of three or more groups, another test, *analysis of variance* (also known as *single-factor analysis of variance* or *one-way analysis of variance*) is necessary. Analysis of variance is similar in principle to the two-sample *t*-test. Using analysis of variance, we determine two values, one value describing the variability between groups, and the other describing the variability within the groups. For the two-sample *t*-test, these values consisted of the difference between mean values and the SE of the difference between the means. For analysis of variance, the square of corresponding values is used. The variability between groups is called the *between-groups variance* (also the *groups variance*); variability within groups is called the *within-groups variance* (also the *error variance*). For the two-sample *t*-test, we divided the difference between the mean of each of the groups by the appropriate SE; similarly, for analysis of variance, we divide the between-groups

* For each comparison in which the investigator permits a type I error of alpha, he or she is (1 - alpha) confident that no error exists. For *n* comparisons, he or she is (1 - alpha) ^{n} confident that no error exists; conversely, the probability of a type I error is [1 - (1 - alpha) ^{n}].

variance by the within-groups variance. This process produces the statistic *F.* As with the *t*-test, this *F* value is compared with critical values from a table of *F* values: if *F* exceeds the critical value for the desired probability, we conclude that it is unlikely that the difference between the mean values occurred by chance, and we reject the null hypothesis. To determine the between-groups variance, we create a sample consisting of the mean values of the individual groups, determine its SS, and divide by the appropriate *df.* However, the resulting value estimates the variance of the mean rather than the variance of the population. Because we know that the variance of the mean is equal to the variance of the population divided by sample size (this is equivalent to saying that SEM is equal to SD divided by the square root of the sample size), we can estimate the between-groups SS by using the following:

where *k* is the number of groups, n_i is the number of subjects in each group, and *X* is the *grand mean* of the sample (the mean of values from all groups). The *between-groups variance* (also known as the *between-groups mean square* [MS]) is then estimated using this equation:

The within-groups sum of squares is obtained by calculating the SS for each individual group and adding these values. This SS is then divided by the appropriate *df* (the sum of *df* of the individual groups, i.e., one less than the size of each group) resulting in the *within-groups MS:*

where *N* is the total number of subjects in all groups. The Sigma within the brackets represents the SS for each of the groups; the outer Sigma means to sum these values. Having estimated the between-groups variance (the between-groups MS) and the within-groups variance (the within-groups MS), we calculate their ratio, *F:*

We then refer to a table of *F* values to learn whether this value exceeds the critical value. If *F* exceeds this value, we conclude that the difference between the mean values of the groups was not likely to occur as a result of the variability within groups. Thus, we can reject the null hypothesis and conclude that a difference exists between the groups.

In Table 21-13 , analysis of variance is used to compare volumes of distribution for histodrenaline (the imaginary drug causing release of either histamine or epinephrine) in

TABLE 21-13 -- Use of Single-Factor Analysis of Variance to Compare Hypothetic Values for Volume of Distribution (mL/kg) of "Histodrenaline" [a] in Three Age Groups

	INFANTS	CHILDREN	ADULTS
	465	291	192
	293	225	212
	371	287	270
	405	302	251
	451	210	290
N	5	5	5
Mean	397	263	243
Grand mean = (397 + 263 + 243)/3 = 301			
Between-group SS = $5(397 - 301)^2 + 5(263 - 301)^2 + (243 - 301)^2 = 70120$			
Between-group *df* = 3 - 1 = 2			
Between-group MS = 70120/2 = 35060			
Infant SS = $(465 - 397)^2 + (293 - 397)^2 +... = 19096$			
Child SS = $(291 - 263)^2 + (225 - 263)^2 + ... = 7134$			
Adult SS = $(192 - 243)^2 + (212 - 243)^2 +... 6564$			
Within-group SS = Infant SS + Child SS + Adult SS = 32794			
Within-group *df* = 3(5 - 1) = 12			
Within-group MS = 32794/12 = 2732.83			
$F_{0.05(1),2,12}$ [b] = 3.89			
$F_{0.0025(1),2,12}$ [c] = 10.3			

Therefore, $P < .0025$ that at least one group mean differs from the others

df, degrees of freedom; MS, mean square; SS, sum of squares.

[a] An imaginary drug causing release of either histamine or epinephrine.
[b] Read, "the one-tailed *F* value when alpha = 0.05, the between-groups *df* = 2, and the within-groups *df* = 12."
[c] Read, "the one-tailed *F* value when alpha = 0.0025, the between-groups *df* = 2, and the within-groups *df* = 12."

infants, children, and adults. The between-groups variance is 35,060, and the within-groups variance is 2,732.83; the resulting value for *F* is 12.83. Because this value exceeds the critical value for *F* for alpha = 0.05 and the appropriate degrees of freedom (note that we must now consider the number of degrees of freedom in both the numerator and the denominator), we can conclude that it is unlikely that the three samples were selected from the same population.

One-Way Analysis of Variance: Intragroup Comparisons

Using analysis of variance, we tested the null hypothesis that there is no difference in the mean value of any of the multiple groups. If we reject the null hypothesis, we can conclude that at least one of the mean values differs from at least one of the other mean values, not that each of the groups is different from each of the other groups. For example, in Table 21-13 , analysis of variance suggests that at least one group differs from the other groups. Examination of the data shows that the mean value for infants differs from the other mean values, and that no difference appears to exist between children and adults. To verify this observation, we need to apply a multiple comparison test. These tests fall into one of several categories, depending on whether the investigator is interested in all possible comparisons between

TABLE 21-14 -- Application of the Student-Newman-Keuls Test for Multiple Comparisons with the Hypothetic Data from Table 21-13

	INFANTS	CHILDREN	ADULTS
Mean	397	263	243
N	5	5	5

Error mean square = 2,732.83

COMPARISON	DIFFERENCE	SE	*q*	*p*[a]	$q_{0.05(2),12}$[b]	CONCLUSION
Infants versus Adults	154	23.4	6.58	3	3.77	$P < 0.05$
Infants versus Children	134	23.4	5.73	2	3.08	$P < 0.05$
Children versus Adults	20	23.4	0.85	2	3.08	$P > 0.05$

Therefore, the mean value for infants differs from that for children and adults; no difference exists between the mean values for children and adults.

SE, standard error.

[a] The number of mean values (groups) across which the comparison is made.
[b] Read, "the *q* value when alpha = 0.05 and degrees of freedom = 12."

pairs (the number of possible comparisons is equal to one-half the product of the number of groups and the number of groups minus one) or only specific ones.

All Possible Comparisons.

Numerous tests permit multiple comparisons, such as the Newman-Keuls test (also known as the Student-Newman-Keuls test), the Duncan test, the least significant difference test [*] , the Tukey test, and the Scheffe method. Although there is no consensus regarding the best multiple comparison test, the StudentNewman-Keuls test exemplifies the general procedure and is described here. To perform the Student-Newman-Keuls test, the investigator calculates the difference between the means of the largest and the smallest groups, followed by the next largest to the smallest, and so on, until all possible differences have been calculated. The SE is determined in a manner similar to that for the *t*-test, as the square root of the ratio of the within-groups MS (obtained from the analysis of variance) to the size of each of the groups [$SE = (s^2 / n)^{1/2}$].

The between-groups differences are then divided by the appropriate SE, much as with the two-sample *t*-test. This process produces the Student-Newman-Keuls statistic, *q;* critical values for *q* can be obtained from a table. In evaluating differences between the extreme means and differences between the less extreme means, the Student-Newman-Keuls test considers the number of ranks (*p*) between the means being compared. [45] As a result, the critical values for *q* are based on the number of groups being spanned in the comparison. In Table 21-14 , the Student-Newman-Keuls test is applied to the hypothetic data of Table 21-12 . Instructions regarding the use of other multiple comparison tests can be found in standard statistics textbooks.

Comparison to the Control Value.

The StudentNewman-Keuls test and other multiple comparison tests described previously are valuable when all possible comparisons must be made. However, the investigator pays a penalty for the opportunity to perform all possible comparisons between pairs, a penalty that may not be acceptable when the investigator is interested in a limited number of comparisons. For example, if subjects were given either placebo or one of four drugs, the investigator may be interested only in the comparison of each of the four drugs with the control state, rather than any comparisons among the four drugs. Although there are ten (i.e., 5 × 4/2) possible comparisons between the five groups, the investigator is interested in only four of these comparisons.

When an investigator is interested in only the comparisons between the control group and each of the test groups, the Dunnett test is most appropriate. First, the difference between the control mean and the mean of each of the other groups is determined. Then, the SE is determined: $SE = (2\ s^2 / n)^{1/2}$ where s^2 is the within-groups MS determined by analysis of variance, and *n* is the size of each of the groups. [*] The differences between the control value and each of the other means is then divided by the appropriate SE; the result is the test statistic, *q*
. As before, these values are compared with the appropriate critical value. Table 21-15 provides an example of how to apply the Dunnett test to compare systolic blood pressure for four hypothetic groups of subjects.

Specific Comparisons.

In certain instances, the investigator may desire to make only specific comparisons among

* Although the least significant difference test is reported by many statistical packages, its use is discouraged by at least one statistician. [29]

With the Student-Newman-Keuls test, if sample sizes are unequal, the SE is calculated as

where s^2 is the within-groups MS, and n_a and n_b are the sizes of each of the samples. Thus, SE may differ for each of the comparisons if sample sizes differ.

* With the Dunnett test, if group sizes are unequal, SE is calculated as

where n_a and n_b are sizes of each of the samples.

TABLE 21-15 -- Application of the Dunnett Test to Systolic Blood Pressure for Hypothetic Subjects Given Placebo or Premedications A, B, or C

	GROUP 1 (PLACEBO)	GROUP 2 (PREMEDICATION A)	GROUP 3 (PREMEDICATION B)	GROUP 4 (PREMEDICATION C)
	131	120	97	134
	127	117	105	147
	110	131	112	122
	125	110	121	138
	147	122	100	129
Mean	128	120	107	134
N	5	5	5	5

Error mean square (determined from analysis of variance) = 104.13

COMPARISON	DIFFERENCE	SE	*q*	*p*[a]	$q_{0.05(2),16}$[b]	CONCLUSION
1 versus 3	21	6.45	3.25	3	2.42	*P* < .05
1 versus 2	8	6.45	1.24	2	2.12	*P* > .05
1 versus 4	6	6.45	0.93	2	2.12	*P* > .05

Therefore, compared to placebo, premedication B (but not premedications A or C) decreases systolic blood pressure.

SE, standard error.

[a] The number of mean values (groups) across which the comparison is made.
[b] Read, "the *q* value when alpha = 0.05 and degrees of freedom = 16."

groups. For example, in comparing the values for desflurane minimum alveolar concentration (MAC) for 6 ethnic groups (e.g., Chinese, Japanese, German, French, Argentinian, and Peruvian), the investigator may be interested in only three (Chinese versus Japanese, German versus French, and Argentinian versus Peruvian) of the 15 (6 × 5/2) possible comparisons. The multiple comparison tests described earlier would be inappropriate for this purpose. If the investigator is interested in only a small number of comparisons, it is occasionally appropriate to perform multiple *t*-tests with the Bonferroni correction (Bonferroni inequality). As mentioned earlier, alpha values are adjusted to the number of comparisons to be performed. If the investigator is interested in performing 3 comparisons with an overall significance level of 0.05, the significance level is adjusted to 0.05/3 or 0.0167. For each of the comparisons, a level of 0.0167 must be achieved to permit the investigator to claim a difference between any of the groups. As the number of comparisons increases, the level of significance required by each (0.05 divided by the number of comparisons) is difficult to achieve, and the test becomes overly conservative (i.e., the investigator is unlikely to detect a difference even if one exists). To use *Bonferroni*' *s* t *-test* (the application of the Bonferroni inequality to the two-sample *t*-test), the investigator must make an a priori decision as to which comparisons will be made. In the example described earlier, the choice of comparisons was based on geographic considerations. It is not considered acceptable to perform multiple *t*-tests, to make an a posteriori decision as to which are the most significant, and then to use the Bonferroni inequality based on the number of comparisons that are likely to be significant.

Repeated-Measures (Two-Way) Analysis of Variance

Just as the paired *t*-test may detect differences not found with the two-sample *t*-test (when the study design has resulted in paired measurements), a paired test corresponding to analysis of variance *(repeated-measures analysis of variance)* may detect differences not found with single-factor analysis of variance. If the investigator obtains more than two measurements on each subject (each measurement on a subject is called a *treatment*), repeated-measures analysis of variance should be employed. Just as the SE for the paired *t*-test was calculated in a different manner than for the two-sample *t*-test, the denominator for repeated-measures analysis of variance is calculated differently than for single-factor analysis of variance. The within-subject variability results from two factors, that is, variability inherent to the subject (equivalent to the error variability for single-factor analysis of variance) and the variability resulting from the treatments. This can be stated as

The within-subject SS is determined by calculating the SS for each subject and determining the sum of these values. The between-treatments (treatment) SS (identical to the between-groups SS for analysis of variance) is calculated from the sample of means for the treatments. The difference between the within-subject SS and the treatment SS is the error SS (equation 20). The variances are determined by dividing the SS by the appropriate *df; F* is the ratio of the treatment variance to the error variance.

Repeated-measures analysis of variance, rather than single-factor analysis of variance, should be used whenever two or more measurements are obtained on the same subject.[*] For example, to assess the effects of neostigmine and

* If repeated-measures analysis of variance is used to compare two measurements, the results will be identical to those of the paired *t*-test, except the analysis of variance is a one-tailed test, whereas the paired *t*-test can be performed as either a one-tailed or a two-tailed test.

TABLE 21-16 -- Application of Repeated-Measures Analysis of Variance to Hypothetic Data for Heart Rate Before and After the Simultaneous Administration of Neostigmine and Atropine

SUBJECT	DRUG ADMINISTRATION			
	BEFORE (BEATS/MIN)	*1 MIN AFTER (BEATS/MIN)*	*5 MIN AFTER (BEATS/MIN)*	*15 MIN AFTER (BEATS/MIN)*

N		5	5	5	5

Mean of individual subjects:

Subject 1 = 78.5

Subject 2 = 97.0

Subject 3 = 65.0

Subject 4 = 75.0

Subject 5 = 74.5

SS for individual subjects:

Subject 1 = $[(67 - 78.5)^2 + (92 - 78.5)^2 + (87 - 78.5)^2 + (68 - 78.5)^2] = 497$

Subject 2 = $[(92 - 97)^2 + (112 - 97)c + (94 - 97)^2 + (90 - 97)^2] = 308$

Subject 3 = $[(58 - 65)^2 + (71 - 65)^2 + (69 - 65)^2 + (62 - 65)^2] = 110$

Subject 4 = $[(61 - 75)^2 + (90 - 75)^2 + (83 - 75)^2 + (66 - 75)^2] = 566$

Subject 5 = $[(72 - 74.5)^2 + (85 - 74.5)^2 + (72 - 74.5)^2 + (69 - 74.5)^2] = 153$

Within-subject SS = 497 + 308 + 110 + 566 + 153 = 1634

Grand mean = (70 + 90 + 81 + 71)/4 = 78

Treatment SS = $5(70 - 78)^2 + 5(90 - 78)^2 + 5(81 - 78)^2 + 5(71 - 78)^2 = 1330$

Treatment *df* = 4 - 1 = 3

Treatment MS = 433.33

Error SS = Within-subject SS - Treatment SS = 1634 - 1330 = 304

Error *df* = 3(5 - 1) = 12

Error MS = 25.33

$F_{0.05(1),3,12}$ [a] = 3.49

$F_{0.0005(1),3,12}$ [b] = 12.7

Therefore, heart rate at one time interval differs from heart rate at another time interval. A multiple comparison test (such as the Student-Newman-Keuls test or Dunnett test) is necessary to determine which of these groups differs from the remainder.

df, degrees of freedom; MS, mean square; SS, sum of squares.

[a] Read, "the one-tailed *F* value when alpha = 0.05, the treatment *df* = 3, and the error *df* = 12."

[b] Read, "the one-tailed *F* value when alpha = 0.05, the treatment *df* = 3, and the error *df* = 12."

TABLE 21-17 -- Inappropriate Application of One-Way Analysis of Variance to the Hypothetic Data from Table 21-16

Grand mean = 78

Between-group SS = $5(70 - 78)^2 + 5(90 - 78)^2$ ... = 1330

Between-group *df* = 4 - 1 = 3

Between-group MS = 433.33

Within-group SS = [(67 - 70) + (92 - 70) + (58 - 70) ...] + [(92 - 90) + (112 - 90) + ...] + [(87 - 81) + (94 - 81) + ...] + [(68 - 71) + (90 - 71) + ...] = 2510

Within-group *df* = 4(5 - 1) = 16

Within-group MS = 156.88

$F_{0.05(1),3,16}$ [a] = 3.24

Therefore, when an inappropriate statistical test is used, *P* > .05

df, degrees of freedom; MS, mean square; SS, sum of squares.

[a] Read, "the one-tailed *F* value when alpha = 0.05, the between-groups *df* = 3, and the within-groups *df* = 16."

atropine on heart rate, we might measure heart rate before drug administration and 1, 5, and 15 minutes after drug administration (Table 21-16) . When repeated-measures analysis of variance is performed, *F* is 17.50, a value that markedly exceeds the critical value. In Table 21-17 , these same hypothetic data are analyzed inappropriately using analysis of variance. When this technique is applied, *F* is 2.83, a value less than the critical value, despite the greater *df.* This situation is analogous to that shown in Tables 21-5 and 21-6 , in which the paired *t*-test suggested differences not supported by the two-sample *t*-test.

As with analysis of variance, repeated-measures analysis of variance permits the conclusion that at least one group differs from the others regarding heart rate and the administration of neostigmine and atropine. In the example shown in Table 21-16 , we were able to conclude that at least one of the groups differs from the others. To determine which of the group means differs, we must apply the multiple comparison tests described earlier.

Nonparametric Analysis of Variance: The Kruskal-Wallis Test and the Friedman Test

A nonparametric version of analysis of variance, the Kruskal-Wallis test, can be used for ordinal data, or for ratio or interval data, particularly those data that are not distributed normally. The test is performed by ranking the values in much the same manner as for the Mann-Whitney *U*-test. The sums of ranks are determined, and a

test statistic, *H,* is calculated:

where n_i is the number of observations in the k^{th} group, *k* is the number of groups, *N* is the total number of observations, and R_i is the sum of ranks in each group. *H* is then compared with the critical value obtained from a table. Although a nonparametric version of the Student-Newman-Keuls test exists, it unfortunately requires equal sample sizes for each of the groups.

The Friedman test is a nonparametric version of repeated-measures analysis of variance. As with the Kruskal-Wallis test, ranks, rather than the individual values, are used in the analysis. The test is extremely powerful for the analysis of data in which repeated measures are obtained on the same subject. Nonparametric versions of tests to perform intragroup comparisons also exist.

Diagnostic Tests

When laboratory tests are used to diagnose the presence or absence of disease states, an ideal test is one for which a positive (i.e., abnormal) test is always associated with the presence of disease (termed *true positive* [TP]; Table 21-18) and a negative (i.e., normal) test is always associated with the absence of disease (*true negative* [TN]). Such a test would be both 100 percent "sensitive" and "specific." However, few laboratory tests meet these criteria.

There are four possible relationships between the result of a test and the presence of the disease. In addition to TP and TN, a test may be positive in the absence of the disease (*false positive* [FP]), or the test may be negative when the disease is present (*false negative* [FN]). The frequency of these latter relationships bears tremendous importance to the utility of the diagnostic test.

The terms sensitivity and specificity are typically used to describe the utility of a test. *Sensitivity* is defined as the fraction of patients with the disease who have a positive test, TP/(TP + FN); it indicates how well a test identifies the

TABLE 21-18 -- Terms Used to Define Sensitivity and Specificity

	DISEASE PRESENT	DISEASE ABSENT
Test Positive	True positive (TP)	False positive (FP)
Test Negative	False negative (FN)	True negative (TN)

presence of disease. *Specificity* is defined as the fraction of patients without the disease who have a negative test, TN/(TN + FP); it identifies how well a test identifies the absence of disease. Most tests yield FP and/or FN and are therefore less than 100 percent sensitive and specific.

If the laboratory test involves quantification (e.g., hyperkalemia may be diagnosed by the presence of a serum potassium value > 5.0 mmol/L), the value at which the disease is considered present ("cutoff") influences the reciprocal relationship between sensitivity and specificity, that is, increasing the cutoff increases sensitivity but decreases specificity. To determine the appropriate cutoff for a new diagnostic test, the investigator determines the sensitivity and specificity associated with different cutoff values. A *receiveroperator curve* (ROC) then displays values for sensitivity plotted against (1 - specificity). If the ROC has a slope of 45 degrees, each incremental gain in sensitivity is matched by an equal loss in specificity, and the test is considered worthless. In contrast, an ROC with a steep section indicates a worthwhile test, and the ideal cutoff is the point at which the ROC bends steeply; that is, a further increase in sensitivity decreases specificity. Reich et al [46] used this approach to develop an "expert system" to assess arterial blood pressure lability during anesthesia (Fig. 21-6) .

Equally important to sensitivity and specificity, but less frequently discussed, is the *positive predictive value* of a test. A test may be 90 percent specific and 90 percent sensitive and used to diagnose a disease that is prevalent in 20 percent of the population. If 100 individuals are selected randomly for testing, 20 should have the disease. Of these, 18 will have TP results. Of the 80 individuals who do not have the disease, 8 will have FP results. Thus, of 26 positive tests, only 18 are correct. The ratio of correct positive diagnoses to total positive diagnoses (69% in this instance) is termed the positive predictive value. With a test with a large positive predictive value (e.g., >95%), a positive result can be assumed to be TP, rather than FP.

The positive predictive value of a test varies with the incidence of the disease in the population being tested. If only one of 10,000 individuals is susceptible to malignant hyperthermia, a test with 99 percent sensitivity and 99 percent

Figure 21-6 A receiver-operator characteristics (ROC) curve is shown; values for sensitivity are plotted against (1 - specificity). Data represent the performance of an "expert system" to assess lability of arterial blood pressure during anesthesia. The labels indicate the "lability index criterion" associated with each pair of sensitivity/specificity values. *(Data from Reich et al [46])*

specificity (which would appear to be excellent characteristics for an assay) would have a positive predictive value of less than 1 percent; that is, fewer than 1 percent of subjects with an abnormal test would be diagnosed correctly. Thus, with rare diseases, an abnormal test does not necessarily indicate the presence of disease, even though the assay is quite sensitive and specific. A parallel statistic, the *negative predictive value,* assesses whether a negative result of the test indicates that the patient does not have the disease.

Contingency Tables, chi^2 Analysis, the Fisher Exact Test, Relative Risk, and Odds Ratios

For data on an ordinal or nominal scale, different techniques are available for the presentation and analysis of results. Histograms, which are valuable for presentation of ratio or interval data, are of limited value, because ordinal and nominal data can assume only a limited number of values. To present ordinal or nominal data collected for two or more variables simultaneously, the investigator might use a *contingency table,* that is, a table displaying the frequency of occurrence of events or characteristics. Contingency tables are described by the number of rows and columns they contain; for example, a 2 × 4 contingency table has two rows and four columns. Table 21-19 is an example of a 2 × 2 contingency table depicting the hypothetic incidences of succinylcholine-induced myalgias with "Antisore" (an imaginary defasciculating drug) or placebo. Examination of these data suggests that the incidence of myalgias is markedly lower after administration of "Antisore" than after administration of a placebo. Statistical confirmation of this observation requires varying the techniques described previously. This section describes analysis of ordinal data using a variation of the *Z* test, followed by an introduction to another variant of the *Z* test, chi^2 analysis. For the data presented in Table 21-19 , the incidence of myalgias in each group can be described as the number of patients having myalgias divided by the total number in that group (*N*). This ratio, the proportion (*p*), is analogous to the central location for ratio or interval data. To perform a statistical analysis, we need to determine the SD for these samples. If we assign the value 1 to subjects having the attribute (in this instance, myalgias), the value 0 to subjects not having the attribute, and the

TABLE 21-19 -- A "2 × 2" Contingency Table Depicting the Hypothetic Incidence of Succinylcholine-Induced Myalgias in Subjects Given "Antisore" (an Imaginary Defasciculating Drug) Versus Placebo

	NUMBER OF SUBJECTS		
AGENT	***MYALGIAS***	***NO MYALGIAS***	***TOTAL***
"Antisore"	8	22	30
Placebo	16	9	25
Total	24	31	55

mean equal to *p,* we can use equation (22) to determine the sample SD:

This equation can be simplified to

Because SE is equal to SD divided by the square root of the sample size, the SE is equal to

Table 21-20 shows the computation of SE for each of the hypothetic samples from Table 21-19 . Then, to compute the test statistic, we must determine the SE of the difference between the two proportions:

where *p* is the proportion determined by combining the groups (e.g., 24/55 for the values reported in Table 21-19) . This method of calculating the SE of the difference between two proportions is similar to that used to determine the SE

TABLE 21-20 -- Calculation of the Standard Error of a Proportion, the Standard Error of the Difference Between Proportions, and the *Z* Statistic for the Hypothetic Data from Table 21-19

S [a] [b]

SE, standard error.
[a] An imaginary defasciculating drug.
[b] Read, "the two-tailed Z value when alpha = 0.05."

of the difference between two means in the two-sample *t*-test. The test statistic *Z* is then calculated as:

This value for *Z* is then compared with the critical value obtained from a table. As before, if the value for *Z* exceeds the critical value, the null hypothesis (that the two samples were drawn from the same population) is rejected, and we conclude that a difference probably exists between the two samples.

This approach to determining statistical difference between proportions is mathematically cumbersome, because the investigator must determine several SD and SE. An alternate approach, chi^2 analysis, arrives at identical conclusions using many fewer mathematic calculations. To use chi^2 analysis, the investigator creates a second contingency table (Table 21-21) , the values of which correspond to the values expected to occur if no difference existed between the two treatments. For example, of the 55 subjects in Table 21-19 , 24 had myalgias, the overall incidence being 43.6 percent. Had there been no difference between treatments, we would expect 13 (actually 13.1) of the 30 subjects given "Antisore" and 11 (actually 10.9) of the subjects given a placebo to experience myalgias. The chi^2 statistic is determined as follows:

where O is the observed frequency and E is the expected frequency. If the observed frequencies are similar to the expected frequencies, the squared differences will be small relative to the expected values, and the value for chi^2 will be small. Conversely, large differences between expected and observed values will result in a large value for chi^2 . This value for chi^2 is then compared with the critical value. To determine the critical value, we must first determine the *df.* Unlike the previously discussed statistical techniques, in which the *df* was a function of the size of the samples, *df* for chi^2 analysis is a function of the dimension of the contingency table, the product of the number of rows minus one and the number of columns minus one. This contingency table includes two rows and two columns, resulting in (2 - 1) × (2 - 1), or 1 *df.* The critical

TABLE 21-21 -- A "2 × 2" Contingency Table of Hypothetic Expected Values for Succinylcholine-Induced Myalgias if No Difference Existed Between "Antisore" (an Imaginary Defasciculating Drug) and Placebo

TABLE 21-22 -- Calculation of the chi^2 Statistic Using the Hypothetic Data from Table 21-19

$chi^2_{0.05(2),1}$ [a] = 3.84
Therefore, *P* < .05

[a] Read, "the two-tailed chi^2 value when alpha = 0.05 and degrees of freedom = 1."

value for chi^2 is determined from the chi^2 table using the appropriate *df.* chi^2 Analysis of the data from Table 21-19 is performed in Table 21-22 . Note that the value for chi^2 , 7.75, approximates the square of the value for *Z* obtained in Table 21-20 (differences are due to rounding errors). This is not a coincidence: chi ^{2} analysis is mathematically equivalent to *Z* analysis.

2 × 2 Tables

Yates Correction

As mentioned earlier, sample variance (Equation 11) underestimates population variability; therefore, a correction factor, a smaller denominator (usually *n* - 1, instead of *n*) must be applied to ensure reliable estimates for various statistics such as *t* and *F.* A similar problem exists with chi^2 analysis of 2 × 2 tables. This problem is usually resolved by using Yates (continuity) correction. Instead of using equation 27 to calculate chi ^{2} , the following equation is preferable:

where hO - Eh means the absolute value of the observed value minus the expected value. Yates correction reduces the numerator for each value and produces values for chi^2 that are smaller than those obtained with Equation 27. These values are less likely to result in a type I error and should always be used to analyze 2 × 2 tables. The data from Table 21-19 are reanalyzed using chi ^{2} analysis and Yates correction in Table 21-23 . There is no comparable correction procedure for larger contingency tables.

A Further Simplification

For a 2 × 2 table, Equation 28 can be further simplified to

where R_i and C_j are the sums of the values in the i^{th} rows and j^{th} columns, respectively, *n* is the total sample size, and n_{ij} are the values in each of the cells of the table. A further

TABLE 21-23 -- Use of Yates Correction to Determine the chi ^{2} Statistic for the Hypothetic Data from Table 21-19

$chi^2_{0.05(2),1}$ [a] = 3.84
Therefore, using the Yates correction, $P < .05$

[a] Read, "the two-tailed chi^2 value when alpha = 0.05 and degrees of freedom = 1."

simplification (but which is mathematically biased because it ignores Yates correction) is

I recommend this latter approach only for casual analysis of data, such as to confirm the accuracy of published data quickly.

Larger Contingency Tables

An investigator frequently obtains data involving more than two groups or possible outcomes. These data can also be presented in contingency tables and analyzed by chi^2 analysis. Table 21-24 displays a larger contingency table (2 × 4) for hypothetic incidences of vomiting associated with four doses of an imaginary antiemetic drug, "Calm." Determination of the chi ^{2} statistic is performed in a similar manner, by summing the squared differences between the observed and expected values and then dividing this value by the expected values. The resulting value is then compared with the critical value for chi ^{2} for three [(4 - 1) × (2 - 1)] degrees of freedom.

Limits of chi ^{2} Analysis

The assumptions of chi^2 analysis are valid only when certain conditions are met. For 2 × 2 tables, the expected value for each of the cells must be at least 5.0 or the resulting value for chi ^{2} will be biased (i.e., may suggest that a difference exists when, in fact, it does not); if the expected value for one or more cells is less than 5, the Fisher exact test (see next section) is recommended. [29] For larger tables, the expected value for each cell should be at least 1.0, and no more than 20 percent of the cells should have expected values of less than 5.0. Violating these conditions biases the estimates for chi ^{2} and should be avoided either by combining columns or rows to form a smaller contingency table or by collecting additional data.

Fisher Exact Test

The chi^2 test described earlier is a mathematically simple approach to examining significance of contingency tables; however, chi ^{2} analysis is biased when its assumptions are violated, particularly when the expected value of a cell is small. In this case, the *Fisher exact test,* a test of binomial distributions, is recommended. The data of Table 21-19 , previously used for a chi ^{2} analysis, can be analyzed using the Fisher exact test. Recognizing that 24 of the 55 total subjects developed myalgias, the chi^2 test assumed an expected value of 13 (actually 13.1) for myalgias in the "Antisore" group. Although 13 is the "most likely" value, we recognize that values of 12 or 14 also are likely. Similarly, values of 10, 11, 15, or 16 are possible, although each less likely than the value of 13. Using binomial distributions, we can calculate the likelihood of all possible distributions of myalgias (assuming an overall incidence of myalgias of 24 of 55). The probability associated with each of these distributions is shown in Table 21-24; these probabilities are determined as follows:

where R_i and C_j are the sums of the values in the ith rows and jth columns, respectively, n is the total sample size, n_{ij} are the values in each of the cells of the table, and the ! sign indicates factorial (e.g., 8! equals 8 · 7 · 6 · 5 · 4 · 3 · 2 · 1).

Of the 25 possible distributions shown on Table 21-25 , 1 equals the actual distribution observed by the investigators,

TABLE 21-24 -- Calculation of the chi^2 Statistic for a "4 × 2" Contingency Table Representing Hypothetic Incidences of Vomiting with "Calm" (an Imaginary Antiemetic)

[a] Of these distributions, the first nine and the final six are as, or more, unlikely (i.e., having the same or a lower probability) than the observed distribution. The cumulative probability of having the values shown in Table 21-14 or a more extreme set of values is therefore (0.0000% + 0.0000% + 0.0000% + 0.0000% + 0.0001% + 0.0010% + 0.0115% + 0.0885% + 0.4805% + 0.1166% + 0.0153% + 0.0013% + 0.0001% + 0.0000% + 0.0000%) or 0.7128%. This is equivalent to stating that $P = .007128$. In this example, the P value obtained with the Fisher exact test is similar to that obtained using chi^2 analysis.

and 14 are more extreme (i.e., less likely) than the actual distribution. The cumulative probability of these 15 "extreme" distributions is .0071 or 0.71 percent. Thus, we can conclude that there is a .71 percent probability ($P = .0071$) that the actual results occurred by chance. Note that the value obtained using the Fisher exact test is similar to that obtained using chi^2 analysis ($P = .0054$); however, when the assumptions of the chi^2 test are violated, the Fisher exact test is recommended.

Relative Risk and Odds Ratios

chi^2 Analysis or the Fisher exact test may be used by the investigator to determine the presence of differences in a 2 × 2 table. However, the resulting statistic and P value do not quantify the relative risks associated with two states. Relative risk is determined as the risk with one state divided by the risk with the other state where

risk is defined as the incidence of the outcome measure in the population. For example, if anesthetic technique A was associated with a 1 percent incidence of postoperative congestive heart failure and technique B was associated with a 0.5 percent incidence, the relative risk would be 2 (1%/0.5%). A confidence limit can be determined for this relative risk ratio.

Frequently, investigators report a minor variant, the odds ratio, instead of the relative risk ratio. The odds ratio is determined as the product of the number of subjects with technique A who develop congestive heart failure and the number of subjects with technique B who do not, divided by the product of the number of subjects with technique A who do not develop congestive heart failure and the number of subjects with technique B who do. Numerically, the values for relative risk and odds ratio are similar. However, ease of calculation appears to have promoted the use of the odds ratio.

Regression Techniques

Analysis of Linear Regression and Correlation Coefficient

Earlier in this chapter, statistics was used to compare values for different variables, such as blood pressure in hypo-volemic versus normovolemic patients, blood pressure before and after the administration of pancuronium, and the effects of placebo versus those of premedications. In these analyses, the independent variable was divided into discrete groups. In certain instances, dividing the independent variable into discrete groups may be undesirable or impossible. For example, the subjects in Table 21-9 were categorized as either normovolemic or hypovolemic, even though there are

Figure 21-7 This scattergram results from the plotting of a hypothetic set of values for two variables (in this instance, blood loss and systolic blood pressure) having a linear relationship.

various degrees of hypovolemia, each of which might be associated with differing amounts of hypotension. To investigate the association between the degree of hypovolemia and the extent of hypotension, the investigator might measure systolic blood pressure while inducing various degrees of hypovolemia by removing blood. These values might then be plotted on a scattergram (see Fig. 21-6) , which is similar to a two-dimensional histogram. The scattergram permits the investigator to examine the relationship between the independent variable (in this case, the amount of blood loss) and the dependent variable (blood pressure). Figure 21-7 shows that larger amounts of volume loss are associated with lower blood pressures.

This relationship also could be analyzed with the Student *t*-test by dividing the independent variable into two groups, mild hypovolemia (less than 10 mL/kg) and severe hypo-volemia (10-25 mL/kg). The investigator would find that blood pressure was lower during severe blood loss than during mild blood loss. Moreover, several smaller groups could be formed, depending on the amount of blood loss, thus permitting the use of analysis of variance.

The limitation of these analyses, however, is that they do not describe the apparently linear relationship existing between blood loss and blood pressure observed in Figure 21-7 . There is no discrete difference in blood pressure with blood loss of more than or less than 10 mL/kg; instead, the relationship between the two variables appears to be continuous. The slope and the position of the line that best describes that relationship are determined using analysis of lin-ear regression. The equation for this line is Y = alpha X + beta where alpha is the slope, and beta the Y intercept, of the line (Y is read Y-hat). The line that fits best is one that minimizes the sum of squared differences between the values of Y and Y. This accounts for the other name for linear regression analysis, *least-squares regression.* The distance between each point and the line is equal to (Y - Y), or [Y - (alpha X + beta)]; the sum of squared distances can be written as

The reader knowledgeable in calculus will realize that when the partial derivatives of the equation with respect to alpha and beta are equal to zero, the sum of squared distance is minimized. These simultaneous equations can be solved to yield the following equations for the slope and intercept of the least-squares regression line:

Table 21-26 demonstrates analysis of linear regression for the hypothetic data in Figure 21-7 . The line produced by this technique (Fig. 21-8) lies close to all the data points.

Just as the index of central tendency was a value near the center of the population, the least-squares regression line lies near the center of the values. Six of the data points are above the line and seven are below.

Using analysis of linear regression, we were able to minimize the sum of squared distances between this sample of points and the regression line. With a second sample, analysis of linear regression would identify a different (although possibly similar) best-fit line. Each different sample would result in a different line, resulting eventually in a family of best-fit lines.

Just as the SEM describes the variability with which the sample mean located the population mean, so do some statistical techniques assess the variability (goodness of fit) of this family of regression lines. The first test, an analysis of variance, evaluates whether the regression analysis suggests

* In a scattergram, the independent variable is plotted on the X axis, the dependent variable on the Y axis. When one variable is used to predict another (e.g., when one assesses the accuracy of end-tidal P_{CO_2} to predict arterial P_{CO_2}), the predictor variable (in this case, end-tidal values) should be plotted on the X axis and the predicted variable (in this case, arterial values) on the Y axis. This permits one to assess the variability in the predicted variable for a given measured value. When there is no causal relationship between two variables (e.g., if one were to examine the relationship between heart rate and blood pressure in subjects who were hypovolemic), either variable can be plotted on the X axis.

Figure 21-8 The best-fit line for hypothetic data in Figure 21-6 using analysis of linear regression.

a trend between the independent and dependent variables. The investigator first determines the *regression SS,* which is equal to the variability resulting from the linear regression:

which has one *df.*

Combining equations 33, 34, and 35 yields

where Sigma *xy* is another notation for Sigma(X_i - X)(Y_i - Y), and Sigma x^2 is equivalent to Sigma(X_i - $X)^2$. As with analysis of variance, the total SS can be partitioned into two components:

where the *residual SS* is the variability not accounted for by the regression, that is, the sum of squared distance between Y_i and *Y:*

The residual SS has *N* - 2 *df.* The ratio between the regression MS and the residual MS,

is then compared with the critical value for *F* obtained from a table. If *F* exceeds the critical value, the regression is significant; that is, a relationship exists between the independent and dependent variables. If *F* is less than the critical value, the slope does not differ from zero, and the analysis does not support the hypothesis that an association exists between the independent and dependent variables.

The residual mean square (often noted as $s^2_{y \cdot x}$) has a second important role. Its square root, $s_{y \cdot x}$, called the *SE of the estimate* (or, occasionally, the *SE of the regression*) represents the average deviation of *Y* values from the regression line. The SE of the estimate provides an estimate for regression analysis in a manner similar to that in which SD describes variability of the sample (i.e., the SE of the estimate is actually the SD, not the SE, of the distance between the Y values and the regression line). For the sample described in Figure 21-7 , the SE of the estimate is 12.3, a value that represents the average distance of the points from the regression line.

The third method of describing fit to the regression line is by determining the correlation coefficient. The variability of the dependent variable, *Y,* has already been partitioned into two components, the component that is accounted for by the regression line (the regression SS) and the component that is not accounted for by the regression line (the residual SS). The sum of this SS, the total SS, can also be expressed as

The ratio of the regression SS to the total SS is equal to the percentage of the variability of one variable explained by the variability of the other variable. This ratio, r^2 , is known as the *coefficient of determination.* If the regression line fits the sample exactly, the error SS is equal to 0 and the regression SS is equal to the total SS. This results in a coefficient of determination equal to 1. The greater the distance between the values in the sample and the regression line, the larger the value of the error SS and the smaller the value of r^2 . The value for r^2 always lies between 0 and 1, with larger values implying a better fit between the regression line and the sample. More commonly reported than r^2 is its square root, *r,* known as the *correlation coefficient* or the *productmoment correlation coefficient.* Because r^2 is always between 0 and 1, its square root will always lie between -1 and +1, and its sign is identical to that of the slope. The advantage of using the coefficient of determination and the correlation coefficient is that they lack units, whereas the slope of the regression line depends on the magnitude of the units used to express the independent and dependent variables.

In addition to these techniques to evaluate the significance and goodness of fit of a regression line, some techniques compare the slopes and positions of two or more regression lines. These techniques can also be applied to two or more dose-response curves or to other data analyzed by linear regression.

The investigator who uses analysis of linear regression must decide which results to report to the reader. It is often tempting to search a computer output for a statement of probability such as *P* = .02. Reporting only this value limits the information provided to the reader, because it provides limited information as to the goodness of fit of the regression line. This is particularly important with large samples in which it is possible to obtain significant probabilities for the regression line (e.g., *P* = .05), despite large SE of the estimate and poor coefficients of determination. The variability of the regression analysis is better described by two statistics, the SE of the estimate and the coefficient of determination (or the correlation coefficient). The SE of the estimate describes the average distance of the points from the regression line, whereas the coefficient of determination describes the proportion of the variance that can be accounted for by the regression.

Figure 21-9 Data for a standard curve to estimate the concentration of a drug using optical density measurements are shown. There are four values at each concentration, and several of the values at low concentrations overlie. Note that the absolute variability is smaller at lower concentrations; in fact, variability is proportional to the concentration.

In the earlier description of analysis of linear regression, the goal was to minimize the sum of the squared distances between the observed points and those predicted by the regression analysis (Equation 32). This approach assumes that each residual distance should contribute equally to the *objective function* (the value to be minimized). For many analyses this is appropriate--this is because the "error" (variance) associated with each of the measurements is constant. However, in certain instances, this assumption is unquestionably violated. For example, an assay might use optical density to estimate the concentration of a drug over a large range of values. Repeated measurements of each of several known concentrations (Fig. 21-9) suggest that there is more variability at higher than at lower concentrations (i.e., variability is proportional to concentration). An unweighted least-squares linear regression might then fail to approximate all the data points, being particularly biased against low values (Fig. 21-10 , solid line). This problem can be addressed by *weighting* the contribution of each squared residual difference to the objective function. A typical

Figure 21-10 Using unweighted linear regression for data, a (solid line) fit to data from Figure 21-9 fails to approximate the values at a drug concentration of 1 ng/mL. A weighted linear regression (dashed line) approximates the data at all portions of the curve. Only values lower than 4 ng/mL and the corresponding regression lines are shown.

weighting scheme, assuming that variability is proportional to concentration (or that variance is proportional to the square of the concentration) might be to multiply each squared residual by the inverse of the square of the concentration; using this new objective function, the *weighted least-squares linear regression* may approximate all the data points better than its unweighted equivalent (see Fig. 21-10 , dashed line). Weighting of the objective function is necessary whenever the variance model is not constant (the case for many drug assays and certain other measurements). Another approach that would likely be successful in this situation is to perform a logarithmic trans-form of the data, then perform an unweighted linear regression.

Bias Analysis

A problem frequently encountered in medicine involves the comparison of two methods of analysis, such as two assays. Although regression analysis is intuitively appropriate for comparison, Bland and Altman [26] argue that a variant is more appropriate because the results of regression analysis might provide false confidence that two measurement methods differ minimally. For example, consider the data shown in Figure 21-11 comparing two fictitious assays for the blood concentrations of an inhaled anesthetic. Although values lie quite close to the regression line and the correlation coefficient approaches unity, the new assay is biased--it yields values consistently larger than the old assay at low concentrations and smaller than the old assay at high concentrations. Comparison of the regression line to the line of unity suggests the presence of this bias.

The variant proposed by Bland and Altman is termed *bias analysis.* Assuming that neither assay is known to be the "gold standard," the difference between the two measurements is plotted against the average of the two measurements.

Figure 21-11 Values for two fictitious assays for the measurement of the blood concentration of an inhaled anesthetic are displayed in a regression analysis. Values for the traditional assay are plotted on the Y axis; the new assay is plotted on the X axis. The best-fit regression line is solid; the line of identity is dashed.

Figure 21-12 Transformed values from Figure 21-11 are displayed. The X axis is the average of the measurements by the two assays; the Y axis is the difference between the two assays. Horizontal lines are displayed at the average difference, the average difference plus two standard deviations of that difference, and the average difference minus two standard deviations of that difference. Systematic bias is more evident in this plot than in the traditional regression analysis.

* The mean and SD of the differences is determined, and the mean is compared to zero (i.e., the average difference between the two assays is compared to zero); in addition, horizontal lines are plotted at the mean difference, the mean difference plus 2 SD, and the mean difference minus 2 SD. The plot is then examined for systematic trends and for individual differences larger than twice the SD. The data from Figure 21-11 , when examined in a bias analysis (Fig. 21-12) , reveal a systematic bias that is more evident than in the regression analysis.

Misuse of Linear Regression Analysis

One assumption of regression analysis is that the data points are selected independently from the population. This would occur if each point was from a separate experiment (e.g., different individuals) or all points were from a single individual but the independent variable changed during the course of the experiment. In some instances, investigators may obtain a small number of observations from each of a large number of individuals. A regression analysis based on this data set is flawed. Consider an investigator interested in determining whether cardiac output estimates obtained from echocardiographic measurements can replace those obtained by thermodilution. Four measurements (e.g., one after induction of anesthesia, a second before institution of cardiopulmonary bypass, a third after bypass, and the fourth during chest closure) are obtained from each of 5 individuals. The investigator plots these 20 values (Fig. 21-13) , recognizing that the thermodilution technique is not the gold standard, and determines that values from the two assays are highly correlated. In turn, the investigator extrapolates, incorrectly, that changes in cardiac output can be tracked by changes in the echocardiographic measure.

Figure 21-13 Values for cardiac output determined by thermodilution are plotted against values estimates determined using echocardiography. Four values were simulated for each of five subjects. Each subject is identified by a different symbol. The solid line is the best-fit linear regression line ($r^2 = .82$; $P < .0001$).

The flaw in this assessment can be seen by examining the data for each individual. Values for a representative subject are displayed in Figure 21-14 . These values fail to reveal a relationship between changes in the two measures. Had a single value from each subject (e.g., the initial measurement) been plotted, the resulting analysis would suggest that the new measurement technique provides a reasonable estimate of the magnitude of cardiac output for an individual. However, the new measurement technique cannot track changes within a given individual.

Regression analysis should not be performed when repeated measurements from individuals are pooled. In this instance, a specialized technique, mixed-effects modeling (which is beyond the scope of this chapter) is an appropriate technique.

Nonlinear and Logistic Regression

Certain types of data, such as the relationship between dose and effect, are appropriately analyzed using regression techniques. On occasion, effect is recorded in terms of a quantal response (e.g., yes or no) rather than discrete values; in this instance, analysis of linear regression may not be the appropriate statistical technique. For example, the relationship

Figure 21-14 Values for a single subject from Figure 21-13 are displayed. There is no relationship between the X and Y axes ($r^2 = .16$; $P > .61$).

* If one assay is known to be the "gold standard," the X axis can be the gold standard rather than the average of the two assays.

between the dose of thiopental and loss of the lid reflex is probably sigmoidal, rather than linear, in shape. Forcing a linear analysis onto nonlinear data may produce spurious results, particularly regarding nonlinear portions of the sigmoid curve. For example, because the middle portion of a sigmoid curve is linear, estimations of the ED_{50} (the dose producing 50% effect) may be accurate using analysis of linear regression; however, analysis of linear regression is likely to produce flawed estimates for ED_{95} (the dose producing 95% effect). The limitation of the linear approach becomes more evident as the value on the X axis (often dose) is extended beyond the ranges under investigation: a linear regression approach might suggest the impossible--effects greater than 100 percent or lower than 0 percent.

Special techniques are available for the analysis of these types of data. One simple technique that could be accomplished readily without a computer was the probit analysis technique popularized by Litchfield and Wilcoxon. [47] The Litchfield-Wilcoxon technique has been popular for the analysis of neuromuscular dose-response data. These data, in which the response versus dose relationship is typically sigmoidal (as are many biologic responses), are translated to probits. However, probit transforms are inappropriate for data at the extremes (e.g., a twitch response recorded as 100 percent depression translates to a probit value of infinity); therefore, extreme values are typically assigned an arbitrary value of eight probits. The transformed probit values, which bear a more linear relation to dose, are then analyzed using unweighted linear regression. This technique is flawed. One assumption of unweighted linear regression is that errors are uniform throughout the measurement scale (a statistician would state that the "variance model is constant"); for measurements of twitch tension, this is equivalent to assuming that measurement error is uniform throughout all levels of twitch depression (a reasonable assumption). However, when the data are translated into probits, the extremes of the response curve are "stretched"; that is, the sigmoidal curve is made linear by deforming the extremes, so that errors associated with these measurements are similarly "stretched." However, investigators typically analyze these probit versus dose data using unweighted linear regression, not accounting for the newly created nonhomogenous variance model. If an investigator were to use properly weighted linear regression, probit transforms would not compromise the analysis.

An alternative to the probit technique is *nonlinear regression.* For example, a sigmoidal curve can be described by the following equation:

where E_{max} and E_0 are maximal and initial responses of the system (e.g., 100% and 0% depression for twitch data), *e* is Euler's constant (2.718), and alpha and beta are parameters that describe the shape (sigmoidicity) and position (e.g., ED_{50}) of the curve. As with linear regression, the goal of this technique is to minimize the sum of the squared distances between the observed and the predicted values (i.e., the points on the fitted curve). Unlike linear regression, for which a

Figure 21-15 Values for a response (e.g., percentage of subjects moving at a certain end-tidal anesthetic concentration) are plotted against the end-tidal anesthetic concentration. Although a linear regression (solid line) approximates the data well, an extrapolation of the linear relationship to higher end-tidal concentrations suggests that fewer than 0 percent of subjects move, an unlikely possibility. In contrast, the sigmoid curve (dashed line) fit by the nonlinear regression technique approximates the data well, but it also suggests that the response asymptotes to the value 0 with increasing end-tidal concentrations. Thus, the nonlinear analysis yields more realistic results.

single "best-fit" solution exists for each data set, there is no unique solution to a nonlinear regression problem. Instead, the investigator approaches the best-fit iteratively, minimizing the sum of squares. Figure 21-15 shows this approach to the analysis of a dose-response relationship. As with linear regression, nonlinear regressions can be analyzed by weighting the contribution of each residual to the sum of squares.

If the data are strictly dichotomous (e.g., alive versus dead), a special case of nonlinear regression, *logistic regression,* is available. The fitted equation for logistic regression is similar to that shown in Equation 41; however, instead of minimizing the sum of squared residual distances, logistic regression uses an approach known as maximum likelihood. Logistic regression is a powerful tool for the analysis of epidemiologic data (e.g., data involving the effects of anesthetic techniques on outcome) and is seen with increasing frequency in the medical literature.

Other nonlinear regression techniques are commonly used in medical research. A familiar example for anesthesiologists is the fitting of compartmental models to pharmacokinetic data. For example, the plasma concentration versus time curve for many intravenous drugs appears to be well fit by a sum of exponentials

where C_p is plasma concentration at time *t* and *k* is the number of compartments. As with linear regression, the goal of this technique is to minimize the (weighted or unweighted) sum of the squared distances between the observed and the predicted values (i.e., the points on the fitted curve).

Sequential Analysis

To compare the results of two treatments, the investigator first estimates the difference in outcomes for each treatment

and uses this difference to estimate how many subjects will be required to demonstrate a statistical difference between treatments. Once the study has commenced, the investigator should not analyze the results until the predetermined number of studies have been performed. [19] In addition, should this number of subjects not yield statistically significant results, the investigator should not increase the number of subjects studied until statistical significance is achieved. These requirements are based on the same rationale as support the prohibition against multiple *t*-tests: the test statistic is based on the assumption that only one comparison is to be made between the two treatments.

In certain instances, it is vital to determine rapidly which treatment is more efficacious. For example, if the cost of conducting trials is excessive, or if knowledge of an improved therapy might greatly influence morbidity, the investigator might desire to learn the difference between treatments quickly. Sequential analysis is particularly suited for this purpose. [48] The investigator uses a chart similar to that shown in Figure 21-16 (Figure Not Available) . Paired subjects are given treatments (e.g., one subject is given an antiemetic drug; another subject a placebo), and their scores regarding some predetermined response (e.g., vomiting) are compared. If scores are the same (e.g., vomiting occurred in both trials), the results are ignored. If a difference exists that favors the antiemetic drug, a mark is made one unit upward and to the right; if a difference exists that favors the placebo, a mark is made one unit downward and to the right. Once the mark leaves the hatched area, the trial is complete. If the resulting line is above the enclosed area, the trial favors the antiemetic drug; if the resulting line is below the enclosed area, the trial favors the placebo. Completion of the trial beyond the right-hand border indicates that no statistical difference exists between the two treatments. Using sequential analysis, Abramowitz et al [49] demonstrated the antiemetic effect of droperidol using only 11 untied treatment pairs and a total of 42 subjects. In contrast, Cohen et al, [50] in a study of 87 subjects, found that the incidence of vomiting was lower in subjects given droperidol than in those given a placebo, but these investigators were unable to demonstrate a statistical difference using chi ^{2} analysis.

Figure 21-16 (Figure Not Available) Using sequential analysis, Abramowitz et al [49] demonstrated that droperidol decreased the incidence of postoperative vomiting. For each untied pair of subjects, the line is extended one box to the right and one box up or down, depending on which subject fared better. The trial is complete when the line exits the borders of the box. *(From Abramowitz et al [49])*

OVERVIEW

This chapter has aimed to provide an introduction to the techniques used in many statistical analyses. Emphasis has been placed on descriptive statistics, particularly on identifying the location and distribution of data. This focus was chosen because of the increasing tendency of investigators to perform complicated analyses using sophisticated statistical techniques without spending sufficient time examining the data. The chapter also emphasized the more common abuses of statistics: reporting variability of the data without identifying whether SD or SE is being used, and the inappropriate use of multiple *t*-tests. Repeated-measures analysis of variance, a statistical technique that is appropriate for many of the studies performed in anesthesia, has been described, with the hope that it will be used with greater frequency.

Undoubtedly, many investigators will continue to view statistical analysis as a necessary evil in research. Despite increased awareness of the abuses of statistics, errors continue to appear in the anesthesia literature (as in all medical literature). However, with time, with improved editorial vigilance, with the availability of newer statistical resources for investigators, and with education for investigators, we are likely to see improvements in the future.

Section 3 - Anesthesia Management

Chapter 22 - Risk of Anesthesia

Lee A. Fleisher

INTRODUCTION

A great deal of attention has focused on the risk of anesthesia, both from the perspective of providing patients with an accurate assessment of the probability of complications and as a means of quality assurance in order to improve outcome. Numerous studies have attempted to define the probability of morbidity and mortality, with wide variability of results. Additionally, risk indices have been developed to identify those patients who have a higher probability of developing complications. In all these studies, as well as in clinical discussions with patients, the key question is what risk are we attempting to define.

For the case of risk of anesthesia, there are multiple factors that enter into the equation. A myopic perspective could simply include morbidity and mortality that occur intraoperatively. From a quality assurance perspective, any death within 48 hours of an anesthetic regimen is evaluated for potential relevancy. Yet, other investigators have evaluated 30-day morbidity and mortality as part of their estimation of anesthetic risk. It is important to define the perspective when evaluating the studies (Table 22-1) (Table Not Available) .

It is also important to differentiate the potential risk solely attributable to administration of anesthesia from those risks that anesthesia may modify. For example, there has been a great deal of research and debate regarding the potential benefits of regional versus general anesthesia for patients undergoing infrainguinal arterial reconstruction. [1] [2] [3] One outcome that has been shown to benefit from regional anesthesia is the risk of graft thrombosis and of the need for reoperation or amputation. Despite two smaller studies demonstrating significant benefit of regional anesthesia, [1] [3] the largest study was unable to demonstrate any difference compared with general anesthesia. [2] Importantly, the two smaller studies had a much higher rate of reoperation than the larger study, a finding suggesting that the benefit may only manifest itself if the rate of complications is sufficiently large. Therefore, assessment of risk depends on the rate of complications.

Traditionally, anesthesiologists and investigators have focused on issues of death and major morbidity such as myo-cardial infarction, pneumonia, and renal failure. It is becoming increasingly important to include outcomes that affect economic issues, quality of life, or satisfaction for the patient (Table 22-2) . For example, nausea and vomiting, which delay or prevent discharge home, are important from an economic and quality of life perspective. Readmission to the hospital after outpatient surgery is now an important component of outcome studies. [4] Overall satisfaction with care is increasingly included as an outcome. [5] [6] [7] Further research will be required to assess the influence of anesthesia care for nonmorbid outcomes and the importance of these outcomes from a patient-oriented perspective.

Many studies have also looked at what some investigators describe as surrogate end points. [8] For example, nausea and vomiting that do not require treatment or do not delay discharge do not have the same impact as those episodes that do affect these outcomes. Myocardial ischemia on the electrocardiogram is another example of a surrogate outcome that may not directly lead to overt morbidity. [9] In determining the risk of anesthesia, it is important to define the outcome of greatest interest.

TABLE 22-1 -- Time Perspective of Anesthetic Morbidity and Mortality Studies

Minor
Nausea
Vomiting
Readmission
Patient satisfaction
Quality of life

Finally, it is imperative to realize that "perioperative" risk is multifactorial and depends on the interaction of factors specific to anesthesia, the patient, and surgery (Fig. 22-1) . With respect to anesthesia, both the effects of the agents and the skills of the practitioner are important. Similarly, both the surgical procedure itself and the surgeon's skills affect perioperative risk. From the patient's perspective, the question remains whether the coexisting disease raises the probability of complications to a level such that the benefit of the surgery is outweighed by the risk. As anesthesiologists, we frequently focus on perioperative risk, yet the patient is most concerned with management of the disease process. As the specialty focuses on its role in the 21st century, it is important to acknowledge the patient's perspective and desire to undergo procedures to prolong life or to improve quality of life. The ability of the anesthesiologist to affect the decision process and overall risk is the future challenge.

Given these varying goals, perspectives, and influences, this chapter attempts to define the current state of knowledge in this area. With the increasing interest in evidence-based medicine, it is important to define what is known and what is not known. Because it would be unethical to compare surgical procedures performed under an "ideal anesthetic" versus a less ideal regimen or no anesthesia, virtually all the studies looking at the factors that contribute to perioperative mortality involve evaluations of large cohorts of patients. However, over the past decade, there have been several well-designed randomized clinical trials to evaluate different anesthetic regimens that have advanced the field. This chapter reviews the literature, with an emphasis on the strength of the evidence for the conclusions.

ISSUES RELATED TO STUDY DESIGN

Types of Studies

In order to interpret the literature, it is important to understand the strengths and limitations of the different study designs. Prospective cohort studies involve the identification of a group of patients who are followed over time for the occurrence of an outcome of interest. The goal is to determine those patients who develop the outcome. For studies of

Figure 22-1 Representation of the influences of different components related to perioperative poor outcomes. Surgical, anesthetic, and patient characteristics all contribute to outcome. Anesthetic contributions can include issues of judgment and mishaps and may relate to the provider. The surgical procedure itself affects outcome, as well as the location of intraoperative and postoperative care.

perioperative mortality, individual cases can be reviewed to determine the cause of mortality. Alternatively, data on all patients in the cohort can be obtained, and those factors that are associated with the development of morbidity or mortality can be discerned. An example of a prospective cohort study identifying factors associated with perioperative cardiac morbidity and mortality is that of Goldman and colleagues, [10] which led to the development of the cardiac risk index.

Another example of a prospective cohort study is one in which patients with a known disease are studied for the development of predefined outcomes. Such studies provide the natural history in patients with the disease. An example would be studies of patients who have sustained a myocardial infarction, the importance of which is that the optimal time between the infarct and surgery can be determined. [11] [12] [13]

Although prospective cohort studies have important value in identifying risk factors for the outcome of interest, there are significant limitations. The selection of the cohort of interest can significantly affect the results obtained. The larger the cohort, the more the results can be generalized. A second bias is that many patients may be lost to follow-up. In perioperative studies, this may not be an important issue for short-term outcomes. Finally, the importance of a risk factor depends on the completeness of the data. For example, if the presence of severe angina was not included in the database, then it could not be a risk factor, and other factors may appear to be more important. [10]

A specific example of a prospective cohort study is the randomized clinical trial. Randomized clinical trials represent the gold standard for evidence of causation. They have defined inclusion and exclusion criteria, treatment protocols, and outcomes of interest. They are usually either single or double blinded (both patient and physician) and are designed to test the effect of a new drug or intervention. They rarely are used as a means of identifying risk, but they may be used to determine if that risk factor is truly linked via a causal relationship or simply an association. In the perioperative period, hypothermia has been associated with an increased incidence of perioperative ischemia, a surrogate marker for morbidity. [14] In a subsequent randomized clinical trial, the use of forced-air warming to maintain normothermia was associated with a significantly lower incidence of perioperative morbid cardiac events. [15] Therefore, randomized clinical trials directed at interventions that reduce the frequency of a given risk factor in the population are often performed after the results of a prospective cohort study to confirm the findings of an association between poor outcome and that factor.

Randomized clinical trials derive their strength from an evidence-based perspective because of their high degree of internal validity; that is, the randomization scheme and the use of placebo (or accepted alternative treatments) provide strong evidence that the results are related to the intervention. Importantly, these trials have a lower degree of external validity because the intervention may not behave in the same manner as when it is diffused into a more heterogeneous population in whom treatment is not defined.

Retrospective studies involve identifying patients who have sustained an outcome and then defining risk factors associated with the outcome. An example of a retrospective design is a case-control study. Case-control studies identify patients with the outcome of interest. Frequently, these patients may be included as part of a prospective cohort study. The prevalence of a risk factor in the patients with the outcome (case) is compared with the prevalence of the risk factor in "matched" controls; the efficiency and power of the results can be maximized. The ratio of cases to controls can be varied, with greater power with an increasing number of controls.

Case-control studies are subject to a number of biases. The exact definitions of cases and controls can influence the analysis. Frequently, patients are matched by age and gender, but other factors may play an important role. It is also critical that the exposure precedes the outcome, and a dose-response gradient further confirms the relationship.

Problems Inherent in Studying Anesthetic Risk

There are several issues related to studying anesthetic risk that can affect findings. As described earlier, there are multiple definitions of perioperative mortality. In particular, the time frame in which a death can be attributed to the surgery and delivery of anesthesia varies. Because in-hospital stays have shortened, many events related to surgery may occur after discharge. This is particularly the case in ambulatory or short-stay surgery, in which recovery from anesthesia occurs at home. As anesthesiologists continue to monitor patients for safety, it will be important to include follow-up beyond the traditional hospital setting. Many recent studies have included such an approach.

A major problem in any study of risk is the actual rate of complications in the population of interest. There are multiple sources of data for studying perioperative risk. Although some of the original studies utilized data from only a single center or small group of institutions, such approaches may not be practical in the current era. As demonstrated throughout this chapter, risk related to anesthesia has decreased over time. For example, the rate of anesthetic-related mortality described in the Confidential Enquiry into Perioperative Deaths (CEPOD) was 1 in 185,000 patients compared to that reported by Beecher and Todd of 1 in 2,680 cases. [16] [17] Considering the current rate, any study would have to be enormous to detect anesthesia-related mortality. Such a study would require information from a large number of sites. Considering concerns in the United States regarding confidentiality and legal liability, such a study could not be undertaken. Such problems may not be inherent in other countries.

Another limitation relates to the issue of the effect of the actual act of studying outcome. As in any study of risk, the actual rate of complication is decreased by increased observation. This is frequently observed as a lower than expected rate of complications in the placebo arm of a randomized controlled trial.

An alternative approach is to identify bad outcomes and to study them for patterns of errors. For example, Cheney et al [18] developed the American Society of Anesthesiologists (ASA) Closed Claims Study. By obtaining the records of major events that led to litigation, these investigators were able

to identify factors that contributed to bad outcomes. Using such methodology, selected morbidity that leads to litigation can be identified. The limitation of this methodology is that the actual rates of complications are unknown, and only the number of closed legals claims is known. Additionally, those cases that do not result in litigation are not included in the database.

Several attempts have been made to establish large epidemiologic databases. The best example of such an approach has been the work of Mangano and the Multicenter Study of Perioperative Ischemia group [19] with regard to cardiac surgery. This group used their database to evaluate issues such as the rate and importance of atrial fibrillation after cardiac surgery. [19] Other approaches include the development of cardiac surgery databases by the Society of Thoracic Surgeons, the Veterans Administration, and the New England Collaborative Project. [20] [21] [22] [23] [24] These databases are used for defining risk factors for poor outcome, for benchmarking local to national complication rates, and as educational tools. Unfortunately, these databases do not include extensive or any information regarding anesthesia practice. Additionally, such databases include a predominance of patients from academic or major medical centers and do not include data from smaller or community hospitals, which may have very different patterns of care. Although these databases may provide extremely important information to improve care, the ability to generalize the results to the nonacademic centers is unknown.

This final issue of the site of surgery may have other implications related to the pattern of care at a particular hospital. Although most studies frequently categorize risk as related to anesthesia, surgery, or patient disease, postoperative care may have a profound impact on risk. For example, the risk of pulmonary embolism may relate to nursing care and the frequency with which a patient is ambulated after surgery. [25] Such variation in the total care provided by a hospital, including the anesthesiologists and surgeons, may significantly affect the results.

One advance in determining local complication rates is the development of hospital information systems. The use of computerized databases in the assessment of risk began with Marx et al. [26] Now, these information systems are almost a requirement of survival for the hospital. The ability to query these systems will make large-scale studies of institutional risk much less burdensome in the future.

When extremely large sample sizes are needed, administrative databases may be among the most cost-effective approaches to this issue. Examples of administrative databases include Medicare claims files, private insurance company claims, and hospital electronic records. These databases include a small number of data points on an extremely large number of subjects. For example, the Medicare database includes financial data, the ninth revision of the International Classification of Diseases codes (ICD-9), and Current Procedural Terminology (CPT) codes for each patient. They also include information regarding location of care and provider type. The Medicare claims files are now being extensively utilized to benchmark rates of mortality and major complications after coronary bypass surgery. [27] Hospitals can compare their rates with those of neighboring and competing hospitals and may use these data as surrogates for quality of hospital care. [28] [29]

MORTALITY RELATED TO ANESTHESIA

The first report of the delivery of anesthesia for an operative procedure was in 1846, using ether. Only 2 years after that report, there was a death attributable to anesthesia. [30] In that report, Hannah Greener died on induction with chloroform. Since that time, there have been numerous investigations into the cause of anesthetic death. The first formal published investigation of anesthetic deaths was by John Snow in 1858. [31] In that report, he analyzed 50 cases of death during chloroform anesthesia. At that time, mortality occurred principally in healthy patients undergoing minor procedures. This suggests that anesthesia was the principal cause of mortality. Subsequent studies report deaths in patients with significant comorbidities who were undergoing major surgical procedures. In these cases, the cause of mortality was frequently multifactorial.

Surgery Without Anesthesia

Surgical procedures were carried out prior to the introduction of anesthetics. The key to success was the speed of the procedure, with successful amputations lasting 30 seconds. Strong assistants and restraints were frequently required. Alternatively, decreased cerebral perfusion via bilateral carotid compression was used to decrease sensation during the procedure. Importantly, surgical procedures were associated with significant risk of death and, at a minimum, severe pain. The development of anesthesia was heralded as one of the great advances of modern medicine, in that it allowed surgery to advance.

Early Studies of Anesthetic Mortality

One of the earliest systematic approaches to anesthetic risk occurred in 1935, when Ruth helped to establish the first anesthesia study commission to analyze perioperative deaths [17] [26] [32] [33] [34] [35] [36] [37] [38] [39] [40] [41] [42] [43] (Table 22-3) (Table Not Available) . Ruth relied on voluntary submission of cases and determined the cause of death by majority vote. Both methodologies would be deemed inadequate in subsequent years.

From a pragmatic standpoint, determining the cause of anesthetic-related mortality is important if information from the analysis can be used to improve subsequent care. This concept was best voiced by Sir Robert Macintosh in 1948. [44] He stated that many anesthetic-related deaths were preventable and that improved education was the best means to avoid unnecessary mortality. He went so far as to suggest that all development of new drugs be halted for 5 years in order to direct more attention to training of young anesthetists. He attempted to focus attention on postoperative care and suggested that more deaths occur after the patient is returned to the ward than intraoperatively. His final comments related to a need for establishing a formal inquiry mechanism for determining the cause of all deaths, because such an analysis could lead to improved practice. In many ways, the CEPOD is the culmination of such a philosophy. [16]

TABLE 22-3 -- Estimates of the Incidence of Mortality Related to Anesthesia Before 1980

(Not Available)

From Ross AF, Tinker JH: Anesthesia risk. In Miller RD (ed): Anesthesia, 3rd ed. New York, Churchill Livingstone, 1990.

The major advance in the analysis of anesthetic risk was the report by Beecher and Todd [17] of anesthetic-related death in 10 institutions, published in 1954. Their study included 599,548 anesthetic regimens. The cause of mortality was determined at the local institution by consensus of a surgeon and the chief anesthetist of the institution. Each death was characterized as having one primary cause, and it may also have had multiple secondary causes. Overall, a patient had a chance of mortality of 1 in 75 cases from one cause or another. These investigators reported that anesthesia was the primary cause of mortality in 1 in 2,680 cases and was either the primary or contributory cause of mortality in 1 in 1,560 cases. Surgical error in diagnosis, judgment, or technique was the primary cause of death in 1 in 420 cases, and patient disease was the primary cause in 1 in 95 cases. Of note, these investigators placed these figures in the perspective of treating other causes of mortality:

> Data are present to show that death from anesthesia is of sufficient magnitude to constitute a public health problem. Anesthesia kills several times as many citizens each year out of the total population of the country as does poliomyelitis. Consideration of the millions of dollars rightly spent in attacking poliomyelitis and the next to nothing, comparatively, spent in anesthesia research makes clear an urgent need.
>
> [17]

Beecher and Todd [17] reported on a number of perioperative care issues that were associated with increased mortality. Mortality was greatest in the first decade of life and in the elderly. Use of curare was associated with a death rate six times higher than no use of curare in patients undergoing major operations (Table 22-4) (Table Not Available) . The proportion of "curare deaths" was similar in patients with and without coexisting disease. These authors suggested that muscle relaxants "be employed only when there are clear advantages to be gained by their use, that they not be employed for trivial purposes or as a corrective for generally inadequate anesthesia." [17]

Dornette and Orth [32] reported on deaths occurring in the operating room during a 12-year period from 1943 to 1954. During this period, 95 patients died on the operating table, 12 patients suffered intraoperative cardiac arrest and died postoperatively, and 1 patient died in the recovery room. This resulted in a total of 108 deaths in 63,105 anesthetic regimens. In 19 cases, the death was judged to be the result of the operation. In 13 patients, preexisting disease was judged to be the cause of death. The patient's condition plus operation was a cause of death in 29 instances. Anesthesia was the primary cause of death in 26 cases, 2 of which were the result of an overdose of local anesthetic by a surgeon, and it was partially the cause of mortality in an additional 21 patients. Therefore, the rate of mortality totally attributable to anesthesia was 1 in 2,427, and death was totally or partially attributable to anesthesia in 1 in 1,343 patients.

Dripps and colleagues [35] at the University of Pennsylvania in Philadelphia surveyed their experience during the

TABLE 22-4 -- Surgery and Associated Anesthesia Deaths with and Without "Curare"

(Not Available)

10-year period from 1947 to 1957. They noted 1,285 operative deaths, defined as death within 30 days, in approximately 120,000 anesthetic regimens, for a gross mortality rate of 1.1 percent. This definition includes late deaths, as opposed to many studies that focus on the intraoperative period or the first 48 postoperative hours. After review of the hospital records, these investigators determined whether anesthesia was definitely or possibly contributory to death. Patients were divided into those who underwent spinal anesthesia or those who had general anesthesia with or without muscle relaxants. In the group who underwent spinal anesthesia, mortality definitely related to anesthesia occurred in 1 in 1,560, and mortality definitely or possibly related to anesthesia occurred in 1 in 780. In the group who underwent general anesthesia, mortality definitely related to anesthesia was 1 in 536, and mortality definitely or possibly related to anesthesia was 1 in 259. Mortality was correlated with physical status, using the ASA physical status classification. The higher mortality compared with other reports may relate to the higher physical acuity at this hospital. Importantly, deaths attributable to anesthesia did not occur in any of the 16,000 ASA class I patients.

Dripps et al [35] compared their data with those of Beecher and Todd. In contrast to the earlier report, they did not find that muscle relaxants were the primary cause of death in their cohort. As noted earlier, there were no deaths in healthy individuals, many of whom had general anesthesia with muscle relaxants. Muscle relaxants contributed to death definitely in 1 of 1,210 patients and definitely or possibly in 1 of 520 patients. The principal intraoperative complications were hypotension and hypoxia. For patients who had spinal anesthesia, virtually all complications occurred intraoperatively, whereas postoperative complications were rare. These authors believed that anesthesia mortality had improved since the start of the study, mainly because of improvements in cardiac resuscitation, the use of more rational transfusion therapy, standard use of recovery rooms, and efficient use of mechanical ventilators.

There were numerous subsequent reports from individual or small groups of hospitals during the subsequent two decades. Gebbie [38] reported on the rate of mortality in an 800-bed general hospital in Ontario, Canada, during the period 1958 to 1964. There were 21 deaths within 10 days of surgery for which anesthesia was deemed totally or partially responsible. This results in a death rate of 1 in 6,158. The most common causes of death were respiratory failure, hypovolemia, and regurgitation. In only 1 case was the anesthesiologist totally responsible for the death, whereas a second death was related to an airway obstruction in the recovery room.

The Baltimore Anesthesia Study Committee reviewed 1,024 deaths on either the day of or the day after a surgical procedure in order to determine the potential contribution of anesthesia. [34] This short period of observation (48 h) compares to the 30-day period used by Dripps et al. [35] This cohort represented 87.5 percent of all such cases in Baltimore hospitals during the 5½-year period between 1953 and 1959. For each case reviewed, the committee determined whether anesthesia was the principal cause or one of several contributing factors. In 196 (19.2%) cases, the committee voted that anesthetic management contributed to the death of the patient. Anesthesia was the principal cause of death in approximately one-third of cases (64/196), with half of those (34/64) related to improper management of the anesthetic (see Table 22-6) (Table Not Available) . The authors estimated the rate of operative mortality as 4 in 10,000 operations using this data and applying rates of surgery from the National Health Survey. Mortality rates were higher in males (7.1/10,000) compared with females (2.7/10,000). The rates were estimated at 3 in 10,000 for patients younger than 15 years of age, decreasing to 1.1 in 10,000 for those 25 to 44 years old and increasing to 27.6 in 10,000 in those older than 75 years. Of all the patients studied, more than 50 percent died in their hospital rooms, a finding leading the authors to emphasize the need for routine utilization of postanesthesia care areas.

In an attempt to educate practitioners and to prevent duplication of preventable causes of death, each of the perioperative deaths in the foregoing study was discussed. The primary cause of death was overdosage of anesthesia in eight patients; four patients died following aspiration, and two patients died of chronic hypoxia from mismanagement of the airway. There were six deaths during transurethral resection of the prostate under spinal anesthesia, which the authors attribute to the spinal anesthesia or vasopressor use in patients with coronary disease. Importantly, this report attempts to define potentially preventable causes of mortality.

Schapira et al [33] reported on mortality within 24 hours of surgery between the years 1952 and 1956 at Montefiore Hospital in New York. They ascribed 27 deaths to anesthesia, 18 primarily related and 9 in which anesthesia was contributory. The overall rate in which death was partially or totally attributable to anesthesia was 1 in 1,232.

Clifton and Hotten [36] reported on 162 deaths associated with anesthesia in 205,640 operations performed in the Royal Prince Alfred Hospital in Sydney, Australia between 1952 and 1962. These investigators calculated that the incidence of mortality totally due to anesthesia was 1 in 3,955, that related to surgery was 1 in 2,311, and that caused by patient disease was 1 in 1,996. The incidence of death was lowest in those younger than the age of 20 and highest in the 21- to 49-year-old group, and it was more common in men. The time of death was most commonly postoperatively during the initial period of the study related to hypotension, which was much less frequent during the final years of the study. This change occurred simultaneously with the more common use of blood transfusion. An additional cause of postoperative mortality was respiratory insufficiency. These authors argued that many of these complications would have been prevented by the use of a recovery unit. The potential safety advantages of a postanesthesia care unit (PACU) was a general theme in these reports from the 1960s.

Dinnick [45] reported on 600 deaths associated with anesthesia as part of a series of investigations sponsored by the Association of Anaesthetists in London. This represents the second report from this group since a committee was established to collect clinical data in 1949. The first report included a review of 1,000 fatalities and concluded that "in the majority of the reports there were departures from accepted practice." [45] The initial report published in 1956 found that regurgitation and vomiting were the main factors in death, whereas the second report, published in 1964, found that low blood volume was more important. Underventilation was the second most common finding, comprising 25 percent of the cases.

Bodlander [41] provided a follow-up report of anesthetic mortality at the Royal Prince Alfred Hospital for the years 1963 to 1972. The incidence of mortality totally attributed to anesthesia decreased to 1 in 1,702, whereas anesthesia contributed to mortality in 1 in 502 cases compared with 1 in 1,208 for the years 1952 to 1962. The reduction in anesthesia-related death was attributed to the increase in the number of qualified staff members and the degree of supervision.

Marx et al [26] evaluated the incidence of death within 7 days of surgery in 34,145 consecutive patients at the Bronx Municipal Hospital Center in New York between 1965 and 1969. A total of 645 patients died, and a death report form was constructed based on one developed by a committee of the New York Academy of Medicine. The deaths were then analyzed in relation to perioperative data available from a computer system. The primary causes of death were patients' preexisting disease in 83 percent of cases, operation in 10 percent, and anesthesia in only 4 percent (1 in 1,265 cases). Several factors were shown to be associated with perioperative deaths. Three hundred eight-four deaths (59.5%) occurred in association with emergency cases, which was a significant difference. Mortality rose progressively with age; however, physical status correlated best with the incidence of mortality.

Marx et al [26] determined the relationship between the type of anesthesia and mortality. Regional anesthesia was associated with the lowest incidence of death and local with the highest, whereas general anesthesia was intermediate. Although this relationship was significantly different among groups, the difference appears to be related to the risk of the patient, a finding supported by a more recent study by Cohen et al. [46]

Farrow et al [47] [48] studied hospital mortality following 108,878 anesthetic regimens in Cardiff, Wales between 1972 and 1977. The crude mortality rate was 2.2 per 100 patients. Mortality was greatest in those patients older than 65 years. Mortality was greatest in men until they reached the age of 65 years. Mortality also increased with the severity of patient disease and with emergency operation.

Harrison [40] evaluated mortality associated with 240,483 anesthetic regimens performed between 1967 and 1976 at Groote Schuur Hospital in Cape Town, South Africa. Data were collected prospectively, beginning in 1956. Deaths for which anesthesia was the cause or a major contributory factor occurred in 0.22 cases per 1,000 anesthetics between 1967 and 1976, compared with 0.33 case per 1,000 operations in the 10 years earlier. Anesthesia contributed to 10 percent of all deaths associated with anesthesia. The most common causes of anesthetic-related mortality, in order of frequency, were hypovolemia, respiratory inadequacy following neuromuscular blockade, complications of tracheal intubation, and inadequate postoperative care. Although the improvement in anesthetic-related mortality could not be directly attributed to specific improvements in care, four specific changes did occur: continuing improvement in routine monitoring, an increase in the ratio of consultants to registrars, a decrease in the case load per anesthesiologist, and the introduction of recovery rooms and intensive care units.

In summary, studies prior to 1980 demonstrated steady improvements in anesthesia-related mortality. Studies performed throughout the world focused on identifying the causative factors for perioperative mortality. Several general themes emerged: anesthesia represents a small but significant cause of perioperative mortality; perioperative respiratory complications represent a major complication; and elucidation of the causes of perioperative mortality and education of these causes should lead to improved outcome.

Anesthetic Mortality Studies After 1980

Whereas studies conducted prior to 1980 focused on a single center or group of institutions, studies since that date have frequently been performed on a national basis. The improvements in anesthetic and overall mortality made the analysis of a single institution inadequate because of the small sample size. For example, Holland [49] reported on death within 24 hours of an anesthetic regimen in New South Wales, Australia. A committee of 6 anesthesiologists, 3 surgeons, an obstetrician, a general practitioner, and a medical administrator was established in 1960 and reviewed all such cases except during a 3-year period between mid-1980 and mid-1983. Four categories were established to define the relationship of anesthesia to operative morbidity and mortality (Table 22-5) (Table Not Available) . During the period from 1960 to 1985, information was obtainable on 92 to 96 percent of all cases. Twenty-five percent of the 5,262 deaths were deemed attributable in whole or part to the anesthetic regimen. The incidence of anesthesia-attributable deaths decreased from 1 in 5,500 anesthetics administered in 1960 to 1 in 10,250 in 1970 and to 1 in 26,000 anesthetics in 1984 (Table 22-6) (Table Not Available) .

From Holland [49]

Based on these estimates, the authors asserted that it was at least 5 times safer to undergo anesthesia in 1984 compared with 1960, particularly in healthy individuals. A subsequent follow-up report stated that factors under the control of the anesthesiologist caused or contributed to perioperative mortality at a rate of 1 in 20,000 operations. [50] The latest report on mortality demonstrated a preponderance of males over females (1.7:1). The reason for this finding is unclear, although it confirms other reports. Importantly, 64 percent of the deaths were inevitable, a finding suggesting that only one-third were preventable.

The New South Wales Committee determined the primary error in management that led to perioperative death mentioned in the previous paragraph. The primary cause was inadequate preparation of the patient, followed by a wrong choice of anesthetic agent. From the committee's standpoint, a wrong choice of agent would include administering a renally excreted agent to a patient with chronic renal failure. The third most common error was inadequate crisis management during the initial decade of the study, but this cause was much less important during the period from 1983 to 1985. In fact, inadequate postoperative management was the second most common cause of problems during the final years of the study.

The New South Wales study of anesthetic-related mortality evaluated the contribution of the "anesthetist" on perioperative mortality. Four groups of providers were identified: specialists, nonspecialists, registrars, and residents. The absolute number of anesthetic-related deaths decreased in all groups, but it was most pronounced in the nonspecialists. During the period from 1960 to 1969, the resident medical officer frequently provided anesthesia. During this same period, it was found that these physicians contributed significantly to the mortality observed among "good-risk" patients, a finding that led to a phasing out of the resident medical officer as a member of the anesthetic work force.

Tiret and colleagues [51] carried out a prospective survey of complications associated with anesthesia in France from 1978 to 1982 in a representative sample of 198,103 anesthetic regimens chosen at random from hospitals throughout the country in a study under the direction of the French Ministry of Health. The sample included a survey of 460 public and private hospitals. The investigators evaluated either deaths or coma within 24 hours of surgery. Both the opinion of the participating anesthesiologist and that of the National Committee of Assessors was determined, and the latter was accepted if there was no agreement. Major complications occurred in 268 patients, with death in 67 patients and persistent coma in 16 patients. Death was totally

TABLE 22-7 -- Incidence of Complications Partially or Totally Related to Anesthesia in 198,103 Anesthetic Regimens

(Not Available)

From Tiret et al [51]

related to anesthesia in 1 of 13,207 anesthetics and partially related in 1 of 3,810 (Table 22-7) (Table Not Available) . Coma occurred in 16 of 198,103 anesthetics, of which 62 percent were deemed totally attributable to anesthesia, with the remainder partially attributable. The French survey confirmed previous findings that major complications occurred more frequently in older patients, those undergoing emergency operations, and those with more extensive comorbidity, as measured by the ASA physical status classification.

One of the most important findings of the survey was that postanesthesia respiratory depression was the most frequent cause of death and coma that was totally attributable to anesthesia (Tables 22-8 (Table Not Available) and 22-9) (Table Not Available) . Almost all the patients who had respiratory depression leading to a major complication received narcotics and muscle relaxants that had not been reversed. These investigators also reported a high incidence of "anaphylactoid shock." The authors contended that this was primarily due to althesin and succinylcholine. Importantly, there was no category of drug overdose, which may have been a more appropriate label for some of these cases.

The study by Tiret and colleagues [51] had the advantage of collecting data prospectively, allowing more accurate estimation

TABLE 22-8 -- Timing of Complications and Mortality Occurrence in a French Survey

From Tiret et al [51]

TABLE 22-9 -- Causes of Death or Coma Totally Attributable to Anesthesia in a French Survey

(Not Available)

From Tiret et al [51]

of overall mortality than many of the other studies completed. A major limitation of the study is that only death within 24 hours was included, thus ignoring late deaths

that were the direct result of intraoperative complications.

Tikkanen and Hovi-Viander [52] studied death associated with anesthesia and surgery in Finland and compared the results in 1986 with those collected in 1975. Mortality related to anesthesia decreased during the 9-year period, with an incidence of anesthesia-related mortality of 0.15 cases in 10,000 procedures in 1986.

Lunn and colleagues [53] [54] [55] published three reports concerning anesthesia-related surgical mortality in the United Kingdom. When a death occurred in a hospital within 6 days of surgery, a questionnaire was sent to the patient's anesthetist and surgeon. In 59.3 percent of 4,034 reported deaths, both the surgeon and the anesthetist returned the forms. The replies were reviewed anonymously by two assessors, and differences of opinion were determined by arbitration. After review, further details were obtained if the reply indicated that anesthesia was at least partly responsible for the death. Their second report was based on an analysis of 197 reports of deaths within 6 days of anesthesia during 1981. Forty-three percent were found by the assessors to have nothing to do with anesthesia, 41 percent were partly due to anesthesia, and 16 percent were totally due to anesthesia. Of the 32 cases in which death was totally due to anesthesia, most cases were due to either faulty anesthetic technique or postoperative respiratory failure.

The pioneering work of Lunn and others led to the development of the CEPOD, [16] [56] which assessed nearly a million cases of anesthesia during a 1-year period in 1987 in three large regions of the United Kingdom. Unique to this study was the establishment of "crown privilege" by the government to allow total confidentiality.

```
The Secretary of State is satisfied that the disclosure
of documents about individual cases prepared for the Enquiry into Perioperative
Deaths would be against the public interest and would undermine the whole basis
of a confidential study. Therefore, the data/information sent to the
confidential Enquiry into perioperative deaths is protected from subpoena.
```

Deaths within 30 days of surgery were included in the study. There were 4,034 deaths in an estimated 485,850 operations, resulting in a crude mortality rate of 0.7 to 0.8 percent. Surgery had contributed totally or partially to death in 30 percent of all patients. Progression of the presenting disease had contributed to death in 67.5 percent of all patients, with progress of an intercurrent disease relevant in 44.3 percent of patients. Anesthesia was considered the sole cause of death in only 3 individuals, for a rate of 1 in 185,000 cases, and anesthesia was contributory in 410 deaths, for a rate of 7 in 10,000 (Table 22-10) (Table Not Available) .

There are several potential causes for the improvement in mortality between the CEPOD study and previous studies, including improvements from the same group. One explanation is that improvement in care led to improvement in outcome. Importantly, many of the deaths in which anesthesia was previously considered totally contributory were now classified as deaths in which anesthesia was partially contributory.

An important aspect of the CEPOD study was that it established both anesthesia-related and surgery-related factors

TABLE 22-10 -- Death Totally Attributable to Each Component of Risk in the Confidential Enquiry into Perioperative Deaths

(Not Available)

Modified from Buck et al [16]

that contributed to mortality. The five most common causes of deaths are shown in Table 22-11 (Table Not Available) . Of the 410 perioperative deaths, there were 9 cases of aspiration or vomit and 18 cases of cardiac arrest. There was a large proportion of elderly women with fractures of the femoral neck, and the death rate was inversely related to the seniority of the operating surgeon and preoperative preparation. Specifically, the operating surgeon was a consultant in only 19 percent of the orthopedic cases compared to 47 percent overall.

The CEPOD study also provided important information regarding anesthetic practice. Patients were seen preoperatively in greater than 80 percent of the cases, but postoperatively in less than 50 percent. Although the electrocardiogram was monitored in 97 percent of the cases, core temperature was assessed in only 7 percent. Of note, muscle relaxants were used in more than 50 percent of the cases, but a nerve stimulator was used in only 14 percent.

The assessors concluded that avoidable factors were pres-ent in about 20 percent of the perioperative deaths. Contributing factors for anesthesiologists and surgeons tended to be failures to act appropriately with existing knowledge rather than a lack of knowledge, equipment malfunction, or fatigue. However, these authors suggested that inadequate supervision was a problem and suggested that no operation in a patient with an ASA physical status index of IV or V be performed without direct consultation with the appropriate anesthesia and/or surgical consultant (Table 22-12) (Table Not Available) .

There have been several large national studies published since the CEPOD. Pedersen and colleagues [57] in Denmark performed a series of studies in the late 1980s to look at the factors attributable to anesthesia that led to serious morbidity or mortality. They performed a prospective study of 7,306 anesthetic regimens. They used a similar approach to previous studies in that three anesthetists reviewed the records of complications and determined whether the cause

[a] Day represents Monday through Friday, 9 AM to 7 PM; night represents Monday through Friday, 7 PM to 9 AM, and Saturday and Sunday.

was attributable to anesthesia (no distinction was made between totally and partially contributable). Complications attributable to anesthesia occurred in 43 patients (1/170), with mortality in 3 patients (1/2,500). Complications, in order of incidence, included cardiovascular collapse (37%; 16/43), severe postoperative headache after regional anesthesia (21%; 9/43), and awareness during anesthesia (19%; 8/43). These investigators assessed that 37 percent of the anesthesia-related morbidity was preventable. The three deaths occurred in severely ill patients (ASA class III or greater), and two deaths were judged to be preventable.

Cohen et al [46] developed a methodology for studying anesthesia outcome in four teaching hospitals in Canada. These investigators developed a new anesthesia record to serve as a data collection instrument. Research nurses reviewed all inpatient records within 72 hours postoperatively, conducted interviews of patients using a standardized instrument, and conducted a telephone survey of the majority of outpatients. Assessment of the contribution of anesthesia to the complication was determined using the classification of the New South Wales Committee on Anaesthesia Mortality (see Table 22-5) (Table Not Available) . In a total of 6,914 adult anesthetics, no deaths were directly attributable to anesthesia.

Warner and colleagues [58] at the Mayo Clinic studied major morbidity and mortality within 1 month of ambulatory surgery in 38,598 patients. Four patients died, 2 of a myo-cardial infarction and 2 in an automobile accident (Fig. 22-2) (Figure Not Available) . The 2 deaths from a myocardial infarction occurred at least 1 week after surgery and were not directly attributable to anesthesia. Considering the rate of mortality directly related to anesthesia described in the CEPOD study, none would be expected in a study of this size.

Use of Computerized Analysis

Increasingly, the use of computerized databases has enhanced the ability of investigators to identify perioperative complications. One of the earliest uses of a computerized analysis of postanesthesia deaths was by Marx and colleagues. [26] They identified 645 individuals who died within 7 days of surgery from a total cohort of 34,145 consecutive surgical patients. The rate of mortality related to anesthesia was 1 in 1,265 cases and 1 in 1,707 cases related to postoperative management. The authors deemed two-thirds of all deaths preventable. Sanborn et al [59] used a computerized anesthesia record to identify intraoperative incidents with high sensitivity and specificity. These investigators were able to demonstrate that perioperative deaths occurred more frequently in those patients who sustained an intraoperative incident than in those who did not.

Figure 22-2 (Figure Not Available) Timing of perioperative events in patients undergoing ambulatory surgery. Many of the events occur within the first 48 hours and are likely related to the stress of surgery. A subset of events occurring after this period may relate to background event rates. The overall rate of morbidity was lower than expected for a similar cohort of age-matched nonsurgical patients. *(From Warner et al [56])*

Other Approaches to Discern the Root Cause of Morbidity and Mortality

Accumulating data clearly demonstrate that risk directly attributable to anesthesia has declined over time. The cause of this reduction in mortality is unclear. Numerous factors have been implicated in the improved outcome, including new monitoring modalities, new anesthetic drugs, and the changes in the anesthesia work force. However, it is difficult to document reduced risk related to any one factor. Issues related to manpower are addressed later in this chapter. Interestingly, although newer monitoring modalities, particularly pulse oximetry, would be expected to lead to improved outcomes, no randomized trial has been able to document such a conclusion. [60] This limitation supports the need to continue monitoring for complications and their root cause with studies such as the ASA Closed Claims Project.

Studies similar to the CEPOD study have not been performed in United States, most likely because of the legal system. Therefore, information related to perioperative mortality has had to be obtained from other sources. This basic concept led to the formation of the anesthesia Closed Claims Study. The Professional Liability Committee of the ASA conducted a nationwide survey of closed insurance claims for major anesthetic mishaps.

Both fatal and nonfatal outcomes were reviewed. Among the fatal events, cases involving unexpected cardiac arrest during spinal anesthesia were observed in 14 healthy patients from the initial 900 claims. [61] The cases were analyzed in detail in order to identify patterns of management that may have led to the event. Two patterns were identified: oversedation leading to respiratory insufficiency and inappropriate resuscitation of high spinal sympathetic blockade.

Tinker et al [62] queried the Closed Claims Study to determine the role of monitoring devices in the prevention of anesthetic mishaps. These investigators reviewed 1,097 anesthetic claims and determined that 31.5 percent of the negative outcomes could have been prevented by the use of additional monitors, primarily pulse oximetry and capnography. Those injuries that were deemed preventable with additional monitoring resulted in dramatically more severe injury and higher costs of settlement than those judged nonpreventable with additional monitoring. In almost 90 percent of the preventable cases (305/346), at least one clinical sign of abnormality had been present from the existing monitors.

Caplan et al [63] reviewed the Closed Claims Study for respiratory events (Table 22-13) (Table Not Available) . These claims represented the single largest class of injury (34%). Death or brain damage occurred in 85 percent of cases. These investigators identified inadequate ventilation, esophageal intubation, and difficult tracheal intubation as the primary causes of respiratory events. Most of the outcomes were thought by the investigators to be preventable with better monitoring (Fig. 22-3) (Figure Not Available) . Although no randomized trial has demonstrated the value of pulse oximetry or capnography, an analysis of claims supports the value of such monitoring. This analysis also formed part of the basis for the ASA Difficult Airway Guidelines and algorithm. [64]

Cooper and colleagues [65] [66] [67] [68] approached the problem of sample size for determining perioperative morbidity by identifying "critical incidences," defined as those that are preventable but that could lead to undesirable outcomes. Such a definition could include events that led to no or only transient effects for the patient. The investigation involved collecting anesthesia-related human errors and equipment failures from anesthesiologists, residents, and nurse anesthetists. In a series of reports, these investigators identified frequent incidences, such as disconnections in breathing circuits, and causes of discovery of errors, such as intraoperative relief. [65] [66] [67] [68] They confirmed that equipment failure was a minor cause of anesthesia mishaps (4%), whereas human error was dominant. They suggested that future studies of anesthesia mortality and morbidity should classify events according to a strategy for prevention, rather than outcome alone.

Buffington et al [69] studied the ability of attendees of an anesthesia meeting to identify five faults intentionally created

Figure 22-3 (Figure Not Available) Relationship between adverse events in the American Society of Anesthesiologists Closed Claims Study and preventable complications. Preventable events were significantly more common in relation to respiratory complications than all nonrespiratory complications. Of the respiratory complications, difficult intubation had the least number of preventable complications. *(From Caplan et al [63])*

TABLE 22-13 -- Distribution of Adverse Respiratory Events in the American Society of Anesthesiologists Closed Claims Study

(Not Available)

From Caplan et al [63]

in a standard anesthesia machine. A survey was distributed, and the answer sheets were scored with respect to the number of correct answers. Only 3.4 percent of the respondents found all 5 faults. On average, the number of faults detected was 2.2. The professional background of the participants did not influence the ability for finding the faults, with similar distributions between physicians and certified registered nurse anesthetists (CRNA). There was a small improvement in fault-finding ability in those with at least 10 years' experience compared with those with less experience. Studies such as these highlight the problem in the practitioner's ability to identify conditions that may lead to anesthetic mishaps. Whether improved technology or education will reduce some basal level of mishaps is unknown.

Analysis of Intraoperative Cardiac Arrests

As opposed to studying perioperative mortality and its association with anesthesia, several studies have evaluated intraoperative fatal and nonfatal cardiac arrests [70] [71] [72] [73] [74] [75] [76] [77] (Table 22-14) (Table Not Available) . In this manner, there are sufficient numbers of complications to perform an analysis at one institution. Keenan and Boyan [78] studied the incidence and causes of cardiac arrest due to anesthesia at the Medical College of Virginia, Richmond, during a 15-year period. There were 27 cardiac arrests during 163,240 anesthetic regimens, for an incidence of 1.7 per 10,000 cases. Death occurred in 14 patients, for an incidence of 0.9 per 10,000 cases. Pediatric patients had a 3-fold higher risk of cardiac arrest than adults. Emergency cases had a 6-fold greater risk. Specific errors in anesthetic management could be identified in 75 percent of cases, most commonly from inadequate ventilation and an absolute overdose of an inhalational agent. The time of day did not appear to influence the rate of anesthetic-related cardiac arrest. From an educational perspective, the authors identified progressive bradycardia preceding all but one cardiac arrest, a finding suggesting that early identification and treatment may prevent complications.

Olsson and Hallen [79] studied the incidence of intraoperative cardiac arrests at the Karolinska Hospital in Stockholm, Sweden from 1967 to 1984. A total of 170 cardiac arrests occurred in 250,543 anesthetic regimens performed. Sixty patients died, resulting in a mortality of 2.4 per 10,000 anesthetics. After elimination of cases of inevitable deaths (e.g., rupture of a cerebral aneurysm, trauma), the mortality caused by anesthesia was 0.3 deaths per 10,000 anesthetics. The most common causes of anesthetic-related cardiac arrest were inadequate ventilation (27 patients), asystole after succinylcholine (23 patients), and postinduction hypotension (14 patients). The incidence of cardiac arrest increased with increasing severity of comorbid disease, as assessed by the ASA physical status classification. In evaluating the incidence of intraoperative cardiac arrest over time, there was a considerable decline from 1967 to 1984 coincident with the increase

in the number of anesthesia specialists employed at the clinic.

The value of studying cardiac arrests may be related to issues of quality of care. The ability to resuscitate patients from an intraoperative cardiac arrest may reflect the skills of the care providers. Future research will be required to determine the validity of such an approach.

Future Issues

Most of the studies to date have focused on in-hospital and short-term mortality, yet perioperative complication may be the event that directly leads to death. For example, a perioperative stroke or myocardial infarction may lead to death after the period of analysis. Even small myocardial infarctions or unstable angina during the perioperative period have been associated with worse long-term survival in several studies. Should these "late" deaths be attributed to anesthetic complications for the purpose of such analyses? From a theoretical standpoint, one study of perioperative beta-adrenergic blockade presents an even greater dilemma. Mangano and colleagues [80] performed a randomized clinical trial in which 7 days of perioperative beta-blockade was compared with placebo in high-risk patients undergoing noncardiac surgery. These investigators reported significantly improved 6-month survival, which remained significant up to the 2 years of follow-up. In a subsequent report regarding this trial, Wallace et al [81] demonstrated that the improved survival in the beta-blocker group was associated with a significantly lower incidence of perioperative myocardial ischemia. Although there have been several questions regarding study design and potential confounding issues related to the conclusions of the study, one guideline advocates the routine use of atenolol for all high-risk patients. The authors of the original study suggested that atenolol resulted in better plaque stabilization during the perioperative period, which improved long-term survival. If the hyperdynamic perioperative state is not well controlled, then this theory would suggest that more plaques become destabilized and progress to acute occlusion and sudden death. If atenolol is not used and patients die within 6 months of surgery, should this outcome be attributed to an error in anesthesia and perioperative management? Part of the answer relies on the strength of this study to support the conclusion that routine use of atenolol does result in improved long-term survival. Because the one study is small and questions remain regarding potential confounding factors, further studies appear warranted before the omission of prophylactic beta-blockade is considered less than the standard of care.

RISKS RELATED TO THE PATIENT

It is well known that perioperative morbidity and mortality increase with increasing patient comorbidity (Ch. 23) . The original ASA physical status scoring system was proposed in 1941 and included six categories. [82] It was originally intended to standardize terminology and to allow statistical analysis of outcomes between sites. [83] The original classification avoided the inclusion of surgical variables and was restricted to preoperative patient characteristics. It was revised in 1961 by Dripps and colleagues [35] to its present form of five categories, which were then adopted by the ASA and are still used today. The simplest example of such a relationship is the incidence of mortality by ASA physical status. In their original study of perioperative mortality, Dripps et al demonstrated that mortality increased as severity of comorbid disease increased, as assessed by the ASA physical status classification.

Several investigators have reevaluated the relationship between operative mortality and ASA physical status classification. The previously described study by Pedersen et al [57] and Tiret et al [51] demonstrated such relationships (Fig. 22-4) (Figure Not Available) . Vancanti et al [84] also demonstrated the relationship between increasing mortality and decreasing ASA physical status in 68,388 cases.

Cohen and colleagues [46] in Canada followed 100,000 anesthetic regimens and determined mortality within 7 days of operation using governmental vital statistics mortality data between the years 1975 and 1984. The investigators established a computerized database for each anesthetic regimen that included age, preoperative conditions, ASA physical status, anesthetic technique, and monitors, among other factors. The overall 7-day mortality rate was 71.04 deaths per 100,000 anesthetics. The mortality rate increased with advanced age and showed a marked increase in patients more than 80 years of age. Rates were low for normal, healthy individuals and for those undergoing minor procedures. The investigators developed a multiple logistic regression model to determine the independent predictors of mortality. Significant risk markers for increasing mortality were advanced age, male gender, increasing physical status score, major or intermediate surgery, emergency procedure, a complication in the operating room, narcotic anesthetic techniques, and administration of only one or two anesthetic drugs (Table 22-15) (Table Not Available) .

In an attempt to look at each of the categories of contributing factors independently, Cohen et al [46] constructed receiver-operator characteristic curves. There was no increment in prediction of mortality higher than that found by the patient plus surgical characteristics. Plots including "other" or anesthesia-related factors showed almost complete overlap with those curves including patient-specific and surgery-specific factors alone.

Figure 22-4 (Figure Not Available) Relationship between American Society of Anesthesiologists (ASA) physical status classification and mortality. Increasing physical status is associated with increasing mortality. Emergency surgery increases risk dramatically, especially in patients in ASA class IV and V. *(From Tiret et al [51])*

TABLE 22-15 -- Risk Factors Associated with Increased Odds of Dying Within 7 Days (All Cases)

(Not Available)

From Cohen et al [46] Copyright 1988, American Medical Association.

One of the limitations of the ASA physical status classification is that ranking is a subjective measure conferred by the practitioner rather than an objective measure determined by the presence of specific disease states. Owens et al [85] evaluated this hypothesis by asking 255 anesthesiologists to classify 10 hypothetic patients. In six of the cases, there was general agreement among the practitioners with regard to the classification of the patient, whereas there was divergence of opinion in the other four cases. The key finding of this study is that the ASA physical status classification is "useful but suffers from a lack of scientific precision." [85]

As opposed to evaluating the risk of overall mortality, many studies have attempted to define patient characteristics associated with morbidity and mortality related to a particular organ system. In evaluating the risk directly related to patient condition, it is important to understand the limitations of the methodology. All such studies evaluate the predictive value of a clinical or laboratory risk factor for a defined perioperative complication. In approaching such an evaluation, a cohort of individuals of interest is defined. In the most optimal state, the study is performed prospectively, and the outcome of interest is assessed in a rigorous, blinded fashion. Unfortunately, many of the studies focus on selected patients and include a retrospective design, features that greatly limit the studies' generalizability and validity. For example, many of the studies evaluating risk factors in patients undergoing vascular surgery only follow patients who are referred for diagnostic testing, not consecutive series.

Many of the studies have adopted the approach of defining a cohort of individuals, determining their clinical and laboratory risk factors, and using multivariate modeling to determine those factors associated with increased risk. Frequently, perioperative risk is used to define both intraoperative and postoperative complications. A major limitation in the use of multivariate modeling for this purpose is the assumption that the intraoperative period is a "black box" and that care is not modified by knowledge of the risk factor (Fig. 22-5) . However, anesthesiologists modify their intraoperative

Figure 22-5 The concept of the "black box" for risk indices. In developing a risk index, patients with a specific risk factor enter the operating room and have a complication at a rate *P.* If the anesthesiologist is aware of the importance of the risk factor and can modify care to reduce such risk (*P*/2), then the risk factor may no longer be significant. Importantly, if the risk factor is ignored, then complications may again occur in such patients.

care in high-risk patients in an attempt to reduce the risk. Therefore, changes in medical care over time and better knowledge of high-risk patients should result in reduction of risk related to specified clinical factors. Therefore, many of the indices developed previously may no longer hold clinical validity.

Finally, in designing a multivariate risk index for perioperative morbidity and mortality, only those factors included in the analysis and in the patient population of interest are included in the final model. For example, if the population studied represents a unique referral bias, then some risk factors may be overrepresented, whereas others may not be present in sufficient quantity to study. An example would be unstable angina in Goldman's original cardiac risk index. [10] Because such

patients would only present for emergency surgery, the risk factor would rarely be represented in many indices.

There are numerous specific disease states that increase perioperative risk. Cardiovascular disease is the most extensively studied, with the goal of identifying patients at greatest risk for fatal and nonfatal myocardial infarctions. One of the earliest attempts to define cardiac risk was performed by Goldman and colleagues [10] at the Massachusetts General Hospital. These investigators studied 1,001 patients older than 45 years of age who were undergoing noncardiac surgery, excluding those patients who underwent transurethral resection of the prostate under spinal anesthesia. Using multivariate logistic regression, these authors demonstrated nine clinical factors associated with increased morbidity and mortality (Table 22-16) (Table Not Available) . Each of these risk factors was associated with a given weight in the logistic regression equation, which was converted into points in the index. An increasing number of points was associated with increasing perioperative cardiac morbidity or mortality.

There have been several attempts to validate the Goldman cardiac risk index (Chs. 25 49 and 51) . Zeldin [86] pro-spectively determined the cardiac risk index in 1,140 surgical patients. They reported that the overall accuracy of the cardiac risk index was as high as in the original study, although the rate of complications in the highest-risk group was lower than originally reported. Larsen et al [87] also found that the cardiac risk index was accurate in 2,609 consecutive unselected patients older than 40 years. The validity of the cardiac risk index is more controversial in patients undergoing vascular surgery. Domaingue et al [88] studied patients undergoing various vascular surgery procedures and reported a higher probability of major cardiac complications than that reported by Goldman et al, but they also demonstrated a higher rate of complications with increasing cardiac risk class. Jeffrey et al [89] evaluated the rate of cardiac complications in 99 patients undergoing elective abdominal aortic surgery and demonstrated a similar pattern of increased overall complication rates with increasing cardiac risk. Importantly, a higher percentage (7%) of patients in the lowest category sustained a cardiac complication. White et al [90] demonstrated the value of the Goldman cardiac risk index for long-term survival after vascular surgery. Several other studies were unable to demonstrate any relationship between the cardiac risk index and perioperative cardiac complications and noted a high incidence of complications in patients with a cardiac risk index of I or II. [91] [92] Interestingly, when the ASA physical status classification was compared with the Goldman cardiac risk index in a cohort of 16,277 patients undergoing noncardiac surgery, [93] both indices demonstrated predictive value, although the objective Goldman cardiac risk index had little value over the more subjective ASA physical status classification.

Other investigators have attempted to develop risk indices. Cooperman et al studied perioperative cardiac risk in 566 patients undergoing major vascular surgery and developed a multivariate logistic regression model for predicting cardiac risk. [93A] Detsky et al [94] studied a cohort of individuals who were referred to an internal medicine service for preoperative evaluation, as opposed to an unselected group of

TABLE 22-16 -- Computation of the Cardiac Risk Index

(Not Available)

From Goldman et al [10]

surgical patients. Many of the factors identified by Goldman et al were confirmed or slightly modified in the Detsky index, although angina was added to the risk factors. Importantly, Detsky et al advocated the calculation of a pretest probability of complication based on the type of surgery, after which the modified risk index is applied using a nomogram. In this manner, the overall probability of complications can be determined as a function of both the surgical procedure and the patient's disease. The Detsky index has been advocated as the starting point for risk stratification for the American College of Physicians guideline on preoperative evaluation. [95]

There have been numerous risk indices developed for cardiac surgery. [96] [97] [98] [99] [100] [101] Again, the goal has been to define those patients at greatest risk for perioperative outcomes, not specific anesthesia-related risk. Many of these indices focus on anatomic considerations for perioperative risk. They are extremely useful in risk adjustment to assess rates of mortality. For example, New York State publishes annual mortality rates for surgeons and hospitals for coronary bypass grafting. [102] [103] [104] In order to be able to compare rates across institutions, it is important to adjust risk so that institutions that perform predominantly high-risk surgery are not penalized.

Vascular surgery represents a cohort of patients with very high perioperative complication rates. [105] Both clinical risk indices and noninvasive diagnostic testing have been used to identify the patients with the highest perioperative mortality and major morbidity. Numerous studies have demonstrated that the presence of a reversible defect on thallium imaging and of new regional wall motion abnormalities on dobutamine echocardiography predicts those patients with a high perioperative risk. [106] [107] [108] [109] [110] [111] [112] [113] [114] [115] As the technology became diffused, the tests lost much of their predictive value because they were used in lower-risk patients. [116] [117] Subsequent studies demonstrated that the tests should only be applied to those at moderate or high risk, and these studies identify a group of clinical patient characteristics that define those in whom the test will have the optimal predictive characteristics. Eagle and colleagues [118] determined the value of clinical risk factors for predicting perioperative cardiac events and the additive value of noninvasive testing based on the preoperative risk profile. Five clinical predictors were identified: age older than 70 years, diabetes mellitus, angina, ventricular ectopic activity under treatment, and Q waves on an electrocardiogram. In patients undergoing major vascular surgery, an increasing number of clinical variables was associated with an increasing perioperative risk. The presence of thallium redistribution after dipyridamole infusion further identified a high-risk cohort in those patients with one or two clinical risk factors. A subsequent multi-institutional report used a bayesian approach to define the additive value of these risk factors and thallium markers to identify high-risk patients. [119]

Vanzetto et al [120] performed a prospective evaluation in which an expanded number of clinical variables was identified in a cohort of patients undergoing major vascular surgery. Cardiovascular morbidity and mortality were determined prospectively in this population. Again, an increasing number of clinical variables was associated with an increasing perioperative risk. Most importantly, dipyridamole thallium imaging was only performed in the subset of patients with two or more clinical variables, and the results of the test were not made available to the clinicians caring for the patients. In this well-performed study, the presence of thallium redistribution again identified a cohort with an incrementally greater perioperative risk compared with patients with negative scans and a similar number of clinical variables.

As part of their study of anesthesia mortality, Pedersen and colleagues [57] also evaluated the occurrence of cardiovascular and pulmonary complications. In the total cohort of 7,306 anesthetic regimens, they reported a 6.3 percent incidence of intraoperative or postoperative cardiovascular complications and a 4.8 percent incidence of intraoperative or postoperative pulmonary complications. Acute myocardial infarction occurred in 0.16 percent of the patients. These investigators evaluated a number of characteristics, including gender, age, presence of ischemic heart disease, duration of anesthesia and type of surgery, and their relationship to cardiovascular and pulmonary complications, and overall mortality in the hospital (Table 22-17) (Table Not Available) . Cardiopulmonary complications were associated with advanced age (>70 y), preoperative signs of ischemic heart disease with recent myocardial infarction, chronic heart failure, chronic lung disease, and abdominal surgery, particularly of an emergency nature. Of interest, these workers noted that the use of pancuronium was associated with worse perioperative outcome, a finding reminiscent of the "curare deaths" of the 1940s and 1950s.

Numerous studies have evaluated the importance of single variables in perioperative risk. The presence of hypertension has been examined in several studies. Goldman and Caldera [121] evaluated a cohort undergoing noncardiac surgery with general anesthesia. Hypertension did not denote a group with increased perioperative risk, although the number of patients with a diastolic blood pressure greater than 110 mm Hg was insufficient to draw any conclusions. This study highlights the problems related to generalization of results, because many subsequent authors suggested that surgery be delayed in patients with a diastolic blood pressure higher than 110 mm Hg. In one of the few studies to demonstrate a relationship, Hollenberg et al [122] identified both hypertension and the presence of left ventricular hypertrophy as predictors of perioperative ischemia, but these investigators did not report on the independent relationship of these predictors with perioperative major morbidity.

The studies of the rate of perioperative reinfarction in patients who sustained a previous myocardial infarction are examples of prospective cohort studies to identify the risk of a particular clinical factor. Traditionally, risk assessment for noncardiac surgery was based on the time interval between the myocardial infarction and surgery. Multiple studies have demonstrated an increased incidence of reinfarction if the myocardial infarction was within 6 months of surgery [11] [12] [13] (Table 22-18) . With improvements in perioperative care, this difference has decreased.

However, this example of assessing risk illustrates the issue of changes in management over time. The importance of the intervening time interval may no longer be valid in the current era of thrombolytics, angioplasty, and risk stratification after an acute myocardial infarction. Although many patients with a myocardial infarction

may continue to have myocardium at risk for subsequent ischemia and infarction,

TABLE 22-17 -- Factors Associated with Increased Perioperative Complications

(Not Available)

From Pedersen et al [203]

other patients may have their critical coronary stenosis either totally occluded or widely patent. For example, the use of percutaneous transluminal coronary angioplasty (PTCA) is associated with a reduced incidence of death or reinfarction within 6 months. [123] Therefore, patients should be evaluated from the perspective of their risk for ongoing ischemia. The American Heart Association/American College of Cardiology Task Force on Perioperative Evaluation of the Cardiac Patient Undergoing Noncardiac Surgery [124] has advocated the use of a myocardial infarction within the past 30 days as the group at highest risk, whereas after that period, risk stratification is based on the presentation of disease and exercise tolerance.

SPECIAL PATIENT GROUPS

Obstetrics

Maternal mortality is very rare (Ch. 57) . The anesthesia-related component of maternal delivery represents only a small fraction of all maternal deaths, making the study of this problem difficult or impossible in any one institution. A series of studies was performed between 1974 and 1985 to determine the rate of complications in both the United States and England. One of the first reports was for the period 1974 to 1978. Kaunitz et al [125] reported an anesthetic death rate of 0.6 per 100,000 births using data from all 50

states. Endler et al [126] studied births in Michigan from 1972 to 1984 and reported 15 maternal deaths in which anesthesia was the primary cause and 4 deaths in which anesthesia was contributory. This resulted in a rate of 0.82 anesthetic deaths per 100,000 live births. Eleven of the 15 deaths were associated with cesarean section. Obesity and emergency surgery were risk factors in many patients. Complications related to regional anesthesia were problems during the early part of the study, whereas failure to secure a patent airway was the primary cause of mortality in later years. There was no anesthesia-related maternal mortality in the final 2 years of the study. The incidence of anesthetic death was markedly higher in black women, a finding that the authors suggest may be related to the inability to detect cyanosis. Rochat et al [127] studied 19 areas of the United States between 1980 and 1985 and reported 0.98 anesthetic deaths per 100,000 live births. Rochat et al noted that maternal mortality did not decrease over the time of the study.

The Confidential Enquiry into Maternal Deaths in England and Wales has been assessing maternal deaths since 1952. [128] All maternal deaths are sent to a district medical officer, who sends an inquiry form to all health practitioners who were involved in the care of these patients. These forms are then evaluated by a senior obstetrician and anesthetic assessor. Morgan [128] reported on the maternal deaths from anesthesia between 1952 and 1981 (Table 22-19) (Table Not Available) . The total maternal mortality has decreased over time, and the percentage of deaths related to anesthesia has increased, although the absolute number of deaths from anesthesia has decreased. During the early years of the study, endotracheal intubation was rarely performed during obstetric anesthesia. After reports advocated the use of endotracheal intubation after thiopental-succinylcholine administration, technical difficulties with intubation were noted. The other major finding is that the experience of the anesthetist in obstetric anesthesia was the most important factor in anesthetic maternal mortality.

There have been several studies that have attempted to define the cause of anesthetic-related maternal deaths. Insights into the cause of maternal mortality can also be elicited from the ASA Closed Claims Study. In 1989, Chadwick et al [129] published a report of closed malpractice claims related to 190 obstetric cases, representing 127 cases of cesarean section and 63 of vaginal delivery. The most frequent complications were maternal death and newborn brain damage. There were 15 maternal deaths in patients who had regional anesthesia and 26 maternal deaths in patients who had general anesthesia. Because the absolute number of patients who underwent each type of anesthesia was unknown, the risk attributable to anesthesia could not be determined, unlike the subsequent report by Hawkins et al. [130]

Hawkins et al [130] obtained data from the U.S. Centers for Disease Control and Prevention (CDC) ongoing National Pregnancy Mortality Surveillance System. Using state data on births and fetal deaths between 1979 and 1990, three obstetric anesthesiologists reviewed the record to determine the possible relation to anesthesia. A total of 129 women died of anesthesia-related causes during the study period, most of whom (82%) during cesarean section, with the incidence decreasing over time (Table 22-20) (Table Not Available) . Importantly, this decrease appears to be related to an increase in the use of regional anesthesia. The primary cause of mortality was related to the type of anesthesia. For general anesthesia, 73 percent of the deaths were related to airway problems. Unlike England, which has the Confidential Enquiry of Maternal Deaths, the United States study lacks the extensive detail for each event and therefore the absolute cause of mortality is somewhat in doubt. In particular, the authors acknowledge that general anesthesia may be used for patients with a higher acuity of disease, and that practice may account for the higher mortality rates. The availability of national databases should allow accurate tracking of mortality in order to ensure that appropriate quality assurance/quality improvement systems are in place.

Gibbs et al [131] surveyed 1,200 hospitals in 1981 and sent questionnaires to the chiefs of anesthesia and obstetrics. Anesthesiologists were available for obstetric anesthesia in only 21 percent of all hospitals, and at night and on the weekends, they were available in only 15 percent. Hospitals with less than 500 deliveries per year had the most striking deficiencies in anesthesia personnel. Even for cases in which general anesthesia was provided for cesarean section, an anesthesiologist was involved in the care 44 percent of the time, although hospitals with more than 1,500 deliveries had an anesthesiologist present 85 percent of the time. The authors did not evaluate the relationship between outcome

From Hawkins et al [130]

and staffing models. The survey was performed again in 1992. [132] Compared with 1981, these investigators noted a marked increase in the availability of labor analgesia and a decrease in the use of general anesthesia. In more than one-half of anesthetic regimens for cesarean section, care was provided by nurse anesthetists without medical direction by an anesthesiologist. How these trends in staffing affect maternal mortality requires further evaluation.

Pediatrics

There are few studies of anesthetic risk in the pediatric population (Ch. 59) . Two themes emerge from these studies: very young infants are at increased risk; and anesthetic risk is reduced in centers with specialized pediatric anesthesia. In the report by Beecher and Todd, [17] there was a "disproportionate number" of anesthetic deaths in children less than 10 years of age.

Graff et al [133] from the Baltimore Anesthesia Study Committee reported on 335 operative deaths in the pediatric age group. Of these deaths, 58 were thought to be either primarily or partially attributable to anesthesia. The percentage of operative deaths attributable to anesthesia was relatively constant between age groups at 16.6 to 21.7 percent. The estimated anesthesia-associated mortality was 3.3 deaths per 10,000 operations for those younger than 15 years, compared with 0.6 for those between 15 and 24 years and 11.7 deaths per 10,000 operations for those older than 64 years of age. More than one-half of the patients were ASA physical status I or II, suggesting that the majority of the deaths occurred in children with good anesthetic risk. The majority of the deaths occurred in tonsillectomy, a finding that most likely reflects that this is the most common operation in this age group. In an attempt to determine the phase of the operation associated with the highest risk, improper management of the anesthetic accounted for approximately one-half of the cases. Respiratory complications were apparent in 82 percent of the anesthetic deaths due to underventilation and aspiration of vomitus or blood. Interestingly, the authors suggested that females are a better operative risk than males in all age groups.

Tiret et al [134] published a study of pediatric anesthesia risk in 1988. They prospectively studied major anesthetic complications in pediatric patients in 440 hospitals in France between 1978 and 1982. There were 27 major complications in 40,240 cases, which included 12 cardiac arrests and 1 death. The incidence of major complications and of cardiac arrest was significantly higher for infants than for children. The rate of cardiac arrests related to anesthesia was highest in infants (19/10,000) and lower in children (2.1/10,000) (Table 22-21) (Table Not Available) . The majority of the complications in infants involved the respiratory system, predominantly airway problems and aspiration. Older children experienced both respiratory and cardiac complications, which were most frequent during induction and recovery.

Cohen et al [135] studied 29,220 anesthetic regimens at the Winnipeg Children's Hospital in Manitoba, Canada. Data were collected from mid-1982 to 1987 and were stored in a databank. Data on patients' coexisting medical conditions and postoperative follow-up were obtained within 72 hours. Complications included death, cardiac arrest, drug incident, and airway obstruction, as well as minor complications including nausea and vomiting, arrhythmias, and sore throat. These investigators reported on the type of operation, with neonates undergoing a higher percentage of major vascular/ cardiac and intra-abdominal procedures, whereas older children had a higher incidence of extremity-related procedures. Intraoperative cardiac arrest occurred most frequently in infants (4/2,901 anesthetics in children <1 y old) compared with older children. Postoperatively, minor events such as nausea and vomiting were more common in older children, whereas respiratory events were more common in infants and younger children (Table 22-22) (Table Not Available) . When compared with adult patients, children experienced different complications

that frequently extended well into the postoperative period. Comparing 2-year periods between 1982 and 1987, the rates of intraoperative events were stable, whereas the rate of postoperative complications decreased. These authors suggested that identification of these problems can lead to changes in management, thus resulting in improved outcomes.

Geriatrics

Numerous studies have documented the importance of advanced age on perioperative risk (Ch. 61) . In many of the original studies on the factors associated with perioperative mortality, both the youngest and oldest patients were shown to have the highest rates of death after surgery. Age has been implicated as one of the factors in the risk indices developed by Goldman, Detsky, and Pedersen and their colleagues. Age is predominantly analyzed as a dichotomous variable, with many studies focusing on age of more than 70 years.

One of the issues regarding the rate of mortality in the geriatric population is the definition of this group. Multiple definitions have been used for advanced age, including patients older than 65, 70, 80, and 90 years. Denney and Denson [136] evaluated risk of surgery in patients older than 90 years of age. They suggested that the prevailing philosophy in 1972 was that surgery may not be appropriate considering the high perioperative risk in this cohort, without objective data to support such a supposition. They reported on 272 patients undergoing 301 operations at the University of Southern California Medical Center in Los Angeles. Contrary to their expected belief, these investigators reported that in more than 70 percent of the nonagenarians, the benefit more than justified the risk they underwent. They reported that serious bowel obstruction was the only underlying comorbidity associated with prohibitive perioperative mortality (63%).

Djokovic and Hedley-Whyte [137] studied the outcome of surgery in 500 patients older than 80 years at the Harvard Medical System in Boston. They noted that mortality was predicted by ASA classification, with greater comorbidity associated with increasing risk. Myocardial infarction was the leading cause of postoperative death. Patients without significant comorbidities (ASA class I) had less than a 1 percent mortality. Their data suggest that surgery is safe in this cohort, and mortality is not a function of age but rather of coexisting disease.

Del Guercio and Cohn [138] evaluated the value of preoperative invasive monitoring in obtaining hemodynamic and cardiopulmonary variables for predicting operative risk in the elderly. Of the 148 consecutive patients older than 65 years studied preoperatively in an intensive care unit, only 13.5 percent had normal physiologic measurements. Advanced and uncorrectable functional deficits were found in 63 percent of outpatients; all those patients who underwent the planned operation died. This finding further supports the contention that age itself is not the risk factor, but rather it is the presence of coexisting disease.

The elderly patient represents a difficult issue for the anesthesiologist. Atherosclerosis increases with advancing age, and the heart muscle itself ages. Further preoperative evaluation in the elderly usually focuses on the identification of comorbidity. Based on the accumulating evidence, it is these factors that influence perioperative risk.

/das/book/view/29494766/875/230.html

RISK DIRECTLY RELATED TO THE ANESTHETIC DRUG

Numerous studies have evaluated the influence of choice of anesthesia on outcome, a question discussed throughout this book (Ch. 6) . From a global perspective, there does not appear to be one best anesthetic technique. In a study by Cohen et al [46] of 100,000 anesthetic regimens performed in Canada, the choice of anesthesia did not provide any additional prognostic information for predicting mortality beyond that of patient disease and the surgical procedure in multivariate analysis. In univariant analysis, monitored anesthesia

care did appear to be associated with a worse outcome, but this finding was attributable to the use of that technique in sicker patients (see Table 22-15) (Table Not Available) .

One question that has plagued the anesthesia literature is the issue of inherent toxicity of the anesthetic agents themselves. There are important distinctions between undesirable side effects of anesthesia and true toxicity. In the initial reports in the middle of this century, there was a great deal of concern about curare toxicity. In more recent times, the issue of anesthetic toxicity has been discussed in particular with respect to two drugs, halothane and sevoflurane. In the case of halothane, the issues were fulminant hepatic necrosis and death, whereas the issue with sevoflurane is whether its metabolite, compound A, is nephrotoxic. After several case reports of hepatic necrosis following halothane anesthesia, a retrospective study of 34 institutions and 856,500 anesthetics was undertaken. [139] [140] [141] In all but 9 cases, the cause of hepatic necrosis could be explained by other causes. Of the remaining 9 cases, only 7 of these patients received halothane. Therefore, halothane could be associated with hepatitis and hepatic failure, but the incidence was very low.

As of 1998, the issue of sevoflurane's renal toxicity remains, but the overall safety of this drug has been sufficiently established by the Food and Drug Administration to allow its continued sale in the United States. There have been laboratory studies to support the contention that sevoflurane reacts with sodalime to form compound A and that this metabolite can lead to renal toxicity. [142] [143] Yet, clinical studies have been unable to confirm this potentially detrimental effect. [144] [145]

There have been numerous studies attempting to define the "safest" anesthetic in high-risk patients. In the late 1980s, there was particular concern that isoflurane could cause coronary steal in patients with a coronary stenosis and collateral vessels and that this could result in myocardial ischemia. [146] [147] A series of studies was conducted to evaluate the rate of perioperative cardiac morbidity and mortality in patients undergoing coronary artery bypass grafting to determine the importance of the agent used for general anesthesia. [148] [149] [150] [151] [152] All these studies demonstrated no difference in outcome, supporting the contention that there is no one safest anesthetic technique.

There has been a series of randomized trials that demonstrate improved outcome with regional compared with general anesthesia. [2] [3] [153] [154] [155] [156] [157] For lower extremity and pelvic surgery, there is a lower incidence of graft thrombosis and of deep vein thrombosis and decreased bleeding. For patients undergoing vascular surgery, the primary finding was a lower incidence of graft thrombosis and of the need for reoperation in patients undergoing infrainguinal bypass surgery; however, the largest of these studies was unable to demonstrate any difference in outcome based on anesthetic technique. [2] [3] [156] As described earlier, the rate of this complication was low in the total cohort in the largest trial, making it impossible to detect any difference based on the actual technique.

RISK RELATED TO SURGERY

It is well recognized that the surgical procedure itself significantly influences perioperative risk. In virtually every study performed, emergency surgery was associated with additional risk. For example, in the study of Goldman and colleagues, [10] emergency surgery was associated with the second highest weight (number of points), behind active signs of congestive heart failure. In that same study, Goldman et al defined intrathoracic and abdominal procedures as having a higher risk.

In some cases, the risk related to surgery is a function of both the underlying disease processes and the stress related to the surgical procedure. Cardiovascular surgery is associated with the highest risk of any procedure. The risks related to cardiac surgery are reviewed in Chapter 49 . Vascular surgery is one of the highest-risk groups of noncardiac procedures. Although aortic reconstructive surgery has traditionally been considered the highest-risk procedure, infrainguinal procedures had a similar rate of cardiac morbidity in several studies. [158] [159] In attempting to analyze the origin of the high complication rate of a relatively peripheral procedure, L'Italien et al [159] demonstrated that the extent of coronary artery disease is higher in the infrainguinal patients, a finding that most likely accounts for the excess morbidity and mortality.

Ashton et al [160] evaluated perioperative morbidity and mortality in a cohort of patients at a Veterans Hospital in Houston, Texas. Although vascular surgery was among the highest-risk procedures, amputations were associated with the highest in-hospital cardiac complication rate within this subgroup. This finding most likely represents the severe nature of the cardiovascular disease of these patients and their prolonged hospitalization in order to facilitate recuperation. Similar to the study by Goldman et al, [10] intra-abdominal, thoracic, and orthopedic surgical procedures were associated with increased risk. In another report, Ashton [160a] evaluated the rate of perioperative myocardial infarction in patients undergoing transurethral resection of the prostate. Despite the high incidence of coronary artery disease in this population, the incidence of perioperative myocardial infarction was only 1 percent.

Numerous studies have evaluated the perioperative complication rate related to superficial procedures. Backer et al [161] evaluated the rate of perioperative myocardial reinfarction in patients undergoing ophthalmologic surgery. These investigators demonstrated that the rate of perioperative cardiac morbidity after ophthalmologic surgery was extremely low, even in patients with a recent myocardial infarction. Virtually all studies have confirmed that anesthesia in ophthalmologic surgery is very safe. Warner et al [58] studied patients undergoing ambulatory surgery and reported no anesthetic deaths in more than 45,000 cases.

Eagle and colleagues [162] evaluated the contribution of coronary artery disease and its treatment on perioperative cardiac morbidity and mortality by surgical procedure. They evaluated patients enrolled in the Coronary Artery Surgery Study who had documented coronary artery disease and who received either medical therapy or coronary revascularization and then underwent noncardiac surgery during the subsequent 10-year period. Their rates of perioperative myocardial infarction and death were determined, and the surgical procedures were divided into three broad categories. Major vascular surgery was again demonstrated to be associated with the highest risk, with a combined morbidity

and mortality of greater than 10 percent. Procedures associated with a combined complication rate of greater than or equal to 4 percent included intra-abdominal, thoracic, and head and neck operations. In all these cases, patients who had prior coronary artery bypass grafting had a significantly lower combined morbidity and mortality than the medically treated group. Low-risk procedures included breast, skin, urologic, and orthopedic surgery. These broad groups of surgical procedures were the basis for defining surgical risk in the American Heart Association/American College of Cardiology Task Force on Perioperative Evaluation of the Cardiac Patient Undergoing Noncardiac Surgery. [124]

RISK RELATED TO LOCATION OF SURGERY AND POSTOPERATIVE MONITORING

It has long been known that perioperative risk varies among hospitals for such major procedures as coronary artery bypass grafting and abdominal aortic aneurysm repair. [163] [164] Multiple studies have documented a relationship between surgical volume and mortality. Although surgical skill most certainly plays a role in the rate of complications and mortality, local factors may also play an important role. For example, low surgical volume may lead to less skilled anesthesia and postoperative care. The influence of each of these factors on overall morbidity and mortality is currently unknown.

Although the value of postoperative intensive care monitoring and care has not been documented in a randomized clinical trial, many investigators have suggested that such care is one of the primary reasons for improved morbidity and mortality in recent years. For the case of patients undergoing major vascular surgery, several investigators have suggested that more intense postoperative monitoring could obviate the need for preoperative cardiac testing and revascularization. [165] [166] One potential value of risk assessment is the identification of patients who would benefit from referral to centers with more extensive perioperative resources. In this manner, patients with a low probability of perioperative morbidity and mortality could have surgery performed locally, whereas those individuals at higher risk could receive the benefit of a larger center.

It is currently estimated that 60 percent of all surgical procedures are performed on an outpatient basis, with the percentage increasing annually (Ch. 65) . When reviewing the literature to determine the safety of this shift from the inpatient to the outpatient arena, there is a striking lack of good evidence to document such safety. As described earlier, Warner et al [58] studied the safety of surgery on an ambulatory basis in 38,598 patients. These investigators documented only 33 episodes of major morbidity or mortality within 1 month of surgery. Major morbidity included 14 myocardial infarctions, 7 central nervous system deficits, 5 pulmonary embolisms, and 5 cases of respiratory failure (see Fig. 22-2) (Figure Not Available) . When adjusted for the age and gender of the population, these rates of major morbidity and mortality were actually lower than expected in the nonsurgical population.

Importantly, Olmstead County, Minnesota, the site of the foregoing study, represents a unique population with high standards for health care. Facilities were immediately available to care for any unexpected emergency or admission. Additionally, the study was performed during an era in which the patient mix was primarily healthy individuals undergoing peripheral or superficial procedures. Importantly, the type or extent of surgical procedure performed in an outpatient setting is constantly changing, and procedures associated with greater perioperative risk are constantly being performed.

The value of overnight observation in a hospital setting as opposed to immediate discharge home has been studied for a number of surgical procedures. One of the first procedures advocated on an ambulatory basis was tonsillectomy. In 1968, a case series of 40,000 outpatient tonsillectomies was reported without 1 death. [167] Details on patient selection and length of postoperative monitoring were vague. Based on insurance company and state mandates, performance of tonsillectomy on an outpatient basis became routine. [168] Beginning in the mid-1980s and continuing in the 1990s, a number of articles evaluated the risk of early discharge. For example, Carithers and colleagues [169] at Ohio State University in Columbus analyzed 3,000 tonsillectomies and argued that early discharge may be both hazardous and economically unwarranted. The rate of readmission for active bleeding between 5 and 24 hours after surgery has been reported to be between 0.2 and 0.5 percent. [170] [171] [172] [173] [174] Although the absolute rate of readmission is low, it represents a substantial risk for children. Whether the benefits of early discharge outweigh the risks is a decision society will have to make.

Another procedure currently being performed on an outpatient basis is mastectomy. An analysis of Medicare claims demonstrated that the rate of outpatient mastectomy has increased from only 2 procedures reported to Medicare in 1986 to 10.8 percent of the mastectomies performed in this population in 1995. [175] The authors compared the rate of readmission within 7 days of surgery for those who had the procedure on an inpatient versus outpatient basis, adjusting for severity of disease. Patients with simple mastectomies performed as outpatients had a significantly higher rate of readmission compared with patients with 1-day stays, with an adjusted odds ratio of 1.84. There were 24.2 readmissions per 1,000 cases for the 1-day length of stay compared with 33.3 readmissions for the outpatients. There were significantly lower rates of readmission for 1-day lengths of stay for infections (4.1/1,000 versus 1.8/1,000 cases), nausea and vomiting (1.1/1,000 versus 0), and pulmonary embolism/ deep vein thrombosis (1.1/1,000 versus 0). Similarly, patients with modified radical mastectomies performed as outpatients had a significantly higher rate of readmission compared with patients who had 1-day stays, with an adjusted odds ratio of 1.72. These authors suggested that patients who have the procedure on an outpatient basis may wait longer at home until seeking medical care and may present with more advanced symptoms.

There is increasing interest in performing surgery and providing anesthesia in office-based settings. There are currently no good data to determine the safety of such practices, although there has been a flurry of high-profile cases

in which patients have died in plastic surgery and dental offices. Importantly, anesthesia and sedation are frequently provided by individuals other than anesthesiologists or nurse anesthetists in these settings. There are reports of office nurses or even clerical help administering anesthetic agents.

There has been one attempt to quantify the incidence of complications in an office-based setting. The American Association for Accreditation of Ambulatory Surgery Facilities mailed a survey to their members to determine the incidence of complications in an office. [176] The overall response rate was 57 percent. Of note, 0.47 percent of patients had at least 1 complication including bleeding, hypertension, infection, and hypotension, and 1 in 57,000 patients died. Assuming that only healthy individuals are seen or very minor procedures are performed in an office-based setting, a rate of mortality that is three times the current estimate for anesthetic-related complications is a concern. Further research and quality assurance mechanisms need to be in place before this practice is generalized. One of the problems inherent to an office-based setting is the inability to perform quality assurance reviews. For example, few, if any, surgeons or anesthesiologists would be willing to allow their "competitors" to review their complications unless they were mandated to perform such a review.

One of the current problems in evaluating the risk of outpatient surgery is the lack of any large database compiled from a diverse group of settings and the lack of uniform standards for quality assurance. Although the Joint Committee for the Accreditation of Heathcare Organizations has begun accrediting ambulatory surgery centers, and two other organizations also provide accreditation, it is still not widespread and remains voluntary. Finally, although ambulatory care centers have led the way in performing appropriate follow-up of their patients at home, it is not uniformly complete. With respect to office-based settings, only three states have regulations as of 1998, and these regulations vary greatly. The implications of a lack of regulation are currently unclear, but issues related to emergency plans and resuscitation equipment may be left to the discretion of the local setting, potentially placing patients at risk.

At the current time, the decision to perform a procedure in an ambulatory setting is based on the surgeon's preference and on insurance company mandates. Frequently, it follows a case series by a surgeon or a review by an in-surance company that demonstrates that healthy individuals can undergo a given procedure safely in an outpatient setting. The need for subsequent medical attention or the use of resources at home is not necessarily taken into account. This may lead to insurance company mandates that the procedure be performed in all patients in an ambulatory setting. This generalization from the healthy to the patient with comorbid disease may not be justified in the absence of data to demonstrate its safety. As an advocate for the patient, the anesthesiologist should continue to

evaluate the safety of such practices and should determine when the risks of ambulatory surgery outweigh any potential benefits. It is also important to determine whether the insurance companies are in essence transferring the risk of undergoing surgery from the medical system to the patient.

RISK RELATED TO THE ANESTHESIA PROVIDER

The issue of added risk associated with the provider of anesthesia is an emotionally charged issue, particularly in the United States. Over the history of the specialty, various individuals have provided anesthesia, including anesthesiologists, general medical officers, residents, and CRNAs.

The importance of the anesthesiologist in outcome is best illustrated by the work of Slogoff and Keats. [177] They studied the importance of perioperative myocardial ischemia as a predictor of cardiac morbidity in patients undergoing coronary artery bypass grafting. They found that a perioperative myocardial infarction occurred significantly more frequently in those patients with prebypass ischemia than in those without ischemia. They then reported the rate of ischemia and infarction by anesthesiologist (identified by number). Anesthesiologist no. 7 had a significantly higher rate of complications than the average for the rest of the group. Therefore, operator technique or experience may affect risk. This observation parallels similar findings that surgical volume (and therefore presumably experience) is associated with outcome.

There have been several studies that have attempted specifically to evaluate the complication rate and risk associated with different care provider models. Bechtoldt [178] on the North Carolina Anesthesia Study Committee evaluated 900 perioperative deaths from an estimated 2 million anesthetic regimens administered in North Carolina from 1969 to 1976. Data were obtained from the medical examiner's report, routine death certificate, and a questionnaire completed by the person who administered the anesthetic. The committee concluded 90 of these deaths were anesthesia related. About one-half of the anesthetic-related deaths occurred in the operating room, of which 19 occurred during induction. These investigators then determined the relationship between mortality and the anesthesia provider based on the total number of anesthetics given by each group attained from a survey of hospitals (Fig. 22-6) (Figure Not Available) .

The lowest rate (1/28,166) of anesthetic-related deaths was associated with the anesthesia care team (physician anesthesiologist/CRNA), and the highest rate occurred in patients who received anesthesia from a dentist (1/11,432) (see Fig. 22-6) (Figure Not Available) . The nurse anesthetist-only cohort was intermediate (1/20,723). The large number of cases in which the care provider was unknown and the reliance on hospital estimates of the number of cases performed by each group makes interpretation difficult.

The Stanford Center for Health Care Research [179] in California also evaluated the impact of provider on outcome of care. These investigators prospectively collected data from 8,593 patients undergoing 15 surgical procedures over a 10-month period from May 1973 to February 1974. Using a risk-adjustment methodology, the actual patient outcome was compared with that predicted based on the patient's health status and operative procedure. The investigators reported that death plus severe morbidity occurred 11 percent more frequently than predicted for patients who received their

Figure 22-6 (Figure Not Available) Relationship between anesthetic provider and anesthetic-related deaths in North Carolina. The actual number of cases performed by each group was estimated from a survey of hospitals. The certified registered nurse anesthetist/anesthesiologist care team was associated with the best outcomes, whereas the surgeon or dentist practicing anesthesia was associated with the worst. *(From Bechtoldt [176])*

care in a nurse-anesthetist setting only, 3 percent less frequently than predicted for patients who received their care in a physician-only model, and 20 percent less frequently than predicted for patients who received their care in an anesthesia care team environment. Because of the small sample size, these findings did not reach statistical significance among the groups. Whether such disparities would remain apparent more than 25 years later requires further evaluation.

The question regarding differences in outcome among providers is extremely difficult from a methodologic standpoint. In fact, specific provider types may make the most impact in specific situations. For example, there may be no difference in outcome for healthy individuals, particularly if no complications occur. In contrast, a patient with significant comorbidity or one who sustained a perioperative complication may benefit from specific skill sets. One method to study such issues is to evaluate the rate of survival from complications. Silber and colleagues [180] at the University of Pennsylvania advocated such an approach. They studied the medical records of 5,972 surgical patients randomly selected from 531 hospitals. They evaluated both patient and hospital characteristics, including the number and type of physicians, board certification status, and ratio of care providers. Thirty-day mortality correlated with patient characteristics. Failure to rescue (prevent death) after an adverse event was inversely associated with the proportion of board-certified anesthesiologists on staff in each facility. Improved perioperative survival was significantly associated with an increased number of board-certified anesthesiologists.

Parallel with the marked increase in the number of anesthesiologists has been a dramatic decrease in malpractice insurance premiums for anesthesiologists. [181] Because these premiums are based on the number and severity of claims, these data would suggest that anesthesia is becoming safer. Despite these findings, in 1998, the Health Care Finance Administration was considering changing the current regulations to allow CRNAs to practice independently. At the time of this writing, the issue remains unresolved. Further research into the importance of anesthesia provider to outcome will be required.

RISK TO THE ANESTHESIOLOGIST

There are several potential risks to the anesthesiologist related to provision of care. These include the medicolegal risk, the risk of an allergic reaction, and the risk of a needlestick injury with transmission of disease from the patient to the practitioner. The medicolegal risks are described in Chapter 85 .

It is becoming increasing apparent that anesthesiologists are at risk for a latex allergy, which could lead to a life-threatening reaction. Many anesthesiologists realize that they are sensitized to latex and take appropriate precautions. The problem is that many sensitized individuals are asymptomatic. Brown et al [182] studied 168 eligible anesthesiologists and nurse anesthetists working in the anesthesia department of the Johns Hopkins Hospital in Baltimore. The prevalence of latex allergy with clinical symptoms and latex sensitization without clinical symptoms was 2.4 and 10.1 percent, respectively. The prevalence of irritant or contact dermatitis was 24 percent. These data suggest that latex is an important problem to the anesthesiologist and that there is a need to transform the hospital to a latex-free environment.

There has always been concern that anesthesiologists are at risk of contracting a disease from a patient. In the past, the risk was primarily for hepatitis, but human immunodeficiency virus (HIV) is an even greater concern today. In a review of the literature, Berry and Greene [183] reported that at least 20 different pathogens have been transmitted through accidental needlestick injuries.

Hepatitis B seropositivity ranged from 12.7 to 48.6 percent of anesthesia personnel in several studies conducted in the United States, a rate at least four times greater than in the general population. [184] [185] [186] The risk of hepatitis B infection

following percutaneous exposure to antigen-positive blood is estimated to be 27 to 43 percent. [187] The development of the hepatitis B vaccine substantially reduced this risk. Hepatitis C virus has been identified as a major cause of post-transfusion hepatitis. There have been several reports of occupationally acquired hepatitis in health care workers. [188] Because up to 50 percent of infected individuals develop signs of chronic liver infection, this represents a potential serious problem.

Among the greatest fears of the health care worker is infection with HIV-1. The risk of acquiring HIV is approximately 0.4 percent from a single percutaneous exposure from blood or bloody fluid from an HIV-infected patient. [189] There has been at least one case report of an anesthesiologist who was infected with HIV from a needlestick during insertion of a central venous catheter into an HIV-positive patient. [190]

There have been several strategies to reduce transmission of communicable disease, which are reviewed in Chapter 84 . Although anesthesiologists traditionally think of the risk to their patients, they must now include the risk to themselves. The widespread adoption of universal precautions should reduce the rate of infection; however, anesthesiologists have not accepted these recommendations widely. In a study of nine hospitals, 59 percent of the contaminated percutaneous injuries were preventable. [191] In a theoretical model of risk of HIV, it was estimated that the 30-year occupational risk is 0.10 to 0.22 percent in low-prevalence areas and 8.26 to 13 percent in high-prevalence areas. [192] The authors of this report suggest that double gloving may reduce risk.

IMPROVING ANESTHESIA SAFETY

Over the past several decades, there have been major initiatives to improve the safety of anesthesia. In 1984, Cooper, Kitz, and Ellison hosted the first International Symposium on Preventable Anesthesia Mortality and Morbidity in Boston. Approximately 50 anesthesiologists attended the meeting from around the world and after much debate established a series of definitions of outcome, morbidity, and mortality (Table 22-23) (Table Not Available) . Such meetings have been held every 2 years since the first symposium.

The Anesthesia Patient Safety Foundation (APSF) was established as a result of the Boston meeting. The society has been active in publishing widely circulated newsletters and awarding annual grants. Similar societies have now been established in other countries, and a national patient safety society has also been created on the APSF model.

Starting with the ASA Closed Claims Study, there has been a great deal of interest in establishing guidelines for the best and safest practice. Practice policies or guidelines are the summation by clinicians of the available evidence about the benefits and risks of a treatment plan. Guidelines are a method of codifying recommendations regarding the use of a given technology. There are several types of recommendations that fall into the general category of a practice parameter. A standard implies that a therapy or practice should be performed on patients with a particular condition. Standards are only approved if an assessment of the probabilities and utilities of the group indicates that the decision

TABLE 22-23 -- Proposed Definitions from 1994 International Symposium on Preventable Anesthesia Morbidity and Mortality

(Not Available)

From Pierce et al [205]

to choose the treatment or a strategy would be virtually unanimous. If a particular therapy or strategy is considered a standard, it is cost-effective for those for whom it is recommended. Standards are intended to be applied rigidly. The ASA has established standards for intraoperative monitoring, which were developed from safety guidelines adopted at the Harvard hospital system. Guidelines are intended to be more flexible than standards, but they should be followed in most cases. Depending on the patient, setting, and other factors, guidelines can and should be tailored to fit individual needs. Like standards, guidelines should be cost-effective. Numerous guidelines have been adopted by the ASA for diverse issues such as the difficult airway, [193] use of pulmonary artery catheter, [194] and use of blood components. [195] The goal is to define the evidence on which optimal practice can be based.

Finally, there is a great deal of interest in the use of anesthesia simulators to train and test individuals and their ability to react to simulated crises. [196] [197] [198] [199] [200] Standardized simulations have been developed on which comparisons among individuals can be made. [201] [202] Further research will be required to determine how best to utilize this technology in anesthesia training and potentially in recertification.

SUMMARY

The risks related to anesthesia have dramatically decreased over the last several decades. It is now clear that death totally attributable to anesthesia is very rare. Both patient disease and the type and perhaps location of surgery have greater impact on overall outcome. With these changes in risk, the anesthesiologist must now focus on nonmorbid outcomes and must continue vigilance to maintain the high standards of hospital-based anesthesia in nonhospital settings.

Chapter 23 - Preoperative Evaluation *

Michael F. Roizen
Joseph F. Foss
Stephen P. Fischer

INTRODUCTION

The ultimate goals of preoperative medical assessment of patients are to reduce the morbidity of surgery, to increase the quality but decrease the cost of perioperative care, and to return the patient to desirable functioning as quickly as possible. Traditionally, these goals have been facilitated by a preoperative meeting between the patient and the anesthesiologist. The meeting has five specific purposes:

1. To obtain pertinent information about the patient's medical history and physical and mental conditions, in order to determine which tests and consultations are needed.
2. Guided by patient choices and the risk factors uncovered by medical history, to choose the care plans to be followed.
3. To obtain informed consent.
4. To educate the patient about anesthesia, perioperative care, and pain treatments in the hope of reducing anxiety and facilitating recovery.
5. To make perioperative care more efficient and less expensive.

Reducing anxiety and obtaining informed consent are discussed in other chapters. The importance of these goals should not be overlooked during preoperative evaluation. Most of the data indicate that recovery occurs more quickly when the anesthesiologist allays the patient's concerns, informs the patient about what is to come, and plans postoperative pain therapy with the patient [1] [2] [3] [4] [5] (Ch. 69).

The other functions of preoperative evaluation are closely related: the acquisition of a pertinent medical history and of information about physical and medical conditions. These functions affect all the decisions about testing, consultation, and discussion of care plans with the patient and lead to patient education, setting expectations for the patient's postoperative pain therapy and recovery plan, and cost reduction.

Thus, the first two functions of preoperative evaluation--optimizing patient health before surgery and/or planning the most appropriate perioperative management--not only improve perioperative outcome but also reduce costs. Data supporting this claim are substantial, but indirect; studies of perioperative morbidity over 4 decades repeatedly show that preoperative patient conditions are significant predictors of postoperative morbidity. [6] [7] [8] [9] [10] [11] [12] [13] [14] [15] [16] [17] [18] [19] [20] [21] [22] [23] [24] [25] [26] [27] [28] [29] [30] Specifically, less severe

---

---

manifestations of adverse preoperative conditions are associated with lower perioperative morbidity and mortality (Table 23-1 (Table Not Available) and Fig. 23-1) (Figure Not Available) . The data imply (but do not prove) that preoperative treatment of conditions such as congestive heart failure and diabetes can reduce the severity of disease and thus perioperative morbidity and mortality. For this to occur, preoperative assessment must be accomplished far enough in advance to give the primary care physician a "second opinion" that guides therapy and consultations toward optimizing the preoperative health status of the patient. This step obliges the preoperative evaluator to take a thorough history and to determine the extent of consultation with the primary care physician that is needed to judge optimal health and the potential for improvement of preoperative status.

Preoperative evaluation produces other benefits as well. Patient education about perioperative care expectations can radically reduce the length of stay and costs (Table 23-2 (Table Not Available) [5]). Moreover, preoperative consultations may initiate additional risk-modification tactics such as reducing tachycardia [5] or the stress on plaque, [31] [32] [33] [34] [35] controlling hypertension, [36] [37] [38] perioperative cessation of smoking, [39] [40] [41] [42] nutritional fortification, [43] [44] immunization, [45] and stamina/strength training [46] [47] and in this way improve perioperative outcome.

Why can't this process of preoperative assessment be accomplished in isolation by a primary care physician or internist? Although much of the process probably could be, a condition considered "optimal for daily life" (e.g., some degree of prerenal azotemia in the patient with congestive heart failure) may not be "optimal preoperative status" (at which time vasodilation may cause hypotension or permanent renal impairment, or both). Furthermore, the process of preoperative evaluation and risk-factor modification requires a broad knowledge of the *content* of scientific perioperative care and a deep understanding of the *context* in which that knowledge is applied. Understanding the context--the environmental, sociologic, ethical, and team concepts and the economic influences--of perioperative care is almost as important as the technical knowledge on which the practice of perioperative care rests. Thus, compulsive attention to the effects of planned perioperative maneuvers on patient physiology would be desirable, perhaps even necessary, if the benefit of such pre-planning is deemed worth the cost. Preoperative evaluation by a physician is not inexpensive. However, later sections of this chapter show how preoperative planning can be much less expensive than current practices because of the

Figure 23-1 (Figure Not Available) Estimated risk of hospital mortality in relation to age, preoperative disease, and surgery. Elective surgery, top triangle; emergency surgery, bottom triangle. *(From Pedersen et al [22])*

TABLE 23-1 -- Mortality Risk for Elective Surgery, Determined for Various Degrees of Coexisting Disease

(Not Available)

Modified from Fowkes et al [16]

ability to order tests selectively and to use education and information tools to increase efficiency, to shorten the length of stay, to reduce the rate of cancellations, and to increase patient satisfaction. In addition, preoperative assessment can uncover hidden conditions that could cause problems both during and after surgery. In this way, the anesthesiologist is able to anticipate problems and to plan therapy intended to prevent or minimize the effects of such problems. [5] [18] [31] [32] [33] [34] [35]

A study at the University of Florida in Gainesville found that preanesthetic evaluations provided information leading to changes in care plans for more than 15 percent of all healthy patients (i.e., American Society of Anesthesiologists [ASA] physical status I and II patients) and for 20 percent of all patients in general. [24] Care plans were changed because of information from observation and history; the most common conditions causing changes were gastric reflux, insulin-dependent diabetes mellitus, asthma, and suspected difficult intubation (Table 23-3) (Table Not Available) . However, the data did not indicate that these changes improved patient outcome. Nevertheless, practitioners seem to believe that the discovery of these conditions calls for a change in plans, which is usually implemented in a way that

delays operating room (OR) schedules and increases costs.

Examples of such last-minute changes are as follows: administration of a histamine (H_2) blocker 1 to 2 hours before, and an oral antacid immediately before, entry to the operating room; the obtaining of equipment to measure blood glucose levels; the obtaining of a history of the patient's diabetic course and treatment from the primary care doctor as well as the patient; and the performance of fiberoptic laryngoscopy or additional procedures requiring skilled help. Thus, even if preoperative evaluation were not to alter outcome to any great degree, its ability to reduce costs by reducing laboratory tests and delays in obtaining equipment or treatments perceived to be beneficial (and medicolegally required) would be substantial and would warrant its use. Data from Stanford University, [25] [26] the University of Chicago, [5] [48] the University of South Florida, [27] the University of Rochester in New York State, [28] the University of Massachusetts, [29] and a community hospital in London, Ontario, [30] all confirm these cost advantages. Furthermore, a negative history and physical can lead to decreased resource utilization for healthy patients [23] and for those with comorbid conditions but without risk factors

TABLE 23-2 -- Benefits of Combining Changes in Pain Therapy With Preoperative Education of the Patient Regarding Perioperative Expectations, as Shown for Three Clinical Pathways[a]

(Not Available)

Modified from Worwag and Chodak [5]

[a] Preoperative education of the surgical patient about perioperative expectations, coupled with changes in pain therapy, can radically reduce the length of stay and costs without loss of patient satisfaction. Pathway 1, data collected before preoperative education and changes in pain therapy; pathway 2, after education and the first change in pain therapy; and pathway 3, after education and further refinement in pain therapy.

TABLE 23-3 -- Medical Problems Discovered on Preanesthetic Evaluations That Could Prompt a Change in Patient Management

(Not Available)

modified from data presented by Gibby et al. [24]

requiring high-intensity care. [49] In addition, preoperative evaluation gives practitioners confidence that they will not be surprised by unexpected patient conditions and gives the patients confidence that the health-care system is responding to their individual conditions.

In the beginning, the preoperative assessment described earlier relied only on accurate history-taking and physical examination. In the 1960s, multiphasic screening laboratory tests were added to the process. This chapter evaluates the goals of preoperative medical assessment and the *relative* importance of history-taking, physical examination, and laboratory testing regarding the improvement of perioperative outcome, but then it goes beyond these knowledge-based steps.

Since the first edition of *Anesthesia* in 1981, Roizen has attempted to describe not only current practice but also the need for innovative change. In the first edition, before the use of diagnosis-related groups (DRG) to establish fees, and before that cost-based push to reduce testing, he discussed the lack of benefit from nonselective laboratory testing. In the second edition, published in 1986, the chapter described how cost-benefit and benefit-risk analyses again pointed to the need to reduce the amount of laboratory testing. The third edition of this chapter, in 1991, also came to a nontraditional conclusion, that anesthesiologists needed to change the way they usually perform preoperative evaluation. The fourth edition of the chapter again suggested a major break with current practice, that unless anesthesiologists instituted a system of performing careful preoperative evaluations on all patients, these clinicians were in danger of doing too little assessment and even too little testing. In some areas of the United States, the pendulum may have swung too far to the "no-test" and only "cursory-assessment" side. Not surprisingly, in this fifth edition, the authors of this chapter accentuate the need to develop consensus in making a preoperative clinic effective for all and in implementing an effective electronic information system (informatics) process. However, we also emphasize the dramatic benefits of instituting a functional preoperative clinic that has gone through the stages of efficient patient evaluation, appropriate test selection, and effective prerequisite education of the patient and that is organized in a way that increases patient satisfaction. We highlight the importance and benefits of adding *patient education* to these processes.

We believe that just as the practice of anesthesia has changed during the past decade, the practice of preoperative evaluation also needs to change to ensure that the best cost-benefit and benefit-risk goals are attained. Specifically, data indicate that we can produce optimal cost-benefit and benefit-risk strategies for perioperative care only when we reduce testing to that indicated by history-taking and when we institute effective patient education informed by appropriate choices for pain therapy. Outcome can be improved, patient satisfaction increased, and hospital stays shortened appropriately when education about pain therapy and about recovery is taught intensively in the preoperative clinic. The difficulty is that we must obtain a thorough history far enough in advance to allow us to perform these selected tests and to implement the necessary therapies without disrupting surgical schedules and the patient's perioperative care plans. This must also be done far enough in advance to give the patient and his or her significant others time to plan for the options that have been selected.

CHANGING NATURE OF PREOPERATIVE EVALUATION

Preoperative evaluation strives to answer three questions: Is the patient in optimal health? Can, or should, the patient's physical or mental condition be improved before surgery? Does the patient have any health problems or use any medications that could unexpectedly influence perioperative events? Such an evaluation must include the long-accepted standard practices: review of hospital charts and prior anesthesia records, consultation with the primary care physician, history-taking, physical examination, evaluation of laboratory tests obtained, ordering of additional laboratory tests, and the discussion of perioperative anesthesia plans (including alternatives for intraoperative and postoperative analgesia) with the patient in a way that provides accurate information and reduces patient anxiety. However, the practice of medicine has changed. The cost-conscious environment of the 1990s has made it difficult for anesthesiologists to achieve these goals using the style of the 1970s and earlier.

For example, the increased need to minimize costs means fewer or no preoperative hospital days for the patient. More than 65 percent of all operations are performed on an outpatient basis; almost 5 percent are performed in the surgeon's office, and another 20 to 30 percent are done as morning admissions. Unfortunately, however, the increasing age of patients often means a greater likelihood of concurrent disease. Unlike the old days, when the entire evening before surgery could be spent learning about the medically complex patient, anesthesiologists are now being asked to perform preoperative evaluation as they "run" from case to case. They are being asked to deliver more for less, to do a more complete job, and to meet the continuing demand of administrators and surgeons to shorten turnover times. In such time-pressured situations, the anesthesiologist may be justifiably uncomfortable about the adequacy and comprehensiveness of the preoperative evaluation. "Did I ask the patient whether he or she had a drink during the past 72 hours, or whether he or she has ever had a problem with drinking?" (These are currently the two most sensitive and specific questions to ask when trying to determine the likelihood of alcoholism. [50] [51]) "Did I forget to ask other questions, for example, whether any family members had hepatitis?" *It is very difficult to make an adequate preoperative evaluation in 5 to 15 minutes, and it is impossible to change any therapy or to optimize any care that requires more than 10 minutes without increasing costs and inconveniencing all concerned.* Furthermore, the pressure to proceed, even when there may be increased or unknown risk, is much greater when time is short than when such evaluations are done in advance. Frequently, old records are not available. [52] In addition, the pressure to proceed quickly probably makes the consent process less informed and the discussion of anxiety relief and preoperative pain therapy plans less thorough. The patient and significant others also have little or no time to "digest" information about what to expect regarding the perioperative care plan.

Do we need to change the system? Clearly, a change is needed if preoperative assessment is to be adequate. To perform these assessments efficiently, the anesthesiologist needs to know about the patient. We also believe that preoperative evaluation is intrinsically valuable and that interacting with the patient in this way is an enjoyable and productive part of the practice of anesthesia. Moreover, for the practical-minded clinician, inadequate preoperative assessment is now one of the top three causes of lawsuits against anesthesiologists. Nevertheless, in the current atmosphere, there is not enough time to assess the patient preoperatively in the traditional method. Before solutions to this problem are suggested, the importance of preoperative assessment is evaluated, as well as the conditions that may be sought and determined from such assessment.

UNCOVERING PATIENT FACTORS THAT INCREASE THE RISK OF ANESTHESIA

This chapter provides information the anesthesiologist needs to know to ensure that the patient is asymptomatic from the standpoint of anesthetic risk. The management of patients found to be symptomatic is discussed in Chapter 25 . Ensuring that the patient is asymptomatic requires knowledge of the patient factors that increase the perioperative risk of anesthesia, because it is those factors that must be eliminated.

Major surgery usually represents a tremendous assault on the human organism. The body has an elaborate defense mechanism that alerts it to, and helps it escape from, trauma. The job of the anesthesiologist is *not* simply to put the patient to sleep and to wake him or her when surgery is over, but to maintain homeostasis during the assault of surgery and to provide pain relief to blunt the effects after the assault. To do this, the anesthesiologist must interfere with the stress response induced by pain, anticipate periods when the stress response will not be present, plan for the rare situations in which the patient's medical problems may occur acutely, and, at the same time, manage the patient's chronic medical conditions.

Even when the stress of surgery is not felt consciously, it evokes a complex physiologic response. Much of this response

---

is meant to allow the body to escape trauma. For example, blood flow is diverted from the kidney and liver to the heart and head, and blood pressure rises. Thus, the system most needed to be in a "good" state of health, the cardiovascular system, has first priority. [9] [18] [19] [20] [21] [22] Elaborate and simple tests and history-taking processes have evolved to evaluate the cardiovascular system, especially in aged patients or patients with comorbid disease. [53] [54] [55] We evaluate the process of history-taking first.

History

Illnesses in systems other than the cardiovascular also have an effect on perioperative risk. The following is a list of relatively common conditions that we ensure are not present before assuming that the patient is asymptomatic. [24] [56] [57] Chapters 22 and 25 discuss the increased risk posed by the problems discovered, and Chapter 25 describes optimization of the patient's physical condition, anticipation of potential problems, and possible therapies for the problems. The evaluation process that follows represents our initial screening procedure for disease. Although the process attempts to be relatively inclusive, it cannot cover all possible conditions that may be encountered when dealing with surgical patients.

First Areas of Concern

Included first in our history are general items, such as whether the patient has received recent medical care, has taken medication, or has allergies. Questions also are asked about prior exposure to anesthetics and subsequent problems:

1. When did you last have anesthesia?
2. Do you have any problems with anesthesia? Have any of your family members had any problems with anesthesia?
3. Do you have allergies?
4. What are you allergic to?
5. Have you had any blood tests in the last 6 months?
6. Have you had a chest x-ray in the last 2 months?
7. Have you had an electrocardiogram (ECG) in the last 2 months?
8. Has your stool been checked for blood in the last year?
9. Have you been a patient in a hospital, an emergency department, or an outpatient surgery center in the last 2 years? If so, why? What part of the hospital (for example, critical care unit)? How long were you there?
10. Do you take any medications?
11. What medications do you take?
12. Do you take any medications not prescribed by your doctor or that you just purchase off the shelf at a drugstore or grocery store?
13. Do you take any supplements or vitamins? (These can interact substantially with perioperative medications. [58])

Also included in this category of questions are items about artificial devices (e.g., hearing aids, false eyes) and use of alcohol:

1. Do you wear contact lenses?
2. Do you currently use eyedrops prescribed by a doctor?
3. When did you have your last alcoholic drink?
4. Have you ever had a drinking problem?

Because patients tend to give socially acceptable answers on sensitive subjects (Trigg DJ et al, unpublished data), [59] when probing in these types of areas, a checklist or computer-aided history may be more valid than an interview. Sensitive subjects include risk factors for use of illegal drugs and for human immunodeficiency virus (HIV) infection. Nevertheless, the personal interview is still essential for in-depth questioning.

Cardiovascular Disease

We try to ensure that the patient does not have the following cardiovascular conditions: congestive heart failure, cardiomyopathies, ischemic heart disease (stable or unstable), valvular or subvalvular heart disease, hypertension (diastolic or systolic [37]), disturbances in cardiac rhythm, pericarditis, arteritis, or other manifestations of atherosclerosis. These conditions require further evaluation to ensure that optimal treatment has been achieved before surgery (Ch. 25) . In the outcome studies described earlier, congestive heart failure incurred the highest risk. [6] [7] [8] [9] [10] [11] [12] [13] [14] [15] [16] [17] [18] [19] [20] [21] [22] Questions cannot be limited to the cardiovascular system. For example, to search for alcoholic cardiomyopathy, the following inquiries are made: Have you had a drink in the last 72 hours? Have you ever had a problem with drinking? As mentioned earlier, these two questions are the most sensitive and specific questions to ask when trying to determine the possibility of alcoholism. [50] Exercise tolerance is also checked, for example, the patient's ability to walk up stairs, play sports, and perform chores (mowing lawns, making beds, vacuuming), without becoming short of breath.

Typical questions regarding the cardiovascular system include the following:

1. What is the most vigorous activity you have done in the last 3 weeks?
2. How far have you walked in the last week without stopping?
3. Can you walk a block without stopping? When did you last do so?
4. Have you ever had a heart attack, or have you ever been treated for a possible heart attack?
5. Do you have heart problems such as skipped heart beats, angina, or chest pain?
6. Have you been told that you have a heart murmur or rheumatic fever?
7. Have you ever been told that you have mitral valve prolapse?
8. Have you ever had heart or lung surgery?
9. Have you ever awakened and felt short of breath?
10. Do you become short of breath after climbing a flight of stairs or after walking a short distance?
11. When did you last climb a flight of stairs? If not recently, when did you last walk two city blocks?
12. Are you able to walk up stairs at the same rate as 5 years ago?

13. Do your ankles ever swell?
14. Are you ever short of breath? When?
15. Do you ever have chest pains, angina, chest heaviness, or chest tightness?
16. Do you ever have indigestion that does *not* occur after overeating?
17. Have you ever been told by your doctor to exercise or diet to control high blood pressure?
18. Have you ever been a patient in a critical care unit (cardiac care unit, intensive coronary care unit)?
19. Have you passed out or nearly passed out in the last year? Why? [60]
20. Do you sleep with more than one pillow at night? (This question is useful only for men and women older than age 60, because 50 percent of women sleep with two pillows [Trigg DJ et al, unpublished data]. [59])
21. Do you currently take water pills or diuretics?
22. Do you currently take potassium pills or powder?
23. Do you currently take anticoagulants or blood thinning medicine?
24. Have you ever been told to take, or have you ever been given, antibiotics before routine dental work?

Some of these questions are asked in a different order, so that the patient is not startled or confused by them, as if they were a "pop quiz." To avoid surprising or confusing the patient, questions are asked in a "set." For instance, all questions related to medication are asked at the same time.

Respiratory and Airway Problems

Because airway problems cause substantial risk, the most important consideration regarding the respiratory system is securing the airway. Therefore, evidence of airway obstruction and of restriction of neck and jaw movement is sought. The end result of exposure to toxins (whether environmental or related to smoking) is also sought: emphysema, bronchitis, and chronic infections. We try to ensure that asthma is not present and that other conditions, such as obesity, have not progressed to the point of limiting respiratory function. The personal interview (no matter when performed) is usually quite efficient in revealing the condition of the airway, respiratory reserve, and the possible need for laboratory evaluation, such as pulmonary function testing with bronchodilators or blood gas analysis, or both (Chs. 15 and 39) . The personal interview may also be the best time to educate the patient and family members about the time needed for cessation of smoking to be beneficial (Ch. 25) . [39] [40]

Questions that usually elicit information about the general condition of the mouth and airway and possible reactions to anesthesia include the following:

1. Do you wear dentures, a crown, a partial plate, or a bridge?
2. Are any of your teeth loose, cracked, chipped, or capped?
3. Have you ever had anesthesia?
4. Have you or any blood relative ever had any problems with anesthesia? This question not only helps to reveal possible airway problems but also elicits information about some rarer diseases, such as malignant hyperthermia, glucose-6-phosphate dehydrogenase deficiency, acute porphyria, allergies, sickle cell disease, neurologic disorders, and hiatus hernia. It usually also elicits concerns about postoperative nausea and vomiting and thus provides an opportunity to reassure the patient, to plan the choice of anesthetic, to ask female patients about their last menstrual period, and to use preanesthetic suggestion, for those physicians believing in the value of this practice.
5. Can you open your mouth fully?
6. Do your joints ever click, pop, or hurt?
7. Have you ever been treated for a problem of the jaw joint (that is, a temporomandibular joint problem)?
8. Have you ever been hoarse for more than 1 month?
9. Do you snore, or do others say you snore? This question proved to be the best predictor of difficult intubation when our computer-based health history was compared with outcome studies, [48] but it was not very specific (four of five patients who answered yes to this question did not have a difficult intubation).
10. Have you ever had cancer?
11. Have you ever had, or been treated for, arthritis?
12. Do you have neck stiffness or problems moving your head?
13. Have you ever been told you had diphtheria? (Diphtheria can cause narrowing of the airway.)

The following questions search for lung disease:

1. Have you ever had pneumonia? When?
2. Have you ever undergone lung surgery?
3. Do you have shortness of breath, wheezing, chest pain, bronchitis, asthma, or emphysema?
4. Do you cough regularly or frequently?
5. Do you cough up mucus (sputum or phlegm)?
6. In the last 4 weeks, have you had a fever, chills, cold, or flu?
7. Have you ever smoked? When did you stop?
8. Have you ever smoked half a pack or more of cigarettes a day on a regular basis?
9. Have you ever smoked a pipe or cigars on a regular basis?

Hepatic or Gastrointestinal Disease

Past and present hepatic disease increases the risk of certain surgical procedures (Ch. 25) , sometimes contributes to abnormal clotting and pharmacokinetics, and may present medicolegal concerns (e.g., in the case of postanesthetic jaundice). Hepatic disease also increases the risk of surgery for nonhepatic problems (Ch. 25)

Gastrointestinal diseases may increase the potential for aspiration of gastric contents. For example, the gastroparesis of ulcer disease is often accompanied by solid food in the stomach, and inflammatory bowel disease may be accompanied by arthritis of the neck. Gastrointestinal disease also increases the potential for dehydration, electrolyte disturbances, and anemia. The presence of gastrointestinal or hepatic disease can give clues about possible endocrine, pulmonary, or cardiac disease (e.g., gastritis in the alcoholic patient could indicate the need to search for alcoholic cardiomyopathy).

Questions that screen for gastrointestinal or hepatic disease include the following:

1. Have you ever been diagnosed as having a hiatus hernia?
2. Have you ever had hepatitis, yellow jaundice, liver disease, or malaria?
3. Have you ever had gallstones or gallbladder disease?
4. Are your stools ever bloody or black and tarry?
5. Have you seen bright red blood on your stool or on toilet tissue after wiping?
6. Have your bowel habits changed this year?
7. Do you often have diarrhea?
8. Have you ever vomited blood, or material that looks like coffee grounds in the last 6 months?
9. Do you have frequent nausea or vomiting?
10. Have you lost weight this year without trying?
11. Has your appetite for food changed in the last year?
12. Are you eating the same foods you ate a year ago?
13. Have you had heartburn within the last month?
14. Are you now being treated, or have you been treated, for ulcer disease?
15. Are you currently taking antacids or Tagamet (cimetidine), Zantac (ranitidine), Pepcid (famotidine), Prilosec (omeprazole), or Axid (nizatidine)?

Bleeding Problems

Bleeding can occur because of a hereditary deficiency of clotting factors or because of abnormal platelet or vascular function caused by disease or drugs. The following questions search for such abnormalities:

1. Have you ever had a blood problem such as anemia or leukemia?
2. Have you ever had a problem with blood clotting?
3. Have you ever had a serious bleeding problem?
4. Have you received a blood transfusion since 1979?

These questions are often asked in two ways, because patients seem to need time to recall such events. For example:

1. Has a family member or blood relative ever had a serious bleeding problem?
2. Have you ever had prolonged or unusual bleeding from cuts, nosebleeds, minor bruises, tooth extractions, or surgery?
3. Have you ever had excessive bleeding that required blood transfusion?

Renal Disease

Renal disease can contribute to bleeding because of a functional platelet deficit associated with renal impairment (Ch. 25) . In addition, renal insufficiency can increase risk because it produces anemia (prior to, or in the absence of, optimal erythropoietin therapy), electrolyte disturbances, peripheral neuropathy, and abnormalities in drug metabolism and excretion. The following questions search for renal disease:

1. Have you ever had any kidney problem?
2. Have you ever had kidney failure, dialysis, or more than two kidney infections?
3. Have you ever had kidney stones?
4. Are you undergoing dialysis for kidney problems?
5. Have you had changes in bowel or bladder function in the last year?
6. Has your appetite for food changed in the last year? (Voluntary avoidance of foods having a high protein content is a subtle sign of renal disease.)

Endocrine Disturbances

Endocrine disturbances and the end-organ effects of diabetes or thyroid, parathyroid, pituitary, adrenal, and carcinoid disease can increase perioperative risk substantially. For instance, morbidity and mortality increase 5- to 10-fold because of the nephropathy and autonomic insufficiency of diabetes (Ch. 25) . The following questions help to ensure the patient does not have endocrine-related diseases:

1. Do you wake up at night to urinate? How often?
2. Have you ever been told that you have diabetes or sugar diabetes?
3. Do you take, or have you taken, steroids, cortisone, or adrenocorticotropic hormone (ACTH) in the last year?
4. Do you perspire (sweat) much more than others or a great deal every now and then?
5. Does your face flush or get red every now and then, even when you are not exercising?

These last two questions attempt to rule out the very hazardous perioperative situations of undiscovered pheochromocytoma and carcinoid syndromes. Both conditions can now be well managed if known in advance (Ch. 25) . Both, however, incur a mortality rate as high as 10 percent if undiscovered prior to operation. The following questions search for symptoms of thyroid and parathyroid disease:

1. Have you ever taken medicine (e.g., Synthroid [levothyroxine]) or had radioactive iodine (^{131}I) for thyroid disease?
2. Do you consistently like the room warmer or colder than your spouse?
3. Do you have muscle cramps or spasms in your legs more than three times a year?

Neurologic Disease

Physical examination can add significantly to one's impressions and can reduce the necessity for some questions, particularly regarding neurologic disease. Nevertheless, to exclude neurologic disease, the following questions are usually asked:

1. Have you ever had a seizure, convulsion, fit, stroke, or paralysis?
2. Have you ever been diagnosed as having a tremor?
3. Have you ever had migraine headaches?
4. Have you ever had nerve injury, multiple sclerosis, or any disorder of the nervous system?
5. Have you ever had numbness, tingling, or the feeling of "pins-and-needles" in your arm or leg that has lasted more than 2 hours?
6. Have you taken antidepressant, sedative, tranquilizing, or antiseizure medications in the last year?

Musculoskeletal Disease

Because arthritis affects the ease of securing the airway, we usually ask about potential musculoskeletal system disease during our search for airway and lung disease. Nevertheless, a brief review could include the following questions:

1. Have you ever had low back pain?
2. Have you been working at your usual job or doing your normal activities in the last week?

3. Have you taken pain pills or had pain shots in the last 6 months?

Sensitive Areas of Concern

One area not yet discussed concerns more difficult-to-manage subjects, such as the possibility of pregnancy in a minor, asymptomatic hemoglobinopathies when intense counseling and consultation service are not available, illicit drug use, and the potential for acquired immunodeficiency syndrome (AIDS). Much like Epstein, [61] Roizen believes that such matters should be handled in concert with hospital or facility policy. However, because this type of information can affect perioperative risk and plans, his usual procedure is to search for clues in the history. If one has taken the time to gain the patient's confidence so that the patient understands that these questions are being asked in order to provide better care, success is possible. If one tries to approach these sensitive areas in the 5 to 15 minutes usually allotted, the process ends up being awkward at best and usually does not succeed. In fact, patients seem to answer these questions more reliably on a checklist paper-and-pencil form or on a computer-based health history (Trigg DJ et al, unpublished data). [48] [59]

Under optimal conditions, the questions that can be asked include the following:

1. Within the last 2 years, have you taken nonprescription drugs, such as cocaine, crack, heroin, or LSD?
2. Have you been exposed to the body fluids (blood, semen, urine, or saliva) of anyone likely to have the AIDS virus?
3. Are you in any of the groups at high risk of AIDS (gays, bisexuals, hemophiliacs, and those who have had sex with a prostitute within the last 12 years)?
4. Would you like to undergo a test to find out whether you have been exposed to the AIDS virus?

It is our belief that AIDS testing will be an especially important consideration from an institutional point of view. In most states, testing requires patient consent. However, soon the decision not to test also may require patient consent. This requirement may arise because zidovudine (formerly known as azidothymidine [AZT]), in combination with other therapy, may delay the onset of AIDS in asymptomatic patients infected with HIV, and the use of triple therapy is now thought to be an issue of patient choice. [62] [63]

Physical Examination

The physical examination again looks for the same conditions sought by history. It consists of the following processes:

1. Determination of arterial blood pressure in both arms, and in at least one arm 2 minutes after the patient assumes the upright position after lying down, and examination of the pulses and of the chest, for heaves, thrusts, pulsations, murmurs, and gallops (third and fourth heart sounds). (Some clinicians believe that obtaining ankle blood pressure is useful in assessing the risk of cardiovascular disease, [64] [65] but this process is not routine.) The carotid and jugular pulses are also examined. Roizen has found that patients expect to be partially undressed for this examination and consider the examiner unprofessional if he or she does not auscultate blood pressure sounds using a bell or diaphragm held to the skin.)
2. Examination of the chest and auscultation of the bases of the heart for subtle rales suggestive of congestive heart failure, or for rhonchi, wheezes, and other sounds indicative of lung disease. (Although history-taking may detect these sounds as accurately as auscultation, the patient expects a "good" physician to auscultate the lungs preoperatively. Thus, this part of the physical examination also helps to increase patient confidence.)
3. Observation of the patient's walk for signs of neurologic disease or to assess back mobility and general health and a check of the eyes for abnormal movement and, along with the skin, for signs of jaundice, cyanosis, nutritional abnormalities, and dehydration. The skin is checked for clubbing. A functional evaluation of cardiovascular risk can be made by observing vigor and stamina in walking. Examination of the airway and mouth for neck mobility, tongue size, oral lesions, and ease of endotracheal intubation (Ch. 39)
4. Examination of the legs for edema, clubbing, mobility, sensation, and adequacy of hair growth (or skin texture) as signs of circulatory competence. Examination of the legs for bruising.

Although these portions of the history-taking and physical examination are routine, they are usually not recorded. Because the Health Care Financing Administration has insisted on recording of procedures as proof of their performance, the authors believe in using information system processes to document what has been done (see later).

DETECTING DISEASE: HISTORY, PHYSICAL EXAMINATION, AND CHART REVIEW VERSUS LABORATORY TESTS

Because more than 80 percent of patients receiving anesthesia are either outpatients or "come-and-stay" patients (i.e., patients admitted to the hospital after surgery), patients cannot be evaluated preoperatively as they were during the 1970s. A new system had to be devised. The resulting set of questions is extensive, consisting of more than 100 items. Roizen believes that use of either a written or an automated questionnaire to ask the screening questions, if coupled with a personal interview to pursue positive answers, does not decrease the accuracy or perceived personalization of the care given (see later) (Trigg DJ et al, unpublished data). [48] [59] [66] [67] [68] [69] [70] Gradually, Roizen began using this combination for inpatients as well (this process is described later in the chapter), especially for "come-and-stay" patients.

That means that *the anesthesiologist*' *s* task is to explore in depth any positive results on history-taking and to spend the rest of the time on issues the patient wants to discuss. Furthermore, storing this information electronically and securely (described later in this chapter) allows any anesthesiologist who is providing care to assess the patient's data the day or night before surgery. Most anesthesiologists have developed ways of putting the classic pattern (chart review; history-taking; physical examination; and discussion of risks, alternative anesthetic plans, and postoperative pain therapies) together so that all these questions are part of a compassionate flow of thought that helps the patient to recall information. A rigid, specific order for questioning is usually unnecessary.

The anesthesiologist must remember that older male patients tend to deny symptoms, often seeing disease as a sign of frailty. Some patients believe their symptoms indicate a life-threatening disease and therefore resist seeking medical help or answering questions until help is imperative. Despite such obstacles to the efficient discovery of pertinent information, seeing the patient before surgery does give the anesthesiologist one strong advantage: patients are usually willing and eager to share information. All surgery is a major event for both men and women; no patient really views any surgery as "minor." Thus, the preoperative interview can elicit vital information.

Some investigators have suggested that anesthesiologists forget the history and just use laboratory screening for disease. A review of the literature forces us to disagree strongly: the history (whether obtained personally, by questionnaire, or by telephone interview by person or computer screening device), and the investigation of positive answers by an in-person interview is many times more effective in screening for disease than use of laboratory tests alone. Moreover, the combination of history and personal interview can be a much less expensive process and avoids the medicolegal problems and inefficiency associated with too much testing.

In fact, the data presented later in this discussion led us to believe that the combination of history (from personal interview or questionnaire supplemented by personal interview) and physical examination is the best tool for optimal evaluation of patients and optimal selection of laboratory tests (i.e., selection of only those tests that have a greater chance of benefiting rather than harming the patient).

The primary problem with ordering batteries of laboratory tests for all patients is that laboratory tests are not very good screening devices for disease. In addition, the subsequent "extra" tests that physicians order as a follow-up to supposedly abnormal results are costly. More important, however, is that nonindicated tests often represent additional risk to the patient, increase medicolegal risk to the physician, and render ORs in outpatient centers and hospitals inefficient.

Laboratory Tests as Effective Screening Devices

In general, results of preoperative laboratory testing have been regarded as supplements to the patient's health history and physical examination. Collectively, this information has been the primary source of patient data available to the anesthesiologist. In the perioperative management of the patient, the anesthesiologist may alter the care of the patient based on preoperative laboratory test results. If a preoperative test suggests a change in the care of an individual such that the health of the patient is improved or a potential problem is avoided, then that test has been beneficial to the patient. *Other preoperative tests, the results of which are normal and merely borderline, may only distract the physician;* the results of these tests create no benefit but merely inconvenience, or worse, harm, through distraction. Finally, if a preoperative test suggests a change in the care of an individual so that the health of the patient suffers or a problem arises, that test decreases the overall quality of medical care and is harmful to the patient. One not uncommon example would be a situation in which abnormal results on a chest radiograph obtained for a 40-year-old man solely because he is scheduled for surgery leads to a computed tomographic needle biopsy that produces normal results but also a pneumothorax. This sequence shows how a "benign" test can result in harm. Thus, testing can incur a risk-benefit ratio that is higher than 1.

On the whole, not much benefit appears to arise from unindicated routine laboratory testing. Leonard and coworkers [71] reported that biochemical screening tests had no significant value in the preoperative screening of pediatric patients expected to be hospitalized for less than 1 week. When Korvin and associates [72] reviewed biochemical tests given routinely to 1,000 patients on hospital admission, none of the tests produced a new diagnosis that was unequivocally beneficial to the patient. In an ambitious, controlled trial of multiphasic screening of 1,500 patients, Olsen and coworkers [73] found no difference in morbidity between control groups and groups subjected to screening tests. Durbridge and colleagues [74] compared 1,500 patients randomly assigned to undergo or not to undergo screening tests on admission. With respect to length of hospital stay or patient outcome, no benefit resulted from the 8,363 extra tests performed for the group undergoing screening tests. Narr et al [23] [75] found that more than 3,000 ASA I or II patients failed to benefit from laboratory testing, and that absence of tests in more than 1,000 ASA I patients (average age, 21.4 y) did not adversely affect medical care.

Many studies have compared the yield from indicated (warranted based on history or risk group) versus unindicated (unwarranted) preoperative testing [76] [77] [78] [79] [80] [81] [82] [83] [84] [85] [86] [87] [88] [89] [90] [91] [92] [93] [94] [95] (Table 23-4) (Apfelbaum JL et al, unpublished data). Few unindicated tests have yielded beneficial changes in perioperative care: at most, only 16 patients of more than 16,000 who had unindicated preoperative tests benefited from such testing. Furthermore, this figure represents the most optimistic interpretation, because 4 patients in the study conducted by Kaplan et al [76] received no benefit, and for at least another 7 patients in the O'Connor and Drasner [81] study, the benefit of treating asymptomatic anemia prior to surgery not incurring blood loss was not clear.

Although laboratory tests can aid in ensuring that a patient's preoperative condition is optimal once a disease is suspected or diagnosed, such tests have several shortcomings as screening devices for the discovery of unknown disease. First, they frequently fail to uncover pathologic conditions. Second, they detect abnormalities the discovery of

TABLE 23-4 -- Reported Yields (Abnormal, Significantly Abnormal, Changes in Care) for Unindicated Versus Indicated Laboratory Testing

which does not necessarily improve patient care or outcome. In addition, laboratory tests are inefficient in screening for asymptomatic diseases. Finally, most abnormalities discovered on preoperative screening, or even on admission screening for nonsurgical purposes, are not recorded (other than on the laboratory report) or pursued appropriately.

By itself, the detection of abnormalities does not justify testing, because most abnormalities in asymptomatic patients do not reflect the presence of disease. For tests reported as continuous results, the distribution of results in a population of patients is gaussian (i.e., normal). The values defining "abnormal" are set arbitrarily, so that test results exceeding those of the highest 2.5 percent of healthy individuals, or falling below those of the lowest 2.5 percent of healthy individuals, are said to be abnormal. Test results between these two extremes are "within the reference range." Therefore, 5 percent of test results from patients without disease will be "outside the hospital reference range." If one were to order 100 hemoglobin determinations for a sample of healthy patients, 5 percent of the results would be expected to be "abnormal." Ordering multiple preoperative tests increases the chances of at least 1 abnormal result.

Assuming that results of tests are independent of one another, the more tests ordered, the higher the likelihood of an abnormal result. For example, if two tests are ordered for a patient without disease, the chance of both being normal is 0.95 × 0.95 or 0.90. For 20 tests, the chance that all would be normal would be only 36 percent. The chance that at least one result would be abnormal is 64 percent. Thus, if one chooses to use more than 13 tests to screen patients before surgery, one should expect at least one abnormal test result.

AIDS testing provides another example. More than 92 percent of the population at low risk of HIV infection who have positive (abnormal) results on two enzyme-linked immunosorbent assays (ELISA) and one Western blot test in reality do not have HIV infection. [94] Therefore, it is not surprising that the benefit from nonselective testing is so low or that so few abnormal results arising from unwarranted tests are cause for action (see Table 23-4) . Mammography is another example. If both mammograms and breast examinations were performed yearly starting at age 40, by age 50 more than 49 percent would have a false-positive test on examination, and more than 20 percent would have a breast biopsy for benign disease. [96]

Even for the very elderly, a patient group at higher risk of morbidity and mortality during surgery, the ultimate benefit of routine laboratory screening is doubtful. Domoto et al [97] examined the yield and benefit of a battery of 19 screening laboratory tests performed routinely in 70 functionally intact elderly patients (average age, 82.6 y) who resided at a chronic care facility. The 70 patients underwent 3,905 screening tests. "New abnormal" results occurred in 5 of the 19 screening tests. Most of these "new abnormalities" were only minimally outside the normal range. Only 4 discoveries (0.1% of all tests ordered) led to a change in patient management, none of which, Domoto and coworkers concluded, benefited any patient in any important way.

Wolf-Klein et al [98] retrospectively studied the results of annual laboratory screening on a population of 500 institutionalized and ambulatory elderly patients (average age, 80 y). From the 15,000 tests performed, 756 new abnormalities were discovered, 690 of which were ignored. Sixty-six of the new abnormalities were evaluated; the result was 20 new diagnoses, 12 of which were treated. Two patients of the 500 ultimately may have benefited from eradication of asymptomatic bacteriuria, although eradication of this condition has not been shown to improve the quality of life or to extend life. [99] [100]

Studies show that the history and physical examination are the best ways to screen for disease. Delahunt and Turnbull [101] evaluated 803 patients who were assessed preoperatively for varicose vein stripping or inguinal herniorrhaphy. A total of 1,972 tests produced only 63 abnormalities not indicated by history or physical findings. Furthermore, in no instance did the discovery of these abnormalities influence patient management. Another study retrospectively evaluated 690 admissions for elective pediatric surgical procedures. [102] Bates and colleagues [103] found that at least 40 percent of repeat tests were redundant in a large teaching hospital. The history and physical examination indicated the probability of abnormalities in all 12 patients for whom an abnormality was detected by laboratory testing. Clinical diagnosis, and not laboratory testing, was the apparent basis for any change in operative plans. Narr and colleagues [23] at the Mayo Clinic found no harm from omitting *all* laboratory testing for ASA I patients. The sample size of this study was large enough to indicate that more harm than benefit would probably occur by testing ASA I patients. One exception should be noted: the median age of these patients was 21.4 years, making the conclusion about testing of ASA I patients more than 40 years of age unclear.

Several studies have compared groups of hospitalized patients undergoing routine laboratory screening tests (to supplement the history and physical examination) with groups not undergoing routine screening tests. Would outcome differ? Wood and Hoekelman [104] found that abnormal results from the history, physical examination, or laboratory examination changed the preoperative clinical course (for all, surgery was postponed) for 28 of 1,924 children. For only 3 of those 28 patients did laboratory tests indicate an abnormality not suggested by the history or physical examination. Thus, the history and physical examination dictated the appropriate laboratory testing for all but 3 of 1,924 patients.

A more specific conclusion is also possible. The abnormalities discovered for these three patients were found on chest radiographs. (These children were part of a study comparing perioperative outcome at two hospitals, one that required chest radiograph as a screening test for elective surgery in children and one that did not.) There were no differences noted in anesthetic or perioperative complications between the two groups. Therefore, Wood and Hoekelman [104] recommended that chest radiographs not be obtained routinely for apparently healthy children.

Even in a referral population, history and physical examination determine more than 90 percent of the clinical course when a patient is referred for consultation about cardiovascular, neurologic, or respiratory disease. [105] Other studies also have demonstrated that the history and physical examination accurately indicate all areas in which subsequent laboratory testing proves beneficial to patients. For example, Rabkin and Horne [106] [107] examined the records of 165 patients having a "new" abnormality on ECG that was "surgically significant" (i.e., a change from a previous tracing

that represents a condition possibly affecting perioperative management or outcome). In only two instances were anesthetic or surgical plans altered by the discovery of "new abnormalities" found on ECG but not indicated by history. Thus, even for these 165 patients, for which the benefits of a laboratory test should have been maximal because abnormalities were detected before surgery, the history or physical examination determined case management most of the time. Furthermore, for one of the two instances of altered case management (a patient who had atrial fibrillation), physical examination should have indicated the need for an ECG. A history or physical examination was not available for the other patient.

Table 23-4 shows that patients who benefit from testing have risk factors, symptoms, or other conditions in their history that call forth testing. In our own study (Apfelbaum JL et al, unpublished data), for patients who were symptomatic with risk factors for disease or who only had risk factors for disease, 606 (5.8%) of 10,419 test results were significantly abnormal. Of these, 124 tests (1.2%) affected care. Of these patients, 6 tests resulted in harm (6 in 10,419, or 0.06%), whereas 91 patients (91 in 10,419, or 0.9%) benefited from a change in care. By contrast, for asymptomatic patients who had no risk factors for disease, only 121 (1.1%) of the 10,899 tests results were significantly abnormal. Of these, 10 tests (13 in 10,899, or 0.01%) affected care. During the study, every change in care that benefited or harmed a patient stemmed from a single test result. Therefore, the 13 "care-affecting" tests represented 13 "care-affected" patients. Of these 13 patients, 5 (in 10,899, or 0.05%) asymptomatic patients were harmed, whereas only 1 (in 10,899 tests results, or 0.009%) of the patients benefited from a change in care. Neither harm nor benefit was thought to result from the other 7 changes in care.

In summary, the studies cited point to the lack of benefit from routine laboratory tests as a method of assessing patients preoperatively. Many of these laboratory tests have been shown to be superfluous to patient care management. History and physical examination are considered the most effective ways of screening for disease. Laboratory tests can be used to screen for disease when the patient has appropriate risk factors and when such tests have proved effective. However, the better use of such tests is to confirm clinical diagnoses or to optimize the patient's condition prior to surgery.

Patient Risk

Unnecessary testing may lead physicians to pursue and to treat patients with borderline and false-positive laboratory abnormalities (Ch. 25) . This observation does not imply that all standard screening tests should be discontinued. Some are beneficial, such as the mammogram for all women older than 40 or 50 years of age, [96] [108] the test for occult blood in stool for all people more than 40 years of age, [88] [89] [90] [92] [93] and the Papanicolaou (Pap) smear for sexually active females. [88] [89] [90] [92] [93] However, few studies have examined whether increased testing and the follow-up on falsepositive test results adversely affect patients. In one study addressing this issue, Roizen et al [56] retrospectively examined the adverse effects of chest radiographs on patients. For 606 patients, 386 additional chest radiographs were ordered without indication of need. Among those 386 patients, the discovery of only one abnormality (an elevated hemidiaphragm probably caused by phrenic nerve palsy) may have resulted in improved care for that patient. On the other hand, the existence of three lung shadows on chest radiographs led to three sets of invasive tests, including a thoracotomy, but no discovery of disease. These procedures caused considerable morbidity, including one pneumothorax and 4 months of disability, for those three patients.

Tape and Mushlin [109] found a similar result when examining the benefits and risks of chest radiographs obtained preoperatively in Rochester, New York. Of 341 patients admitted for vascular surgery, 9 had radiographic findings that led to clinical action. Specifically, three patients (two with congestive heart failure and one with pulmonary fibrosis) may have benefited from the findings. However, all three patients were known by history to have the disease shown on chest radiographs. In addition, six patients were subjected to a potentially detrimental clinical response. Two had a false diagnosis of tuberculosis, with subsequent therapy for one patient; two others had false diagnosis of nodules, and the last two had falsely normal chest radiographic readings. All the beneficial effects attributed to preoperative chest radiographs accrued to patients who had obvious clinical history of pulmonary or cardiac disease. Orkin [110] further explained the basis of the risk of testing asymptomatic patients.

Similarly, in another study we participated in, even though few patients benefited by preoperative testing that was warranted by history or risk factors (91 of 1,746), even fewer were harmed by such testing (1 patient) (Apfelbaum JL et al, unpublished data). By contrast, testing of asymptomatic patients was more risky than beneficial to patient health. Specifically, 1 in every 2,000 preoperative tests (1 in 300 patients) led to patient harm because of the pursuit of abnormalities indicated by those tests; 1 in 10,000 tests (1 in 1,746 patients) led to benefit (Apfelbaum JL et al, unpublished data).

In another study, Turnbull and Buck [78] examined the charts of 2,570 patients undergoing cholecystectomy to determine the value of preoperative tests. With four possible exceptions, history and physical examinations successfully indicated the need for all tests that ultimately benefited the patients. Again, for those four patients, it is doubtful that any benefit actually occurred as a result of preoperative tests. Among them was a patient who had emphysema detected only by chest radiograph. This patient had preoperative physiotherapy without subsequent postoperative complication. Two patients had unsuspected hypokalemia (potassium levels of 3.2 and 3.4 mEq/L in blood) and received treatment prior to operation. Current data in the literature indicate that no harm occurs to patients undergoing

surgery with this degree of hypokalemia and that severe harm may be caused by treating such patients with oral or intravenous administration of potassium (Table 23-5) . [111] [112] [113] [114] [115] The fourth patient possibly benefiting from preoperative testing had an asymptomatic hemoglobin concentration of 9.9 g/dL and was given a blood transfusion prior to cholecystectomy. Because cholecystectomy is not normally associated with major blood loss, one could conclude that this patient also received no benefit from preoperative laboratory testing and its pursuit but was exposed to the risk of transfusion.

TABLE 23-5 -- Risk of Potassium Supplementation[a]

	ROUTE OF ADMINISTRATION			
	ORAL	***IV***	***ORAL AND IV***	***ALL ROUTES***
Patients (no.)	1,910	2,192	819	921
Death	3 (0.2%)	3 (0.15%)	1 (0.1%)	7 (0.14%)
Life-threatening reaction or death	6 (0.3%)	7 (0.35%)	14 (1.7%)	28 (0.57%)
Hyperkalemia	74 (3.9%)	34 (1.6%)	71 (8.7%)	179 (3.6%)
Other side effects	53 (2.8%)	18 (0.8%)	33 (4.0%)	283 (5.7%)

Data from Lawson [114] and Lawson et al [115]

[a] One in 200 patients given potassium supplementation dies or has a life-threatening reaction.

Thus, it is not clear that any patient in this study benefited from preoperative screening tests given without indication for need by history or physical examination.

In another study, only 2 patients at most (who had eradication of asymptomatic bacteriuria) benefited from the 9,720 screening tests that were obtained. [116] At least one patient was seriously harmed from pursuit and treatment of abnormalities on screening tests. For this patient, atrial fibrillation and congestive heart failure developed after institution of thyroid therapy for borderline low thyroxine and free thyroxine index tests. It is unclear whether these investigators examined other patients for potential harm arising from the pursuit and treatment of abnormalities on screening tests.

To determine benefits and risks, screening mammography was evaluated in a real-life practice setting. [96] Although yearly screening was beneficial, more than 20 percent of the women who did not have disease were subjected to a breast biopsy. Furthermore, more than 49 percent of these "normal" women would have been subjected to a breast biopsy if each had had a yearly mammogram and clinical breast examination. Thus, even when benefits exceed risk, there is substantial risk to routine testing.

[d] Test not obtained preoperatively.

Medicolegal Liability

"Extra testing"--testing not warranted by findings on a medical history--does not provide medicolegal protection against liability (Ch. 85) . Studies show that 30 to 95 percent of all unexpected abnormalities found on preoperative laboratory tests are not noted on the chart before surgery [76] [87] [98] [104] [106] [107] [117] [118] [119] [120] [121] [121] [122] [124] [125] [126] (Table 23-6) . This lack of notation occurs not only at university medical centers but at community hospitals as well.

Moreover, the failure to pursue an abnormality appropriately poses a greater risk of medicolegal liability than does failure to detect that abnormality. [127] In this way, extra testing increases the medicolegal risk to physicians. In addition, the Health Care Financing Administration is attempting to make failure to pursue abnormalities grounds for charging physicians with inadequate practice. However, such lack of attention to unexpected abnormalities is a completely reasonable response: the foregoing data [128] (Fig. 23-2) (Figure Not Available) indicate that most unexpected abnormalities in asymptomatic patients occur in patients who are actually healthy.

Furthermore, pursuit of unexpected abnormalities in asymptomatic patients is more likely to harm than to benefit such patients. For these reasons, we differ with Ross and Tinker, [129] who seem to believe that obtaining an unindicated test poses no liability if it is pursued. It is logical that pursuit of unindicated testing poses liability, because the tests were not warranted, and the statistics of testing theory and data in the literature indicate that the pursuit of such abnormalities is more likely to cause harm than to prove beneficial. Thus, the problems associated with nonselective batteries of tests include both direct and indirect risks to patients and society (Table 23-7) .

Operating Room Schedules

According to hospital administrators in the United States, surgeons say they order preoperative tests to satisfy anesthesiologists: surgeons find it easier just to order all the tests and let the anesthesiologist analyze them. Surgeons also believe that it is much more efficient to order batteries of tests than to have an anesthesiologist, who sees the patient the night before or the morning of surgery, obtain the tests on an emergency basis. This line of reasoning overlooks the fact that abnormalities arising from tests performed in the battery fashion are usually not discovered until the night before or the morning of surgery, if at all. Then, the discovery of abnormal results delays or postpones OR schedules, because effort and time are wasted to obtain consultant review of false-positive or slightly abnormal results. Moreover, data show clear cost reductions from delegating test selection to anesthesiologists, [26] [27] [28] [29] [30] as well as other benefits from educational practices that are discussed later in this chapter. [5] [31] [32] [33] [34] [35] [36] [37] [38] [39] [40] [43] [44] [45] [46] [47] [130] [131] See also Chapter 82 .

PREOPERATIVE TESTING

Most hospitals, many anesthesia departments, many outpatient surgical centers, and now many office-based surgical facilities have rather arbitrary rules and recommendations regarding tests that should be performed before elective surgery. With good intentions, anesthesiologists tried to follow those rules, and problems began. The inexpensive multiphasic screening batteries of tests subsequently developed by the Kaiser Hospitals and Health Plan seemed to be the answer to this confusing and arbitrary process. [132] Physicians believed that they could now order inexpensive batteries of

Figure 23-2 (Figure Not Available) Probability of at least one abnormal result on multiple independent trials of tests, each with a probability (P_N) of a normal result, for selected values of P_N . *(From Berwick [126])*

TABLE 23-7 -- Consequences of Using Nonselective Batteries of Preoperative Tests

	CONSEQUENCES
Direct risks to patients	*False-positive* results (i.e., an erroneous "abnormality" on a radiograph or electrocardiogram) may initiate follow-up activities that are harmful to the patient.
	False-negative results encourage the overlooking of true problems or instill a false sense of security.
Indirect risk to patients	Diverts physician's attention to nonvital issues.
Cost to society	Reduces resources available to care for others.
Cost to physicians	Failure to pursue abnormalities increases medicolegal risks.

tests and thus efficiently screen for disease. However, physicians were still trying to determine which tests to order before surgery and what to do with the unexpectedly abnormal result on the morning of surgery. Kaiser found that this system of preoperative multiphasic screening was not practical. [133] The system produced so many false-positive and false-negative results that the subsequent harm vastly outweighed any possible benefit. Nevertheless, the notion of "the more testing, the better" still remains.

Low Predictive Value of an "Abnormal" Laboratory Test Result

Understanding what constitutes an "abnormal" laboratory test result requires an appreciation of the way "normal" values are determined. A normal range is based on the typical distribution of the gaussian curve. [134] For example, assuming a gaussian distribution and hemoglobin values of 13.5 to 16.7 g/dL ("reference range") for healthy men, one can expect 5 percent of "normal" men to have a test result outside that range.

Of prime importance in preoperative evaluation is knowing the percentage of abnormal laboratory test values that truly indicates disease. If the anesthetic management of a patient is altered because of test abnormality, that abnormality should indicate a condition (1) that poses a significant risk of preoperative morbidity that can be lessened by preoperative treatment, (2) that cannot be discovered through history-taking and physical examination, and (3) that is sufficiently prevalent in the population to justify the risk of performing the follow-up test. To be cost-efficient, the test should be sufficiently "sensitive" (have "positivity in disease") and sufficiently "specific" (have "negativity in health"); that is, test results should be positive if the patient has disease and negative if the patient is healthy. [133] [134] [135] [136] [137] In fact, what a clinician really wants to know is what a positive or negative test means for the individual patient. The values representing the predictive ability of a positive or negative test ("positive predictive values" and "negative predictive values") depend on the pretest population probability. [137] [138] [139]

We should now consider the significance of false-positive and false-negative results and the prevalence of disease in the test population in relation to abnormal laboratory test results. (We are indebted to Drs. Jorgen Hilden and Anders Hald, whose comments have helped to make this section clearer.) For example, patients with pneumonia would have the notation "pneumonia" (or some significant abnormality) written as the diagnosis on their chest radiograph reports. Let us also assume that the specificity of a test (its negativity in health) is 98.3 percent; that is, 983 of 1,000 people who actually do not have asymptomatic pneumonia have a comment such as "without evidence of pneumonia" or "normal" written on their chest radiograph reports. Let us further assume that 0.5 percent of the asymptomatic population younger than age 40 who are about to undergo routine elective surgery has pneumonia. Given the preceding assumptions, what is the likelihood that a person whose chest radiograph report reads "pneumonia" would actually have pneumonia?

If we test 100,000 asymptomatic persons, and 0.5 percent are assumed to be diseased, this means that 500 people would have undetected pneumonia. If the sensitivity of chest radiographs to pneumonia is assumed to be 75 percent, 375 of these people would have abnormal radiographs. Then, if specificity is assumed to be 98.3 percent, 97,809 of the 99,500 healthy people would have normal results on chest radiographs. This means that 1,691 (1.7%) would have abnormal radiographic results. Thus, of 2,066 patients having a diagnosis of pneumonia based on chest radiographs, 1,691 (82%) of the results would be falsely positive. Therefore, it is entirely possible that 82 percent of the chest radiographs indicating "infiltrate compatible with pneumonia" in otherwise asymptomatic persons would actually be describing totally healthy people. Expressed in another way, when the foregoing assumptions are applied, the likelihood that an asymptomatic person would actually have pneumonia when the chest radiograph contains that notation is only 18 percent; that is, for this patient group, the predictive value of a positive test (the "positive predictive value") is only 18 percent.

Only patients with abnormal test results who actually have disease ("true positives") benefit from laboratory testing. Let us assume that 2.2 percent of the chest radiographs in the population younger than age 40 are positive, and that for each true-positive, perioperative mortality decreases by 50 percent. If we use the 82 percent false-positive rate derived previously, the number of patients benefiting per 1,000 radiographs is 3.9 (true-positives per 1,000 = all positives - false positives, i.e., [2.2% × 1,000] - [82% × 2.2% × 1,000] = 3.9 patients). Therefore, a reduction in operative mortality of 50 percent, or 1 per 20,000 (i.e., 3.9 × 0.5 × 0.00005), gives 0.000095 fewer deaths per 1,000 operations when preoperative chest radiographs are obtained.

Hilden and Hald (personal communication) question whether this is a logical calculation. One study, for example, analyzed outcomes for asymptomatic patients. [140] The death rate for this group was 1 in 10,000. Of these deaths, more than 90 percent were caused by avoidable problems unrelated to unknown diseases. Therefore, at most, fewer than 10 percent of the deaths among asymptomatic individuals could be attributed to preoperative conditions, and probably fewer than 10 percent of those deaths (or <1% of the total, or 1 in 1,000,000) would be related to pneumonia. Thus, the intuitive value is similar to what we have estimated. Furthermore, from an examination of the data in Tables 23-4 and 23-8 , it is evident that few chest radiographs in the asymptomatic population younger than age 40 led to benefit. In

addition, the harm from these tests has not yet been considered.

[a] These data constitute an edited summary of the date presented by various articles, edited to select abnormalaties that might change management of anesthesia.
[b] Abnormalities not already known or suspected by history or physical examination
[c] Patients were asymptomatic.
[d] Combined studies in younger-than-40 population excluding two studies, those by rees al [149] and Collen et al [132]
[e] 0% changed treatment.
[f] Tape amd Mushlin [109] studied vascular surgery patients; Turnbull and Buck, [78] chp;ecystectomy patients; abd weibman and colleagues, [164] cancer patients.

Translating this figure into the present value for years of life saved per 1,000 chest radiographs yields the following: 0.000095 fewer deaths per 1,000 operations × 22.62 years saved per life saved = 0.0022 years of life. The figure 22.62 is the present value of 60 more years of life for a 20-year-old, per Neuhauser. [134] At the University of Chicago, this 0.0022 years of life saved would cost $78,000 (anteroposterior and lateral chest radiographs cost $78, not including fees for consultations, repeated radiographs, or other laboratory tests or procedures). Therefore, each year of life saved by obtaining chest radiographs costs about $35,500,000 ($78,000 divided by 0.0022).

However, just as there are other costs (e.g., pursuing some false-positive chest shadows results in computed tomographic needle biopsies and lobectomies in totally healthy patients [74] [75] [76] [77]), there are other benefits (e.g., treatment of some patients having solitary nodules or mediastinal masses may prolong life). Let us arbitrarily assume that these costs and benefits are equal. One is forced to conclude that screening for an asymptomatic disease having a low prevalence rate is a very expensive and possibly risky procedure.

Simplified Benefit-Risk Analysis of Testing

The foregoing analysis is only a cost-benefit analysis and not a benefit-risk analysis and therefore disregards the possible harm of unwarranted testing, which in fact does incur risk (Fig. 23-3) . Let us assume that the chest radiograph in the population younger than age 40 has a sensitivity of 75 percent and a specificity of 95 percent. (These values are better than the best in the literature for readings referenced by a single radiologist.) Let us also assume that the prevalence of disease

detectable by the test is 0.5 percent, that the benefit from true-positives is 20 in 100 (better than the best in the literature) [75] [76] [77] [78] [79] [80] [81] [82] [83] [84] [85] [86] [87] (see Table 23-4) (Apfelbaum JL et al, unpublished data), and that harm from false-positive results is 6 in 100 (see earlier discussion) [56] [109] (Apfelbaum JL et al, unpublished data). For the asymptomatic population younger than age 40, the result would be harm to 3 individuals and benefit to only 0.8 individuals per 1,000 chest radiographs (Table 23-9) . Similar analyses are possible for other tests and situations (see Table 23-9).

Lead-Time and Length-Time Biases

Two important concepts related to the reported benefits and risks of screening tests deserve consideration: lead-time and length-time biases. [141] These two factors can indicate an apparent benefit of testing when there is none. Let us examine screening for lung cancer in smokers and screening for breast cancer. In a Czechoslovakian trial of screening of smokers, men at high risk were randomly assigned to either chest radiography twice a year or to no screening. [142] No difference in mortality from lung cancer occurred. However, the 5-year survival rate from the time of diagnosis was 23 percent for the screened group and 0 percent for the control group. Thus, this apparent improvement was entirely owing to earlier diagnosis ("lead-time bias"). In fact, mortality from lung cancer was actually higher in the

screened group, indicating that the real effect of screening and subsequent intervention was negative.

Black and Welch [141] reviewed the only other trial of screening strategies using diagnostic radiology evaluated in a randomized trial. In the only randomized trial of mammographic screening--the Malmo mammographic screening trial [143] --the benefits of this test also seem to disappear. Women older than 45 years of age were randomly assigned

Figure 23-3 Theory and actuality of what happens to well-being as testing increases. The straight line represents the common theory that "the more testing, the better," that is, that well-being increases with testing. The A-to-E curve shows what actually happens as testing increases. At a certain point (C), more harm than good may result. Therefore, point C represents the optimal point in the well-being versus testing relationship. The goal of using guidelines is to direct resources from point E to point C (to reduce testing and to increase well-being). Unless health-care providers allocate health resources in a cost-efficient manner, governmental restrictions will move testing from point C to point A, that is, will ration testing that improves well-being

to either regular mammography or no screening. Although survival from the time of diagnosis was 80 percent higher for the screened group, no difference existed in mortality from the time of randomization. Thus, the apparent increase in the survival rate for screened patients was entirely owing to lead-time bias (earlier diagnosis) and length-time bias (less severe cases diagnosed) associated with screening test detection, and not to any benefit from the screening strategy itself.

Before one concludes that no testing should occur preoperatively, let us remember that detection of subclinical conditions in high-risk groups and optimization of therapy for clinical conditions can result in less perioperative morbidity, fewer changes in perioperative plans, and better informed discussions of risk with the patient and significant others.

Laboratory Test Abnormalities in Asymptomatic Populations

Does Surgical Procedure Influence Laboratory Test Choice and Requirements?

A decade ago, the answer to this question was no. Today, the answer is yes. Some operations incur such low rates of morbidity and mortality that a test is not indicated unless it is necessary for "routine" preventive care of the patient. Examples are diagnostic knee arthroscopy and cataract extraction. [144] Table 23-10 divides procedures into three types. Type A procedures are minimally invasive operations that produce little tissue trauma and minimal blood loss. We believe that *no* laboratory testing is indicated for these operations, based on preoperative status alone (such a division was proposed in the ASA's draft guidelines for preanesthesia evaluation). Obviously, some laboratory testing may be required for patients undergoing such procedures, in order to provide preventive care for those patients or to optimize their medical condition (even a haircut can pose a risk for someone in severe congestive heart failure). On the other hand, type B and C procedures are progressively more risky and invasive. For these procedures, it becomes increasingly important to optimize any adverse conditions--even the less severe ones--that exist preoperatively. Therefore, type B and C procedures often require more preoperative testing.

TABLE 23-9 -- Hypothetic Benefit-Risk Analyses for Two Tests, Under Three Circumstances

TEST:	CHEST RADIOGRAPH	ELECTROCARDIOGRAM	
PATIENT:	**< 40-YEAR-OLD ASYMPTOMATIC PATIENT**	**30-YEAR-OLD ASYMPTOMATIC MAN, TO SEARCH FOR MI**	**47-YEAR-OLD ASYMPTOMATIC MAN, TO SEARCH FOR MI AND CONDUCTION DISTURBANCE**
Sensitivity of test	75%	33%	50%
Specificity of test	95%	90%	90%
Prevalence of disease detectable by test	0.5%	2.1%	15%
Benefit from true-positives	20%	20%	20%
Harm rate for false-positives	6%	6%	6%
Benefit per 1,000 patients			
Predicted true-positives	3.8	7	75
Benefited patients	0.8	1.4	15
Harm per 1,000 patients			
Predicted false-positives	49	97.9	85
Harmed patients	3	5.9	5.1
Conclusion:	*Harm greater than benefit: do not test!*		*Benefit greater than harm: test!*

MI, myocardial infarction

TABLE 23-10 -- Types of Surgical Procedures for Which Anesthesia May Be Administered

TYPE	GENERAL DEFINITION	SPECIFIC EXAMPLES
Type A	*Minimally invasive* procedures that have little potential to disrupt normal physiology and are associated with only rare periprocedural morbidity related to the anesthetic. These procedures rarely require blood administration, invasive monitoring, and/or postoperative management in a critical care setting.	Cataract extraction, diagnostic arthroscopy, postpartum interval tubal ligation
Type B	*Moderately invasive* procedures that have a modest or intermediate potential to disrupt normal physiology. These procedures may require blood administration, invasive monitoring, or postoperative management in a critical care setting.	Carotid endarterectomy, transurethral resection of the prostate, and laparoscopic cholecystectomy
Type C	*Highly invasive* procedures that typically produce significant disruption of normal physiology. These procedures commonly require blood administration, invasive monitoring, or postoperative management in a critical care setting.	Total hip replacement, open aortic aneurysm resection, aortic valve replacement, and posterior fossa craniotomy for aneurysm

Chest Radiographs

What abnormalities on chest radiographs would influence management of anesthesia? Certainly, it may be important to know about the existence of the following conditions before proceeding to anesthesia and surgery: tracheal deviation or compression; mediastinal masses; pulmonary nodules; a solitary lung mass; aortic aneurysm; pulmonary edema; pneumonia; atelectasis; new fractures of the vertebrae, ribs, and clavicles; dextrocardia; or cardiomegaly. However, a chest radiograph probably would not detect the degree of chronic lung disease requiring a change in anesthetic technique any better than would the history or physical examination. Table 23-8 [77] [78] [80] [91] [97] [98] [104] [132] [145] [146] [147] [148] [149] [150] [151] [152] [153] [154] [155] [156] [157] [158] [159] [160] [161] [162] [163] [164] [165] [166] shows the prevalence of conditions that a chest radiograph may detect. These data show that abnormalities are rare in the asymptomatic individual. In fact, the risks associated with chest radiographs probably exceed their possible benefit if the patient is asymptomatic and younger than 75 years. This analysis is predicated on maximizing benefit to all patients as a general

group, because one cannot say which individual patients will benefit and which will be harmed. Thus, chest radiographs are not warranted for any asymptomatic patient who is less than 75 years of age and free of risk factors. In fact, this conclusion may apply to patients older than 75 years of age as well.

Electrocardiograms

The incidence of ECG abnormalities has been determined by studies on patients (Hsu J et al, unpublished data) [78] [79] [132] [133] [167] [168] [169] [170] [171] [172] [173] and epidemiologic surveys of healthy people (Ch. 32) . [146] The abnormalities on ECG that have the potential to alter management of anesthesia are as follows: atrial flutter or fibrillation; first-, second-, and third-degree atrioventricular block; changes in ST segment suggesting myocardial ischemia or recent pulmonary embolism; premature ventricular and atrial contractions; left or right ventricular hypertrophy; short P-R interval; Wolff-Parkinson-White syndrome; myocardial infarction; prolonged QT segment; and tall peaked T waves. What is the incidence of finding these abnormalities on the 12-lead preoperative screening ECG but not on a standard monitor lead I or an MCL_5 lead applied immediately before induction of anesthesia in the OR?

Before answering that question, some qualifiers apply. First, few of the studies on the incidence of ECG abnormalities (Apfelbaum JL et al, unpublished data) [78] [79] [167] excluded patients having histories or physical examinations indicating cardiac problems. Second, the studies do not distinguish those findings evident on monitoring leads from findings evident on only 6-lead or 12-lead ECGs [77] [78] [79] [91] [98] [106] [107] [116] [132] [152] [166] [167] [168] [169] [170] [171] [172] [173] [174] [175] (Table 23-11) .

The data in Table 23-11 and elsewhere [175] [176] show that abnormalities on ECG are relatively common and increase exponentially with age. Averaging all those data indicates that the incidence of abnormal preoperative ECG results would exceed 10 percent at 40 years of age and would be 25 percent by 60 years of age. These estimates pool abnormalities for both sexes. Clearly, those studies that looked for abnormalities on ECG after first ensuring the patient was asymptomatic (McKee and Scott, [77] Yipintsoi et al, [167] and Blery et al [91]) found a much lower incidence of significant abnormalities. McKee and Scott [77] found no abnormalities significant to perioperative care for 160 individuals who had no cardiac symptoms and were less than 60 years of age, and only 2 abnormalities for 163 patients older than 60 years of age. Moorman and colleagues [172] found only 1 of 275 asymptomatic patients 45 years of age or younger who had abnormalities on preoperative ECG. In the study by Blery and coworkers, [91] only 0.6 percent of 2,256 patients younger than age 40 who had no cardiac or pulmonary symptoms had an abnormality on preoperative ECG. Our group found no abnormalities on ECG that were significant to, or altered, perioperative care among 510 patients judged to be asymptomatic

AV, atrioventricular; LVH, left ventricular hypertrophy; MI, myocardial infarction

[a] All studies are 12-lead studies, except for that of Collen et al, [132] which is a 6-lead study.
[b] These data constitute an edited summary of data given in several series, edited to select abnormalities that might change management of anesthesia. *Numbers in parentheses indicate abnormalities judged retrospectively by the authors of the paper to be significant to perioperative management.*
[c] Values are approximations that represent "best-guess" numbers from data not explicitly stated in the reports.
[d] Patients were asymptomatic
[e] Apfelbaum JL et al, unpublished data (patients were asymptomatic)

on the basis of results from a video questionnaire [171] (Apfelbaum JL et al, unpublished data). This study is discussed later in the chapter.

How useful is it to repeat an ECG if the patient has had an ECG within the past 2 years? Rabkin and Horne [106] [107] addressed this question. "New abnormalities" on a subsequent ECG occur with significant frequency, approximately 25 to 50 percent as frequently as all abnormalities occurring on the previous ECG (Table 23-12) . Thus, one would be justified in obtaining a screening ECG prior to elective surgery for all patients older than 40 years of age, even those who have recently had an ECG, if it is older than 2 months or was abnormal. (See Table 23-9 for an analysis of the risk versus benefit of obtaining an ECG for asymptomatic patients.)

Some physicians have questioned even that conclusion. Goldberger and O'Konski [176] believe that the most important potential benefit of the preoperative ECG is detection of previously unrecognized myocardial infarction. This risk increases with age. However, even for the highest-risk group, men 75 years of age or older, the estimated incidence of unrecognized Q-wave infarction within the preceding 6 months is relatively small (<0.5%). Goldberger and O'Konski concluded that the risk of obtaining a preoperative ECG and subsequent reactions probably exceeds its benefit if patients are asymptomatic, do not have important risk factors for coronary disease, and are less than 45 (men) or 55 (women) years of age. If the data in Table 23-11 are used and the benefit-risk analysis described in the section on chest radiographs is applied, an ECG is indicated for asymptomatic patients undergoing type B or C procedures who are more than 40 (men) or 50 (women) years of age.

These processes do not account for the differences in physiologic age that exist among patients of the same calendar age. We believe that those differences are important. Although we also believe that physiologic age ("RealAge" [177] [*]) should be the factor used to determine the need for testing, this hypothesis has not been widely tested. We know that conditions such as normal blood pressure, regular vigorous exercise, the absence of exposure to cigarette smoke, and

* Dr. Roizen is a scientific advisor to RealAge, Inc.; he has an equity interest in that company, and he has a book published by Harper Collins, entitled *RealAge: Are You As Young As You Can Be?*

TABLE 23-12 -- Patients Found to Have a New Abnormality on Electrocardiogram and a Previous Electrocardiogram [a]

	NEW ABNORMALITY WITH A PREVIOUSLY			
	NORMAL ECG		*ABNORMAL ECG*

AV block	2 (1.0%)	3 (2.3%)	1 (0.3%)	

AV, atrioventricular; ECG, electrocardiogram; LVH, left ventricular hypertrophy; PAC, premature atrial contractions; PVC, premature ventricular contractions; SVT, supraventricular tachycardia

Data from Rabkin and Horne [106] [107]

[a] Numbers in parentheses are percentages of patients; two-thirds of patients had a previous ECG within 2 years of their new ECG.

control of stress can all decrease physiologic age ("RealAge" [177]) by more than 8 years. Therefore, we delay routine ordering of ECGs for 10 calendar years for any male or female patient for whom these advantageous conditions apply.

Hemoglobin Level, Hematocrit Level, and White Blood Cell Counts

The classic references on hemoglobin level, hematocrit level, and white blood cell counts, and the inferences they allow, have stood the test of time. We describe them now, so that the reader will understand the rationale for decisions and practices used even today.

Wasserman and Gilbert [178] found that of 28 patients with uncontrolled polycythemia (hemoglobin level >16 g/dL) who underwent major surgery, 22 (79%) had complications and 10 (36%) died. This group was compared with 53 patients who had controlled polycythemia (hemoglobin level <16 g/dL) and major surgery; 15 (28%) had complications, and 3 (5%) died. For both groups, most of the complications were related to polycythemia (e.g., hemorrhage or thrombosis). Other data confirm that polycythemia is an independent risk factor for cardiovascular mortality. [179] Admittedly, the study of Wasserman and Gilbert [178] had deficiencies. It was a retrospective study, and no period of time was given. "Minor" surgery was excluded. Moreover, the study did not explain why polycythemia was controlled preoperatively for some patients but not for others. Nevertheless, knowledge and pretreatment of polycythemia decreased perioperative morbidity and mortality.

No such evidence exists for normovolemic anemia. Rothstein [180] concluded that a hemoglobin level of 9 g/dL is adequate for patients older than 3 months of age but should exceed 10 g/dL for younger patients (Chs. 46 and 47). As emphasized by Roy and colleagues, [83] the age of the patient at the time of discovery of anemia often points to its cause. Anemia in the neonatal period is often attributable to recent blood loss, isoimmunization, congenital hemolytic anemia, or congenital infection. Anemia first detected 3 to 6 months after birth suggests a congenital disorder of hemoglobin synthesis or structure. Therefore, assays of hemoglobin concentration in the first 6 months may represent the first opportunity for analysis. This use of the perioperative period for screening (or case finding) necessitates a proactive procedure for referring the patient/parents for counseling and/or treatment (ideally integrated through an automated information ["informatics"] system linking preoperative clinic and primary care physicians). Thus, preoperative evaluation can add to a patient's prior medical database.

This point--that preoperative evaluations and documentation of data from the history are often incomplete--was reiterated by Hackmann and colleagues [82] in their study of the prevalence of anemia. They pointed out that several patients whose anemia was not properly suspected had conditions (Hirschsprung disease, pyloric stenosis, or history of anemia accompanying juvenile rheumatoid arthritis) that should have alerted the anesthesiologist. These investigators also emphasized the importance of obtaining a thorough history.

Should asymptomatic anemia be treated prior to surgery that is associated with no blood loss, as O'Connor and Drasner [81] and others have done? Does this practice produce more benefit than harm? Does iron therapy at this early age contribute to late ischemic heart disease? Is this the function of preoperative testing, to spot chronic conditions? Although there are no definite answers to these questions, we agree with O'Connor and Drasner that these practices are indicated if one sets up the preoperative assessment to function in that role. This would mean that the anesthesiologist and the clinic would constitute second-opinion consultants to the primary care physician. It would also require that the preoperative assessment be performed sufficiently early (
1 wk before surgery) and be vested with enough authority to postpone surgery in a timely enough fashion to avoid any decrease in OR efficiency.

If the preoperative assessment is not done in advance or is not vested with sufficient authority, perhaps asymptomatic anemia prior to surgery not involving blood loss should not be treated preoperatively. These impressions seem to be confirmed by studies showing that patients survive anesthesia and type A surgery when hemoglobin levels are higher than 80 g/L. [181] [182] No data confirm the hypothesis that preoperative treatment of moderate or mild normovolemic anemia in such patients decreases perioperative morbidity or mortality. Similarly, no data exist regarding the possible harm from abnormal white blood cell counts found preoperatively. Therefore, the following ranges of "surgically acceptable values" are arbitrary: for hematocrit level, 29 to 57 percent for men and 27 to 54 percent for women; for white blood cell count, 2,400 to 16,000/mm^3 for both men and women. When values fall outside these ranges, we recommend seeking an alternative diagnosis before instituting anesthesia or surgery. [183]

How many healthy patients have this degree of abnormality in hematocrit level or white blood cell count? No such patient was found in either study among the 223 or 2,010 patients judged healthy by history (i.e., history indicated no need for tests). [76] [171] Table 23-13 provides the only other available data, which are limited. If we assume that 10 percent of all abnormalities are outside the "surgically acceptable" range [184] (see Table 23-13) , and if we apply the benefit-risk analysis described in the section on chest radiographs, we would conclude that either preoperative hematocrit or hemoglobin levels should be determined for all female surgical patients and for all male surgical patients more than 64 years of age who are undergoing type B or C surgical procedures. Red cell antigen screening would be warranted for all patients undergoing procedures involving possible blood loss of more than 2 U/70 kg body weight (type B and C surgical procedures). [185] [186] White blood cell counts appear to be rarely, if ever, justified for asymptomatic patients.

Blood Chemistries, Urinalysis, and Clotting Studies

What blood chemistries would have to be abnormal, and how abnormal would they have to be, to justify changing one's perioperative management? Abnormal hepatic or renal function may change the choice and dose of anesthetic or adjuvant drugs. Approximately 1 in 700 supposedly healthy patients actually harbors hepatitis, and 1 in 3 of

[a] Patients were asymptomatic.
[b] Five hundred twenty patients were examined, but no age distribution was presented.
[c] Abnormalities significant to perioperative management.
[d] Carmalt and coworkers found that 24.5% were new abnormalities; 2 patients had hemoglobin values of less than 8 g/dL, 17 had values of 8 to 10 g/dL, and 21 had values of 10 to 12 g/dL.

those patients will become jaundiced. [187] [188] However, our group found no asymptomatic patient who denied exposure to hepatitis who then became jaundiced after uneventful surgery [171] (Roizen MF, unpublished data for more than 11,500 patients in a prospective study of the "HealthQuiz," discussed later; Hsu J et al, unpublished data). These data suggest that either the screening history suffices or the incidence of asymptomatic hepatitis is decreasing.

Data from the National Veterans Affairs Surgical Risk Study [44] found that albumin level was an important predictor of perioperative morbidity and mortality in every surgical specialty. Therefore, one could argue for determining albumin levels, especially for all class C procedures.

Table 23-14 presents the available data regarding abnormalities found on screening blood chemistries. Unexpected abnormalities are reported for 2 to 10 percent of patients screened, and these abnormalities lead to many additional tests that usually (
80%) have no significance for the patient. In fact, as described in the section on laboratory tests as ineffective screening devices, if 20 chemistry tests were ordered for a healthy individual, there would be a 64 percent chance that results from at least 1 test would be abnormal (see Fig. 23-2 (Figure Not Available)). Unexpected abnormalities that are significant arise in 2 to 5 percent of patients studied. Of these abnormalities, approximately 70 percent are related to blood glucose [189] and blood urea nitrogen (BUN) levels. Note that the screen for diabetes may soon shift from random determinations of blood glucose levels to determination of the concentration of glycosylated hemoglobin (Hb A_{1c}) 2 hours after a glucose load or a meal. The 9 to 20 additional tests on the screening simultaneous multichannel analysis (SMA) of 12 to 20 variables lead to very few important discoveries affecting anesthesia. In fact, the falsepositive rate is so high (i.e., 96.5% for the test for calcium) that the value representing cost versus benefit for most of these tests (even when the tests are free) is negative, as is the

[e] Symptomatic or asymptomatic patients
[f] Pertains to all abnormalities for all electrolytes measured, not just K^{+}

value representing benefit versus risk. Examination of the data reported by Berwick [128] in Table 23-14 helps to clarify the difficulty of screening. More than 75 percent of the abnormalities (see the line for the Berwick study, "76,519" in Table 23-14) were not even outside the range that caused the laboratories at these health screening fairs to notify the patient or physician of an abnormal value (see line containing 86,006 in Table 23-14) , let alone be judged significant to the patient's health.

If a screening test for hepatitis is desired, because the incidence of hepatitis is 0.14 percent and/or because one wishes to avoid the potential legal problems of postanesthetic jaundice, only three tests seem justified: determination of serum glutamic-oxaloacetic transaminase (SGOT) or its successor aspartate aminotransferase (AST), blood glucose (or its successor, Hb A_{1c}), and BUN. Even then, BUN is indicated only for patients more than 65 years of age, and glucose (or Hb A_{1c}) is indicated only for individuals more than 75 years of age. In fact, if the data from our group on asymptomatic liver disease can be generalized, no blood chemistry tests are warranted for patients less than 65 years of age. Furthermore, because the antibody test for hepatitis C is useful after infection has occurred, the medicolegal risk posed by postanesthetic jaundice should be even less. [190]

Abnormalities are commonly found on urinalysis [78] [79] [80] [81] [87] [97] [98] [103] [116] [120] [121] [132] [166] [191] [192] (Table 23-15) (Apfelbaum JL et al, unpublished data). The quality of urinalysis results obtained by dipstick technique has been variable at best. [193] In addition, these abnormal results usually do not lead to beneficial changes in management. Most of the results that do lead to beneficial changes could have been obtained by history or determination of BUN and glucose (or Hb A_{1c}) levels, tests that are already recommended for all patients more than 65 and 75 years of age, respectively. Thus, urinalysis, although initially inexpensive, becomes an expensive test to justify on a benefit-cost or benefit-risk basis.

Although partial thromboplastin time (PTT) and prothrombin time (PT) are useful tests with which to screen patients who have a history of bleeding, their value as screening tests for asymptomatic patients has never been

shown [75] [76] [78] [80] [86] [91] [95] [117] [194] [195] [196] [197] [198] [199] [200] [201] [202] [203] (Table 23-16) . Virtually no asymptomatic patient in the literature has had unequivocal benefit from clotting function studies performed preoperatively (see Table 23-16). Most patients show symptoms or have a medication history suggesting the possible need for clotting function tests. Suchman and Mushlin [199] and Macpherson [200] reviewed the data, as we did, [56] and came to the same conclusion: preoperative clotting function testing for asymptomatic patients who have no risk factors for coagulopathy is incapable of predicting perioperative bleeding.

BT, bleeding time; PLT CNT, platelet count; PT, prothrombin time; PTT, partial thromboplastin time.

[a] Number in parentheses represents number of patients.
[b] An abnormal PTT was not more likely to predict hemorrhage than was a normal PTT and was not helpful in preoperative management.

Figure 23-4 (Figure Not Available) Procedure for determining whether coagulation tests are needed. PT, prothrombin time; PTT, partial thromboplastin time. *(Modified from Roizen and Hurd [201])*

No information is gained from either an abnormal or a normal result on clotting studies in low-risk patients. Figure 23-4 (Figure Not Available) presents an algorithm that can be used to segregate high-risk and low-risk patients. [201]

One patient deserves special comment: the patient taking aspirin or aspirin-containing compounds. Aspirin at a dose of 3 to 10 mg/kg of body weight per day does not

seem to pose a risk of bleeding. However, data are not available for 300 mg or more administered within 12 hours of surgery. Because the pharmacokinetics of aspirin changes when more than 2 g/70 kg is consumed per day, a patient should be evaluated if he or she has not discontinued aspirin consumption sufficiently early to ensure no appreciable level of acetylsalicylic acid in the blood for 24 hours before surgery. (This is the period acetylsalicylic acid would have to be absent for the generation of the approximately 50,000 new platelets/mm^3 needed for normal platelet aggregation.) The patient should also be evaluated if surgical hemostasis cannot be ensured, or if a regional procedure into a closed space is planned. Nonsteroidal anti-inflammatory drugs present similar problems. [202] (For further explanation of these situations, see the section in Chapter 25 regarding interruption of a drug regimen prior to surgery.)

Tests for HIV, Pregnancy, Hemoglobinopathies, Malignant Hyperthermia, Magnesium Deficiency, and Low Albumin Levels

Tests for HIV infection, pregnancy, and screening for hemoglobinopathy and malignant hyperthermia raise ethical questions that may require close attention to institutional policy and the immediate availability of counseling services. Moreover, all these tests have risks. The physician may therefore decide to limit testing to only "at-risk" populations (e.g., for pregnancy testing, only female patients who believe they may be pregnant). Magnesium (Mg) testing is a special concern.

Testing of asymptomatic patients for AIDS is not likely to be the most effective way of uncovering the disease. Of the more than 700,000 people in the United States who have had AIDS, fewer than 200 have not been gay, had sex with a prostitute or engaged in other "at-risk" sexual behavior, used intravenously administered drugs or shared needles, had a "needlestick," been cared for by a family member with AIDS, or received a blood transfusion after 1979. One program

Figure 23-5 Suggested procedure for screening patients at high risk of malignant hyperthermia.

screening for HIV in asymptomatic individuals was able to produce an "acceptably low false-positive rate" by diagnosing HIV infection only after one sample of blood produced positive results on three different tests and after the second sample of blood had been used for verification. [94] Thus, for pregnancy, hemoglobinopathies, and HIV infection, the history is still the best tool for identifying those who should be tested or those who are at risk of the condition.

In the past, no screening test existed for susceptibility to malignant hyperthermia (MHS) other than a personal or family history of the condition (Ch. 27) . Several tests have become available, but none uses genetic testing. Despite previous studies suggesting a single localization of this disorder to chromosome 19q, Levitt and colleagues [204] [205] observed evidence for significant genetic heterogeneity in MHS. Nevertheless, they found seven MHS families in which the identified genetic aberrations appear linked to chromosome 17q11.2-24. Because the gene encoding the adult muscle sodium-channel alpha-subunit (SCN4A) has also been localized to this region of the long arm of chromosome 17, this area may be the site of a primary defect in MHS. However, because the specific site cannot yet be identified, linkage analysis for MHS coupled with polymerase chain amplification may be used in the future to screen for MHS in high-risk patients.

It is still too early to predict the usefulness of these tests as a screening procedure for MHS or even for other genetic diseases such as diabetes. Other screening tests for MHS have not been reliable enough to use for any but "at-risk" individuals (e.g., children with a history of myopathies who are undergoing surgery for strabismus; patients having a family history of problems with anesthesia; or patients with a history of abnormally red appearance, thermoregulation, and reactions to minor stresses) (Fig. 23-5) (Ch. 27) .

Mg deficiency represents another special situation. Putatively it is much more common than other ion deficiencies, and Mg treatment has been advocated as extremely beneficial. [206] However, because no data appear to link preoperative treatment of Mg deficiency with benefit, screening with tests appears superfluous. Let us expand on this concept.

Hypomagnesemia is a prevalent laboratory finding in hospitalized patients (11-16%; Table 23-17) (Table Not Available) . The total serum level of Mg represents the protein-bound (physiologically inactive) Mg, as well as the ionized (physiologically active) Mg. Total serum Mg constitutes less than 1 percent of total body Mg, there being no constant ratio between the two values.

Fanning and colleagues [207] showed that intravenous administration of Mg for 4 days after coronary artery bypass grafting decreased the incidence and severity of atrial fibrillation. Specifically, 14 patients in the control group had 42 episodes of fibrillation, 2 of whom required cardioversion. By contrast, 7 patients in the Mg-treated group had 12 episodes of atrial fibrillation, and none required cardioversion. In a similar study, intraoperative administration of Mg after cardiopulmonary bypass decreased the frequency of postoperative ventricular arrhythmias (8 of 50 [16%] in the Mg-treated group versus 17 of 50 [34%] in the placebo-treated group, $P < .04$). [208]

Some investigators believe that serum Mg should be measured routinely in hospitalized patients because of the high prevalence of hypomagnesemia coupled with the difficulty of diagnosing hypomagnesemia on clinical grounds alone. [206] [209] One investigator argues that common sense dictates that nonessential surgery be deferred until Mg depletion has been corrected, again with no data to support such an assertion. [210] Neither Dr. Jo (personal communication) nor we could find any data indicating better outcome

TABLE 23-17 -- Prevalence of Hypomagnesemia Among Hospitalized Patients

(Not Available)

because of routine detection and correction of hypomagnesemia. The benefit of decreased frequency of cardiac dysrhythmias after cardiac surgery [207] [208] occurred with or without preoperative hypomagnesemia. If one is going to use Mg empirically, one probably should have a measure of renal function and should monitor Mg levels (or reflexes in the awake patient), but no data indicate that such levels should be routinely determined before surgery.

The Veterans Affairs cooperative studies found that albumin levels were an important predictor of outcome after surgery. [44] [186] Furthermore, changes in this level after enteral nutrition have been important predictors of perioperative outcome in malnourished or otherwise very sick patients (Ch. 25) . It may therefore be time to add this laboratory test for patients undergoing surgical class C procedures and for patients who have a physiologic age (a RealAge) of more than 85 years who are undergoing surgical class B procedures.

Even sophisticated laboratory tests have not been better in controlled trials than the history and physical examination in estimating the risk from a diagnosis. This lack of benefit from laboratory testing has applied to diagnoses as relatively amenable to laboratory diagnosis as the differential diagnosis of systolic murmurs [211] or assessment of nutritional status [212] or of cardiac or gastrointestinal disease. [60]

IMPLEMENTING ACCURACY AND EFFICIENCY IN PREOPERATIVE EVALUATION

The ability of preoperative evaluation of even healthy patients (ASA physical status I or II) to detect important symptoms and medical history makes its benefit greater than its risk. Furthermore, preoperative evaluation done in advance is ultimately cost-efficient, because it minimizes expensive delays on the day of surgery. (Table 23-18 shows the laboratory tests recommended for asymptomatic patients by various investigators and institutions.) In addition, such assessment could be used to limit the amount of testing to only that warranted by symptoms or risk grouping (Table 23-19) . The protocol described in Table 23-19 (and the algorithms derived from it, Figs. 23-4 (Figure Not Available) to 23-12) do have certain requirements, if the patient's preoperative condition is to be optimized. A careful history and physical examination must be performed. In addition, any condition indicating the existence of one of the disease entities presented in Table 23-19 must be searched for, and that condition must be specifically tested for in patients undergoing type B or C surgical procedures. This protocol clearly places the burden of accuracy on the history-taker. Furthermore, use of the protocol does require that a system be in place so that the physician performing the assessment views the test results and communicates the readiness of the patient for surgery, or the need for further testing/consultation, to the primary care physician, surgeon, and scheduling system. *This step places an additional burden on the preoperative assessor: he or she must determine what degree of consultation with the primary care physician and surgeon is necessary to judge optimal health for perioperative care.*

Two possible objections by the assessor come immediately to mind:

1. Why can't the primary care physician do the evaluation and send it to me?
2. It is a time-consuming process for which I receive no compensation.

In their simplest forms, the answers to those objections are:

1. The primary care physician is not specifically trained in preoperative assessment.
2. Ultimately, preoperative evaluation is very costeffective for the institution, the health-care payers, and the patients. It would be justifiable to compensate the anesthesiologist for preoperative assessment at the same rate as for OR time.

With regard to the *first objection*, although the primary care physician can render a patient's condition optimal for daily life, he or she does not have the anesthesiologist's

depth of understanding of the physiologic changes caused by surgery or the requirements that must be met to facilitate class B and C surgical procedures and to optimize perioperative outcome. One example is induction by the primary care physician of some degree of prerenal azotemia for the patient with congestive heart failure. Even though prerenal azotemia may make the patient more comfortable for the conditions of daily life, it would predispose the patient to hypovolemic disaster during surgery. Unfortunately, careful attention to optimizing of the perioperative condition is highly desirable, but it is just not compatible with the current state of knowledge and functioning of primary care physicians. Such education is more available and of better quality than in prior decades, [213] [214] [215] [216] [217] [218] [219] and many reports have highlighted the importance of this aspect of care. [9] [217] [219] Nevertheless, the training, knowledge, and ability of primary care physicians are still very deficient in this aspect of consultation.

In addition, the preoperative meeting of anesthesiologist and patient should serve other important functions: informing the patient about treatment options and educating the

[a] For minimally invasive procedures (type A, e.g., cataracts, diagnostic arthroscopy), no tests are indicated. For moderately invasive surgery (type B procedures, in which blood loss or hemodynamic changes are rare), clinical judgment is needed when selecting tests.
[b] Not all diseases and pertinent conditions are included in this table. Therefore, the physician should use judgment regarding patients having diseases and conditions that are not listed.

Figure 23-6 Evaluating cardiovascular risk for patients undergoing noncardiac surgery: the procedure for determining which cardiovascular laboratory tests are necessary. patient about anesthesia, perioperative care, and pain treatment in the hope of reducing anxiety and facilitating recovery. [5] At this time, neither of these functions can be performed adequately by most primary care physicians, and there is no one better trained to do so than anesthesiologists.

With regard to the *second objection,* it is cost-efficient for both the institution and the health-care provider to have the anesthesiologist perform preoperative assessments, *provided a system is set up to make the process cost-efficient.* In the OR, the anesthesia service earns revenue only when a patient is undergoing surgery. Thus, the goals of the hospital in producing a cost-efficient OR environment and the goals of the anesthesia department are closely aligned. Long turnover times, unused OR time, and delays in the OR schedule have many disadvantages. They waste resources of the anesthesia department, reduce the cost-efficiency of hospitals, impede teaching, frustrate surgeons, and decrease harmonious teamwork among health-care providers. Such inefficiencies make

Figure 23-7 Procedure for determining when pulmonary function tests are warranted.

Figure 23-8 Procedure for determining when a chest radiograph should be obtained.

the hospital, surgical center, or office-based surgical facility less competitive when fees are determined on the basis of capitated care (payment of fixed fees), a DRG, or an ambulatory care group (ACG). Therefore, it is optimal to facilitate smooth transfer of the patient into the OR. In addition, if preoperative assessment by an anesthesiologist were supplemented by automated information systems linking primary care provider, surgeon, OR, and perioperative care site, more cost-efficiencies could be obtained. For example, a history would not be obtained by the internist, surgeon, surgical resident, anesthesiologist, anesthesia resident, and three teams of nurses--all with imperfect information transfer among them, much duplication of laboratory services, and many delays. Thus, even though the rules for payment have changed under capitated care (Fig. 23-13) , it is cost-efficient for the operative environment to have a system by which preoperative assessment occurs sufficiently early to minimize OR delays, to reduce unwarranted testing, to facilitate relief of patient anxiety, and to speed recovery.

For the anesthesiologist, several effective systems could be instituted. Supported by consultation 1 week or more before surgery, or by some other second-opinion mechanisms encouraged by appropriate "CPT" codes (i.e., the "current procedural terminology" of the American Medical Association) and fee schedules, such systems *could* pay for themselves (Fig. 23-14) . Initiating such a system would not be easy, but

Figure 23-9 Procedure for soliciting the signs and symptoms of significant liver disease that warrant the performance of liver function tests.

Figure 23-10 Procedure for determining when blood urea nitrogen (BUN) or creatinine levels should be obtained.

failure to do so will make the anesthesiologist and the practice site less efficient and more costly, less marketable and desirable to patients, and a continuing source of frustration to surgeons, OR administrators, and the anesthesiologist.

Danger of Underordering Tests

Inadequate preoperative evaluation leads to the missing of potential problems or to delays in the OR schedule for at least 15 percent of even healthy (ASA I) patients.[24] In addition, trying to reduce testing without such a system of assessment in place may not be beneficial. Since 1979, physicians at three university practices were found to decrease the ordering of unwarranted tests almost 1.5 times as fast as they decreased the ordering of indicated tests (19.6 and 12.9%, respectively). This would be good *if* the benefit from decreasing unjustified tests outweighed the benefit of ordering the truly useful ones. However, the possible benefit from a justified test is probably more than 1.5 times the possible

Figure 23-11 Procedure for determining when blood glucose levels should be obtained.

Figure 23-12 Procedure for determining when hemoglobin levels or a hematocrit should be obtained.

benefit from not ordering an unjustified test, at least regarding preoperative tests. Therefore, the net changes that have occurred in preoperative test selection since 1979 may not be beneficial. One is forced to conclude that a better system for obtaining the warranted tests and for eliminating the unwarranted tests may be a necessary supplement to education and to standard endorsements for the reduction of costs and errors if selective application of laboratory tests is to be beneficial.[220] This process calls forth use of information systems and an evaluative clinic. The need for an information system and clinic to make the idea work is accentuated by data on the errors we make when selecting tests without the availability of an information system.

Errors Made by Physicians When Ordering Tests

Selecting tests when there are no information systems to help has one major problem: it is a difficult procedure for

Figure 23-13 Rules for reimbursement of health-care costs have changed. In the former system of fee-for-service care, the more services given the patient, the greater the reimbursement. The present system of capitated care greatly reduces that incentive, and less care becomes the reality. As a result, the health-care provider is actually providing less care for relatively more reimbursement. Furthermore, the health-care provider now assumes the risks created by a reduced level of health care for the patient.

physicians to complete successfully. *Even when physicians agree to use specific, agreed-on criteria based on history and physical examination to order tests selectively and thereby to reduce routine testing, they still make a surprising number of mistakes when ordering tests.* Approximately 30 to 40 percent of patients who *should* have certain tests (based on agreed-on criteria such as those in Table 23-19) do not receive such tests, and 20 to 40 percent of patients who should *not* have certain tests are nevertheless subjected to them. For instance, Blery and coworkers [91] examined 3,866 surgical patients in France. Even after medical personnel had been educated regarding which criteria indicated a need for which tests, 30 percent of the tests were ordered without need; another 22 percent of tests should have been ordered but were not. Thus, surgeons and anesthesiologists not only increased costs but also failed to obtain possibly valuable information.

These mistakes occur mainly because integrating the history, physical examination, and indications for laboratory tests is not an easy process. Even when criteria for testing have been previously agreed on by surgeons and anesthesiologists, the number of variables one must remember makes arriving at the correct conclusions a complex task. As an example, let us consider how many mistakes are made regarding one commonly used preoperative test, the chest radiograph.

Charpak et al [221] examined the value of preoperative screening chest radiographs for 3,849 patients. Surgeons and anesthesiologists agreed that any of the following findings on history or physical examination would warrant ordering of a chest radiograph: any lung or cardiovascular disease; any malignant disease; current smoking for patients older than 50 years of age; major surgical emergencies; immunodepression; or, for immigrants, absence of prior health examination. Surgeons made their decision regarding ordering of chest radiographs after seeing the patient. Even with this agreement on criteria, of 1,426 chest radiographs that should have been ordered for this group of 3,849 patients, 271 were ordered but not warranted, and 596 were not ordered but should have been. Although clinical judgment may account for some of these discrepancies, most of these lapses appear simply to be errors. If so many errors occurred for a single test, even more errors would be likely if patients were subjected to multiple testing.

Data from studies performed by our group confirm this rate of error. [220] We tested the hypothesis that for the period 1979 through 1988, physicians voluntarily and

substantially reduced the ordering of preoperative tests not justified by history and physical examination. Reviewing 2,093 medical records from every other year of that period (and studying 4 operations at each of 3 cities), we investigated the indications for, and the performance of, preoperative tests. During this period, the incidence of unwarranted laboratory tests obtained preoperatively decreased from 32.2 to 25.8 percent. This decrease was irregular and varied from operation to operation, from test to test, and from city to city.

Furthermore, an unexpected 12 percent decrease (92.9-80.9%) in the ordering of *indicated* preoperative tests also occurred. Overall, 66.9 percent of tests obtained preoperatively in 1979 were not warranted, decreasing to 60.1 percent in 1987. If the possible benefit of ordering only appropriate tests outweighed the possible harm of not ordering a needed test, the net result would still be a benefit to society. Unfortunately, however, the possible benefit of performing a needed test is probably more than twice the possible harm of performing an unnecessary test.

We conclude that the pressures to order tests more optimally and to do assessments more quickly have not been accompanied by changes in practice patterns that ultimately benefit the patient. In order for the net benefit to accrue to the patient, a better *information* system is needed for obtaining the truly necessary tests and for not ordering the unwarranted ones. On the other hand, punitive measures to reduce testing may save money from testing but impair health care. That may be the approach the Health Care Financing Administration is attempting, now requiring the use of diagnosis-related codes (International Classification of Diseases, ninth edition [ICD-9]) for reimbursement of testing.

Can physicians do better at preoperative evaluation than the 5- to 15-minute history-taking prior to induction of anesthesia for outpatient or "come-and-stay" patients (those to be admitted after surgery)? They can, and should, for their patients' sake and their own sake. The British have reached the same conclusion. [222] [223] A change in the system of obtaining patient histories and ordering tests has been advocated even for internists. [224] [225] [226] [227] [228] [229] [230] [231] [232] [233]

Just as the need for a more effective *theoretical* system of preoperative evaluation became evident, the study just described reinforced our belief that the actual *information* system used for ordering tests also needed to change, in order to improve the efficiency of the process.

INFORMATION MANAGEMENT IN PREOPERATIVE EVALUATION

Being unaware of previously occurring in-hospital and perioperative events can lead to perioperative disaster in a subsequent surgical procedure. For example, an unanticipated difficult airway or allergic reaction that occurred earlier but is not known can (and has) contributed to disasters in subsequent anesthesia care. Avoiding such disasters

Figure 23-14 Billing form used to report preoperative second opinion or consultation activities to payers.

would seem to be a solvable problem in an age of records, paper or otherwise. Yet anyone who has practiced in a large modern-day American hospital (university or community) knows that past charts are often not available. Even when the patient is seen in a surgeon's office or a perioperative clinic, the transfer of records and consent forms can be a weak link in the chain. Enter the information age and the promise of making the chain perfect.

Information Systems and Preoperative Evaluation

Because we currently practice in an environment called the "Information Age," how is it possible that we still have trouble obtaining the information we need? As our health- care institutions switch to electronically stored patient records, this problem should vanish. However, these institutions

and a variety of vendors that now offer "solutions" for automating the preoperative assessment frequently fail to provide operational solutions. These "turnkey" products are often isolated implementations of paper records. Such preoperative systems have not achieved wide acceptance. [234] [235] [236] [237] However, planned with the overall goals of the preoperative evaluation in mind, information systems can be used successfully to improve patient care and the efficiency of the overall system.

Such a system requires an accurate and complete database on the patient's current health status and past anesthesia and surgical experiences. The sources for these data may be varied and collected at disparate locations and times. The ideal database would include the history of the current surgical problem and past medical, social, and surgical histories. It would also include review of organ systems, current physical examinations and perioperative plans, and notes on discussions with the patient and significant others. This database can also be used when providing ancillary services such as laboratory tests and consultations. Once the perioperative plan has been formulated, a record can be clearly communicated to the patient, the surgeon, and the anesthesiologist's colleagues. Finally, by establishing an accurate baseline status, the information that has been acquired can be used to initiate quality assurance procedures. This section provides an introduction to the use of information systems and identifies important issues for the clinician who is considering implementing such a system.

Collection of Data

Traditionally, the physician obtained needed information by talking with the patient, scanning the available paper chart, calling other physicians, and collecting reports from laboratories or consultants. These data were then recorded in a note. The information was often incomplete at the time the note was written (missing laboratory data or uncompleted consultation). Thus, the note that may have needed to be updated often was not.

To standardize the format and to help the physician obtain important information, many facilities use forms that range from simple headings placed on a page to detailed checklists. As physician contact time has become more limited, ancillary personnel have been recruited to help acquire and assemble the required data. Patients are also being asked to spend time completing checklists or questionnaires that cover many points in their history. Compared with the current procedure, automation should be able to improve many of these processes. For example, the use of electronic information systems ("informatics") could reduce or eliminate the redundant entry of information into a record, a situation that frequently creates discrepancies in that record.

The expense of obtaining these histories increases because we often rely on professionals to obtain the routine history rather than focus on the details that are abnormal or important to the planned care. The process could be less expensive if patients completed the screening process themselves. There are many ways the patient could do this. When patients are given a clear reason for their input and a clear and simple format for answering questions, the patient-completed questionnaire can be an accurate and powerful tool. [6] [237]

One of the first systems used for this purpose was originally called the HealthQuiz. [*] Now called the HealthQuiz Plus 2, this system has evolved in a way that parallels many other trends in information management. Developed in 1987, the system consisted of a laptop device that had a simple liquid crystal display and three buttons: the patient answered "yes," "no," or "not sure" to health-related questions. The HealthQuiz proved to be a simple enough system, not unlike many of the small electronic games becoming popular at the time, and it was readily accepted by patients. Its program consisted of a branching algorithm made up of 254 items. The wording of each question was carefully prepared and validated so that consistent answers were given whether the patient responded to a human or to a computer or was later asked the same question again. The initial questions were standard health-history items pertinent to anesthesia care and were based on health-maintenance guidelines. [59] [66] Subsequently, a variety of questionnaires were developed for general medicine, pediatrics, and preventive health.

Although compact and easy to use, the HealthQuiz required the use of a dedicated unit for producing the questionnaire. The unit, which produced a written report, was usually located only in preoperative clinics. In 1993, the rapid expansion of the Internet into health care and even the patient's home prompted the development of a networked version of the system, the HealthQuiz Plus 2, which could be accessed from any computer by means of an Internet browser. This Internet process enables any physician or patient who has a computer to complete the questionnaire at a wide variety of locations and at a convenient time. This concept has been extended, and now the patient can also complete the questionnaire from any touch-tone phone. Furthermore, the system allows for on-line viewing of the report and the ability to hone in on questions, suggested laboratory tests, or risk assessments to examine the underlying questions, answers, and logic. The data are also available at the point of care and are easily transferred into other medical information systems. For example, justification of laboratory tests by the assignment of diagnosis-related codes (ICD-9) is produced for each test suggested, and this information can be given to the laboratory to aid in reimbursement (Figs. 23-15 and 23-16) . Such procedures supersede the old but still often used paper-and-pencil check-off lists (Figs. 23-17 and 23-18) .

Although the value of the preoperative evaluation has been discussed, efforts to improve efficiency cause anesthesiologists to examine whether some patients may

still be just as effectively assessed immediately before surgery. To be

* Dr. Roizen developed this video preoperative health questionnaire at the University of Chicago to help ameliorate the problem of inefficient preoperative assessments and test selection methods. Consequently, the University of Chicago owns the rights to commercialize the product and has transferred the rights to the HealthQuiz to University Community Health Care, Inc., which developed it further and provided a telephone version. If this product is successful, the Department of Anesthesia and Critical Care at the University of Chicago may benefit financially. Both the University of Chicago and Johns Hopkins University in Baltimore may also benefit from commercialization of this technology and the applications described herein (see website www.Healthquiz.com for further explanations).

Figure 23-15 The HealthQuiz Plus 2 computer device uses the patient's answers to its questionnaire to produce this summary of the patient's health history and suggested laboratory tests, annotated with International Classification of Diseases (ICD-9) codes. BMI, body mass index; BP, blood pressure; BUN, blood urea nitrogen; CREAT, creatinine; CV, cardiovascular; DOB, date of birth; DOE, dyspnea on exertion; ECG, electrocardiogram; GI, gastrointestinal; HQASA 1-5; HR, heart rate; HT, height; Hx, history; IVDA, intravenous drug abuse; PSH, past surgical history; PULM, pulmonary; SOB, shortness of breath; S/P, status post; WT, weight.

successful, this plan should accomplish three key goals: (1) gain information about the planned procedure; (2) determine the patient's current health status; and (3) optimally allow for the patient to obtain information about the planned anesthetic before surgery. Surgical stress scales are being developed to stratify the need for evaluation and testing of patients. Tools such as the patient-completed health history, along with accessibility to previous information on perioperative care and other available data, can provide the second leg of the triad with minimal provider resources yet they can identify patients who need to come to a clinic for additional evaluation. Finally, on-line educational resources, perhaps in association with a brief call from the anesthesiologist, can complete the process of discussing the anesthesia plan with the patient. This plan could allow patients to present on the day of surgery yet minimize the potential for the discovery of unplanned conditions that would delay care, disrupt the OR schedule, or, worse, lead to adverse events.

Physician, hospital, and health-system methods for data gathering that include radiology reports, laboratory test reports, and prior operative notes and anesthetic records are just now becoming more widespread. They can use not only standard computer terminals but also handheld devices. These systems are able to decrease redundant data entry by communicating with other data sources, such as hospital billing systems (for demographic data), patient-completed questionnaires, and data from other providers. Such processes also allow more than one provider to record information for the evaluation and to communicate that information effectively to the anesthesiologist at different times or locations.

The provider systems are still evolving. Ease of use and ease of data entry are very important for acceptance by physicians, who seem to have a short tolerance time for clumsy system performance. Moreover, because typing on a computer can interfere with the physician-patient interaction,

Figure 23-16 Example of the summary sheet that gives the physician the rationale for each of the tests suggested for the patient. This sheet is generated by the HealthQuiz computer device, which uses the patient's answers to the HealthQuiz questionnaire, plus 480 algorithms programmed into the device, to make its decisions; it also provides International Classification of Diseases, ninth edition (ICD-9) codes for each choice.

a conscious effort must be made to move away from the computer and to address the patient directly, so that he or she does not "feel like a number."

Laboratory systems, pharmacies, and administrative billing systems have led the way in providing on-line data systems. [238] These data may be integrated into the collection process if suitable computer interfaces can be constructed. More problematic is the incorporation of notes or other nondigital data from outside sources. Unfortunately, manual transcription of these notes cannot capture certain kinds of data such as that on ECGs, or signatures. Although information systems are being adapted to transfer image-based data--perhaps by scanners or fax machines--at present there are few standard ways to facilitate exchange of these kinds of data.

A related problem is obtaining historical information and the past chart. Most institutions have large volumes of information on paper records that are available to varying degrees. As any system is developed and implemented, allowances must be made for the period in which the electronic and paper systems exist side by side until the paper records have been incorporated into the electronic system.

Collation of Data: Perioperative Database

Databases consist of an "engine" and an interface. The engine is the computer program that actually stores and retrieves information. Many commercial engines such as Dbase, Foxpro, Sybase, Access, and Filemaker, as well as proprietary programs written by vendors, are available. Although a full discussion of the different engines is beyond the scope of this chapter, several questions need to be addressed when evaluating any database system.

First, these systems range from intensely complex, requiring a full-time programmer available for maintenance and modifications, to relatively user-friendly, perhaps maintainable by a physician who has some background in database management. When selecting a system, the potential

Figure 23-17 Sample checklist for determining which preoperative laboratory tests should be obtained. CPK, creatine phosphokinase; ECG, electrocardiogram; HCT, hematocrit; Hgb, hemoglobin; PT, prothrombin time; PTT, partial thromboplastin time; SIADH, syndrome of inappropriate antidiuretic hormone secretion; SMA 6 and SMA 12, simultaneous multichannel analyses of 6 and 12 blood components, respectively; WBC, white blood cells.

buyer must consider the resources necessary for maintenance. Second, these systems vary in their ability to exchange information with other database systems, such as a hospital-based information system. We believe that the ease of exchange, both now and in the future, should be considered in the selection of a system. Third, the hardware that implements the system also warrants some consideration, although to a lesser degree than the previous two criteria. Today, processor speed and storage on desktop systems are making the selection of hardware a less critical issue than before. Fourth and finally, thoughtful design of the interface system is very important, because this feature determines the everyday ease and usefulness of the system. Forty-five percent of medical information systems that are installed are not successful, even though they are technologically sound. Many of these failures arise from nonacceptance by users.

Clinicians want an easy way to specify how they move information in and out of the system (the interface) and to be able to modify that interface without being charged for each change in format of the report. Programs such as Filemaker and Access include so-called "drag-and-drop" designs that allow the user to create new input and report forms easily. Other systems may require programming assistance or, in the case of a proprietary system, a more formal process with the vendor, in order to change the system. With the rapid changes in health care, any system will need to be improved and changed on a regular basis in order to obtain maximum benefit from the system.

The hardware systems that run these programs have become more affordable and accessible. Again, a detailed discussion of specific hardware is beyond our scope, but some broad issues should be addressed. Many of these systems can run on personal computers. The clinical environment, however, is much more demanding than the office environment. The physician working in an office can tolerate a certain amount of instability and downtime on a computer. In a clinical environment, however, these conditions cannot be allowed without considerable consequences. For example, if a paper record is unavailable for one or two cases, the cases may be delayed 20 minutes. If the server or network is unavailable, 15 ORs will be delayed for 20 minutes. Clinical systems should have adequate back-up so that they

can meet the clinical demands of being available 24 hours a day. The cost of having adequate back-up and supporting personnel must be included in any planned installation. Maintenance

costs for information systems can be as high as 70 percent of the total system's cost over the life-span of the system. [239]

Integration of Information

If an electronic information system only collects information and duplicates the current paper system, the cost-benefit advantage is likely to be marginal. Furthermore, it is highly unlikely that merely automating the collection of data will produce significant time savings. The benefits become clear when data are analyzed and disseminated.

The first benefit concerns the reporting of data to facilitate evaluation, discussion, and subsequent care of the patient. By necessity, the paper record had to report data in the order recorded. Reexamination of the paper report may show that simple electronic reformatting of the displayed information, bringing key points to the top and emphasizing them, would benefit the person receiving the report. If the reports are available on-line, they no longer need a linear presentation at all. Only the key points may be initially presented, with additional details available through a mechanism that allows the user to select a statement or fact on the screen and to obtain additional details or information.

The computer can also help the physician clinically. It can provide reference material on unfamiliar conditions or drugs--sometimes even automatically, as in the case of warnings about possible drug interactions. In addition, when an institution wants to guide and track use of its resources, the computer can suggest preferred clinical pathways. The system may actually do an initial analysis of the data, based on algorithms, to assist in clinical decision-making. The ASA and other standard-setting organizations, including the state of Maine, recognize the importance of clinical judgment and the interaction between patient and physician (Fig. 23-19) (Figure Not Available) . An example of this assistance to the clinician is the HealthQuiz Plus 2 program, which not only collects patient-provided information, but also applies algorithms that include guidelines, facts about the performance of a variety of tests, and the prevalence of disease, based on the patient's information. The program then provides an initial assessment of risk and suggests appropriate laboratory tests. (All these processes facilitate reimbursement for test ordering.) The tests guide the physician in the assessment of the overall clinical situation and in the creation of a care plan. This system

Figure 23-18 Sample patient questionnaire for determining which preoperative laboratory tests should be obtained.

has been shown to reduce the ordering of tests without overlooking those that are medically warranted. Moreover, such systems have the advantages of always posing a comprehensive set of questions to the patient and of not forcing the clinician to compromise comprehensiveness because of time constraints. Beers and colleagues [240] showed that such a system did a better job of obtaining accurate and complete patient histories than time-pressed clinicians. Computer-assisted analysis of data will expand as we develop ways for computers to use all the data they have accumulated.

Research can be another opportunity for benefit. [241] [242] [243] [244] [245] [246] [247] However, as an initial warning, we emphasize that these systems build large data sets rapidly, and the temptation to search the data for a correlation is both strong and misguided. Correlations found in this manner are often misleading and, only if supported by logic, may at best provide the basis for asking more formal questions. Pursuit of these questions, in a prospective fashion, can be rewarding. If the interface is readily flexible, both the input and the analysis can be modified to address specific issues. In the future, the ability to connect the preoperative data with outcomes captured electronically will only increase the usefulness of these databases as tools.

Through improved coding and billing, the use of preoperative databases has been shown to improve economies and cost recovery. [26] [27] [247] These improvements in cost-recovery mechanisms, along with the improvements in laboratory utilization and reimbursement for medically indicated ICD-9-coded test ordering, may justify the cost of implementing a system in the context of a preoperative clinic (see later).

Dissemination of Information

One of the main reasons for instituting an electronic record is to ensure availability of the collected and analyzed data on the day of surgery. At one institution, as many as 20 percent of manually completed forms were being lost in the process. This loss would happen most frequently when either the date or location of surgery was changed after the preoperative visit. Many practitioners also find themselves working at multiple sites, either within the same institution, at different surgeons' offices or ambulatory care centers, or across the city or even across state lines. The ability to review information for any patient at any site the night before surgery allows the anesthesiologist to better plan and prepare

for the next day's cases, and to call the patient, with substantial knowledge about that patient. This process enhances both patient care and efficiency of the ORs.

The information has additional uses. Billing can be based on information about the planned procedure from the preoperative visit, a circumstance that enhances proper reimbursement. Other institutional forms that have redundant information, such as check-in sheets for the morning of surgery, can be replaced or eliminated, and this also increases OR efficiency.

Institutions will vary in the frequency with which patients return, but having the basic information for a patient from a previous procedure can be timesaving for subsequent elective operations. It can even be lifesaving in the event of an urgent procedure for which old records are unavailable and the patient cannot provide a history.

Every discussion of information systems should consider security and confidentiality. The same access that is necessary for efficient dissemination of information can have very negative effects on patient trust and a significant legal impact if improperly used. It is crucial that any system have both controlled access and accurate logging of use to minimize the opportunity for inappropriate use and to identify abuse. Users of the system must be informed of the significant and strictly applied penalties for improper use of the records. Additional protection of patient data is being provided by rapidly evolving legislation and frequent advances in technology, such as encryption. This area requires expert assistance, both technical and legal, that should be obtained by anyone who is implementing an information system containing patient data.

Improving Patient Satisfaction With Preoperative Evaluation

We have used our information system to increase patient satisfaction with preoperative evaluation in several ways (Foss JF et al, in preparation). We found that the most important factor in decreasing patient satisfaction was delay in

Figure 23-19 (Figure Not Available) Two standards published by the American Society of Anesthesiologists (ASA) in the *ASA Directory of Members 1994.* (A) Statement on routine preoperative laboratory and diagnostic screening. The routine use of laboratory or diagnostic screening tests is not an essential part of the preanesthetic evaluation of patients. (B) Basic standards for preanesthesia care. The history, physical examination, and chart review are essential when obtaining tests as part of preanesthesia care. *(From American Society of Anesthesiologists [282])*

seeing a physician. Therefore, we use our information system to decrease this time interval.

Our system logs the arrival time of the patient at the clinic. After the patient has completed the self-administered questionnaire on health matters, the computer system uses those answers to determine the risk status of that patient, categorized as HealthQuiz ASA status 1 through 5. A "triage nurse" then uses that risk status, definitions of the three levels of surgery (minimally invasive surgery, surgery of moderate intensity, or major surgery), and the functional age of the patient (i.e., *physiologic,* not chronologic, age [RealAge]) to determine what level of visit with the anesthesiologist is required. A comprehensive visit takes 20 minutes or more and assesses the patient who has a HealthQuiz ASA status of 1.75 or higher, *or* is undergoing major surgery, *or* has a RealAge of more than 65 years. The next category, the visit of intermediate intensity, takes 15 to 25 minutes. These patients have a HealthQuiz ASA status of 1.5 to 2, *or* are undergoing type B surgery, *or* have a RealAge of 61 to 65 years. Finally, the "expedited visit" takes 5 to 10 minutes and evaluates the patient who has a HealthQuiz ASA status of 1.74 or less, *and* is undergoing minimally invasive surgery, *and* has a RealAge of less than 61 years.

Once the appropriate level of visit has been determined, the patient is made ready to see the anesthesiologist. He or she is placed in an examination room and is dressed from

the waist up in a hospital gown. Blood pressure, heart rate, height, and weight are recorded, and a self-entered history is completed by the patient.

The patient's status is entered into the computer system, and the times to each room are tracked on the local area networked computer system. A red light signals when an "expedited patient" is ready to be seen. The anesthesiologist often excuses himself or herself from the comprehensive-visit patient and sees the expedited patient as soon as possible. (Comprehensive-visit patients seem not to object to the interruption, because they understand that they require, and will receive, extra physician time.) The total time for patients is not reduced, but the delay until the patient first sees the physician is decreased.

Another way we use our informatics system to improve patient satisfaction is to ask patients to complete another self-administered questionnaire after surgery. The questionnaire, which is given by phone or, if in-hospital, by computer or paper and pencil, assesses the patient's satisfaction with the anesthesia service's performance and pain therapy. Feedback for such results has improved performance of the physicians in satisfying patients' pain-relief requirements.

Thus, we use an informatics system to increase patient satisfaction directly, by shortening the time before the patient sees a physician, and by improving pain therapy. We also believe, however, that many other uses of informatics increase patient satisfaction indirectly. These uses fall broadly into the category of patient education. For example, in this stillexperimental role, our information system helps us to learn which patients desire video presentations about their anesthesia and surgery, which we are then able to provide.

Information systems are not a replacement for good care, nor is it likely that they will decrease the time spent with patients. If carefully designed and implemented, information systems can enhance the acquisition and management of data, so that physicians can spend more of the time they do have with patients attending to their care. Although such systems can decrease the risks of caring for a patient by providing a complete working database, they are also capable of introducing new risks regarding confidentiality of data and dependence on availability of the system. No matter how much automation, education, or informatics you decide to employ, the decision most important to success is to marshal the resources and consensus of department members and users (surgeons, obstetricians, radiologists, administrators) to compel such a considerable undertaking.

GAINING THE RESOURCES AND CONSENSUS TO INITIATE AND MAINTAIN AN ANESTHESIA PREOPERATIVE EVALUATION CLINIC

The anesthesiologist is the specialist most knowledgeable in evaluating and managing operative medical complexities as they relate to anesthesia and surgery. "The assessment of, consultation for and preparation of patients for anesthesia," is contained within the American Board of Anesthesiology's definition of the practice of anesthesiology in its *Booklet of Information* (Raleigh, NC, American Board of Anesthesiology, 1996, p 2). This assessment of the patient begins with the preoperative evaluation.

As changes in the health-care system decrease reimbursement and the length of stay in the hospital, more and more surgical patients are entering the hospital on an outpatient basis or as same-day admissions. [248] [249] This trend is expected to increase and reflects not only a national and even international cost-conscious environment but also the expanding market for managed care.

Same-day admissions present the anesthesiologist with a formidable challenge from both an organizational and a clinical perspective. The amount of time available to evaluate even medically complex patients has decreased. Providing quality, cost-effective preparation of patients before surgery is a central issue in the optimal perioperative management of the patient. This requirement and the consequent need to redefine and expand the traditional practice of anesthesia, especially outside the OR, have been accepted as necessary among anesthesiologists in both academic and community practices. [250] [251] [252]

The preoperative evaluation is often the first encounter a patient has with anesthesia and health-system-based or hospital-based services. Examination facilities, personalized services, and organizational efficiency during the evaluation often influence a patient's perception of the quality of health care at that institution. As mentioned, we have found that the rapidity with which a physician sees the patient is *the* most important factor in determining patient satisfaction with the preoperative process (Foss JF et al, in preparation). Facilitation of this process by an electronic medical record, coupled with "time-stamped" computer records, is discussed in the previous section.

The establishment of an anesthesia preoperative evaluation clinic (APEC) [25] [26] [253] [254] [255] [256] [257] [258] has become an important and formal process over the past several years at many private and academic institutions. A centralized APEC is a positive investment for the anesthesia group and the hospital, because it becomes a recognized center for decreasing perioperative costs, improving the efficiency of clinical services, implementing clinical pathways that educate and increase market share, and increasing patient and surgeon satisfaction with perioperative services.

Developmental and Organizational Changes

The goal of the APEC is to provide a comprehensive anesthesia service for physicians and their presurgical patients. One centralized location provides all anesthesia consultations, physical examinations, laboratory and ECG services, educational resources, and hospital registrations and insurance authorizations. The objective is effectiveness, efficiency, and equality of care for all patients. Modifying the existing clinical practice in order to provide cost-effective preoperative evaluation is within the ability of each anesthesiologist and can be approached from a variety of methods, educational tools, and uses of data (Table 23-20) .

The APEC may not be suitable in its entirety for all academic departments or private individuals and groups that administer anesthesia. However, many of the concepts and methods described can be adapted to smaller centers and to

TABLE 23-20 -- Key Areas to Consider in Promoting Cost-Effective Preoperative Preparation

1. Physician education and modification of physician practice (e.g., learn the cost of each diagnostic test ordered preoperatively, plan length of stay with pain therapy practitioners)
2. Practice guidelines
3. Clinical pathways (requires interdepartmental teamwork)
4. Information sharing (e.g., in areas of evaluative protocols and avoiding duplication of services)
5. Economic analysis (e.g., cost-identification, effectiveness, or cost-benefit studies)
6. Medical resource management (e.g., in the efficiency and effectiveness of the preoperative process)
7. Education about, and reassessment of, perioperative satisfaction and plans for perioperative pain therapy
8. Outcomes measurement and management

the private sector. Certain advantages do accrue when an APEC is established, but implementation may require stages of change and growth. (We advocate taking incremental steps up the organizational ladder to efficiency: improvement of preoperative testing, implementation of education about perioperative care, and then implementation of education about expectations on pain therapy.) Our collective experience is that instituting such a clinic requires a commitment from more than just the anesthesia department. Without the support of surgical services and without administrative, financial, and emotional commitment, the APEC will not meet its full potential and may even incur extra costs rather than savings. However, with such commitment, the health system will increase the quality of its care and will decrease costs. Nevertheless, logical as it is, such commitment will not come easily.

The development of the APEC represents a collaboration between hospital administration and the departments of anesthesia, surgery, gynecology, and nursing. Implementation of a successful APEC requires the commitment of money and time, defined organizational goals, changes in support resources, intradepartmental teamwork, and determination of the hospital and several departments to make effective changes in the existing operational procedures. Table 23-21 shows the operational goals for an APEC.

A timeline for the development of an APEC should be defined for hospital administration in a business plan. The plan would clearly describe not only reasonable and sustainable goals but also the financial, political, and emotional support necessary for success of the APEC. The plan would also include analysis of the existing method of providing preoperative evaluation, recommended changes, developmental strategies, descriptions of APEC management and organizational imperatives, and an evaluation of financial risk.

The development of an APEC begins with a departmental commitment to improve the current system. Even the simplest of changes can enhance the quality of patient care. For example, having a patient complete an anesthesia medical questionnaire at the surgeon's office and then having that information transmitted to the

anesthesiologist for review several days before surgery would greatly increase the anesthesiologist's awareness of the patient's medical status. The patient questionnaire could be completed by phone after the surgeon's nurse has entered some basic demographic data about the patient into the automated phone system (see previous section on informatics). The information could then be made available to the surgeon, OR, and anesthesiologists the day before the anticipated surgery. This practice could reduce the delays and cancellations that occur when unexpected medical problems are present or unresolved at the scheduled time of surgery.

Necessity for Teamwork

The APEC is an integrated partnership having visible alliances with the departments of anesthesia and nursing, often surgery and obstetrics, but always the hospital or health-system administration. Frequently, the existing system of preoperative assessment is beleaguered by the need for change in many of the time-honored traditions, structures, and processes.

Figure 23-20 shows the fundamental goals the APEC strives to accomplish. These goals recognize and encourage clinical responsibility in the portioning of services and, most important, in the sharing of financial costs and savings in the APEC enterprise; that is, because the department that bears the cost of making the APEC work is not always the department that enjoys the subsequent savings, transfers of funds are necessary to make the system really work fairly for all

TABLE 23-21 -- Operational Goals for an Anesthesia Preoperative Evaluation Clinic

1. To improve the patient's perception of the preoperative evaluation experience by increasing personalized patient care, comfort, and convenience.
2. To provide a centralized site for preoperative evaluation.
3. To institute an anesthesia scheduling system for timely patient access and flow.
4. To ensure the presence of an anesthesiologist on site when patients are present.
5. To appoint a medical director of the APEC to coordinate all activities.
6. To ensure the availability of medical records and surgical notes at the time of the preoperative evaluation.
7. To decrease logistical shuffling of patients to multiple hospital service areas.
8. To integrate and coordinate services through on-site facilities for admitting/registration, insurance authorization, laboratory tests, and electrocardiographic studies.
9. To improve the education of patients and families about the elements of their surgical procedure and the proposed anesthesia care, including postoperative pain-control options.
10. To educate patients about what to expect regarding postoperative feeding and discharge needs.
11. To ensure and coordinate cost-effective ordering of preoperative laboratory and diagnostic studies.
12. To provide an anesthesia medical consultation service for evaluation of medically complex inpatients and outpatients.
13. To decrease the number of cancellations and delays in the operative procedures on the day of surgery.
14. To enlist the skills of a nurse practitioner to assist in preoperative evaluations and patient/family education.
15. To develop protocols, policies, and clinical pathways.
16. To perform quality assurance reviews.
17. To maximize efficiency in operating room function and turnover time by coordinating all preoperative information at one location, the APEC.
18. To enhance patient and surgeon satisfaction.

APEC, anesthesia preoperative evaluation clinic

Figure 23-20 The anesthesia preoperative evaluation clinic is a constructive partnership working toward the achievement of common goals. The sharing of resources and budgetary costs is apportioned.

concerned. These transfers, plus agreement on the incentives and goals, should be considered *before* institution of the clinic.

To encourage the referral of patients to the APEC by surgeons, anesthesiologists should identify the clinical, and perhaps marketing, advantages. Interviewing surgeons regarding their concerns and problems with preoperative assessment helps to identify the changes that will be necessary. Likewise, administrators should be interviewed regarding their desires for efficiency of patient care, for increased patient education and satisfaction, and for marketing advantages. Such a process marks the anesthesiologist as an active partner and a resource for improving perioperative care.

In addition to the primary mandate of patient safety, our surgical colleagues are also concerned with avoiding cancellations and OR delays, and in reducing costs and improving patient satisfaction through education, in order to facilitate marketing. To enhance the anesthesiologist's commitment to the APEC and to increase the patient referral base, an "informal assurance" may be given that if the patient is deemed appropriate and remains medically stable, the patient's care will proceed to surgery without cancellation or delay. This process requires that the entire anesthesia group support the APEC program and protocols, and it means that not all physicians can give consultation in the APEC. It also means that this position requires an experienced clinician.

Economic Concerns and Benefits of Developing a Clinic

What are the costs and benefits of the APEC, and who ultimately supports the APEC financially? This last question is pertinent because the costs of an APEC are borne by one group, but the benefits accrue to another. One of the basic principles of economic analysis of a new venture is that comparison and choices must be made between the existing use of resources and the proposed alternative. An economic clinical analysis should evaluate both the cost and the outcome when comparing all the variables that would pertain to changing of the existing manner of preoperative assessment to that of an APEC.

Any financial support given to an APEC by a hospital would be based on price, quality, and value. Therefore, a cost analysis of the current system of preoperative evaluation would describe the problems, effectiveness, and cost of the traditional system and the subsequent surgical effectiveness of the new system. This document is more effective if it is comprehensive and focuses on opportunities for improvement. It could be supported by recent publications demonstrating cost-effectiveness and improved outcomes when an APEC has been established. An APEC that offers no improvement in outcome and an increase in cost is unsuitable and economically detrimental to the hospital or health system, as well as to the anesthesia department.

The strategic alliance and partnership with hospital/ health-system administration and the departments of nursing and surgery (obstetrics, gynecology, and radiology) toward the common goals of improvement in quality, cost reductions, and reduced length of stay through educational programs require that the financial support and gains of the APEC be delegated responsibly and fairly. For example, the facility and professional staff and the maintenance, equipment, registration, and phlebotomy personnel associated with an APEC would incur cost to the hospital/healthsystem administration. Nursing and educational resources would be supported through the department of nursing or anesthesia cost center. Similarly, benefits from reductions in length of stay and reduced OR times and cancellations should be shared among the parties.

The APEC staff can be cross-trained to provide services to other areas of the OR during periods of reduced patient volume. This sharing of resources would decrease APEC costs and increase APEC profits. An anesthesiologist would serve as medical director of the APEC. Financial support for the APEC would come from both the department of anesthesia and the hospital/health-system administration, because the APEC is a hospital-centered partnership. Similarly, in providing resources for the APEC, profits recovered from decreased costs elsewhere and increased market share should be shared among the departments, including surgery.

TABLE 23-22 -- Outline of a Business Plan for an Anesthesia Preoperative Evaluation Clinic

I. **Executive summary** (one-paragraph summary of the APEC program)

II. **Description** of an APEC
Objective or mission of the APEC (Fig. 23-20)
Names of the proposed APEC medical director, department chair
Location within the hospital designated for the APEC (define an area, even if currently occupied)
The development stage (is there an existing preoperative program?)
The services of an APEC (operational goals, Table 23-21)
Anesthesiology specialty information (i.e., anesthesiologists are the experts in operating room medicine and preoperative evaluation)

III. Analysis of general factors affecting **viability** of the APEC
Volume and medical condition of preoperative patients (present a graph for past years)
Anticipated growth trends
Vulnerability to economic factors (e.g., fee-for-service is decreasing, managed care is increasing, and hospitals need to decrease costs)
Technologic factors (e.g., anesthesia and surgical procedures are becoming increasingly complex)
Regulatory issues (the APEC conforms to all local, state, and federal policies)
Financial considerations

IV. Definition of **target markets**
All outpatient and same-day admissions (i.e., increased smooth flow of the healthy patient through the health-care system and educational processes, often starting in the surgical office)
Medically complex patients undergoing anesthesia and surgery

V. Discussion of factors relating to **competition**
Competitive position of the APEC (the anesthesiologist is the operating room and preoperative medicine expert)
Barriers to entry (primary care physicians/consultants believe they have sufficient specialty knowledge to clear patients for anesthesia and surgery)
Future competition (see earlier)

VI. Description of effective **marketing strategies**
Increased visibility, which increases viability of the APEC
Use of hospital/health-system news media to explain who anesthesiologists are and what they do
Formation of strategic partnerships with the departments of nursing, surgery, and gynecology, and with the hospital/health-system administration
Informal assurance that cases will be facilitated by anesthesia if seen in the APEC
Presentations at surgical, medical, gynecologic, pediatric, and administrative grand rounds and conferences

VII. Description of **operational aspects** of the APEC
Facilities (e.g., examination rooms, phlebotomy/ECG room)
Equipment and supplies
Variable labor requirements (e.g., nurse practitioner, anesthesiologist)
Daily anticipated operations and flow
Quality assurance and utilization review (Table 23-24)
Management information systems

VIII. Description of **management and organization** of the APEC
Clinical and administrative director
Inclusion of the department of nursing, and hospital administration
Organization management (presented in a flow chart)

IX. Description of the **developmental goals** of the APEC
Short-term goals (changes in clinical practice)
Long-term goals (e.g., renovation of facilities)
Time line (demonstrates a developmental plan)
Growth strategy (projection of 6-month, 1-year, and 5-year goals)
Evaluation of risk (as long as patients have surgical needs, risk is minimal)

X. Discussion of **financial matters**
Income statement (consider a facility fee, anesthesia medical consultation charge, projected hospital/health-system cost savings, and market share enrichment)
Variable expenditures (i.e., APEC personnel and resources: 90% of expenditures, facility housekeeping and supplies)
Balance sheet

APEC, anesthesia preoperative evaluation clinic

Development of an APEC and financial commitment in an era of cost containment require a business plan to secure support of the hospital or health-system administration. This plan should show an overall cost reduction that should be shared, because incentives determine the success of the process. Table 23-22 suggests the sequential elements of an APEC business plan.

Strategic Need to Market the Clinic

The concept of public relations and marketing of the APEC may be unfamiliar to the anesthesiologist. Increased visibility of the anesthesiologist in an APEC increases awareness of the clinical expertise of the anesthesiologist and his or her role in developing clinical pathways and pain therapy that decrease the patient's length of stay. For example, at one of our institutions, preoperative evaluation and postoperative pain-therapy groups are linked (i.e., provided by the same team of physicians, a subgroup of a department) in order to facilitate patient education and rapid discharge. The result has been superior satisfaction on the part of patients and other health-care providers.

Hospital/health-system publications, presentations at medical, surgical, and gynecologic grand rounds (and administrative grand rounds, if such exist at one's institution), and personal communication with physicians all increase the awareness of surgeons, hospitals, and health systems regarding

TABLE 23-23 -- Facilities of the Anesthesia Preoperative Evaluation Clinic at Stanford University Hospital and the University of Chicago [a]

The APEC at Stanford University consists of the following facilities (information for the University of Chicago is shown in brackets):

1. Five combination office and examination rooms [10]
2. A patient and family education room (preoperative teaching) [1]
3. A patient-centered media and video room [0]
4. A phlebotomy and electrocardiography room [8 are set up for this]
5. An on-site office for the APEC medical director [1]

6. A registration and reception area [1]
7. On-site restroom facilities [2]
8. A large, comfortable patient lounge [1]
9. An area for admitting and financial services [yes]
10. Approximately 2,200 square feet for facilities [2,600]
11. Conference room and shared chart and computer support room [University of Chicago only]

APEC, anesthesia preoperative evaluation clinic

[a] All areas are accessible to wheelchairs.

the direct influence of the APEC and anesthesiologist on cost-effective preoperative patient management. Many hospitals have an office of planning and development or a media center that can participate in marketing and educational strategies that would promote the APEC, its policies, and its educational programs.

Renovation of Facilities

The centralization and modernization of preoperative evaluation procedures represented by an APEC are long-term investments in the proper facilities, and they benefit the patient, anesthesia group, and hospital. Focusing all services into one area produces a center that is visible and efficient. Table 23-23 shows the facilities that constitute the APEC at Stanford University Hospital and at the University of Chicago.

Daily Operations and Procedures

The daily operations of an APEC vary according to patient volume, severity of the patient's medical conditions, availability of the facility, and employee resources. However, we are able to suggest a general operational structure that represents several APECs currently in existence.

A full-time APEC facility serves 40 to 60 patients a day. The full-time APEC requires availability of assessment from 8 AM to 6 PM Monday through Friday. The average time needed from check-in to discharge of ASA I patients is 40 minutes; for ASA II patients, it is 60 minutes; and for ASA III or IV patients, it is 80 minutes. Approximately one-third of that time is spent with a clinician. If fewer than 25 patients are seen a day, a half-day clinic may be appropriate. In this instance, physicians may rotate to the OR after 5-hour stints, because work in the APEC is intense.

To allow patients to be evaluated in a timely and efficient manner, the APEC appointment schedule is made available to the surgical specialty clinics. The surgeon's specific OR reservation can be linked to the requirement that a patient must also have an APEC appointment. This practice not only facilitates anesthesia appointments but also encourages the delivery of patient-centered care.

Previously, most patients ("drop-ins") would come to the APEC in large numbers in the midafternoon and would consequently experience long waits for anesthesia evaluation. Although this situation has been greatly improved by scheduling of appointments, some flexibility regarding "drop-ins" helps to accommodate patients requiring urgent surgical decisions and those from outside the hospital area.

After registration, the patient is processed through hospital/health-system admissions, utilization review, and financial services, located in the APEC. These processes are coordinated with the patient's completion of a preoperative questionnaire [259] (HealthQuiz Plus 2 or similar processes), which seeks information about pertinent medical history, previous surgeries, and medications. Processing of the patient through these services and completion of the questionnaire are scheduled with the goal of maximizing the efficient use of physician time. The patient's historical medical record is available at the time of the APEC appointment; the medical records department has received, by electronic communication and 24 to 72 hours in advance, a list of the patient's scheduled appointments for that day.

The anesthesia evaluator interviews and examines the patient and obtains (via facsimile and phone) whatever outside medical information is needed to complete the assessment. At one of our sites (the University of Chicago), all this information is directly entered into a patient database (see earlier). Appropriate laboratory, diagnostic, and ECG requirements are determined and are obtained on site in the APEC clinic. The centralization of services provides a significant convenience to patients, who no longer need to visit several hospital sites to complete preoperative requirements. ECGs are evaluated before the patient leaves the APEC. All laboratory tests are reviewed at the end of the clinic day.

A perioperative educator, usually a nurse, provides individualized education for the patient and family in the preoperative teaching center located in the APEC. Preoperative education increases the patient's understanding of what to expect regarding postoperative pain therapy and, by decreasing anxiety and fear, achieves its goal of increasing patient comfort. Additionally, preoperative patient education reduces pain and the length of stay in the phase II recovery area and inpatient facilities, and it sets the expectations regarding recovery and the needs of the patient on discharge from the hospital. The educational program is organized with the help of the specific surgical service and the office of hospital/health-system planning in order to provide patients with videotapes and descriptions of expectations and plans.

The personal interaction with a perioperative educator allows each patient to discuss concerns and to ask questions about his or her anesthesia and surgery, the rehabilitation process, pain-management options, and the expected hospital course. "Standardized care plans" written for each surgical procedure are used to focus on specific perioperative information and to provide an overview of the events on the day of, and after, surgery.

Previously, each surgical service had a nurse educator who provided perioperative education for patients. The

APEC program reduced use of this hospital resource significantly and currently coordinates all education through the centralized APEC location. The preoperative teaching center has a variety of anatomic models, brochures, charts, prostheses, specific videotapes made for this process, and other items to help patients understand their proposed anesthetic, surgical, and perioperative management. Some items can even focus on preventive long-term care, such as cessation of smoking, exercise programs, control of blood pressure, and medications. The anesthesia perioperative database program generates written instructions for the patient and significant others. These instructions specify where to go, when to be there, which medications to take, and what to expect in the perioperative period.

Staff members telephone patients on the evening before surgery [260] to confirm arrival time, to reinforce instructions, and to answer any questions. This contact by telephone helps to avoid delays and cancellations on the day of surgery.

Anesthesia Medical Consultation

The APEC provides another important service, the anesthesia medical consultation. This is not simply a routine preoperative examination but a conference requested by a primary care physician or surgeon who seeks advice on the suitability of the patient for anesthesia in light of the patient's medical condition. Obtaining these consultations 6 or more days before the planned day of surgery has many advantages. It facilitates the planning of intraoperative anesthesia and monitoring requirements, the obtaining of outside consultations and additional testing, and preparation for perioperative pain therapy and discharge. Although this system seems formidable, it is assembled in small steps by a team. The members of the team agree in advance not only to develop the plan, but also who has responsibility for each aspect of the plan.

An anesthesia medical consultation increases the awareness of surgeons and patients regarding the expertise of the anesthesiologist on perioperative medicine. For one thing, this type of consultation may initiate diagnostic and/or therapeutic actions for a specific medical problem. For example, instead of providing a general "clearance" for anesthesia and surgery, the APEC anesthesiologist may recommend referral of the patient to a specialist such as a cardiologist, for evaluation of a

specific intraoperative concern.

The expertise of the anesthesiologist is also evident when he or she is involved in the decision-making process regarding consultations. Fischer [25] reported a 73 percent reduction in unnecessary consultations to medical specialties when the anesthesiologist was involved in the consultation decision process. By reducing questionable consultations and further diagnostic studies, hospital costs decreased. Quality assurance data seemed to indicate no adverse patient outcome.

Regarding billings, APEC consultations are first coded using the CPT of the American Medical Association. Then a professional fee is submitted, and reimbursement is requested. Although routine visits (those usual in the past) are not billed for, the educational/evaluation process that differs from the past is billed for, and any savings that accrue from reduced length of stay are shared, in order to fund the clinic.

Perioperative Quality Assurance Indicators

The APEC is a multidisciplinary arrangement that requires changes in the existing clinical practices and hospital resources. Hospital/health-system administration, surgeons, and other physicians monitor its performance and outcome. A database system allows entry and analysis of quality assurance indicators for the APEC. This information can measure the effectiveness of activities that improve performance, cost and resource data, savings, and potential organizational inefficiencies and benefits.

System problems that cause costly surgical delays or cancellations, together with practices requiring improvement or enhancement, are easily identifiable. Figure 23-21 summarizes data from the previous section on preoperative informatics to suggest a database format that would allow evaluation of quality assurance indicators for an APEC.

Cost-Effectiveness of the APEC

To enhance market share and profitability, health-care institutions have focused heavily on cost reductions. [23] Several authors have reviewed the economic principles and issues associated with analysis of health-care costs.

In preparing a patient for surgery, physicians are directly responsible for providing and ordering virtually all the patient's evaluations, preoperative diagnostic tests, and referrals to specialists. The responsibilities of the anesthesiologist are unique in the preoperative process. The anesthesiologist is the final clinical pathway or "gatekeeper" for the patient entering the OR and for the facilitation of postoperative pain therapy. As such, the APEC anesthesiologist is a central figure in the review and implementation of practice guidelines [5] [261] [262] [263] [264] [265] and clinical pathways and also participates in sharing of information (such as patient evaluation protocols and consultations), avoiding duplication of services, identifying costs and benefits, and evaluating the management of medical resources and measurements of outcome.

Because the anesthesiologist is the specialist best able to evaluate intraoperative medical complexities as they relate to anesthesia and surgery, he or she is also best qualified to define and coordinate the appropriate preoperative studies needed for optimal intraoperative management of the patient.

Diagnostic Studies and the Clinic

Using guidelines and clinical judgment seems to be more cost-effective than using only clinical judgment or batteries of tests. Therefore, the APEC uses guidelines described earlier concerning the ability of preoperative diagnostic studies to determine which preoperative tests should be undertaken. These guidelines are provided to the surgeons for review and are based primarily on the patient's age, medical status, proposed surgical procedure, and judgment of the clinician.

Four studies reported a reduction in testing and hospital costs when preoperative diagnostic testing was coordinated

Figure 23-21 A quality assurance form used by an anesthesia preoperative evaluation clinic to assess the quality and efficiency of its service. H&P, history and physical examination; MUGA, multiple uptake gated analysis; PFT's, pulmonary function tests

through the anesthesiologist in the APEC. The reductions in testing and in average hospital costs per patient were, respectively, 55.1 percent and $112.09, [25] 28.6 percent and $20.89, [258] 55 percent and $137 [27] ; Roizen et al [259] reported a $100 decrease in costs.

Delays and Cancellations in the Surgery Schedule

Considerable hospital cost is incurred when an OR is vacant because of a cancellation or delay in surgery on the day

TABLE 23-24 -- Decrease in Surgical Cancellations for Patients Evaluated in the Anesthesia Preoperative Evaluation Clinic

INVESTIGATORS	DECREASE IN SURGICAL CANCELLATIONS
Fischer [25]	88%
Pollard et al [26]	20%
Boothe [257]	60%
Macarthur et al [254]	5 times lower

of surgery. These delays and cancellations can be a significant source of frustration for both the physician and patient, while multiple resources await the arrival of the next patient.

Day-of-surgery delays and cancellations, OR downtime, and loss of hospital revenue decrease when an unstable medical condition is determined *before* the day of surgery. Several authors have reported decreased day-of-surgery cancellations when patients were referred to an APEC prior to the day of surgery (Table 23-24) . Reductions in delays and cancellations increase revenue and produce a positive response from the surgeons and the hospital administration. The anesthesiologist becomes the primary physician identified with preoperative cost containment and improved quality of perioperative patient care. Furthermore, educating the patient about what to expect regarding postoperative pain therapy and feeding decreases the length of stay in the hospital.

Incentives for Cost Reductions

The contribution of the anesthesiologist to cost savings for the hospital or health system is often not obvious and is frequently difficult to quantify. However, the APEC provides several areas of identifiable cost reductions to the hospital or health system for which the anesthesiologist is directly responsible.

A contractual agreement negotiated with the hospital or health system could recognize that the department of anesthesia can influence hospital or health-system costs in the care of patients. The anesthesia department could enter into the hospital capitation risk pool and could share revenue linked to the APEC contribution to

cost-effective care.

Fischer [25] reported a 1-year hospital cost reduction of $1.01 million in unnecessary preoperative testing, and Starsnic et al [25a] noted a 1-year cost reduction of $643,056 when preoperative diagnostic studies were coordinated through the APEC.

Evolution of Anesthesiology

Health care is in an active state of transformation and reform. The next decade will be a transition-rich environment for consolidations, affiliations, and a wide range of strategic business relationships. The anesthesiologist-directed preoperative evaluation clinic represents a successful partnership between hospital and physician and a framework for growth in our specialty.

Anesthesiologists are being asked to provide optimal, efficient patient care within the limitation of finite resources. Current dynamic changes in the field of anesthesiology require a fundamental reassessment and restructuring of the manner in which clinical anesthesia care is provided.

The anesthesia preoperative evaluation is a medical assessment of the patient's current condition, integrated with the anesthesiologist's unique knowledge of the potential clinical and operative events that may occur. The expanding role of the anesthesiologist beyond the OR has redefined the specialty to the hospital, to our colleagues, and to the community regarding the anesthesiologist's clinical expertise, effectiveness, and contribution to quality patient care.

A successful APEC provides the foundation for preparation of the patient for surgery. It returns considerable advantage for the anesthesiologist, improves the quality of care and value for patients, and provides visible hospital leadership in responding to rapidly changing health-care demands.

Summary

Our primary goal has to be efficient delivery of quality care. Patients undergoing surgery move through a continuum of medical care to which a primary care physician, an internist, an anesthesiologist, and a surgeon work in partnership to ensure the best outcome possible. No aspects of medicine require greater cooperation than the performance of surgery and the perioperative care of a patient. For the anesthesiologist, this responsibility should start in a preoperative clinic. The importance of integrating practice is even greater because of the increasing life-span of our population. As the number of elderly patients increases, so does the need for preoperative consultation to plan for comorbidities and multiple drug regimens, knowledge of which is crucial to successful patient management.

At a time when medical information is encyclopedic, it is difficult for even the most conscientious anesthesiologist to keep abreast of medical issues relevant to perioperative patient management. Thus, the proposed preoperative assessment clinic facilitates those most sought-after goals: improved quality of care and reduced costs. We physicians can demonstrate to our constituency, the patients, and to their watchdog, the government, that the present system of preoperative evaluation can be changed to increase efficiency, to reduce costs substantially, and to improve the quality of care. At the same time, anesthesiologists would be able to lessen their own anxiety about performing the very best evaluation possible.

ACKNOWLEDGMENTS

The authors gratefully acknowledge the contributions of Dr. Raj Kim, who coauthored the analysis of benefit versus risk for laboratory tests, plus Table 23-4 ; and of Dr. Allan Jo, who provided the superb summary of testing for, and treatment of, magnesium deficiency.

Chapter 24 - Pulmonary Function Testing

Thomas J. Gal

INTRODUCTION

Pulmonary function testing continues to play a role in traditional preoperative evaluation of patients undergoing major surgery. Although simple and risk free, such testing is often performed in reflex fashion without real indications because of limited physiologic and clinical insight on the part of many practicing physicians. As a result, they are often uncomfortable interpreting test data and are unsure of what the data mean or what was actually measured.

Such preoperative screening is aimed at identifying individuals with abnormal lung function in hopes of altering their outcome by reducing the risk of postoperative ventilatory impairment and other respiratory complications. The subjective information provided by the medical history and the findings on physical examination seldom identify the actual abnormalities of respiratory function and are often poor indicators of the severity of disease. In contrast, pulmonary function testing provides objective standardized measurements for assessing the presence and severity of respiratory dysfunction. Such measurements also enable the clinician to follow the progression of any impairment and to document the response to therapy such as bronchodilators. These tests fall into two major groups: those that detect abnormalities of gas exchange and those that relate to the mechanical ventilatory function of the lungs and chest wall. This discussion deals principally with the latter group.

The cornerstone of all pulmonary function testing is, of course, clinical spirometry. There are numerous other tests, including some that purport to indicate mild abnormalities of lung function. This presentation attempts to review the actual measurement techniques and to interpret the physiologic basis and significance of many of these tests. The aim is to provide a better understanding of the defects identified by each testing scheme. Such information does not merely serve to impress a board examiner or a colleague; it also enhances the anesthesiologist's role as a consultant in the ra-tional perioperative management of the patients evaluated. The actual management considerations include risk of postoperative morbidity, resectability of lung tissue, and management of the anesthetic.

CLINICAL SPIROMETRY

Vital Capacity

The most common measurement of lung function is the vital capacity (VC). John Hutchinson is given the credit for inventing the spirometer and for coining the term *vital capacity* in the mid-19th century. [1] The VC is simply the largest volume measured after an individual inspires deeply and maximally to total lung capacity (TLC) and then exhales completely to residual volume (RV) into a spirometer. The maneuver is performed without concern for rapidity of effort. Normal values for VC are lower in supine subjects than in sitting ones and vary directly with height and inversely with age. A given VC is generally suspected of being abnormal if it falls below 80 percent of the predicted value. Patients with abnormally low values for VC are said to have

restrictive disease. The decreased VC associated with restrictive disease may result from lung pathology, such as pneumonia, atelectasis, and pulmonary fibrosis. It may also occur with a loss of distensible lung tissue, such as that following surgical excision. Decreased VC is also seen in the absence of lung disease. In this case, muscle weakness, abdominal swelling, or pain may prevent the patient from obtaining either a full inspiration or a maximum expiratory effort.

Time-Expired Spirogram

If after a maximal inspiratory effort a subject exhales as forcefully and rapidly as possible, the maneuver is termed the forced VC (FVC), and the exhaled volume is recorded with respect to time. The rate of air flow during this rapid forceful exhalation indirectly reflects the flow resistance properties of the airways. In the presence of airway obstruction, FVC tends to be less than the standard VC because airways reach flow limitation early, and air trapping occurs. In healthy subjects, the two maneuvers usually result in nearly equal measured volumes. Because the FVC maneuver is an artificial one, patients must be instructed carefully and often require practice attempts before performing the test adequately. Generally, three acceptable tracings are required for analysis. These FVC maneuvers must be characterized by an initial full inspiration to TLC, followed by an abrupt onset of exhalation and continued maximum effort throughout exhalation to RV. The exhalation should take at least 4 seconds and should not be interrupted by coughing, glottic closure, or any mechanical obstruction. [2]

The FVC is reduced by the same conditions that reduce VC. Therefore, in order to identify airway obstruction, flow rates are determined by calculation of the volume exhaled during certain time intervals. Most commonly measured is the volume exhaled in the first second, or the forced expiratory volume in 1 second (FEV_1). The FEV_1 can be expressed as absolute volume in liters, and typical values for various patient groups are listed in Table 24-1 . The FEV_1 provides an even better perspective on the degree of airway obstruction when it is expressed as a percentage of the FVC (FEV_1/FVC%).

For the purposes of reporting and calculating values, the largest observed FVC and FEV_1 from any of the three acceptable spirograms are used, even if they are not obtained from the same curve. [2] Normal healthy subjects can exhale 75 to 80 percent of the FVC in the first second; the remaining volume is exhaled in two or three additional seconds

TABLE 24-1 -- Clinical Ranges for Forced 1 Second Expiratory Volume (FEV_1) in Liters

CLINICAL RANGE	PATIENT GROUP
3.0-4.5	Normal adult
1.5-2.5	Mild-to-moderate obstruction
<1.0	Qualifies as handicapped
0.8	Disability
0.5	Severe emphysema

Figure 24-1 Forced vital capacity (FVC) maneuver in a subject with a normal lung. Exhaled volume is plotted against time as the subject expires forcefully, rapidly, and completely to residual volume (RV) after a maximal deep inspiration to total lung capacity (TLC). (FEV_1, forced expired volume in 1 second; $FEF_{200-1200}$, forced expiratory flow between 200 and 1200 mL of expired volume; $FEF_{25\%-75\%}$, forced expiratory flow over the midportion of vital capacity, i.e., from 25 percent to 75 percent of expired volume.)

(Fig. 24-1) . Disease such as asthma and bronchitis, which obstruct the airway, reduce expiratory flow rates and, thus, reduce FEV_1 and FEV_1/FVC percent. An obstructive defect is essentially characterized by a disproportionate decrease in air flow rate relative to the actual volume exhaled (FVC) and indicates airway narrowing and flow limitation during expiration. Values for FEV_1/FVC that are less than 70 percent reflect mild obstruction, whereas those less than 60 percent suggest moderate obstruction and those less than 50 percent, severe obstruction. Because the FEV_1/FVC represents a ratio, it is important to realize that identical values, such as 50 percent, may not indicate equivalent degrees of lung dysfunction. For example, a patient with an FEV_1 of 1.5 L and an FVC of 3.0 L does not have the same degree of impairment as a similar-sized patient with an FEV_1 of 0.75 L and an FVC of 1.5 L. Nevertheless, in both, the FEV_1/FVC ratio is 50 percent.

Restrictive diseases are not usually associated with airway obstruction but do cause decreases in FVC. Although the absolute volume of FEV_1 may be reduced on a similar basis, the FEV_1 expressed as a percentage of FVC is usually normal (i.e., FEV_1/FVC >70 percent). The essential physiologic characteristic of a restrictive defect is a reduction in total lung volume, that is, TLC. However, the presence of such a defect is usually implied whenever FVC is reduced and the ratio of FEV_1/FVC is normal or increased. The impact of various mechanical abnormalities on VC and these dynamic lung volumes is summarized in Table 24-2 .

The maximal flow rate during an FVC maneuver occurs in the initial 0.1 second and is termed the peak flow measured in liters per second or liters per minute. Peak flow can be estimated by drawing a tangent to the steepest part of the FVC spirogram, but this method is subject to large errors. More commonly, maximal flow is measured as the average

TABLE 24-2 -- Forced Vital Capacity (FVC) and 1-Second Forced Expiratory Volumes (FEV_1) in Disease States

	FVC(L)	FEV_1 (L)	FEV_1 /FVC%
Airway obstruction (asthma, bronchitis)	Normal	Decreased	Decreased
Stiff lungs (pneumonia, pulmonary edema, pulmonary fibrosis)	Decreased	Decreased	Normal
Respiratory muscle weakness (myasthenia gravis, myopathies)	Decreased	Decreased	Normal

flow during the liter of gas expired after the initial 200 mL during an FVC maneuver (see Fig. 24-1) . This is usually designated as forced expiratory flow between 200 and 1200 mL of FVC ($FEF_{200-1200}$); however, the term maximal expiratory flow rate has also been used. This flow is slightly lower than the true peak flow, which can be measured conveniently with a hand-held flowmeter (Fig. 24-2) or more accurately with a pneumotachygraph. Peak flow is markedly affected by obstruction of large airways and is particularly responsive to bronchodilator therapy. Because repeat measurements are convenient to obtain, peak flow rates can be utilized to monitor therapeutic responses in acute asthma. Normal values in healthy males under 40 years of age are typically 500 L/min or more. Values less than 200 L/min in surgical candidates suggest impaired cough efficiency and the strong likelihood of postoperative complications. [3] The test is much less unpleasant and exhausting for patients than the FVC maneuver and thus provides a valuable tool to identify gross pulmonary disability at the bedside.

Although peak flow is largely a function of the caliber of the airways, it is also highly dependent on expiratory muscle strength, as well as on patient effort and coordination. As a result, the measurement can be variable. In contrast, high degrees of effort are not required to achieve maximal expiratory flow at intermediate and low lung volumes during forced expiration. Therefore, flow is often measured over the middle half of the FVC (i.e., between 25 and 75% of expired volume). This parameter, formerly called the maximal midexpiratory flow, is now referred to as the forced midexpiratory flow ($FEF_{25\%-75\%}$). Because the flow does not include the initial highly effort-dependent portion of forced expiration, $FEF_{25\%-75\%}$ is often referred to as "effort independent." This designation is not entirely appropriate, because $FEF_{25\%-75\%}$ can be decreased by marked reductions in expiratory effort and by a submaximal inspiration before the maneuver. The latter artificially reduces FVC and, along with it, the $FEF_{25\%-75\%}$. The same flow rates may also decrease with truly maximal effort, compared with slightly submaximal effort. [4] [5] This phenomenon has been termed "negative effort dependence" and appears to be an artifact of measuring volume changes at the mouth rather than actual changes in thoracic gas volume, which differ in the dynamic airway compression that occurs with truly maximal effort.

The $FEF_{25\%-75\%}$ is therefore a highly variable spirometric index, largely because of its dependence on the absolute volume of FVC, as well as on changes in expiratory time with varying degrees of airway obstruction. Values for $FEF_{25\%-75\%}$ in healthy young men average 4.5 to 5.0 L/sec, but because of wide variations even in normal subjects, the predicted limits of normal may be as low as 2 L/sec. The measurement has often been proposed as a sensitive indicator of early obstruction in the small distal airways. However, patients undergoing spirometry for suspected airway obstruction virtually always had normal values for $FEF_{25\%-75\%}$

Figure 24-2 Three hand-held peak flow meters. The classic Wright meter (Air Med Limited, Harlow, England) and the Assess peak flow meter (Health Scan Products, Cedar Grove, NJ) provide actual quantitation of peak flow rate, and the smaller Peak Flow Monitor (Biotrine Corp., Woburn, Mass) allows the patient to tape over the holes before blowing. If the flow rate indicated by the first uncovered hole is reached, a horn-like sound is produced by a metal reed-like device within the tube.

when FEV_1 /FEV was 75 percent or greater. [6] One exception to this may occur in patients with restrictive ventilatory defects. In these patients, the $FEF_{25\%-75\%}$ may be markedly reduced and the FEV/FVC percent normal. However, lung volumes, as reflected by TLC, FVC, and absolute volume of FEV_1, are all reduced. Therefore, $FEF_{25\%-75\%}$ does not appear to be any more sensitive than FEV_1 in detecting mild abnormalities of lung dysfunction.

Maximal Breathing Capacity

Dynamic lung function is also routinely evaluated in many pulmonary function laboratories by measuring the maximum breathing capacity or, more specifically, the maximal voluntary ventilation (MVV). This is the largest volume that can be breathed per minute by voluntary effort and reflects an estimate of the peak ventilation available to meet physiologic demands. The patient is instructed to breathe as hard and fast as possible for 12 seconds. The measured volume is extrapolated to 1 minute and is expressed as liters per minute. Because high rates of air flow are required for MVV, the measurement is significantly affected by changes in airway resistance. MVV is usually reduced in patients with obstructive airway disease and correlates reasonably well with FEV_1 measured in liters ($FEV_1 \times 35$ approximates MVV). Discrepancies between the measured MVV and that predicted by FEV_1 often indicate inconsistent or submaximal inspiratory effort. [7] The MVV as a comprehensive test of ventilatory function is altered by factors other than airway obstruction. These include the elastic properties of the lung and chest wall, respiratory muscle strength, learning, coordination, and motivation. In healthy male adults, MVV averages 150 to 175 L/min. This extremely high level of ventilatory effort cannot be maintained for much longer than 1 minute. However, approximately 80 percent of the MVV can be maintained by healthy subjects for as long as 15 minutes, and up to 60 percent of MVV can be sustained for even longer periods. Abnormally low values (<80 percent of those predicted) do not identify specific defects but do indicate gross impairment in respiratory function. The unique value of the test in the surgical candidate may lie in its dependence on intangible variables, such as cooperation, motivation, and stamina.

Respiratory Muscle Strength

All measurements of pulmonary function that require patient effort (e.g., FVC, FEV_1 peak flow, and MVV) are influenced by the strength of the respiratory muscles. The latter can be specifically evaluated by measurement of maximal static respiratory pressures. The pressures are generated against an occluded airway during a maximal forced inspiratory or expiratory effort and are usually measured with simple aneroid gauges. [8] Maximal static inspiratory pressure is measured when inspiratory muscles are at their optimal length near RV (Fig. 24-3) . Similarly, maximal static expiratory pressure ($P_{E}max$) is measured when expiratory muscles are optimally stretched after a full inspiration to near TLC. In young adult males, maximal static inspiratory pressure is about -125 cm H_2O, whereas $P_{E}max$ is about +200 cm H_2O.

The pressures measured at the mouth include that generated by the respiratory muscles and a portion resulting from the elastic recoil of the respiratory system. The latter is essentially zero at functional residual capacity (FRC). Pressures measured at FRC are simply less than at the extremes of lung volume (see Fig. 24-3) but unlike the other values reflect solely the pressure developed by the respiratory muscles.

A maximal static inspiratory pressure of -25 cm H_2O or less indicates severe inability to take a deep breath, whereas a $P_{E}max$ of less than +40 cm H_2O suggests severely impaired coughing ability. Although these pressures are not measured routinely in all pulmonary function laboratories, they are particularly useful in the evaluation of patients with neuromuscular disorders. In these patterns, the VC has long been used to indicate the severity of respiratory muscle weakness and to predict respiratory failure. Measurements of respiratory muscle strength have been shown to identify more readily the patients in whom respiratory muscle weakness is the prime cause of hypercapnic respiratory failure. [9]

Figure 24-3 Normal values for maximum static inspiratory ($P_{I}max$), and expiratory ($P_{E}max$) pressure measured at the mouth are plotted as a function of lung volume from residual volume (RV) to total lung capacity (TLC). (FRC, functional residual capacity.)

Figure 24-4 Elastic recoil pressures for the lung (PI), chest wall (Pcw), and total respiratory system (Prs) are plotted as a function of lung volume. (VC, vital capacity; TLC, total lung capacity; RV, residual volume; FRC, functional residual capacity.)

PHYSIOLOGIC DETERMINANTS OF MAXIMUM FLOW RATES

The maximal flow rates that can be achieved during pulmonary function testing maneuvers depend on three factors, each of which is highly influenced by the volume of the lung at the time. Foremost of these factors is the degree of effort, or the driving pressure generated by muscle contraction. The expiratory effort reflected by P_{Emax} is maximal at high lung volumes near TLC and decreases as lung volume decreases (see Fig. 24-3) . Maximal inspiratory effort (maximal static inspiratory pressure), conversely, is achieved at low lung volumes near RV and diminishes at higher lung volumes.

Another important determinant of maximal flow is the elastic recoil pressure of the lung (PI). At all lung volumes from RV to TLC, the lung has a tendency to recoil inward (Fig. 24-4) . The PI, therefore, is greater at TLC (25-30 cm H_2O) and lowest at RV (2-3 cm H_2O). The PI is opposed by the outward recoil of the chest wall (Pcw), except at very high lung volumes. The recoil pressure of the respiratory system (Prs) is the algebraic sum of PL + Pcw. Note that PI and Pcw are equal and opposite at a certain point (i.e., Prs = 0). This volume is the FRC that is the respiratory system's normal resting volume.

A third factor, which opposes these two driving pressures, is the resistance to flow provided by the airways. This airway resistance (Raw) is determined by the size of the airways. Because airways are largest at high lung volumes and smallest at RV, Raw is greatest at RV and least at TLC (Fig. 24-5A) . The inverse relationship between Raw and lung volume is not linear. Therefore, the reciprocal of Raw, conductance (Gaw), which is related to lung volume linearly (Fig. 24-5B) , is often utilized to identify bronchoconstriction or bronchodilation.

Flow-Volume Relationships

Because all of the determinants of maximal flow are dependent on lung volume, a useful format to assess the flow resistive properties of the airways is to plot flow as a function of volume during the FVC maneuver. At the beginning of the forced expiration, the rate of flow quickly rises to a maximal or peak value at a lung volume very near to TLC. As expiration continues, lung volume decreases, airways narrow, resistance increases, and flow rates progressively decrease. The impact of obstructive airway disease on such flow rates is emphasized in Figure 24-6 . In the patients with airway obstruction, flows are reduced over the full range of lung volume from TLC to RV.

The influence of expiratory effort on the flow-volume curves is very important. An individual can actually inscribe different flow-volume curves with differing efforts, although each may have the same FVC (Fig. 24-7) . At large lung volumes close to TLC, air flow rises with increasing effort (curve A). With decreasing effort, curves B and C exhibit decreased flows in this high range of lung volume, but all three curves merge at a point and continue together to RV. At these intermediate and low lung volumes, only moderate effort is needed to produce maximal flow. Because increased expiratory effort has little effect on increasing these flows, there is little difference between the three curves, and this portion of the curve is referred to as "effort independent."

Figure 24-5 The hyperbolic relationship of airway resistance (Raw) to lung volume (A) is contrasted with the linear relationship (B) of its reciprocal airway conductance (Gaw). (RV, residual volume; TLC, total lung capacity; FRC, functional residual capacity.)

Figure 24-6 Idealized maximum expiratory flow-volume curves in normal subjects are contrasted with those typically seen in patients with obstructive airway disease. Expiratory flow is plotted as a function of lung volume during maximal expiration from total lung capacity (TLC) to residual volume (RV).

At this point, flow is largely a function of the other two variables (PI and Raw). Once again, exaggerated effort may decrease these same flows as with $FEF_{25\%-75\%}$. [4] [5]

The rate of air flow during forced expiration is influenced not only by the effort expanded but also by the lung volume at which the expiratory maneuver is begun. True maximum flows occur only when expiration is begun at or near TLC.

Figure 24-7 Forced expiratory flow-volume curves in a normal subject. The exhalation from total lung capacity (TLC) to residual volume (RV) was performed at three levels of effort ranging from maximal (A) to minimal (C).

Figure 24-8 Forced expiratory flow-volume curves inscribed during maximal maneuvers performed by beginning at total lung capacity (TLC) and at 2 and 4 L below TLC.

When forced expirations are begun with maximal effort from volume below TLC (Fig. 24-8) , peak flow is not as high but flows quickly conform to the same performance envelope as if the maneuvers were begun at TLC. Even some healthy subjects can exhibit a decreased FEV_1/FVC ratio on the normal volume time spirogram when the forced expirations are started from such submaximal volumes. Therein lies some of the advantage of a flow-volume plot as opposed to the volume-time tracing with conventional spirometry.

Airway Compression and Flow Limitation

The failure of increasing effort to further augment flow over the lower two-thirds of the VC results from dynamic compression of the airways. This has been described in a model of flow limitation termed the equal pressure point (EPP) concept. The pressure head, which serves to move air from the alveoli to the mouth, is provided by the alveolar pressure (Palv). At any given lung volume, alveolar pressure is the sum of lung elastic recoil pressure (Pl) and pleural pressure (Ppl). At any lung volume when there is no flow, such as end-inspiration (Fig. 24-9A) , Ppl is subatmospheric and counterbalances Pl. Thus, this sum--Palv--is zero, as are pressures at the mouth and through the remaining airways. During forced expiration (Fig. 24-9B) , Ppl rises above atmospheric (becomes positive). The increased Palv again is the sum of Pl and Ppl. Pressure is dissipated along the airway to overcome resistance to flow and finally reaches zero at the mouth. At some point along the airway, the intraluminal pressure falls to a level that equals the surrounding pleural pressure. This site is referred to as the EPP. Toward the mouth (downstream), the lateral

pressure within the airway lumen is less than the compressing Ppl, and the airways

Figure 24-9 A model depicting the equal pressure point (EPP) concept of expiratory flow limitation (see text for explanation). (Pm, mouth pressure; Paw, intraluminal airway pressure; Pl, pleural pressure; Palv, alveolar pressure.)

tend to collapse. Once maximal flow is reached, further increases in Ppl from extra effort do not affect air flow in the upstream segment (from EPP toward the alveoli), because the driving pressure along this portion of the airway is equal to Pl. Therein lies the origin of the term "effort independent." The increased Ppl simply produces more compression of the downstream airways (from EPP to mouth). Thus, increasing effort produces more and more airway compression but fails to increase flow.

The principal value of this dynamic airway compression is in the production of an effective cough. Even though maximum flows may not be reached, the compressed downstream airway develops an increased linear velocity of air flow, which maximizes the removal of secretions along airway walls. At intermediate lung volumes, EPPs lie in segmental bronchi, but they may move farther upstream toward the alveoli at lower lung volumes. The dynamic compression involves primarily the lobar and mainstream bronchi and the intrathoracic trachea. Coughing is, therefore, most effective in removing material from these relatively large airways.

Sites and Mechanisms of Decreased Air Flow in Disease

Abnormal expiratory flow rates may be seen in many disease states and may result from alterations in any of the three major determinants of flow, ($P_{E}max$, Pl, and Raw), as seen in Table 24-3 . For example, the patients with neuromuscular disease who may exhibit decreased expiratory flows include those with myasthenia gravis, muscular dystrophy, Guillain-Barre syndrome, and spinal cord transection. Decreased ability to generate expiratory effort is the principal cause of low expiratory flows in these patients, who seldom exhibit increases in Raw or decreases in Pl. Other categories of restrictive disease, such as musculoskeletal deformities (kyphoscoliosis, ankylosing spondylitis, and interstitial lung disease), are often associated with near-normal muscle strength. In these situations, expiratory flows may actually be slightly increased because of an increased Pl associated with reductions in lung volume. Reduced lung volumes associated with long-term neuromuscular disease may likewise be associated with increases in Pl, which may result in more normal expiratory flow rates.

TABLE 24-3 -- Mechanisms for Decreased Expiratory Flow Rates

DISEASE	PHYSIOLOGIC VARIABLES		
	PEmax	***Raw***	***Pl***
Neuromuscular weakness		N	N
Emphysema	N	N	
Asthma, bronchitis	N		N
Peripheral airway disease	N	N	N

Symbols:
, increased;
, decreased

N, normal; $P_{E}max$, maximum static expiratory pressure; Raw, airway resistance; Pl, lung elastic recoil pressure

The classic example of decreased expiratory flow associated with decreased lung recoil (Pl) is emphysema. In this disease, expiratory muscle strength is usually adequate, and lung distention tends to increase airway size, such that Raw is also usually normal. In patients with bronchitis and asthma, conversely, airway narrowing is prominent. In these two variants of obstructive lung disease, the major factor reducing flow is an increased Raw. Early changes in these obstructive lung diseases may be confined to the smaller peripheral airways. Narrowing in these airways may reduce expiratory flows at middle and low lung volumes but does not appreciably affect measurements in Raw or the other determinants of air flow.

MEASUREMENT OF AIRWAY OBSTRUCTION

Airway Resistance

Of the standard techniques used to evaluate airway obstruction, Raw measurements appear to be the most direct. The technique is rapid and noninvasive and requires merely that a subject pant once or twice per second through a mouthpiece and with a nose clip in place. During normal breathing, a major fraction of the resistance to air flow resides in the nose, pharynx, and larynx and can mask changes taking place in the lungs. The use of a mouthpiece bypasses the nose in order to minimize the effects of the upper airway on the measurement. The panting maneuver is likewise utilized to keep the larynx dilated and to reduce its influence on the total resistance to air flow. The measurements of Raw requires the subject to sit in a constant volume body plethysmograph ("body box"), which also permits the recording of thoracic gas volume and thereby provides an accurate appraisal of the effects of lung volume on Raw. Lung volume is estimated by use of Boyle's law to relate changes in box pressure and mouth pressure, and Raw is calculated from changes in box pressure and flow. [10] The subjects initially pant against a closed mouthpiece, usually at end-expiration. Thus, thoracic gas volume (FRC) is calculated from relationship of box pressure to mouth pressure (Fig. 24-10) . The shutter in the mouthpiece is then opened, and continued panting inscribes the relationship between box pressure and flow at the mouth to derive Raw. The upper limit of normal Raw is usually considered to be 2 cm H_2O/1 second. In order to eliminate passive changes in Raw as a result of difference in lung volume, the reciprocal of Raw, Gaw, is calculated. The Gaw is usually divided by the lung volume at which the measurement is made (usually FRC) to obtain specific Gaw. The coefficient of variation (standard deviation/mean × 100) in normal baseline values for the same subject is usually small (<10 percent). Therefore, specific Gaw is a highly reproducible measurement that can identify changes in the caliber of the intrapulmonary airways. However, a significant portion of normal airway resistance resides in the upper airways. The latter can be significantly increased with head flexion, which reduces the caliber of the hypopharynx. [11] [12] Therefore, it is important that patients position themselves as erect as possible when attached to the mouthpiece in the body box.

Figure 24-10 Diagram of the constant volume body plethysmograph to measure airway resistance and lung volume. When subject pants against an obstructed mouthpiece (shutter closed), box pressure (Pb) is plotted against mouth pressure (Pm). Changes in Pb are converted in changes in lung volume by calibrating the box with known volumes of added gas and observing Pb changes. As subject pants through the open mouthpiece, flow (V) replaces Pm on the plot, and airway resistance is computed from the relationship between Pb and V.

Forced Expiratory Maneuvers

Despite the specificity and sensitivity of Raw measurements, airway obstruction is more commonly evaluated by measurements of maximal forced expiration. The indices obtained from forced expiration, unlike Raw, are determined by a complex interrelationship of flow-resistive properties of intrathoracic airways and elastic recoil of the lung. The simplest of such measurements is the peak expiratory flow, which is conveniently measured with a variable orifice flowmeter. Because the peak flow occurs early in a forced expiration, flow limitation has not occurred in the airways, and thus, flow is highly dependent on effort and subject cooperation. However, because the variation for the measurement in the same subject is surprisingly low, peak expiratory flow is a fairly reproducible test of airway function.

Another extensively used indirect measure of airway dimensions is the FEV_1 . Again, during the first 25 percent of an FVC maneuver, flow reflects dimensions of the airways between the alveoli and the mouth and is effort dependent. Although the physiologic parameters governing the remaining flow are complex, FEV_1 , like peak flow, is simple and reproducible and is thus a useful index of airway function. The measurement is subject to day-to-day variability, which is greater in patients with obstructive airway disease than in normal patients. [13] These changes in FEV_1 must exceed 15 percent in order to signify bronchodilation or constriction in patients. An even greater potential variability applies to $FEF_{25\%-75\%}$ measurements. In addition, one must account for the possibilities of negative effort dependence and, more importantly, the changes in FVC that might occur. For example, in bronchodilation, FVC may increase but may actually produce a misleading decrease in $FEF_{25\%-75\%}$. [14] Thus, the measurement should be adjusted to the same absolute lung volume, that is, the same segment of FVC below TLC (Fig. 24-11) .

Traditionally, the response to bronchodilators is expressed as the percentage change in FEV_1 from a baseline value. Healthy normal subjects and those with very mild obstruction typically exhibit a minimal increase in FEV_1 (<5%). Likewise, patients with severe baseline obstruction respond poorly because of accompanying secretions and airway edema. The most dramatic improvement occurs in patients with moderate obstruction such that response to bronchodilators follows a "bell-shaped" distribution. [15]

Additional assessment of the flow-resistive properties of the airways can be obtained from maximal expiratory flow volume (MEFV) curves, which illustrate the relationship between air flow and lung volume during an FVC maneuver (see Fig. 24-6) . A typical response when bronchoconstriction is induced consists of diminished flows throughout the sole MEFV curve envelope (Fig. 24-12) . Ventilatory flows and FVC usually decrease, and RV increases. Therefore, expiratory flows must be measured at the same reference lung volume. This is usually at a fixed percentage of the baseline or normal FVC and requires that all curves be superimposed at TLC.

In normal subjects, full inflation to TLC may remove the bronchoconstriction induced by mechanical stimuli or drugs, whereas in asthmatics, an increase in bronchomotor tone may accompany the same deep inspiration. To overcome these variable effects of a full inspiration on bronchial tone, flows can be measured with partial expiratory flow volume

Figure 24-11 Forced expiratory spirograms before (A) and after bronchodilator therapy (B). Note the increase in forced vital capacity in B, but flow over its midportion ($FEF_{25\%-75\%}$) is decreased unless adjusted to the same volume, i.e., the portion of FVC below total lung capacity (TLC). The artifact results from the increased FVC as a result of bronchodilation. Note: when $FEF_{25\%-75\%}$ is measured over the same actual volume segment as in A, the value increases.

curves. In this case, the maximal forced expiration is started at or slightly above the middle of FVC (Fig. 24-13) . In all cases, the partial expiratory flow volume curve is followed by a full inhalation to TLC and a maximal forced exhalation to RV to obtain a reference MEFV curve. Flows are usually measured between 20 and 40 percent of VC above RV. Because partial expiratory flow volume curves are unaffected by changes in upper airway resistance, they are sensitive to the change in the intrapulmonary airways and have been suggested as a useful alternative to Raw for detecting bronchoconstrictor and bronchodilator responses.

Flow-Volume Loops

The finding of reduced peak flow, MVV, and FEV_1 without additional clinical evidence of chronic obstructive lung disease may indicate the presence of an obstructing lesion of the upper airway, larynx, or trachea. In some cases, this obstruction may be suspected by a careful history and physical

Figure 24-12 Maximum expiratory flow-volume curves before (solid line) and after (broken line) induced bronchoconstriction. Flow is plotted against expired volume expressed in liters from total lung capacity (TLC) to residual volume (RV). Forced 1 second expiratory volumes (FEV_1) are indicated with arrows on each curve.

examination, but in many instances, it may stimulate diffuse airway obstruction and may suggest a marked degree of lung dysfunction. The latter is most likely to occur in patients who are going to undergo head and neck surgery who may present for operative procedures related to these lesions.

Figure 24-13 Partial expiratory flow-volume curves before (A) and after (B) bronchodilator treatment. Forced expiration is begun just above midpoint of vital capacity (VC). Flows are quantitated at 20 and 40% VC above residual volume (RV). A reference maximum expiratory curve (C) is also inscribed by beginning exhalation from total lung capacity (TLC).

Flow-volume loops provide a graphic analysis of flow at various lung volumes and have been utilized to discriminate between patients with upper obstructive lung lesions. Both flow and volume are plotted simultaneously on an X-Y recorder as subjects inhale fully to TLC and then perform an FVC maneuver. This is followed immediately by a maximal inspiration as quickly as possible back to TLC (Fig. 24-14) . Expiratory flow decreases over the latter half of the exhaled volume, despite the sustained expiratory effort indicated by the high positive pleural pressure. During maximal inspiration, airways do not undergo compression. Rather, with increasing inspiratory effort, airways become distended by the subatmospheric (negative) pleural pressure, and flow is increased. Thus, the entire inspiratory portion of the loop, as well as the expiratory curve near TLC, is highly dependent on effort. The ratio of expiratory flow to inspiratory flow at 50 percent of VC (mid-VC ratio) is normally about 1.0. This ratio is particularly useful in identifying the presence of upper airway obstruction, in which case inspiratory flow tends to be reduced more than expiratory flow, and the mid-VC ratio is increased (i.e., >1).

Flow-volume loops not only aid in suspecting upper airway obstruction but may also help to localize the site and the nature of the obstruction. Several characteristic patterns have been described. Perhaps the most common lesion is a fixed obstruction, such as a benign stricture resulting from tracheostomy or tracheal intubation. A tumor or mass such as a goiter may also produce a similar picture, as would breathing through a fixed external resistance. No significant change in airway diameter occurs during inspiration or expiration. As a result, expiratory flows show a plateau of constant flow over the effort-dependent portion of VC. Inspiratory flows show a similar plateau (Fig. 24-15A) . Because

Figure 24-14 Schematic representation of a maximum inspiratory ($\dot{V}_I$) and expiratory ($\dot{V}_E$) flow volume loop in a normal subject. The pleural pressure (ppl) associated with the maximal efforts are plotted as a function of lung volume from total lung capacity (TLC) to residual volume (RV). $\dot{V}_I$ and $\dot{V}_E$ at the midpoint (50%) of vital capacity are indicated by arrows.

Figure 24-15 Maximum inspiratory and expiratory flow-volume curves (flow- volume loops) in four types of airway obstruction.

both are reduced to nearly the same extent, the mid-VC ratio remains approximately 1.0.

A lesion whose influence varies with the phase of respiration is termed a variable obstruction. In order to understand the impact of such lesions on flow, it is necessary to characterize the behavior of the three basic partitions of the airway (Table 24-4) .

Variable extrathoracic obstructions (Fig. 24-15B) are most commonly associated with vocal cord paralysis, which is usually accompanied by inspiratory stridor. A similar pattern may be seen with marked pharyngeal muscle weakness in curarized volunteers [16] and in chronic neuromuscular disorders. [17] The flow pattern has also been noted occasionally in patients with severe obstructive sleep apnea. During forced inspiration, the negative transmural pressure inside the airway tends to collapse the airway with increasing effort and, thus, reduces inspiratory flow. During expiration, the positive pressure within the upper airway tends to decrease the obstruction so that expiratory flow is reduced far less and

may even be normal. The mid-VC ratio of expiratory to inspiratory flow is often greater than 2.0.

The other form of variable obstruction occurs intrathoracically and is usually caused by tumors of the tracheal or major bronchi. During forced expiration, the high pleural pressures decrease airway diameter and may increase the obstruction. A plateau flow usually occurs during expiration when the compressed airway lumen assumes its minimal size at the area of the lesion (Fig. 24-15C) . During inspiration, the lowering of pleural pressure surrounding the airway tends to decrease the obstruction, such that the inspiratory portion of the flow-volume loop may be normal. The mid-VC ratio of expiratory flow is low as in the case of diffuse airway obstruction (Fig. 24-15D) . However, the shapes of the curves differ. Curve D, an example of diffuse or distal airway obstruction, exhibits abnormal decreased flow in the segment near RV. Curve C, conversely, demonstrates normal flow in this area.

The physiologic diagnosis of upper airway obstruction is sometimes difficult in the patients with diffuse airway obstruction, such as chronic bronchitis and asthma. These conditions themselves produce significant abnormalities of the flow-volume loop (see Fig. 24-15D). Therefore, flow-volume loops clearly identify upper airway

obstruction best in the absence of significant generalized airway disease.

/das/book/view/29494766/875/254.html

TESTS OF EARLY LUNG DYSFUNCTION

During the past 2 decades, there has been continued interest concerning disease in the peripheral airways. Several terms, such as "small airway disease," "early obstructive lung disease," and "minimal airway dysfunction," have been used to describe abnormalities of the small peripheral airways.

The basic concept has evolved that peripheral airway obstruction is a forerunner of chronic bronchitis and emphysema. These processes are thought to be moderately advanced and irreversible by the time routine indices of pulmonary function, such as FVC and FEV_1, become abnormal. Testing of such early lung dysfunction has included measurements of abnormal resting gas exchange, distribution of ventilation, airway instability, and variables derived from maximum expiratory flow-volume curves.

The initial enthusiasm with which these tests were greeted has been tempered somewhat by the complexity of the equipment required and their inherent variability because of technical and biologic factors. Furthermore, these test results did not always correlate with respiratory symptoms and, more importantly, with pathology in the small airways, that is, respiratory bronchioles <2 mm in diameter. [18] Despite this lack of specificity, these tests are sensitive indices of abnormal function of airways and lung parenchyma, and an understanding of their physiologic principles provides important perspective and insight into abnormalities of pulmonary function.

Alveolar-Arterial Oxygen Tension Difference

Abnormally high alveolar-arterial oxygen tension gradients during room air breathing are common in asymptomatic smokers and in patients with minimal signs of chronic bronchitis. Although the alveolar-arterial oxygen tension gradient appears to be a sensitive means of detecting regional ventilation-perfusion inequalities, the test is not widely used for screening purposes, because of the difficulty in measuring alveolar oxygen tension (P_{AO_2}), which must be estimated from the alveolar air equation. The oxygen tension of the warmed humidified inspired gas in the trachea is represented as P_{IO_2}. [19] The gas in the alveoli, however, also contains carbon dioxide. As a rule, less carbon dioxide is produced than oxygen consumed. This ratio of carbon dioxide production to oxygen consumption is the respiratory exchange ratio (R), which is usually assumed to be 0.8. A simple calculation of P_{AO_2} for bedside use may be derived by dividing Pa_{CO_2} by R, or simply multiplying the carbon dioxide value by 1.25, and then subtracting the value from P_{IO_2}. Therefore, the alveolar gas equation may be written simply as

$$P_{AO_2} = P_{IO_2} - Pa_{CO_2}/R$$

The normal alveolar-arterial oxygen tension gradient with subjects breathing room air averages 8 mm Hg in young persons and increases linearly with age. By the 8th decade, the typical values may reach 25 mm Hg. This widening of the alveolar-arterial oxygen tension gradient with age and in disease states results solely from decreases of Pa_{O_2}, not P_{AO_2}.

Frequency Dependence of Compliance

Another phenomenon demonstrable in asymptomatic smokers and attributed to small airway dysfunction is a decrease in dynamic compliance with increased rates of breathing. This was one of the first tests to be proposed as an indicator of small airway dysfunction and can still be regarded as somewhat of a standard. Compliance is considered frequency dependent if the dynamic compliance at any of the increased breathing rates falls to less than 80 percent of the static compliance. Most workers have measured dynamic compliance as the change in lung volume during a tidal breath divided by the maximal change in transpulmonary pressure. The static compliance is derived from the slope of an inspiratory static pressure-volume curve over the usual range of tidal volume. Both compliance measurements require the insertion of an esophageal balloon to estimate transpulmonary pressure (difference between esophageal pressure and mouth pressure). Because of the sophisticated equipment required and the discomfort associated with balloon insertion, the test is not technically suited for general screening purposes. Nevertheless, frequency dependence of compliance is commonly used as a reference for other tests in identifying peripheral airway dysfunction.

In normal lungs, alveoli fill and empty synchronously at all physiologic respiratory rates. Therefore, compliance is not commonly dependent on respiratory frequency. Frequency dependence of compliance, conversely, implies asynchronous behavior wherein some regions of the lung are moving out of phase with others. The rate at which alveoli respond to a given pressure change by a change in volume is determined by their time constant, the product of their resistance and compliance. The more restricted or more compliant a unit of lung is, the longer it takes for air to enter or leave.

When various areas of the lung have different time constants, they fill and empty at different rates. During slow breathing, air can still be so equally distributed that dynamic compliance is not altered appreciably. However, during rapid breathing, air moves less rapidly into areas with long time constants, especially those with a high resistance. There is insufficient time to expand these areas. As a result, greater transpulmonary pressure is required to move the same volume of air, and dynamic compliance falls.

This asynchronous behavior of lung units has been ascribed solely to obstruction in the small airways. However, other factors may cause time-constant discrepancies throughout the lung and must be eliminated before changes in dynamic compliance are attributed solely to small-airway obstruction. These may include abnormal lung elasticity, obstruction in the large central airways such as might occur with a bronchial tumor, and diffuse airway constriction. In the case of the former, static compliance would be abnormal, whereas abnormally increased airway resistance is likely in the latter two situations.

Multiple-Breath Nitrogen Washout

Measurements of the uneven distribution of ventilation are also sensitive to mild airway obstruction. If the resident nitrogen in the lung is washed out by breathing 100 percent oxygen, the concentration of nitrogen decreases as cumulative expired volume decreases. When the distribution of ventilation is normal and uniform, the lung appears to behave as a single compartment that produces a relatively fast single exponential washout curve for nitrogen (Fig. 24-16). In the abnormal patient with lung disease and nonuniform

Figure 24-16 Schematic representation of multiple breath nitrogen washout curves in a young healthy nonsmoker (normal) and an asymptomatic smoker (abnormal). Expired nitrogen concentration is plotted on a logarithmic scale against cumulative expired volume during pure oxygen breathing.

ventilation, the curve deviates from the single exponential and appears to contain more than one ventilatory compartment. Different lung units have their nitrogen diluted at different rates. The fast, well-ventilated alveoli cause a rapid decrease in expired nitrogen, whereas slow, poorly ventilated areas produce a prolonged tail on the washout curve. Ingram and Schilder [20] reported a direct relationship between nitrogen clearance and frequency dependence of compliance. Unequal time constants throughout the lung may explain both phenomena. Although multiple-breath nitrogen washout appears to be a sensitive test, appropriate analysis of the curve is tedious and requires computerization in order to be practical as a screening test.

Single-Breath Nitrogen Washout

Inequality of ventilation can also be measured by the single-breath nitrogen test, which has been used extensively since its original description by Fowler [21] in 1949. The expired nitrogen concentration was measured after inspiration of 1 L of oxygen from FRC. The change in nitrogen concentration between 750 and 1250 mL of expired volume was originally used as an index of uneven ventilation. Later, it was shown that this change in nitrogen concentration could also be measured from the plot of nitrogen versus lung volume in the resident gas technique as used to measure closing volume (CV). Instead of inspiring only 1 L, the patient makes a full inspiration from RV to TLC with pure oxygen. A line of best fit is drawn through the alveolar plateau (phase III, Fig. 24-17) , and the increase in nitrogen concentration per liter is quantitated. The alveolar nitrogen slope with this technique is less steep than the original Fowler technique. This results from the fact that oxygen is preferentially distributed to the lung bases when only 1 L is inspired from FRC. The nitrogen in lung apices is less diluted with oxygen, compared with when oxygen is inspired over the whole range of VC. This higher apexto-base nitrogen gradient (original standard technique) produces

Figure 24-17 Schematic representation of the plot of nitrogen (N_2) concentration versus expired volume during the closing volume (CV) measurement with resident gas technique. (CC, closing capacity, the sum of residual volume [RV] and CV; TLC, total lung capacity.)

a steeper rise in exhaled nitrogen than the new technique, in which less of an apex-to-base nitrogen gradient is established.

The slope of the alveolar nitrogen plateau ($^{Delta}N_{2\%}$ /L) is larger in old than in young subjects, reflecting the increasing uneven ventilation with age. Buist and Ross [22] found that $^{Delta}N_{2\%}$ /L was less than 2 percent in male nonsmokers regardless of age and as high as 10 percent in smokers. They also noted that nearly half of the asymptomatic smokers they tested had an abnormal alveolar nitrogen slope compared with their own predicted values. Therefore, quantitative analysis of the alveolar plateau (phase III) appears to be a sensitive test of early changes in the lungs of cigarette smokers. When found to be abnormal, there is a reasonable likelihood of structural abnormalities.

Closing Volume

One of the tests most frequently associated with the concept of small airway obstruction is the measurement of CV. The term describes the lung volume at which airways in dependent areas in the lung begin to close or, more precisely, cease contributing to the expired gas. This phenomenon presumably occurs because of gravity-dependent gradients in pleural pressure. At or near RV, the lower portions of the lungs are subjected to pleural pressures in excess of airway pressures. Hence, these airways are prone to close or, more precisely, contribute little to the expired gas.

The CV test attempts to detect the lung volume at which this phenomenon occurs. The basic technique is to tag these dependent lung areas by giving them a different concentration of a tracer gas than the ones that remain open near end-expiration. As a subject inspires from RV to TLC, a concentration difference for the tracer gas is created between the top and the bottom of the lung as a result of differences in distribution of ventilation. During the subsequent slow exhalation, the changing concentration of tracer gas is plotted against lung volume on an X-Y recorder. Two methods utilize

this principle to estimate CV: the bolus technique and the resident-gas technique.

The bolus technique employs a bolus of tracer gas. Although xenon and argon were originally used, the easier availability of helium has made it most popular. The technique depends on the principle that a bolus of gas inspired at RV is distributed preferentially to the apical lung areas because small airways in dependent lung zones are far less patent at these low lung volumes. Therefore, the preexpiratory concentration gradient created for the tracer gas results in the apical areas' containing most of the marker gas, whereas lower basilar areas contain very little.

The resident gas technique also depends on the creation of a preexpiratory concentration gradient of marker gas from top to bottom of the lung. However, it differs from bolus technique in two ways. First, the tracer gas is the nitrogen already present or resident in the lungs. Second, there is normally little difference in nitrogen concentration at TLC between the top and the bottom of the lung when a person is breathing air. Therefore, a preexpiratory concentration gradient is artificially created by the use of oxygen to dilute the nitrogen normally present in the lungs. The nitrogen in all alveoli is not diluted equally. At RV, the alveoli at the bottom of the lung are smaller than those at the top. At TLC, all alveoli reach essentially equal volumes. Thus, during inspiration from RV to TLC, the lower basal alveoli undergo almost one and a half times the volume change undergone by the upper or apical alveoli. As a result, the nitrogen in the lower zones is diluted more by the inspired oxygen than is the nitrogen in the upper zones. There is approximately a 2:1 concentration gradient for nitrogen between top and bottom of the lungs.

In normal subjects, the nitrogen concentration appearing at the mouth after inspiration of 100 percent oxygen changes gradually throughout the expiration. A typical trace displays four basic phases (see Fig. 24-16) . The first three are familiar from Fowler's original single-breath nitrogen test. Phase I contains expired gas essentially free of marker, representing emptying from the dead space of the apparatus as well as of the conducting airways (anatomic dead space). Phase II consists of a rapid rise in the concentration of marker gas, which mixes with dead space gas as alveolar emptying begins. Phase III, or the alveolar plateau, is produced by the mixing of expired air with marker gas from all lung regions, each with different concentrations. The "ripples" appearing during phase III are termed "cardiogenic oscillations" because they correspond to cardiac systole and are believed to rise as a result of interruptions in gas flow from the dependent lung zones during cardiac systole. The alveolar plateau exhibits a small positive slope even in normal lungs; the extent of this rise has been used as an index of abnormality, as discussed previously.

Near the end of expiration, another abrupt increase in tracer gas concentration occurs (phase IV). The point at which phase IV begins has been designated the CV because the dependent airways have presumably closed or, more correctly, have essentially ceased contributing to the expired gas. Now, the exhaled gas arises almost entirely from the upper lung zones, whose concentration of marker gas (in this case, nitrogen) was high. The CV is the difference in volume between the onset of phase IV and RV. Because it represents a portion of the VC maneuver, it is usually expressed as a percentage of VC (CV/VC percent). Most published values for CV in normal healthy subjects in the sitting position are between 15 and 20 percent of VC.

The terminology is confused by another term, "closing capacity" (CC). This term is used to designate the volume between the onset of phase IV and zero lung volume; it thus includes CV and RV. Because it is the absolute lung volume at which phase IV occurs, it is usually expressed as a percentage of TLC (CC/TLC percent).

Although the onset of phase IV is usually taken to represent a unique volume at which actual closure of the small airways occurs, Hyatt and Rodarte [23] suggested that rather than closing off, the small airways may merely be emptying more slowly because of dynamic compression and the resultant increased resistance to flow. This impression is based on the evidence that phase IV occurs at the time the lungs reach flow limitation and continue to empty at a decreased rate despite increasing transpulmonary pressures. This same phenomenon occurs during the later portions of the MEFV curve. In fact, high expiratory flow rates, such as those characterizing the MEFV curve, can actually increase the lung volume at which phase IV occurs, presumably because of some dynamic airway compression. Thus, in order to produce a satisfactory trace when measuring CV, one must ensure that expiration be performed slowly (about 0.5 L/s). This can be ensured by introducing mechanical resistance into the breathing circuit.

Whether the mechanism is closure or compression, most observers have noted significantly increased values for CC in cigarette smokers when compared with

nonsmokers of the same age. These findings have been cited as evidence of small airway disease. However, Hoeppner et al [24] suggested that these changes in CC in smokers reflect a loss of elastic recoil and not necessarily intrinsic small airway pathology. This same relationship between CC and lung elastic recoil is clearly demonstrated by the changes that occur with age. The progressive reduction in lung recoil and its associated tethering action on the bronchioles produce an increase in CC with advancing age; until age 65, CC exceeds the FRC (CC > FRC), even in seated individuals. [25] Young children who exhibit reduced values for lung elastic recoil likewise have increased closing capacities. [26] The smallest CC values occur in subjects during the late teens, when maximal values for static elastic recoil are observed.

Regardless of whether an increased CV represents intrinsic airway disease or parenchymal disease with loss of elastic recoil, the sensitivity of the measurement renders it a likely indicator of early functional abnormality that may represent lung disease. Perhaps the major obstacle to its application has been the difficulty of establishing well-defined limits of normality because of variability between measurements even under ideal conditions.

Maximum Expiratory Flow Rates

The frictional resistance of the small airways affects flows at low lung volumes, that is, after more than 50 percent of FVC has been expired. Reduced values for flow at the "foot" of the MEFV curve (see Fig. 24-6) have often been observed in smokers compared with nonsmokers, when no differentiations were possible on the basis of FEV_1 measurements. Unfortunately, normal variations sometimes make quantitation and interpretation of these flows at low lung volumes difficult.

Because of this difficulty in defining abnormal flows at low lung volumes, a modification of the maneuver has been devised to detect mild airway obstruction. The MEFV curves inscribed after inspiration of a gas mixture of low density (80 percent helium and 20 percent oxygen) are compared with those obtained during the breathing of air. Maximum flow in normal individuals is dependent on the density of the gases breathed and increases with gases of low density. However, this is true during the FVC maneuver only as long as the EPPs remain predominantly in the larger, more central, airways. In these airways, most of the resistance to air flow is due to connective acceleration and turbulence, both of which are density dependent.

In patients with obstructive lung disease, because of diminished elastic recoil and increased resistance of small upstream airways, the EPPs lie in the small airways, even at higher lung volumes. As a result of this peripheral airway obstruction, flow is less density dependent and does not increase with helium. Unfortunately, this response to breath-ing helium, although physiologically interesting, is too highly variable, even in normal subjects because of variations in lung recoil, airway geometry, performance, and interpretation, to lead to precise diagnosis concerning airway dysfunction.

Defining Normal Values

An important aspect of pulmonary function testing lies in defining what is normal and what indicates the presence of respiratory disease. The results are commonly interpreted in relation to reference values to determine whether or not they lie within a certain normal range. One statistically acceptable approach is to define as abnormal the lowest 5 percent of the reference population. For most tests, the results of large numbers of normal patients have been used to generate regression equations based on age, gender, race, and most importantly, height. [27] Although a number of clinical laboratories simply designate that values of FVC and FEV_1 less than 80 percent are predicted as abnormal, this arbitrary standard has no statistical basis and should be avoided. [28]

If one assumes a gaussian distribution, the 95 percent confidence limits can be derived as 1.65 times the coefficient of variation. The latter is the quotient of the standard deviation and the mean. For FVC and FEV_1, coefficients of variation are 12 to 13 percent in large groups of normal subjects. [29] Thus, a value 1.65 times these variations indicates that a measurement must be about 21 percent lower than the mean to be considered abnormal. Interestingly, the coefficient of variation for $FEF_{25\%-75\%}$ is about 25 percent in similar populations. Thus, values must be 40 percent below the population before they are truly considered abnormal.

PULMONARY FUNCTION TESTING IN SURGICAL PATIENTS

Significant postoperative changes in pulmonary function in many surgical patients include such phenomena as reduced lung volumes, rapid shallow breathing, and impaired gas exchange (Ch. 25) . These alterations in pulmonary function may occur as a result of the anesthetic, the surgical procedure, the associated body position, or the medications administered immediately after surgery. It has been suggested that the changes that occur in normal patients may be more severe in patients who undergo surgery with compromised pulmonary function and thus may produce significant postoperative pulmonary complications. Such complications usually include bronchospasm, bronchitis with purulent sputum, disabling cough pneumonia, and respiratory failure, as indicated by altered blood gases. Indeed, preexisting lung dysfunction is the major factor associated with postoperative pulmonary problems. Also important are incisional site and size, as well as possible surgical trauma to lung tissue. Both of these render the patient for thoracic surgery a prime candidate for evaluation.

The large body of literature suggests that preoperative pulmonary function testing provides the clinician with important information regarding the potential for postoperative respiratory morbidity. If pulmonary function data are of value, which patients are candidates for such testing? Although no general agreement exists as to which patients should be tested, the prime candidates are those in whom there is reasonable expectation of abnormal pulmonary function. This broad list has long included the following:

1. Patients with any evidence of chronic pulmonary disease
2. Heavy smokers with history of persistent cough
3. Patients with wheezing or dyspnea on exertion
4. Patients with chest wall and spinal deformities
5. Morbidly obese patients
6. Patients with thoracic surgery
7. Elderly patients (>70 years of age)
8. Patients who are to undergo upper abdominal surgery

Conflicting data abound regarding these broad criteria. This has led the American College of Chest Physicians to propose a more stringent set of guidelines. Adherence to these stricter American College of Chest Physicians guidelines has been recommended as a means of decreasing unnecessary and costly spirometric testing. [30] The American College of Chest Physicians criteria confine preoperative spirometry to patients who are to undergo lung resection, those who undergo cardiac and upper abdominal surgery in the presence of a history of smoking and dyspnea, and patients with pulmonary symptoms and uncharacterized disease who undergo prolonged lower abdominal surgery.

Initial identification of most of these patients is accomplished by history, physical examination, and chest x-ray studies. The chest film is a particularly valuable clinical marker for clinically severe disease, especially if lung hyperinflation is identified. The latter was associated with a 33 percent rate of significant postoperative pulmonary complications. [31]

The question then arises as to which pulmonary function studies are appropriate for preoperative evaluation. The objective of testing in the preoperative setting is not to detect mild early lung disease but rather to predict the likelihood of pulmonary complications. No single test appears to be the best predictor of risk, probably because none assesses all of the factors that are important regardless of whether complications will occur. The optimal scheme for evaluating patients preoperatively is by means of arterial blood gas analysis and the FEV_1, FVC, FEV_1/FVC percent, peak flow, and

forced midexpiratory flow, which can be obtained from a single spirometric study. Abnormalities on such spirometric tests seem to correlate with the incidence of postoperative pulmonary complications. [4]

Although the emphasis in evaluating preoperative pulmonary function is largely aimed at predicting the risk of postoperative complication, the identification of abnormal lung function and in particular obstructive airway disease is also important to reduce intraoperative morbidity. A reduced FEV_1/FVC, for example, not only documents the existence of airway obstruction but also suggests the likelihood of increased airway reactivity. The site and the nature of many surgical procedures often provide very little latitude for choosing between regional and general anesthesia. In patients with airway obstruction and heightened airway reactivity, airway instrumentation, such as laryngoscopy and tracheal intubation, is fraught with the hazard of provoking reflex bronchoconstriction, particularly under light planes of anesthesia. In many patients with obstructive airway disease, the deeper levels of inhalation anesthesia required to blunt such airway reflexes are difficult to achieve because of poor ventilation perfusion matching and, if achieved, are poorly tolerated by the cardiovascular system. Thus, it is important to utilize other prophylactic measures to minimize airway responses. These may include anticholinergics and beta agonists inhaled as aerosols before surgery and intravenous opioids and lidocaine administered before airway instrumentation.

Patients with abnormally low FEV_1 values before surgery are likely to experience severe hypercapnia if they are allowed to breathe spontaneously under general anesthesia. [32] The magnitude of the carbon dioxide increase is directly related to the degree of reduction in FEV_1 and develops largely because the rapid shallow breathing pattern characteristic of anesthetized patients worsens ventilation perfusion matching. It is therefore essential to control ventilation in such patients. With controlled ventilation, low respiratory rates (<10/min) are desirable to minimize ventilation/perfusion mismatch, which largely arises because of the prolonged time required to move air in and out of the obstructed airways. Because of this obstruction, low inspiratory flow rates have long been advocated to minimize peak airway pressure and presumably barotrauma and circulatory disturbances; however, evidence suggests the opposite. In patients with chronic obstructive pulmonary disease ventilated with customary tidal volumes (10 mL/kg), respiratory system resistance actually decreased as inspiratory flow rates were increased from 0.25 to 1.5 L/s. [33] The authors postulated that this effect was due to decreases in thoracic tissue resistance or was a reflection of time constant inequalities and or the visco-elastic behavior of the respiratory system. Other studies have shown that a high inspiratory flow rate in such patients produced improved gas exchange and was not complicated by barotrauma or circulatory depression. [34] [35] An important consequence of the increased inspiratory flow rate was a reduced inspiratory time, which then allowed increased time for exhalation. This increased expiratory time provides more complete emptying of alveoli, which must do so through high-resistance airways. Conversely, with a shorter expiratory time, which inevitably occurs with the increased inspiratory time needed with a lower inspiratory flow, alveoli are not allowed to empty completely. In addition, they actually receive less gas volume at the same distending pressures during inspiration.

/das/book/view/29494766/875/256.html

EVALUATION OF THE PATIENT FOR LUNG RESECTION

Resection of lung disease results in a greater impairment in postoperative lung function than most other types of surgery (Ch. 48) . Lung resection in patients with pulmonary dysfunction is associated, not surprisingly, with a high risk of postoperative complications, even the possibility of death. These patients require a more extensive pulmonary evaluation, particularly if removal of an entire lung is anticipated. A major aim of the evaluation is to decide whether the removal of lung tissue can be tolerated without compromising pulmonary function to a degree that the patient dies of pulmonary insufficiency or is severely disabled. The long-term ability to withstand such lung resection relates to the amount and the functional status of the lung parenchyma removed and more importantly to the function of the remaining lung tissue. Removal of lung from an already compromised patient may be followed by inadequate gas exchange, pulmonary hypertension, and incapacitating dyspnea.

Although much of the literature in this area emphasizes long-term disability in the pneumonectomy patient, in patients undergoing lobectomy, the immediate impact on pulmonary function may be as great because of surgical trauma to the remaining tissue of the same lung. The pulmonary function studies must be viewed in light of the patient's age, the status of the cardiovascular system, and the patient's cooperation and motivation. Data in pneumonectomy patients indicate that whole lung removal is likely to be tolerated if the preoperative pulmonary function meets the following criteria [36] : (1) FEV_1 greater than 2 L and FEV_1 /FVC ratio of at least 50 percent, (2) MVV greater than 50 percent of predicted, and (3) ratio of RV to TLC less than 50 percent.

If any of these criteria are not met, more sophisticated testing of split lung function is indicated in order to estimate the relative functional contribution of each lung. If, for example, the lung to be removed contributes less to ventilatory function than the other lung, low spirometric values are not as ominous. Usually, split function testing consists of xenon radiospirometry to assess ventilation and macroaggregates of iodine or technetium to scan perfusion. The relative contribution of each lung to either total ventilation or perfusion can be used to predict postoperative pulmonary function. A predicted postoperative FEV_1 of at least 800 mL is required before pneumonectomy should be performed. The risk of significant resting carbon dioxide retention and resting dyspnea appears to be high with FEV_1 values less than this. If surgery is still contemplated in the face of this low predicted FEV_1 , an invasive study is recommended. The pulmonary artery of the lung to be removed can be subjected to occlusion by a balloon. If pulmonary hypertension (mean pulmonary arterial pressure >35 mm Hg) and arterial hypoxemia (Pa_{O_2} <45 mm Hg) do not occur, it can be assumed that the remaining lung may be able to accommodate the entire cardiac output. Such a patient may be allowed to undergo surgery in spite of failure to fulfill the mechanical ventilatory criteria. The indications for performing this invasive procedure are not agreed on universally, but many physicians still heed the advice of Olsen et al [36] that balloon occlusion, if feasible, should be performed when the less invasive studies are inconclusive.

The past decade has seen an increased emphasis on preoperative evaluation of exercise capacity before lung resection.

Continued observations suggest that a patient's maximal oxygen uptake during exercise (V_{O_2} max) was an accurate preoperative means of identifying patients likely to experience postthoracotomy morbidity. [37] The V_{O_2} max is essentially a measure of physical fitness and thus reflects the ability to survive the stresses of the perioperative period and beyond. During exercise, the lung must accommodate the increased ventilation and blood flow, much like the remaining lung will experience after pneumonectomy. Patients with V_{O_2} max values of 20 mL/kg/min or more had minimal morbidity. Those with a V_{O_2} max of 15 mL/kg/min or less had increased cardiopulmonary complications, whereas those whose V_{O_2} max was less than 10 mL/kg/min appeared to have an unacceptably high risk and a mortality rate of greater than 30 percent in the short term. Insight into these V_{O_2} max values is provided by evidence that a two-flight stair climb (20 steps/min) without dyspnea approximates a V_{O_2} max of about 16 mL/kg/min. [38] The ability to walk 180 feet in 1 minute corresponds to about 12 mL/kg/min.

It appears that resting pulmonary function testing does not accurately predict exercise performance in patients with more severe lung disease. [39] Thus, cardiopulmonary exercise testing may be necessary to evaluate the degree of impairment. Exercise testing has become attractive because it reflects gas exchange, ventilation, tissue oxygenation, and cardiac output. When the latter is increased, blood flow to the pulmonary vascular bed increases, much like occurs when flow is diverted to the lung tissue remaining after resection. Thus, any patients who otherwise might have been considered inoperable on the basis of FEV_1 values might be considered to be operative candidates because of their performance and high V_{O_2} max during exercise. Conversely, patients with marked reductions in exercise oxygen consumption before surgery appear to be at high risk for postoperative morbidity, regardless of how well they performed on routine and split-function pulmonary testing.

PREOPERATIVE MEASURES TO IMPROVE LUNG FUNCTION

Aside from assessing operability in candidates for lung resection, the major goal of identifying preoperative pulmonary dysfunction is to alter outcome by reducing the morbidity and mortality associated with postoperative pulmonary complications (Chs. 23 and 25) . The assumption is that the patients identified as abnormal may benefit from the therapeutic measures to improve lung function, and thus the likelihood of postoperative complications may be reduced. Several groups have applied such therapy to poor-risk patients and have produced a decrease in the postoperative complications to levels approaching those found in patients with normal function. [40] [41] [42]

Usually, the therapy is carried out for 48 to 72 hours before surgery. However, it is equally important that some of the measures be continued after surgery as well. The treatment regimen is aimed largely at four modalities: (1) smoking cessation, (2) mobilization of secretions, (3) therapy for bronchospasm, and (4) improving motivation and stamina. Although it is generally assumed that smoking cessation is followed by a decrease in volume of airway secretions and airway reactivity as well as improved mucociliary transport, these beneficial effects take 2 to 4 weeks to develop. [43] The shorter-term (48-72 hours) effects may actually be associated with increased secretions and hyperactive airways. The major benefit from discontinuing smoking in the immediate preoperative period appears to be the decrease in carboxyhemoglobin content and thus better oxygen availability to the tissues. There is additional evidence that the sensitive upper airway reflexes of smokers are reduced by abstinence. [44] It is therefore reasonable to expect that adverse events so common during induction of anesthesia (cough, breath holding, and laryngospasm) would be reduced. [45]

The removal of secretions is an important component of preoperative preparation because their persistence increases the likelihood of infection and increased airway reactivity. Antibiotic therapy for patients with chronic bronchitis may be helpful, but the secretions are best loosened by adequate hydration, both systematically and by heating of aerosol therapy. The use of mucolytic agents and oral expectorants is at best of questionable benefit and is fraught with the hazards of increasing airway irritability and other side effects, such as gastrointestinal irritation. Mucociliary clearance is impaired in such patients, and cough is infestive because of an inability to generate sufficient air flow rates. Therefore, mechanical measures must be utilized to dislodge secretions and move them into the more proximal airways, where cough can more readily remove secretions. Such therapy is limited to percussion and vibration as well as postural drainage.

Reactive airways and reversible air flow obstruction are common features, especially in patients presenting for thoracic surgery. Thus, the use of medications to establish and sustain normal airway function is important in the perioperative period. beta $_2$ -Sympathomimetic aerosols are the mainstays for treatment and prevention of bronchospasm. The use of the quaternary anticholinergic compound ipra-tropium may also be helpful, particularly in patients in whom tachycardia is a concern with beta$_2$ -sympathetic drugs. [46] Theophylline is also often added to this regimen; however, there is considerable concern regarding toxicity and limited efficacy of intravenous theophylline when administered acutely.

The final preparative measure in thoracotomy patients concerns improving motivation and stamina. Education and practice with incentive spirometry devices are important in the maintenance of postoperative lung volume and coughing efficacy. Such preparation and continued postoperative use appears to be far more effective than intermittent positive-pressure breathing therapy. [47]

Utilization of the preparatory respiratory care maneuvers ultimately benefits the patient and contributes to reducing the incidence and the severity of postoperative respiratory complications. The question remains, however, of whether such an improved outcome actually reflects pulmonary function on spirometric testing. It may be unreasonable to expect a dramatic reversal in air flow obstruction and improved blood gases with such a brief (48-72 hour) regimen. Gracey et al [48] attempted to improve pulmonary function before surgery in patients with chronic obstructive pulmonary disease with such a standardized regimen. Although this therapy produced statistically significant changes in several tests of pulmonary function, the functional significance of the changes was doubtful. Nevertheless, the incidence of

complications in these improved patients was dramatically reduced, as in other studies. There are no definitive data that can identify whether this reduced complication rate results specifically from the preparation regimen, the use of specific agents or techniques, or just the added attention paid to patients in whom airway obstruction or other pulmonary dysfunction is identified.

It appears reasonably well established that patients whose clinical history and physical examination suggest the presence of pulmonary disease are at increased risk if spirometric results are abnormal. It is unclear exactly what should be done for such patients with abnormal test results short of an abbreviated regimen of preoperative preparation and concern intraoperatively for controlling airway reactivity. Equally uncertain is which test best predicts risk and what further testing is appropriate for patients with abnormal spirometric results. Nevertheless, in those about to undergo pulmonary resection, exercise testing seems to provide the best predictive insight.

Chapter 25 - Anesthetic Implications of Concurrent Diseases [*]

Michael F. Roizen

/das/book/view/29494766/875/260.html

INTRODUCTION

This chapter discusses conditions requiring special preoperative evaluation and intraoperative management. Patients undergoing surgery move through a continuum of medical care to which a primary care physician, an internist or pediatrician, an anesthesiologist, and a surgeon or radiologist or obstetrician-gynecologist contribute to ensure the best outcome possible. No aspect of medical care requires greater cooperation among physicians than does the performance of a surgical operation and the perioperative care of a patient. The importance of integrating physicians' expertise is even greater within the context of the increasing life span of our population. [1] As the number of the elderly and the very old (those >85 years of age) grows, so does the need of surgical patients for preoperative consultation that helps plan for comorbidity and multiple-drug regimens, knowledge of which is crucial to successful patient management. At a time when

* *See Appendix I, Practice Guidelines for Preoperative Fasting and the Use of Pharmacologic Agents to Reduce the Risk of Pulmonary Aspiration*

medical information is encyclopedic, it is difficult for even the most conscientious anesthesiologist to keep abreast of the medical issues relevant to perioperative patient management. This chapter reviews such issues.

As with "healthy" patients (Ch. 23) , it is the history and physical examination of these patients that most accurately predict not only the associated risks but also the likelihood that a monitoring technique or change in therapy will be beneficial or necessary for survival. This chapter emphasizes those instances in which specific information should be sought in history-taking, physical examination, or laboratory evaluations. Although controlled studies designed to confirm that optimizing a patient's preoperative physical condition would result in lower morbidity have not been performed for most diseases, it is logical to assume that such is the case. Studies showing the benefits of optimizing specific preoperative conditions are highlighted. The fact that such preventive measures would cost less than treating the morbidity that would otherwise occur is an important consideration in a cost-conscious environment.

Recent data indicate that minimally invasive procedures such as cataract extraction, magnetic resonance imaging, or diagnostic arthroscopy (see Table 23-10) , performed in conjunction with the best current anesthetic practices, pose no greater risk than that of daily living and thus might not be considered an opportunity for special evaluation. Nonetheless, preanesthetic evaluations were found to provide information that led to changes in health-care plans for more than 15 percent of all American Society of Anesthesiologists (ASA) I and II patients (and for >20% of all patients in general) at the University of Florida (Gibby GL, et al, personal communication). Although these changes in care plans were attributable to data found on history and observation (the most common being gastric reflux, diabetes mellitus requiring insulin, asthma, and suspected difficult intubation), no data show that patient outcome was improved by such changes. Nevertheless, logic caused practitioners to alter plans for such patients in ways that would delay operating room schedules and increase costs. Examples would be administering a histamine type-2 antagonist 1 to 2 hours before and an oral antacid immediately before entry to the operating room, obtaining equipment to measure blood glucose levels, obtaining a history of the patient's diabetic course and treatment from the primary care doctor as well as from the patient, and obtaining a fiberoptic laryngoscopic examination or additional skilled attention. Thus, even if preoperative evaluation were not to alter outcome in an important way, its ability to reduce costs by reducing unwarranted laboratory testing and delays in obtaining treatment and equipment perceived to be beneficial (and medicolegally required) would be substantial and would warrant its use.

Examples of determining the costs of such benefits can be found in Chapter 23 or in this chapter in the section on preoperative preparation of the patient with cardiovascular disease. Conditions discussed in this chapter are:

1. Diseases involving the endocrine system and disorders of nutrition
2. Diseases involving the cardiovascular system
3. Disorders of the respiratory and immune system
4. Diseases of the central nervous system (CNS), neuromuscular diseases, and mental disorders
5. Diseases involving the kidney, infectious diseases, and disorders of electrolytes
6. Diseases involving the gastrointestinal (GI) tract or the liver
7. Diseases involving hematopoiesis and various forms of cancer
8. Diseases of aging or that occur more commonly in the aged, as well as chronic and acute medical conditions requiring drug therapy (Chs. 53 - 55 and 61) .

ROLE OF THE PRIMARY CARE PHYSICIAN OR CONSULTANT

The role of the primary care physician or consultant is not to select or suggest anesthetic or surgical methods but rather to optimize the patient's preoperative status regarding those conditions that increase the morbidity and mortality associated with surgery.

Quotations and a table in the Medical Knowledge Self-Assessment Program published in 1992 by the leading organization representing internists, the American College of Physicians, highlight this role for the consultant [2] :

Consultation practice is an important component of virtually every internist's professional activity and in some specialties accounts for up to 50 percent of patient care time. Effective interaction with colleagues in other specialties requires a thorough grounding in the language and science of these other disciplines as well as an awareness of basic guidelines for consultation [Table 25-1] (Table Not Available) .... The consulting internists' role in perioperative care is focused on the elucidation of medical factors that may increase the risks of anesthesia and surgery.... Selecting the anesthetic technique for a given patient, procedure, surgeon, and anesthetist is highly individualized and remains the responsibility of the anesthesiologist rather than the internist.

Optimizing a patient's preoperative condition is a cooperative venture between the anesthesiologist and the internist, pediatrician, surgeon, or family physician. If the primary care physician cannot affirm that the patient is in the very best physical state attainable (for that patient) by that physician and his or her consultants, the anesthesiologist and the physician should do what is necessary to optimize that condition. Failing to consult with the primary care physician preoperatively is as risky as not checking the oxygen in the spare tanks. In fact, statements that describe the preoperative physical

TABLE 25-1 -- Guidelines for Consultation Practice

(Not Available)

From the American college of Physicians [2]

condition of the patient (e.g., "This patient is in optimum shape" and "I believe the mitral stenosis is more severe than the slight degree of mitral insufficiency") are much more useful to the anesthesiologist than are statements that suggest overall clearance ("cleared for surgery") or perioperative procedures ("prevent hypoxia and hypotension").

Primary care physicians can prepare and treat a patient for optimal conditions for daily life. However, they do not have the depth of understanding of the anesthesiologist regarding the physiologic changes brought on by surgery and the manipulations of functioning that must be made to facilitate surgery and optimize perioperative outcome. One example would be the primary care physician's induction of some degree of prerenal azotemia for the patient with congestive heart failure. The volume depletion associated with prerenal azotemia may make the cardiac patient more comfortable in daily life but would predispose him or her to hypovolemic disaster during surgery. Thus, although it would be desirable for the primary care physician to start the process of preparing the patient for the needs of surgery, this activity would not be compatible with the current state of knowledge or functioning of the vast majority of primary care physicians. Although such education is more available and of better quality than in prior decades, [3] [4] [5] [6] [7] and although Mangano and colleagues, [7] Goldman and associates, [8] Charlson et al, [9] and even cardiologic organizations [10] have provided considerable data regarding the importance of this aspect of care, the training, knowledge, and ability of primary care physicians are still deficient in this aspect of consultation. Without understanding the physiologic changes that occur perioperatively, it is difficult to prescribe the appropriate therapy. It is therefore part of the anesthesiologist's job to educate the patient's consultants as to what information is needed from the preoperative consultation.

DISEASES INVOLVING THE ENDOCRINE SYSTEM AND DISORDERS OF NUTRITION

Pancreatic Disorders

Preoperative Diabetes Mellitus

This section makes nine major points regarding diabetes:

1. Diabetes itself may not be as important to perioperative outcome as its end-organ effects (see point 3 for exceptions). Although the presence of diabetes has long beenassumed to increase perioperative risk, results from epidemiologic studies may not support this assumption. These studies segregated the effects of diabetes per se on the organ system, from the effects of the complications of diabetes (e.g., cardiac, nervous system, renal, and vascular disease) and the effects of old age and the accelerated aging that diabetes causes. Surgical mortality rates for the diabetic population are on average five times higher than those for the nondiabetic population. [11] [12] However, in epidemiologic studies in which diabetes itself was segregated from the complications of diabetes (including cardiac and vascular disease) and old age, this finding was questioned. [12] [13] Similarly, if diabetics undergoing major vascular surgery are compared with nondiabetics who are matched for type of surgery, age, sex, weight, and complicating diseases, there is no difference in the mortality rate or the number of postoperative complications. [13]
2. Because diabetes represents at least two disease processes, its perioperative management may differ.
3. Chronic "tight" control of type I diabetes probably prevents, retards, or even ameliorates, to some degree, some of the chronic complications of diabetes. [14] However, current debate centers on the benefit associated with tight control and on the benefit-to-risk ratio. The evidence indicates that tight control of blood glucose might benefit the pregnant diabetic (and her future offspring) [15] (Ch. 57) , the diabetic undergoing cardiopulmonary bypass (Chs. 49 and 50) , and those undergoing (global) CNS ischemia [16] [17] (Chs. 19 and 52) . Little evidence indicates that tight control is of substantial benefit to any other group; the benefit-to-risk ratio of tight control has not been examined for any other group of patients. [3]
4. Different regimens permit almost any degree of perioperative control of blood glucose levels, but the tighter the control desired, the more frequently blood glucose levels must be monitored. Three treatment regimens are outlined later.
5. The major risk factors for diabetics undergoing surgery are the end-organ diseases associated with diabetes: cardiovascular dysfunction, renal insufficiency, joint collagen tissue abnormalities (limitations of neck extension, [18] poor wound healing), inadequate granulocyte production, and neuropathies. [11] [13] [19] Thus, a major focus of the anesthesiologist should be the preoperative evaluation and treatment of these diseases to ensure optimal preoperative conditions.
6. Regional anesthesia may be indicated to facilitate some procedures. The following considerations should be kept in mind regarding the use of regional anesthesia for diabetic patients. Local anesthetic requirements are lower and the risk of nerve injury is higher in diabetic patients. [20] [21] Also, combining local anesthetics with epinephrine may pose even greater risk of ischemic and/or edematous nerve injury in the diabetic.
7. Nosocomial infection rates can probably be decreased with outpatient surgery; complications may be decreased in those diabetics most at risk by either tight control of blood glucose or intense postoperative care, or both.
8. The United States has been experiencing a great and progressive growth in the number of people who are known to be diabetic. That growth parallels a gain in weight in the adult population that causes type II diabetes.
9. Both forms of diabetes cause accelerated aging. Thus, the risks involved in caring for someone with diabetes are similar to those for someone much older, i.e., someone who has a much higher physiologic age (or "RealAge" [22]).

More than 90 percent of the 16 million diabetics in the United States have non-insulin-dependent (type II) diabetes. Those with this type of disease tend to be elderly, overweight, and relatively resistant to ketoacidosis and susceptible to the development of a hyperglycemic-hyperosmolar nonketotic state. Plasma insulin levels are normal or elevated but are relatively low for the level of blood glucose. This hyperinsulinemia by itself is postulated to cause accelerated cardiovascular disease. [23] [24]

Insulin originates in the pancreas. Pancreatic islets are composed of at least three cells: alpha cells that secrete glucagon, beta cells that secrete insulin, and delta cells that contain secretory granules. Insulin is first synthesized as proinsulin, converted to insulin by proteolytic cleavage, and then packaged into granules within the beta cells. A large quantity of insulin, normally about 200 units, is stored in the pancreas; continued synthesis is stimulated by glucose. There is a basal, steady-state release of insulin from the beta granules and additional release controlled by stimuli external to the beta cell. Basal insulin secretion continues in the fasted state and is crucial to the inhibition of catabolism and ketoacidosis. Glucose and fructose are the primary regulators of insulin release. Other stimulators of insulin release include amino acids, glucagon, GI hormones (gastrin, secretin, cholecystokinin-pancreozymin, and enteroglucagon), and acetylcholine. Epinephrine and norepinephrine inhibit insulin release by stimulating alpha-adrenergic receptors and stimulate insulin release at beta-adrenergic receptors.

Diabetes mellitus is a heterogeneous group of disorders that have the common feature of a relative or absolute lack of insulin. The disease is characterized by a multitude of hormone-induced metabolic abnormalities, by a diffuse microvascular lesion, and by long-term end-organ complications. Diabetes can be divided into two very different diseases that share these end-organ abnormalities. Type I diabetes is associated with autoimmune diseases and has a concordance rate of 40 to 50 percent (i.e., if one of a pair of monozygotic twins had diabetes, the likelihood that the other twin would have diabetes is 40 to 50%). In type I, the patient is insulin deficient and is susceptible to ketoacidosis if insulin is withheld. For type II diabetes, the concordance rate is 100 percent (i.e., the genetic material is both necessary and sufficient for the development of type II diabetes). These patients are not susceptible to the development of ketoacidosis in the absence of insulin, and they have peripheral insulin resistance. Gestational diabetes develops in more than 2 percent of all pregnancies.

Type I and type II diabetes differ in other ways as well. Contrary to a long-standing belief, patient age does not allow a firm distinction between type I and type II diabetes; an older person can develop type I diabetes. A diabetesproducing variant of coxsackie B4 virus has been isolated from the pancreas of a patient who died of diabetic ketoacidosis (type I diabetes). This virus was also recovered from mice bred to be diabetes-prone after inoculation of the virus had produced hyperglycemia and pancreatic beta cell necrosis coincident with rising antibody titers. [25] Thus, the intrinsic genetic "vulnerability" in insulin-dependent type I diabetes mellitus may consist of diminished capacity of beta cells to survive exposure to potentially damaging extrinsic agents.

A recent series uncovered a genetic focus for some forms of diabetes, and another linked autoantibodies (some related to early-life exposure to cow's milk) to the glucose transporter in the pancreas as a major initiator of insulin deficiency in type I diabetes. Experimental treatment with cyclosporine to prevent diabetes after early discovery is based on suppressing the autoimmunity. Type I diabetes is associated with a 15 percent prevalence of other autoimmune diseases, including Graves disease, Hashimoto thyroiditis, Addison disease, and myasthenia gravis.

Currently, therapy for type II diabetes usually begins with exercise and dietary management. A 5- to 10-kg weight loss over 8 weeks, associated with a 20 percent reduction in calories and an increase in daily physical activity to 30 minutes, is often associated with normalization of fasting blood glucose. [26] However, this is a difficult task for many patients, who then progress to the use of oral hypoglycemic medications that act by stimulating release of insulin by pancreatic beta cells and by improving the tissue responsiveness to insulin by reversing the postbinding abnormality. The common orally administered drugs are tolazamide (Tolinase),

tolbutamine (Orinase), and the newer sulfonylureas glyburide (Micronase) and glipizide (Glucotrol). These latter drugs have a longer blood glucose-lowering effect, which persists for 24 hours or more, and fewer drug-drug interactions. Oral hypoglycemic drugs may produce hypoglycemia for as long as 50 hours after intake (chlorpropamide [Diabinese] has the longest half-life). Other drugs include metformin, which decreases hepatic glucose output and may increase peripheral responsiveness to glucose; acarbose, which decreases glucose absorption; and troglitazone, which increases peripheral responsiveness to insulin. [27] Progressively, physicians advocating tight control of blood sugar levels give insulin to "maturity onset" insulin-dependent diabetic patients twice a day or even more frequently. [28] [29]

Insulin-dependent diabetics tend to be young, nonobese, and susceptible to the development of ketoacidosis. Plasma insulin levels are low or nonmeasurable, and therapy requires insulin replacement. Patients with insulin-dependent diabetes experience an increase in their insulin requirements in the postmidnight hours; this may result in early-morning hyperglycemia (dawn phenomenon). This accelerated glucose production and impaired glucose utilization are the result of nocturnal surges in growth hormone secretion. [30] Diabetics taking insulin and nondiabetics have steady-state levels of insulin in their blood. (Unfortunately, traditional values for insulin pharmacokinetics derive from studies designed as though the diabetic received only one shot of insulin in a lifetime.) Absorption of insulin is highly variable and is dependent on the type and species of insulin, the site of administration, and subcutaneous blood flow. Nevertheless, the steady state is dependent on periodic administration of the preparations received by the patient. Thus, it seems logical to continue perioperatively the combinations of preparations the patient has been receiving chronically, after examining the patient's blood-glucose monitoring logbook for the degree of control. (In the author's clinical experience, erratic control can foreshadow perioperative hypoglycemia.)

Acute complications for the diabetic patient include hypoglycemia and diabetic ketoacidosis, as well as hyperglycemic, hyperosmolar, nonketotic coma. Diabetic patients are also subject to a series of long-term complications, including cataracts, neuropathies, retinopathy, and angiopathy involving peripheral and myocardial vessels, that lead to considerable morbidity and premature mortality. Many of these complications will bring the diabetic patient to surgery. The evidence that hyperglycemia itself accelerates these complications or that tight control of blood sugar levels decreases the rapidity of the progression of microangiopathic disease is becoming more definitive. [14] [15] [16] [17] [18] [19] [20] [21] [22] [23] [24] [25] [26] [27] [28] [29] [30] [31] [32] [33] [34] [35] [36] [37] [38]

Glucose itself may be toxic: High levels can promote

nonenzymatic glycosylation reactions, leading to the formation of abnormal proteins that may decrease elastance and wound-healing tensile strength. The decrease in elastance is responsible for the stiff joint syndrome and for fixation of the atlanto-occipital joint that makes intubation difficult. [18] [33] [34] Furthermore, elevations in glucose may increase production of macroglobulins by the liver, thereby increasing blood viscosity, and may promote intracellular swelling by favoring the production of nondiffusible, large molecules (e.g., sorbitol). Newer drug therapies (e.g., aldose-reductase inhibitors) aim to decrease intracellular swelling by inhibiting formation of such large molecules.

A controversy now exists as to how tightly blood sugar levels should be controlled chronically. The controversy centers on whether attempts to attain normal blood sugar levels in diabetic patients are of greater benefit than risk. [35] Insulin itself may have toxicity for small blood vessels, and retinopathy initially worsens with tight control. However, accumulating data, much from the Diabetes Control and Complications Trials, clearly indicate that tight control of blood glucose levels reduces the risk of chronic complications in type I diabetics [14] (Table 25-2) (Table Not Available) . Similar studies relating to the long-term outcome for type II diabetics will be released by the United Kingdom group in the next two years.

Perioperative management of the diabetic patient may affect surgical outcome. Physicians advocating tight control of blood glucose levels point to the evidence of increased wound-healing tensile strength and decreased wound infections in animal models of diabetes (type I) under tight control. [36]

It has long been known that neuropathy, atherosclerosis, and small vessel disease may contribute to wound failure. Experimental studies suggest that hyperglycemia itself may cause deficient wound healing. Several investigators have shown that diabetic animals have delayed healing with poor collagen formation and poor tensile strength of deep surgical wounds. [38] These abnormalities can be corrected by the administration of insulin. Goodson and Hunt [36] reported that obesity, insulin resistance, hyperglycemia, and depressed leukocyte function interfere with collagen synthesis and lead to impaired wound healing. These investigators demonstrated slowing of granulocyte influx and retardation of early capillary ingrowth. Synthesis of protocollagen and collagen was decreased in the wounds of diabetic animals. In insulin-deficient animals, administration of insulin is crucial for early development of granulation tissue and for subsequent fibroblast growth and collagen synthesis. [38] Insulin is necessary in the early stages of the inflammatory response but seems to have no effect on collagen formation after the first 10 days.

In studies of corneal wounds, identical healing rates were observed in diabetic and nondiabetic animals and in human subjects. Healing epithelial wounds have minimal leukocyte infiltration; unlike deep wounds, they are not dependent on collagen synthesis for the integrity of the tissue. Thus, simple epithelial repair is not inhibited in the diabetic patient, whereas the repair of deeper wounds is impaired with respect to collagen formation and defense against bacterial growth.

Infections account for two-thirds of postoperative complications and about 20 percent of perioperative deaths in diabetic patients. Experimental data suggest many factors that can make the diabetic patient vulnerable to infection. Many alterations in leukocyte function have been demonstrated in hyperglycemic diabetics, including decreased chemotaxis and impaired phagocytic activity of granulocytes, as well as reduced intracellular killing of pneumococci and staphylococci. [39] [40] When diabetic patients are treated aggressively and blood glucose levels are kept below 250 mg/dL, the phagocytic function of granulocytes is improved and intracellular killing of bacteria is restored to near-normal levels. [41]

Diabetic patients have been thought to experience more infections in clean wounds than nondiabetics. In a review of 23,649 surgical patients, the rate of wound infection in clean incisions was 10.7 percent for diabetics versus 1.8 percent for nondiabetics. [42] However, when age is accounted for, the incidence of wound infection for diabetic surgical patients does not differ significantly from that for nondiabetic patients. In addition, hyperglycemia may worsen neurologic outcome after intraoperative cerebral ischemia.

Blood glucose levels may affect neurologic recovery after a global ischemic event. In a study of 430 consecutive patients resuscitated after out-of-hospital cardiac arrest, mean blood glucose levels were higher in patients who never awakened (341 ± 13 mg/dL) than in those who did awaken (262 ± 7 mg/dL). [43] Among patients who awakened, those

TABLE 25-2 -- Tight Control of Blood Glucose Levels Reduces Chronic Complications in Type I Diabetic Patients

(Not Available)

Modified from Reichard et al [14]

with persistent neurologic deficits had higher mean glucose levels (286 ± 15 mg/dL) than patients without deficits (251 ± 7 mg/dL). These results are consistent with the finding that hyperglycemia during a stroke is associated with poorer short- and long-term neurologic outcomes. Although several questions remain, the likelihood that blood glucose is a determinant of brain damage following global ischemia is supported by the vast majority of animal studies after *global* CNS ischemia, [16] and by most but not all studies after *focal* CNS ischemia. [17] The preponderance of data after CNS ischemia indicates that levels of glucose higher than 150 or 250 mg/dL have an adverse effect on CNS recovery. Until better data are available, many will argue that the diabetic patient about to undergo surgery in which hypotension or reduced cerebral flow may occur should have a blood glucose level below 200 mg/dL during a period of cerebral ischemia. Some special situations, such as surgery requiring cardiopulmonary bypass, surgery for pregnant patients, and emergency surgery on patients with diabetic ketoacidosis or hyperosmolar nonketotic coma, may also influence how tightly one should manage the patient's glucose level.

Diabetics undergoing coronary artery bypass graft (CABG) surgery in 1980 had a perioperative mortality rate of 5 percent, compared with 1.5 percent for nondiabetics. [44] In this study, and in most other studies of diabetic patients undergoing CABG surgery, important additional risk factors or confounding variables were not considered, including the incidence and extent of hypertension, ventricular dysfunction, congestive heart failure, or severity of coronary artery disease.

In this study of 340 diabetics and 2,522 nondiabetics undergoing CABG surgery, only a moderate increase in the operative mortality for diabetics (1.8% versus 0.6%) was demonstrated. [44] In the post-bypass phase, patients with diabetes were found to require inotropic therapy and intra-aortic balloon pump support five times more frequently than nondiabetics. There are several possible reasons. Diabetics with angina have more extensive coronary artery disease than do nondiabetic patients. They are also more likely to have hypertension, cardiomegaly, diffuse hypokinesis, and prior myocardial infarction. Insulin-dependent diabetics with coronary artery disease, impaired stress responses, and autonomic nerve dysfunction appear to have stiffer ventricles with greater elevation of left ventricular end-diastolic pressure than do matched nondiabetic controls. [45] [46] [47] During cardiopulmonary bypass, hypothermia and stress reactions decrease the response to insulin and result in marked hyperglycemia (even when the perfusate and intravenous solutions do not contain glucose). Administration of washed cells has been advocated for small individuals, as acid citrate dextrose or adenine-supplemented blood can result in significant hyperglycemia. These changes are exaggerated in the diabetic patient, and insulin administration may have little effect until rewarming is achieved. In a number of recently reported cases, inotropic agents were ineffective in maintaining cardiac contractility, although filling pressures, sinus rhythm, serum electrolytes, and arterial blood gases were adequate. Blood sugar levels were elevated in each case. After intravenous infusion of insulin, effective myocardial contractions returned, allowing easy and rapid bypass weaning. The effect of glucose levels during cardiopulmonary bypass on neurologic outcome is both unclear and controversial. [48] [49] A cautious prognosis should be given to the diabetic coronary bypass patient with poor ventricular function, as surgical mortality may be 10 to 15 percent. [44]

Many diabetics requiring emergency surgery for trauma or infection have significant metabolic decompensation, including ketoacidosis. Often, little time is available for stabilization of the patient, but even a few hours may be sufficient for correction of fluid and electrolyte disturbances that are potentially life-threatening. It is futile to delay surgery in an attempt to eliminate ketoacidosis completely if the underlying surgical condition will lead to further metabolic deterioration. The likelihood of intraoperative cardiac arrhythmias and hypotension resulting from ketoacidosis will be reduced if volume depletion and hypokalemia are at least partially treated.

Insulin therapy is initiated with a 10-unit intravenous bolus of regular insulin, followed by continuous insulin infusion. The rate of infusion is determined most easily if one divides the last serum glucose value by 150 (or 100 if the patient is receiving steroids, has an infection, or is considerably overweight). The actual amount of insulin administered is less important than regular monitoring of glucose, potassium, and pH level. Because the number of insulin-binding sites is limited, the maximum rate of glucose decline is fairly constant, averaging 75 to 100 mg/dL/h regardless of the dose of insulin. [50] During the first 1 to 2 hours of fluid resuscitation, the glucose level may fall more precipitously. When serum glucose reaches 250 mg/dL, the intravenous fluid should include 5 percent dextrose.

The volume of fluid required for therapy varies with overall deficits, ranging from 3 to 5 L to as high as 10 L. Despite losses of water in excess of losses of solute, sodium levels are generally normal or reduced. Factitious hyponatremia caused by hyperglycemia or hypertriglyceridemia may result in this seeming contradiction. The plasma sodium concentration decreases by about 1.6 mEq/L for every 100 mg/dL increase in plasma glucose above normal. Initially, normal saline is infused at the rate of 250 to 1,000 mL/h, depending on the degree of volume depletion and on cardiac status. Some measure of left ventricular volume should be monitored in diabetics who have a history of myocardial dysfunction. About one-third of the estimated fluid deficit is corrected during the first 6 to 8 hours, and the remaining two-thirds, over the next 24 hours.

The degree of acidosis present is determined by measurement of arterial blood gases and an increased anion gap:

Acidosis with an increased anion gap (
16 mEq/L) in the acutely ill diabetic may be caused by ketones in ketoacidosis, lactic acid in lactic acidosis, increased organic acids from renal insufficiency, or all three problems. In ketoacidosis, plasma levels of acetoacetate, beta-hydroxybutyrate, and acetone are increased. Plasma and urinary ketones are measured semiquantitatively with Ketostix and Acetest tablets. The role of bicarbonate therapy in diabetic ketoacidosis is controversial. Myocardial function and respiration are known to be depressed at a blood pH level below 7.0 to 7.10, yet rapid correction of acidosis with bicarbonate therapy may result in alterations in CNS function and structure. This may be caused by (1) paradoxical development of cerebrospinal

fluid and CNS acidosis resulting from rapid conversion of bicarbonate to carbon dioxide and diffusion of the acid across the blood-brain barrier, (2) altered CNS oxygenation with decreased cerebral blood flow, and (3) the development of unfavorable osmotic gradients. After treatment with fluids and insulin, beta-hydroxybutyrate levels decrease rapidly, whereas acetoacetate levels may remain stable or may even increase before declining. Plasma acetone levels remain elevated for 24 to 42 hours, long after blood glucose, beta-hydroxybutyrate, and acetoacetate levels have returned to normal; the result is continuing ketonuria. [50] Persistent ketosis, with a serum bicarbonate level of less than 20 mEq/L in the presence of a normal glucose level, represents a continued need for intracellular glucose and insulin for reversal of lipolysis.

The most important electrolyte disturbance in diabetic ketoacidosis is depletion of total body potassium. The deficits range from 3 to 10 mEq/kg body weight. Rapid declines in serum potassium level occur, reaching a nadir within 2 to 4 hours after the start of intravenous insulin administration. Aggressive replacement therapy is required. The potassium administered moves into the intracellular space with insulin as the acidosis is corrected. Potassium is also excreted in the urine with the increased delivery of sodium to the distal renal tubules that accompanies volume expansion. Phosphorus deficiency in ketoacidosis caused by tissue catabolism, impaired cellular uptake, and increased urinary losses may result in significant muscular weakness and organ dysfunction. The average phosphorus deficit is approximately 1 mmol/kg body weight. Replacement is needed if the plasma concentration falls below 1 mg/dL. [50]

Glucotoxicity

This idea has been alluded to previously, but the *chronic* tight control of blood glucose has been motivated by a theoretical concern about five potential glucotoxicities, plus the results from one major randomized outcome study on type I patients. (The Diabetes Control and Complications Trial has reported its 12-year follow-up data for type I patients and will soon have a report on type II patients.)

Glucose itself may be toxic: High levels can promote nonenzymatic glycosylation reactions that lead to the formation of abnormal proteins. These proteins may decrease elastance--which is responsible for the stiff joint syndrome (and the fixation of the atlanto-occipital joint that makes intubation difficult)--and wound-healing tensile strength. Furthermore, elevations in glucose may increase production of macroglobulins by the liver (which would increase blood viscosity) and promote intracellular swelling by favoring production of nondiffusible, large molecules (such as sorbitol). Newer drug therapies (e.g., aldose-reductase inhibitors) aim to decrease intracellular swelling by inhibiting formation of such large molecules.

Glycemia also disrupts autoregulation. Glucose-induced vasodilation prevents target organs from protecting against increases in systemic blood pressure. A glycosylated hemoglobin level of 8.1 percent is the threshold at which the risk of microalbuminuria increases logarithmically. A person with type I diabetes who has microalbuminuria of more than 29 mg/d has an 80 percent chance of experiencing renal insufficiency. The threshold for glycemic toxicity differs for various vascular beds. For example, the threshold for retinopathy is a glycosylated hemoglobin value of 8.5 to 9.0 percent (12.5 mmol/L or 225 mg/dL), and, for cardiovascular disease, an average blood glucose value of 5.4 mmol/L (96 mg/dL). Thus, different degrees of hyperglycemia may be required before different vascular beds are damaged, or certain degrees of glycemia are associated with other risk factors for vascular disease. Another view is that perhaps severe hyperglycemia and microalbuminuria are simply concomitant effects of a common underlying cause. Diabetics in whom microalbuminuria develops are more resistant to insulin, insulin resistance is associated with microalbuminuria in first-degree relatives of type II diabetics, and persons who are normoglycemic but subsequently have clinical diabetes have atherogenic risks before onset of disease.

Tight control may retard all of these glucotoxicities and may have other benefits in retarding the severity of diabetes itself. [51]

Thus, management of intraoperative glucose might be influenced by specific situations, such as type of operation, pregnancy, [52] [53] and expected global CNS insult; bias of the patient's primary care physician; or type of diabetes. Type I diabetic patients definitely need insulin and might be considered candidates for tight control of blood glucose levels. Type II diabetic patients have insulin, and current data indicate they do not benefit from tight perioperative control. [54]

The key to managing blood glucose levels in diabetic patients perioperatively is to set clear goals and then to monitor blood glucose levels frequently enough to adjust therapy to achieve those goals. Three regimens that afford various degrees of perioperative control of blood glucose levels are discussed in the following sections.

Classic"Nontight Control" Regimen

Aim

To prevent hypoglycemia. To prevent ketoacidosis and hyperosmolar states.

Protocol

1. Day before surgery: Patient should be given nothing by mouth after midnight; a 13-ounce glass of clear orange juice should be at the bedside or in the car for emergency use.
2. At 6 AM on day of surgery, institute intravenous fluids using plastic cannulae and a solution containing 5 percent dextrose, infused at the rate of 125 mL/h/70 kg body weight.
3. After institution of intravenous infusion, give one-half the usual morning insulin dose (and usual type of insulin) subcutaneously.
4. Continue 5 percent dextrose solutions through operative period, giving at least 125 mL/h/70 kg body weight.
5. In recovery room, monitor blood glucose concentrations and treat on a sliding scale. Such a regimen has been found to meet its goals. [55]

"Tight Control" Regimen 1

Aim

To keep plasma glucose levels at 79 to 120 mg/dL; this practice may improve wound healing and prevent wound infections, improve neurologic outcome after global or focal CNS ischemic insult, or improve weaning from cardiopulmonary bypass.

Protocol

1. Evening before operation, determine preprandial blood glucose level.
2. Through a plastic cannula, begin intravenous infusion of 5 percent dextrose in water at the rate of 50 mL/h/70 kg body weight.
3. "Piggyback" to the dextrose infusion an infusion of regular insulin (50 units in 250 mL or 0.9% sodium chloride) and an infusion pump (Fig. 25-1) . Before attaching this piggyback line to the dextrose infusion, flush the line with 60 mL of infusion mixture and discard the flushing solution. This approach saturates insulin-binding sites of the tubing. [56]
4. Set the infusion rate, using the following equation: Insulin (U/h) = plasma glucose (mg/dL)/150. (Note: This denominator should be 100 if patient is taking corticosteroids, e.g., 100 mg of prednisolone a day or its equivalent, not to include inhaled steroids.)
5. Repeat measurements of blood glucose levels every 4 hours as needed, and adjust insulin appropriately to obtain blood glucose levels of 100 to 200 mg/dL.
6. The day of surgery, intraoperative fluids and electrolytes are managed by continuing to administer non-dextrose-containing solutions, as described in steps 3 and 4.
7. Determine plasma glucose level at the start of operation and every 1 to 2 hours for the rest of the 24-hour period. Adjust insulin dosage appropriately.

Figure 25-1 Arrangement of intravenous lines for infusion of regular insulin in a regimen tightly controlling blood glucose levels in diabetic patients undergoing surgery.

Although I have not found the need to treat hypoglycemia (i.e., blood glucose levels of <50 mg/dL), I have been prepared to do so with 15 mL of 50 percent dextrose in water. Under such circumstances, the insulin infusion would be terminated. Such a regimen has been found to accomplish its goals, with the exception of such tight goals for blood glucose, even in very "brittle" diabetics (i.e., those extremely resistant to treatment) given high doses of steroids. [57]

"Tight Control" Regimen 2

Aim

Same as for "Tight Control" Regimen 1.

Pancreatic Disorders

Preoperative Diabetes Mellitus

"Tight Control" Regimen 2

Protocol

1. Obtain a "feedback mechanical pancreas" and set the controls for the desired plasma glucose regimen.
2. Institute two appropriate intravenous lines. This last regimen may well supersede all others if the cost of a mechanical pancreas can be reduced and if control of hyperglycemia is shown to make a meaningful difference perioperatively.

Despite the fact that hyperglycemic type I diabetic patients have a higher incidence of wound infections, a lower wound-healing tensile strength, and a higher incidence of renal transplant rejections than normal patients, [39] [42] it does not necessarily follow that short-term tight control of blood glucose levels perioperatively would reduce morbidity and mortality. For example, in one study, the incidence of perioperative mortality was 11 times higher for diabetic patients than for asymptomatic healthy patients. [58] However, in several other studies, [11] [12] [13] [59] no increase in wound or systemic infections or in any measure of perioperative morbidity or mortality could be attributable to diabetes itself. Also, when corrections were made for calendar age and endorgan disease (cardiovascular) in those studies, the increases in morbidity for diabetic patients seemed to disappear. [11] [12] [13] [59]

Diabetes and Accelerated Physiologic Aging

Adverse perioperative outcomes have repeatedly and substantially correlated with age of the patient, [7] [9] [12] [22] [58] [60] [61] and diabetes does cause physiologic aging. When the results of the Diabetes Control and Complications Trials are translated into age-induced physiologic changes, the type I diabetic who has poor control of blood sugar ages approximately 1.75 years physiologically for every chronologic year of the disease and 1.25 years if blood sugar has been controlled tightly. [22] The type II diabetic ages about 1.5 years for every chronologic year of the disease and about 1.20 years with tight control of blood sugar. [22] Thus, when providing

care for a diabetic patient, one must consider the associated risks to be those of a person who is much older physiologically. That is, the diabetic's physiologic age ("RealAge") is considerably higher than his or her calendar age just by virtue of having the disease. [1]

The increased prevalence of obesity and lack of physical exercise seem to be major contributors to the increased prevalence of type II diabetes. As with type I diabetes, tight control of blood sugar, increased physical activity, and reduction in weight appear to reduce the accelerated aging of type II diabetes and even to delay substantially the appearance of the disease. Although such a reduction in aging should reduce the perioperative risk for diabetic patients, no controlled trials have confirmed this theory.

Other Conditions Associated With Diabetes

Diabetes is associated with microangiopathy (in retinal and renal vessels), peripheral neuropathies, autonomic dysfunction, and infection. Diabetics are often treated with angiotensin-converting enzyme inhibitors even in the absence of gross hypertension in an effort to prevent the effects of disordered autoregulation, including renal failure. [62]

Before surgery, assessment and optimization of treatment of the potential and potent end-organ effects of diabetes are at least as important as an assessment of the diabetic's current overall metabolic status. Information about a diabetic patient that might merit special attention before surgery includes the therapeutic, dietary, and exercise regimens; adequacy of glucose control; prior surgical and anesthetic responses; and the presence of the end-organ effects of diabetes. In the author's experience, many diabetic patients pay extreme attention to glucose control, expect each physician to ask about it, and are annoyed (and probably rightly so) if the physicians treating them in the perioperative period are not at least as concerned about glucose level as the patient has had to be. Thus, if just to avoid making the patient angry (and, I believe, for more value than that), the anesthesiologist should inquire in some depth about the diabetic's control of blood glucose levels. Basic laboratory examinations might include determination of fasting blood sugar levels, electrolytes, blood urea nitrogen (BUN) or creatinine levels, and an electrocardiogram (ECG). Scheduling the operative procedure early in the day avoids prolonging the catabolic state and minimizes the risk of preoperative hypoglycemia.

Patients with diabetes and hypertension have a 50 percent incidence of autonomic neuropathy; those without hypertension have a 10 percent incidence. If one is to believe the few studies we have, the presence of autonomic neuropathy makes the operative period more hazardous and the postoperative period crucial to survival. Evidence of autonomic neuropathy might be routinely sought prior to surgery. Patients with diabetic autonomic neuropathy are at increased risk of gastroparesis (and consequent aspiration) and of intraoperative and postoperative cardiorespiratory arrest. Data indicate that diabetics who exhibit signs of autonomic neuropathy, such as early satiety, lack of sweating, lack of pulse rate change with inspiration or orthostatic maneuvers, and impotence, have a very high incidence of painless

Figure 25-2 Gastric emptying time (mean±SD) for a solid test meal for three groups of patients: diabetics (line 1); diabetics given metoclopramide (10 mg intravenously) 1.5 hours before the test meal (line 2); and nondiabetics (line 3). *(From Wright et al [886])*

myocardial ischemia [47] [55] [56] [57] [58] [59] [63] [64] and of gastroparesis. Some investigators have successfully used 10 mg of metoclopramide preoperatively to facilitate gastric emptying of solids (Fig. 25-2) . Interference with respiration or sinus automaticity by pneumonia or by anesthetics, pain medications, or sedative drugs appears to be the precipitating cause in most cases of sudden cardiorespiratory arrest. Measuring the degree of sinus arrhythmia or beat-to-beat variability provides a simple, accurate test for significant autonomic neuropathy. The difference between maximum and minimum heart rate on deep inspiration is normally 15 beats/min but was found to be 5 beats/min or less in all patients who sustained cardiorespiratory arrest. [63]

Other characteristics of patients with autonomic neuropathy include postural hypotension with a decrease in blood pressure of more than 30 mm Hg, resting tachycardia, nocturnal diarrhea, and dense peripheral neuropathy. Diabetics with significant autonomic neuropathy may have impaired respiratory responses to

hypoxia and are particularly susceptible to the action of drugs that have depressant effects. Such patients may warrant very close, continuous cardiac and respiratory monitoring for 24 to 72 hours postoperatively, although such logical treatment has not been tested in a rigorous, controlled trial. [65] In the absence of these conditions, the author favors outpatient surgery for the diabetic (Table 25-3) .

Perhaps most important, diabetic patients have an increased incidence of atherosclerosis and all its complications. These patients are particularly susceptible to episodes of painless myocardial ischemia and cardiovascular instability. [66] [67] [68] [69] In fact, over 80 percent of the ischemic episodes that occur in both patients who have myocardial ischemia and in those who are diabetic are "silent." However, a 65-year-old diabetic is as likely to die of a cardiovascular event in the next several years as is a person who has just had a

TABLE 25-3 -- Should a Diabetic Be an Outpatient or a Morning Admittance Patient?

OUTPATIENT IF	MORNING ADMITTANCE PATIENT IF
Can evaluate history in advance	Cannot evaluate history
End-organ disease does not require invasive monitoring	End-organ disease requires invasive monitoring
Prehydration is available or is unnecessary	Needs careful prehydration
No CNS ischemia or cardio-pulmonary bypass is planned	CNS ischemia is present or cardio-pulmonary bypass is planned

Plan higher admit rate (no data)	Social care network is unsuitable

heart attack (Table 25-4) (Table Not Available) . [70] These data dramatically illustrate the increased risk of cardiovascular disease in the diabetic who does not have symptoms. As with other endocrinopathies, the cardiovascular system should be a focus for the anesthetist's attention for the diabetic patient.

Insulinoma and Other Causes of Hypoglycemia

Hypoglycemia can be caused by such diverse entities as a pancreatic islet cell adenoma or carcinoma, large hepatoma, large sarcoma, alcohol ingestion, hypopituitarism, adrenal insufficiency, altered physiology after gastric surgery, hereditary fructose intolerance, antidiabetic drug ingestions, galactosemia, or autoimmune hypoglycemia. [71] The last four entities cause postprandial reactive hypoglycemia. Because restriction of oral intake prevents severe hypoglycemia, the practice of giving the patient nothing by mouth and infusing small amounts of a solution containing 5 percent dextrose greatly lessens the possibility of postprandial reactive hypoglycemia. The other sources of hypoglycemia can cause serious problems during the perioperative period. [72]

The symptoms of hypoglycemia fall into two groups: adrenergic excess (tachycardia, palpitations, tremulousness, or diaphoresis) and neuroglycopenia (headache, confusion, mental sluggishness, seizures, or coma). Because all these symptoms may be masked by anesthesia, blood glucose levels should be determined frequently in such patients to ensure that hypoglycemia is not present. Because manipulation of an insulinoma can result in massive insulin release, this tumor should probably be operated on only at centers equipped with a mechanical pancreas; such machines have on-line blood glucose analysis and a glucose infusion setup.

A different point of view was expressed by Muir and colleagues, [73] who managed 38 patients undergoing insulinoma resection. Every 15 minutes, these investigators noted the plasma glucose concentration in these patients, in whom a mechanical pancreas produced no increase in plasma glucose. Although 9 of the 38 patients became significantly hypoglycemic (i.e., plasma glucose concentrations of <50 mg/dL), only 4 of 253 measurements taken before resection showed a decrease in glucose of more than 20 mg/dL in any 15-minute period. Muir et al [73] believe that intermittent sampling of plasma glucose (every 15 minutes) may be satisfactory as long as the plasma glucose concentration is kept at 60 mg/dL or above. In this series, the absence or presence of a hyperglycemic rebound after tumor resection was not of predictive value in determining completeness of insulinoma resection(s). Other causes of hypoglycemia do not involve the release of insulin in such vast quantities (or at all); therefore, less frequent (every 1 to 2 hours) intraoperative blood glucose determinations and continuous dextrose infusion appear to be sufficient.

The perioperative use of the somatostatin analogue octreotide, which suppresses insulin release from such tumors, appears to make the perioperative period a logarithm safer in anecdotal experience. Whether all tumors respond to this agent similarly and thus radically reduce hazard from insulinoma resection remains to be determined. [74]

Disorders of Nutrition

Hyperlipidemias and Hypolipidemias

Hyperlipidemia may result from obesity, estrogen or corticoid therapy, uremia, diabetes, hypothyroidism, acromegaly, alcohol ingestion, liver disease, inborn errors of metabolism, or pregnancy. Hyperlipidemia may cause premature coronary or peripheral vascular disease or pancreatitis. [75] Hypercholesterolemia,

TABLE 25-4 -- Seven-Year Risk of Cardiovascular Events in Type II Diabetics Without Prior Myocardial Infarctions [a]

(Not Available)

Modified from Haffner et al [76]

[a] The 7-year risk of cardiovascular events in type II diabetics who have *not* had a prior myocardial infarction (MI) is the same as for nondiabetics who *have* had a prior MI. Age- and sex-adjusted (median age at start, approximately 58 y).

a form of hyperlipidemia, appears to be associated with premature atherosclerosis. Most cholesterol is carried in serum by low-density lipoprotein (LDL), whereas approximately 30 percent of total serum cholesterol is carried by high-density lipoprotein (HDL). HDL cholesterol is carried in roughly equivalent amounts on two types of HDL: on a less dense HDL_2 subfraction that is negatively associated with coronary artery disease and on a more dense HDL_3 subfraction that is unrelated to coronary artery disease.

In regard to the production of atherosclerosis, LDL is distinguished from HDL by associating L with "lousy" and H with "healthy." That is, the oxidized form of LDL constitutes a risk factor for atherosclerosis, whereas HDL is believed to carry dangerous cholesterol away from the periphery to be metabolized by the liver and is therefore protective. Levels of HDL are 25 percent higher in women than in men; low levels of HDL in women are associated with premature atherosclerosis. Cigarette smoking lowers HDL levels, whereas regular exercise (particularly, strenuous exercise, but even nonstrenuous exercise) and small daily intake of alcohol raise HDL levels. However, alcohol increases HDL_3 , the HDL subfraction thought to be inert with respect to coronary artery disease. Octogenarians have high levels of HDL.

Data showing that coronary events can be reduced by treating individuals with even normal levels of LDL cholesterol with the "statins"--drugs that raise HDL and lower LDL cholesterol levels--have resulted from a decade of rapid progress in preventing reinfarction in high-risk patients. [76] [77] [78] [79] [80] Secondary prevention efforts

were successful when these high-risk patients stopped smoking; reduced blood pressure; controlled stress; increased physical activity; and used aspirin, vitamin E, beta-blocking drugs, angiotensin inhibitors, diet, and other drugs to reduce their levels of LDL and to increase their levels of HDL. [81] [82]

Although controlling diet remains a major treatment modality for all types of hyperlipidemia, [83] the drugs clofibrate (Atromid-S) and gemfibrozil, used to treat hypertriglyceridemia, can cause myopathy, especially in patients with hepatic or renal disease; clofibrate is also associated with an increased incidence of gallstones. Cholestyramine binds bile acids, as well as oral anticoagulants, digitalis drugs, and thyroid hormones. Nicotinic acid causes peripheral vasodilation and probably should not be continued through the morning of surgery. Probucol (Lorelco) decreases the synthesis of apoprotein A1; its use is associated on rare occasion with fetid perspiration and/or prolongation of the QT interval and with sudden death in animals.

The West of Scotland Coronary Prevention Study [77] [78] and its congeners produced convincing evidence that drugs in the "statin" class (3-hydroxy-3-methylglutaryl coenzyme A [HMG-CoA] reductase inhibitors) prevent the morbidity and mortality related to arterial aging and vascular disease, as well as their consequences--coronary arterial disease, stroke, and peripheral vascular insufficiency. Thus, the statins--lovastatin (Mevacor), pravastatin (Pravachol), simvastatin, fluvastatin, and atorvastatin--are mainstays of therapy.

But the report of Downs et al [77] from the Air Force/Texas Coronary Atherosclerosis Prevention Study went farther. It showed a 37 percent reduction in the risk of first acute major coronary events in patients who had not only no risk factors for coronary artery aging but also normal (average) LDL cholesterol levels (Table 25-5) . In this study, lovastatin did not alter mortality rates; however, that had been true for many early short-term trials with the statins. Although much of the effect of the statins has been attributed to their lipid-lowering effects, statins have also been shown to modify endothelial function, inflammatory responses, plaque stability, and thrombogenicity. [84A] While the report of Downs and colleagues broadened the use of statins, they remain the mainstays of therapy for the hyperlipidemias. They are drugs that block HMG-CoA reductase, the rate-limiting enzyme of cholesterol synthesis. Their use is occasionally accompanied by liver dysfunction, CNS dysfunction, and severe depression not related to the high cost of each drug and its congeners.

Hypolipidemic conditions are rare diseases often associated with neuropathies, anemia, and renal failure. Although anesthetic experience with hypolipidemic conditions has been limited, some specific recommendations can be made: continuation of caloric intake and intravenous administration of protein hydrolysates and glucose throughout the perioperative period.

Obesity

Thirty percent of adults in the United States weigh more than 20 percent above what is considered the optimum body

Data from Roizen [265]

[a] Body mass index (BMI) = weight (in kilograms) ÷ height^2 (in meters)
[c] Without shoes
[b] Without clothes

weight for their height. One measure of obesity is body mass index, for which a value above 31 represents morbid obesity and its risks and a value above 27 for women and 28 for men corresponds to weight 25 percent above ideal (Table 25-6) . The pathophysiologic consequences of obesity involve every major organ system. Many of the metabolic, hormonal, and physiologic changes associated with obesity (e.g., insulin resistance, decreased number of insulin receptors, and subsequent diabetes mellitus) can be induced by overfeeding normal subjects and can be reversed by weight reduction. Obesity itself, its complications, and its treatment have significance for the anesthesiologist. A person who is 30 percent overweight has a 40 percent increased chance of dying from heart disease and a 50 percent increased chance of dying from a stroke. Obesity is also associated with higher resource utilization (more perioperative days in the hospital) and greater perioperative morbidity and mortality. [84B] [85]

Although many conditions associated with obesity (diabetes, cholelithiasis, cirrhosis) contribute to morbidity, the main concerns for the anesthesiologist are derangements of the cardiopulmonary system. [86] [87]

In the obese patient, gas exchange may be impaired by not only altered cardiopulmonary mechanisms but also management of a difficult airway. Obstruction of the airway by the abundant soft tissue in the upper airway frequently produces hypoxemia and hypercarbia, and obesity significantly increases the risk of difficult tracheal intubation. [88] [89] Functional residual capacity decreases because the weight of the torso and abdomen makes diaphragmatic excursions more difficult and more position-dependent, a problem made worse by mechanical ventilation. For many obese patients, this process causes functional residual capacity to be less than closing volume and decreases the time of safe apnea before hypoxia occurs (Amalraj S, personal communication) (Fig. 25-3) . Furthermore, obese patients have increased volume and acidity of gastric juices preoperatively (Fig. 25-4) , perhaps indicating the wisdom of premedicating such patients with cimetidine, ranitidine, Bicitra, or metoclopramide. (The simplest, least expensive scientifically tested regimen appears to be administration of cimetidine the night and morning before surgery [Fig. 25-5] (Figure Not Available) [Amalraj S, personal communication].) Others would conclude that awake intubation is indicated, but preference for this technique must be balanced by the realization that most episodes of gastroesophageal reflux and the greatest potential for pulmonary aspiration occur from and during "bucking" on an endotracheal tube. [90] [91] Obesity is also a significant risk factor for postoperative hypoxemia, [92] a situation partially remedied by placing the patient in the semirecumbent (rather than supine) position for the first 48 to 72 hours of recovery. [93]

Cardiac output must increase approximately 0.1 L/min to perfuse each kilogram of adipose tissue. As a result, obese patients often have hypertension, which can cause cardiomegaly and left ventricular failure. Care should be taken to use a blood pressure cuff of correct size when quantitating the degree of hypertension present.

The obese may have limited cardiac reserve and a poor tolerance for stress induced by hypotension, hypertension, tachycardia, or fluid overload associated with the preoperative period. Massively obese patients with carbon dioxide retention are called pickwickian, alveolar hypoventilation being the hallmark of this condition. Other components of the pickwickian syndrome are somnolence, hypoxemia, failure of the right side of the heart, and secondary polycythemia. Many of these patients have right ventricular failure (see Ch. 49 for monitoring considerations). Thus, preoperative assessment should include not only history-taking and physical examination accentuating drug therapy and cardiopulmonary problems but also an ECG examination (looking

Figure 25-3 Duration of safe apnea before hemoglobin desaturation in obese and normal weight patients (90% oxygen saturation), as reported by various studies. *(Amalraj S, personal communication)* BMI, body mass index.

specifically for left or right ventricular hypertrophy, ischemia, and conduction defects). If obesity is severe, arterial blood gases might also be analyzed to quantitate the degree of hypoventilation and to aid in assessing the most appropriate time to extubate the trachea. More extensive pulmonary function tests and preoperative treatment of any treatable abnormality (e.g., infectious and bronchospastic components of pulmonary disease) may be indicated for the obese patient who smokes or has pulmonary symptoms (e.g., chronic cough, sputum production, wheezing, shortness of breath at rest or on minor exertion).

Other features of obesity are of interest to the anesthesiologist as well. Because of excessive and extensive subcutaneous fat and large size of the extremities, proper positioning

Figure 25-4 Relationship between weight and risk factors for pulmonary aspiration, as reported by four studies. *(Amalraj S, personal communication)*

Figure 25-5 (Figure Not Available) Effect of drugs on the risk of pulmonary aspiration in obese patients, as reported by various studies. *(Amalraj S, personal communication)*

of the patient, placement of monitoring devices, and establishment of intravenous sites are more difficult to accomplish, and blood pressure (and cuff size choice) is less easy to ascertain than for patients of normal weight. Obese persons may metabolize lipophilic drugs to a greater degree (and for longer periods) than their thin counterparts. More fluorine is produced from enflurane given to obese patients than to thin ones. One would assume that responses to drugs stored in fat (e.g., narcotics, barbiturates, volatile anesthetics) would be prolonged in the obese. There is no evidence, however, that the use of the more soluble anesthetics delays recovery time in obese subjects. The dose requirements of pharmacologic agents used for analgesia and airway management are also altered by significant obesity (body mass index >27.5). Obesity increases the volume of distribution of sufentanil and slows its elimination. In one study, the elimination half-life of sufentanil was 208 minutes for eight obese patients (mean weight, 94 kg) versus 135 minutes for eight controls (mean weight, 70 kg). [94] Similarly, muscle relaxants that depend on hepatic blood flow for their elimination (i.e., pancuronium, vecuronium, and rocuronium) appear to have dosage requirements that are directly proportional to body surface area, as well as longer twitch recovery times. The 25 to 75 percent twitch recovery time for vecuronium was 38.4 minutes for obese patients (mean weight, 93 kg) versus 17.6 minutes for nonobese patients (mean weight, 61 kg) (Ch. 12) . [95] Furthermore, there is an increased incidence of wound infection, deep vein thrombosis, and pulmonary embolus; the latter two should probably be guarded against with subcutaneous heparin and early ambulation. [96]

The anesthesiologist should also be aware of conditions caused by remedies to obesity. [97] Drastic dieting can produce acidosis, hypokalemia, and hyperuricemia; protein hydrolysate liquid diets are associated with intractable ventricular arrhythmias. [98] These problems seem to have disappeared as the diets have changed from hydrolyzed collagen fasts to the currently used very-low-calorie diet. [99] Metabolic complications of jejunoileal bypass include hypokalemia, hypocalcemia, hypomagnesemia, anemia, renal stones, gout, and liver abnormalities. An attempt to reverse these abnormal conditions should be made before induction of anesthesia and may consist of infusing solutions containing amino acids. Because of the high morbidity associated with jejunoileal bypass, this procedure has been replaced by gastric plication or bypass surgery. However, long-term data concerning the chronic morbidity of these two procedures are not available.

Drug treatment for obesity also has implications for the anesthesiologist. Amphetamines (and probably mazindol) given *acutely* increase anesthetic requirements; by contrast, amphetamines administered *chronically* decrease anesthetic requirements. (See the section on chronic drug therapy.) Amphetamines may interfere with the action of vasoactive drugs given to treat hypotension or hypertension.

Since many obese patients have tried drug therapies, the anesthesiologist should consider asking questions about use of adjuvants. If such drugs have been used, the anesthesiologist might consider auscultation and echocardiography to search for mitral valve regurgitant lesions, as some dietary aids (notably "phen-fen") have been associated with these conditions. Because other dietary herbs are known to cause

liver dysfunction, determining whether these adjuvants have been used may be important. Fenfluramine (a drug that inhibits the serotonergic system) by itself may decrease both anesthetic requirement and blood pressure.

Anorexia Nervosa, Bulimia, and Starvation

Many endocrine and metabolic abnormalities occur in the patient with anorexia nervosa, a condition characterized by starvation to the point of 40 percent loss of normal weight, hyperactivity, and a psychiatrically distorted body image. Many anorectic patients exhibit impulsive behavior, including suicide attempts, and intravenous drug use is much more common than in the general population. Acidosis, hypokalemia, hypocalcemia, hypomagnesemia, hypothermia, diabetes insipidus, and severe endocrine abnormalities mimicking panhypopituitarism need attention before anesthesia and surgery. Similar problems occur in bulimia (bulimorexia), a condition that may affect as many as 50 percent of female college students. [100] As in severe protein deficiency (kwashiorkor), anorexia nervosa and bulimia may be accompanied by ECG alterations, including prolonged QT interval, atrioventricular (AV) block and other arrhythmias, sensitivity to epinephrine, and cardiomyopathy. [100] [101] Total depletion of body potassium makes the addition of potassium to glucose solutions useful; however, in these patients, fluid administration can precipitate pulmonary edema. Esophagitis, pancreatitis, and aspiration pneumonia are more frequent in these patients, as is delayed gastric emptying. Thus, invasive monitoring (radial artery and pulmonary artery catheterization) may be indicated for anorectic, bulimic, and malnurtured patients requiring emergency surgery. Elective surgery probably should be delayed until abnormalities are treated.

Hyperalimentation (Total Parenteral Nutrition)

Hyperalimentation (i.e., total parenteral nutrition [TPN]) consists of concentrating hypertonic glucose calories in the normal daily fluid requirements. The solutions contain protein hydrolysates, soybean emulsions (i.e., Intralipid), or synthetic amino acids. The major benefits of TPN or enteral nutrition have been fewer complications postoperatively and shorter hospital stays for patients scheduled to have no oral feeding for 7 days or who were malnourished preoperatively. [102] [103] Starker and colleagues [104] found that response to TPN, as monitored by serum albumin levels, predicted postoperative outcome. [105] The group having a rise in serum albumin with TPN had diuresis, weight loss, and fewer complications (1 of 15 patients) than the group that gained weight and had a decrease in serum albumin (8 of 16 patients had 15 complications) (Fig. 25-6) (Figure Not Available) . These data are echoed by those in the Veterans Affairs studies, which reported that serum albumin level was one of the most powerful predictors of perioperative outcome. [6] [61]

The major complications of hyperalimentation are sepsis and metabolic abnormalities. The central lines used for TPN require application of an absolutely aseptic technique

Figure 25-6 (Figure Not Available) (A-C) The response to administration of hyperalimentation (repletion), as measured by variations in serum albumin levels, predicted the outcome of surgery. Those patients who responded (B) to nutritional support with increased albumin levels had significantly better outcome than those whose albumin level did not increase (C). See text for a more complete explanation. *(Adapted from Starker et al [889])*

and should not be used routinely as an intravenous route for drug administration. Major metabolic complications of TPN relate to deficiencies and to development of hyperosmolar states. Complications of hypertonic dextrose can develop if the patient has insufficient insulin (diabetes mellitus) to metabolize the sugar or if insulin resistance occurs (e.g., because of uremia, burns, or sepsis). [102]

Gradual decrease in the infusion rate of TPN prevents the hypoglycemia that can occur on abrupt discontinuance. Thus, the infusion rate of TPN should be decreased the night before anesthesia and surgery or continued throughout the operation at its current rate. The main reason for slowing or discontinuing TPN before anesthesia is to avoid intraoperative hyperosmolarity secondary to accidental rapid infusion of the solution or hypoglycemia if the infusion is discontinued because of the high levels of endogenous insulin and lower levels of glucose present in usual crystalloid solutions. [102] Hypophosphatemia is a particularly serious complication that results from the administration of phosphate-free or phosphate-depleted solutions for hyperalimentation. The low serum phosphate level causes shifts of the oxygen dissociation curve to the left. The resulting low 2,3-diphosphoglycerate and adenosine triphosphatase levels mean that cardiac output must increase for oxygen delivery to remain the same. Hypophosphatemia of less than 1.0 mg/dL blood may cause hemolytic anemia, cardiac failure, tachypnea, neurologic symptoms, seizures, and death. In addition, long-term TPN is associated with deficiencies in trace metals such as copper (refractory anemia), zinc (impaired wound healing), and magnesium.

For these reasons, I have adopted the following practices. [102] The infusion of TPN or enteral nutrition is reduced beginning the night before surgery, substituting 5 or 10 percent dextrose solution preoperatively. If serum glucose phosphate and potassium concentrations (measured preoperatively) are abnormal, they are restored to within normal limits. Strict asepsis is maintained. Conversely, I often continue

infusing the TPN solution by using a pump system or enteral nutrition, strictly maintaining its normal rate and asepsis, administering all fluids through a different intravenous site, and performing a rapid-sequence induction of anesthesia (for those who received enteral nutrition).

Also see Chapter 74 .

Adrenocortical Malfunction *

Three major classes of hormones--androgens, glucocorticoids, and mineralocorticoids--are secreted by the adrenal cortex. [105] [106] For each class, an excess or a deficiency of hormone produces a characteristic clinical syndrome. The widespread use of steroids can also make the adrenal cortex unable to respond normally to the demands placed on it by surgical trauma and subsequent healing. [107] [108] [109] [110] [111] [112] [113] [114] [115] Unfortunately, the lack of a wide variety of abdominal imaging procedures, plus the underuse of those procedures that do exist, has meant that many adrenal masses have been discovered only incidentally. [116] [117] [118] Because etomidate is an anesthetic that profoundly limits adrenal reserves, it is often the anesthesiologist who comes into contact with abnormalities of adrenocortical function.

Controlled comparisons of perioperative management for patients who have disorders of adrenal function are lacking. [105] However, a review of the possible pathophysiologic changes in the adrenal cortex and techniques for their management should enable us to improve the perioperative care of patients with adrenal abnormalities.

Physiologic Properties of Adrenocortical Hormones

Androgens

Androstenedione and dehydroepiandrosterone, weak androgens arising from the adrenal cortex, [119] constitute major sources of androgens in women. Excess secretion of androgen causes masculinization, pseudopuberty, or female pseudohemaphroditism. With some tumors, androgen is converted to an estrogenic substance, in which case feminization results. [119] No special anesthetic evaluation is needed for such patients. Some congenital enzyme defects that cause androgen abnormalities also result in glucocorticoid and mineralocorticoid abnormalities that should be evaluated prior to surgery. [119] Most of these patients are treated with exogenous glucocorticoids and mineralocorticoids and consequently require supplementation of these hormones perioperatively (see later).

Glucocorticoids

The principal glucocorticoid, cortisol, is an essential regulator of carbohydrate, protein, lipid, and nucleic acid metabolism. Cortisol is believed to exert its biologic effects through a sequence of steps initiated by hormone binding to stereospecific intracellular cytoplasmic receptors. This bound complex stimulates nuclear transcription of specific messenger ribonucleic acids (mRNAs). These mRNAs are then translated to give rise to proteins that mediate the ultimate effects of hormones.

Most cortisol is bound to corticosterone-binding globulin (CBG, transcortin). It is the relatively small amounts of unbound cortisol that enter cells to induce actions or to be metabolized. Conditions that induce changes in the amount of CBG include liver disease and nephrotic syndrome, both of which result in decreased circulating levels of CBG, and estrogen administration and pregnancy, which result in increased CBG production. Total serum cortisol levels may become elevated or depressed under these conditions that alter the amount of bound cortisol, and yet the unbound, active form of cortisol is present in normal amounts. The most accurate measure of cortisol activity is the level of urinary cortisol--that is, the amount of unbound, active cortisol filtered by the kidney.

The serum half-life of cortisol is 80 to 110 minutes. [111] However, because cortisol acts through intracellular receptors, pharmacokinetic data based on serum levels are not good indicators of cortisol activity. After a single dose of glucocorticoid, serum glucose is elevated for 12 to 24 hours; improvements in pulmonary function in patients with bronchial asthma can still be measured 24 hours after glucocorticoid administration. [111] Treatment schedules for glucocorticoid replacement are based, therefore, not on the measured serum half-life, but on the well-documented prolonged end-organ effect of these steroids. Hospitalized patients requiring chronic glucocorticoid replacement therapy are usually treated twice daily, with a slightly higher dose given in the morning than in the evening, to stimulate the normal diurnal variations in cortisol levels. [105] For patients who require parenteral "steroid coverage" during and after surgery (see later paragraphs), administration of glucocorticoid every 12 hours is appropriate. [109] [110] Relative potencies of glucocorticoids are listed in Table 25-7 . Cortisol is inactivated primarily in the liver and is excreted as 17-hydroxycorticosteroid. Cortisol is also filtered and excreted unchanged into the urine.

The synthetic glucocorticoids vary in their binding specificity in a dose-related manner. When given in supraphysiologic doses (more than 30 mg/d), cortisol and cortisone bind to mineralocorticoid receptor sites and cause salt and water retention and loss of potassium and hydrogen ions. [111] When these steroids are administered in maintenance doses of 30 mg/d or less, patients require a specific mineralocorticoid for electrolyte and volume homeostasis. [111] Many other steroids do not bind to mineralocorticoid receptors, even at high doses, and have no mineralocorticoid effect [111] (see Table 25-7) .

Secretion of glucocorticoids is regulated by pituitary adrenocorticotropic hormone (ACTH). ACTH is synthesized from a precursor molecule (preopiomelanocortin) that breaks down to form an endorphin (beta-lipotropin) and ACTH. Episodic secretion of ACTH has a diurnal rhythm normally greatest during the early morning hours in men, later in women, and is regulated at least in part by light-dark cycles. Its secretion is stimulated by release of corticotropin-releasing factor from the hypothalamus. (An abnormality in the diurnal rhythm of corticoid secretion has been implicated

* Much of this section was modified from Lampe and Roizen. [105]

TABLE 25-7 -- Relative Potency and Equivalent Doses for Commonly Used Glucocorticoids

STEROIDS	RELATIVE GLUCOCORTICOID POTENCY	EQUIVALENT GLUCOCORTICOID DOSE (mg)
Short-acting		
Cortisol (hydrocortisone)	1.0	20.0
Cortisone	0.8	25.0
Prednisone	4.0	5.0
Prednisolone	4.0	5.0
Methylprednisolone	5.0	4.0
Intermediate-acting	5.0	4.0
Triamcinolone		
Long-acting		
Betamethasone	25.0	0.60
Dexamethasone	30.0	0.75

Data from Axelrod [111]

as a cause of so-called "jet lag.") Cortisol and other glucocorticoids exert negative feedback at both pituitary and hypothalamic levels to inhibit secretion of ACTH and corticotropin-releasing factor.

Mineralocorticoids

Aldosterone, the major mineralocorticoid secreted in humans, comes from the zona glomerulosa of the adrenal cortex and causes reabsorption of sodium and secretion of potassium and hydrogen ions, thereby contributing to electrolyte and volume homeostasis. [120] This action is most prominent in the distal renal tubule but

also occurs in salivary and sweat glands. The major regulator of aldosterone secretion is the renin-angiotensin system. Juxtaglomerular cells in the cuff of the renal arterioles are sensitive to decreased renal perfusion pressure or volume and, consequently, secrete renin. [120] Renin splits the precursor angiotensinogen (from the liver) into angiotensin I, which is further converted by a converting enzyme, primarily in lung, to angiotensin II. Angiotensin II binds to specific receptors to increase mineralocorticoid secretion, which is also stimulated by increased potassium concentration and, to a lesser degree, by ACTH. [120]

Adrenocortical Hormone Excess

Glucocorticoid Excess

Glucocorticoid excess (Cushing syndrome) resulting from either endogenous oversecretion or chronic treatment with high-dose glucocorticoids produces a moon-faced plethoric individual having a centripetal distribution of fat (truncal obesity and skinny extremities), thin skin, easy bruising, and striae. Muscle wasting is common, but the heart and diaphragm are usually spared. These patients often have osteopenia due to decreased formation of bone matrix and impaired absorption of calcium. Fluid retention and hypertension (because of increases in renin substrate and vascular reactivity caused by glucocorticoid) are common. Such patients may also have hyperglycemia and even diabetes mellitus resulting from inhibition of peripheral use of glucose, as well as anti-insulin action and concomitant stimulation of gluconeogenesis.

The most common cause of Cushing syndrome is the administration of glucocorticoids for such conditions as arthritis, asthma, and allergies. [105] In these conditions, the adrenal glands atrophy and cannot respond to stressful situations (e.g., the preoperative period) by secreting more steroid. Thus, additional glucocorticoids may be required perioperatively (see the later section, *The Patient Taking Steroids for Other Reasons*). Spontaneous Cushing syndrome may be caused by pituitary production of ACTH (60-70% of all spontaneous cases), which is usually associated with pituitary microadenoma, or nonendocrine ectopic ACTH production (principally by tumors of the lung, pancreas, or thymus). [121] Ten to twenty percent of cases of spontaneous Cushing syndrome are caused by an ACTH-independent process, either an adrenal adenoma or carcinoma.

Special preoperative considerations for patients having Cushing syndrome include regulating diabetes and hypertension and ensuring that intravascular fluid volume and electrolyte concentrations are normal. Ectopic ACTH production may cause marked hypokalemic alkalosis. [105] Treatment with the aldosterone antagonist spironolactone will stop the potassium loss and help mobilize excess fluid. Because of the high incidence of severe osteopenia and the risk of fractures, meticulous attention must be paid to positioning of the patient. [105] In addition, glucocorticoids are lympholytic and immunosuppressive, increasing the patient's susceptibility to infection. [122] [123] The tensile strength of healing wounds decreases in the presence of glucocorticoids, an effect that is at least partially reversed by topical administration of vitamin A. [122]

Specific considerations pertain to the surgical approach for each cause of Cushing syndrome. For example, nearly three-fourths of cases of spontaneous Cushing disease result from a pituitary adenoma that secretes ACTH. [121] Our perioperative treatment for patients who have Cushing disease and a pituitary microadenoma differs from that for patients who have a pituitary adenoma associated with amenorrhea and galactorrhea. [121] The patient with Cushing disease tends

to bleed more easily and (on the basis of anecdotal evidence) tends to have a higher central venous pressure. Thus, during trans-sphenoidal tumor resection in such patients, the author routinely monitors central venous pressure and maintain it in the low end of the normal range. In other cases of trans-sphenoidal resection of microadenoma, such monitoring is needed only infrequently.

Ten to fifteen percent of patients with Cushing syndrome have adrenal overproduction of glucocorticoids from an adrenal adenoma or carcinoma. [105] If either unilateral or bilateral adrenal resection is planned, the author normally begins administering glucocorticoids at the start of resectioning of the tumor. Although no definitive studies exist, I normally give 100 mg of hydrocortisone hemisuccinate or hydrocortisone phosphate every 12 hours intravenously. I reduce this amount over 3 to 6 days until a maintenance dose is reached. Beginning on day 3, I also give a mineralocorticoid, 9alpha-fluorocortisol (0.05-0.1 mg/d). For certain patients, both steroids may require several adjustments. This therapy continues if the patient has undergone bilateral resection. For the patient who has undergone unilateral adrenal resection, therapy is individualized according to the status of the remaining adrenal gland. At the University of California, San Francisco, the incidence of pneumothorax in adrenal resection approached 20 percent during the early 1980s; this rate is similar to the incidence at the University of Chicago at present. The diagnosis of pneumothorax is sought and treatment is begun before the wound is closed.

Bilateral adrenalectomy with Cushing syndrome has a high incidence of postoperative complications and a perioperative mortality rate of 5 to 10 percent; it often results in permanent mineralocorticoid and glucocorticoid deficiency. Ten percent of patients with Cushing syndrome who undergo adrenalectomy have an undiagnosed pituitary tumor. After reduction of high levels of cortisol by adrenalectomy, the pituitary tumor enlarges. [121] These pituitary tumors are potentially invasive and may produce large amounts of ACTH and melanocyte-stimulating hormone, thereby increasing pigmentation. [121]

Adrenal adenomas are generally treated surgically; often the contralateral gland resumes functioning after several months. Frequently, however, the effects of carcinomas are not cured by surgery. In such cases, administration of inhibitors of steroid synthesis, such as metyrapone or mitotane (*o,p* -DDD[2,2-bis(2-chlorophenyl-4-chlorophenyl)-1,1-dichloroethane]), may ameliorate some symptoms but may not improve survival. These drugs and the aldosterone antagonist spironolactone may aid in reducing symptoms in the case of ectopic ACTH secretion if the primary tumor proves unresectable. Patients given these adrenal suppressants are also prescribed chronic glucocorticoid replacement therapy (that is, the goal of therapy is complete adrenal suppression). These patients should be considered to have suppressed adrenal function, and glucocorticoid replacement should be increased perioperatively.

Mineralocorticoid Excess

Excess mineralocorticoid activity (common with glucocorticoid excess, since most glucocorticoids have some mineralocorticoid properties) leads to potassium depletion, sodium retention, muscle weakness, hypertension, tetany, polyuria, inability to concentrate urine, and hypokalemic alkalosis. [124] These symptoms constitute primary hyperaldosteronism, or Conn syndrome (a cause of low-renin hypertension, as renin secretion is inhibited by the effects of the high levels of aldosterone).

Primary hyperaldosteronism is present in 0.5 to 1.0 percent of hypertensive patients who have no other known cause of hypertension. [124] Primary hyperaldosteronism most often results from unilateral adenoma, although 25 to 40 percent of patients have been found to have bilateral adrenal hyperplasia. Intravascular fluid volume, electrolyte concentrations, and renal function should be restored to within normal limits preoperatively by administering the aldosterone antagonist spironolactone. The effects of spironolactone are slow in onset and increase for 1 to 2 weeks. [124] A patient who has a serum potassium level of 2.9 mEq/L may have a deficit of body potassium of as little as 40 mEq or as much as 400 mEq. Frequently, at least 24 hours is required to restore potassium equilibrium. [125] [126] [127] [128] A normal serum potassium level does not necessarily imply correction of a total body deficit of potassium. In addition, patients with Conn syndrome have a high incidence of hypertension and ischemic heart disease; hemodynamic monitoring should be appropriate for the degree of cardiovascular impairment. [129] A retrospective anecdotal study indicated that intraoperative hemodynamic status was more stable when blood pressure and electrolytes were controlled preoperatively with spironolactone than when other antihypertensive drugs were used. [106] However, the efficacy of optimizing the perioperative status of patients who have disorders of glucocorticoid or mineralocorticoid secretion has not been clearly established. The author has assumed that gradual restoration of a normal condition is good medicine and that it would decrease perioperative morbidity and mortality.

Adrenocortical Hormone Deficiency

Glucocorticoid Deficiency

Withdrawal of steroids or suppression of synthesis by steroid therapy is the leading cause of underproduction of corticosteroids. [105] The management of this type of glucocorticoid deficiency is discussed in the next section, *The Patient Taking Steroids for Other Reasons.* Other causes of adrenocortical insufficiency include defects in ACTH secretion and destruction of the adrenal gland by autoimmune disease, tuberculosis, hemorrhage, or cancer; some forms of congenital adrenal hyperplasia (see previous discussion); and administration of cytotoxic drugs.

Primary adrenal insufficiency (Addison disease) is associated with local destruction of all zones of the adrenal cortex and causes both glucocorticoid and mineralocorticoid deficiency if the insufficiency is bilateral. Autoimmune disease is the most common cause of primary (nonexogenous) bilateral ACTH deficiency in the United States, whereas tuberculosis is the most common cause worldwide.

Autoimmune destruction of the adrenals may be associated with other autoimmune disorders, such as Hashimoto thyroiditis. Enzymatic defects in cortisol synthesis also cause glucocorticoid insufficiency, compensatory elevations of

ACTH, and congenital adrenal hyperplasia. [119] Because adrenal insufficiency usually develops slowly, such patients develop marked pigmentation (from excess ACTH trying to stimulate an unproductive adrenal gland) and cardiopenia (apparently secondary to chronic hypotension). [105]

Secondary adrenal insufficiency occurs when ACTH secretion is deficient, often because of a pituitary or hypothalamic tumor. Treatment of pituitary tumors by surgery or radiation may result in hypopituitarism and consequent adrenal failure. [105]

If unstressed, glucocorticoid-deficient patients usually have no perioperative problems. However, acute adrenal crisis (addisonian crisis) can occur when even a minor stress (for example, upper respiratory infection) is present. [105] [130] Preparation of such a patient for anesthesia and surgery should include treatment for hypovolemia, hyperkalemia, and hyponatremia. [113] Because these patients cannot respond to stressful situations, it was traditionally recommended that they be given a stress dose of glucocorticoids (about 200 mg hydrocortisone/70 kg body weight/d) perioperatively. However, Symreng and colleagues [109] gave 25 mg of hydrocortisone phosphate intravenously to adults at the start of the operative procedure, followed by 100 mg intravenously over the next 24 hours. Because using the minimum drug dose that would produce an appropriate effect is desirable, this latter regimen seems attractive. Such a regimen has proved to be as successful as the regimen using maximum doses (about 300 mg hydrocortisone per 70 kg body weight/d--see *The Patient Taking Steroids for Other Reasons*). Thus, I now recommend giving 100 mg of hydrocortisone phosphate intravenously every 12 hours. [105] [109] [110]

Mineralocorticoid Deficiency

Hypoaldosteronism, a less common condition, [131] can be congenital or can occur after unilateral adrenalectomy or prolonged administration of heparin. It can also be a consequence of long-standing diabetes and renal failure. Nonsteroidal inhibitors of prostaglandin synthesis may also inhibit renin release and exacerbate this condition in patients who have renal insufficiency. [131] Plasma renin activity levels are below normal and fail to increase appropriately in response to sodium restriction or diuretic drugs. Most symptoms are caused by hyperkalemic acidosis rather than hypovolemia; in fact, some patients are hypertensive. These patients can have severe hyperkalemia, hyponatremia, and myocardial conduction defects. [131] These defects can be treated successfully by administering mineralocorticoids (9alpha-fluorocortisol, 0.05-0.1 mg/d) preoperatively. [131] Doses must be carefully titrated and monitored to avoid an increase in hypertension.

The Patient Taking Steroids for Other Reasons

Perioperative Stress and the Need for Corticoid Supplementation

Many experimental studies and other reports (mostly anecdotal) concerning the adrenal responses of normal patients to the perioperative period, and the responses of patients taking steroids for other diseases, indicate the following:

1. Perioperative stress relates to the degree of trauma and the depth of anesthesia. Deep general or regional anesthesia causes the usual intraoperative glucocorticoid surge to be postponed to the postoperative period. [132] [133]
2. Few patients who have suppressed adrenal function have perioperative cardiovascular problems if they do not receive supplemental steroids perioperatively. [108] [109] [110] [111] [112] [113] [114] [115]
3. Although a patient who chronically takes steroids occasionally becomes hypotensive perioperatively, only rarely has this event been documented sufficiently to implicate glucocorticoid or mineralocorticoid deficiency as the cause. [108] [109] [110] [111] [112] [113] [114] [115]
4. Acute adrenal insufficiency occurs only rarely but can be life-threatening. [108] [109] [110] [111] [112] [113] [114] [115]
5. There is little risk in giving these patients high-dose steroid coverage perioperatively. [109] [110] [130]

In a recent well-controlled study of glucocorticoid replacement in primates, the investigators clearly defined the life-threatening events that can be associated with inadequate perioperative corticosteroid replacement. [110] This study further defined the physiologic and hemodynamic consequences of inadequate cortisol replacement; an alternative dose regimen is suggested that has stood the test of a decade and has altered management methods to possibly improve patient safety. In this study, adrenalectomized primates and sham-operated controls were maintained on physiologic doses of steroids for 4 months. The animals were then randomly allocated to groups that received subphysiologic (one-tenth the normal cortisol production), physiologic, or supraphysiologic (ten times the normal cortisol production) doses of cortisol for 4 days preceding abdominal surgery (cholecystectomy). Hemodynamic variables were measured by means of arterial and pulmonary artery catheters. The animals were maintained on their randomized dosage schedules during and after surgery. The group given subphysiologic doses of steroid perioperatively had a significant increase in postoperative mortality. The death rates for the physiologic and supraphysiologic replacement groups were the same and did not differ from the rate for sham-operated controls. Death in the subphysiologic replacement group was related to severe hypotension associated with a significant decrease in systemic vascular resistance and a reduced left ventricular stroke work index. The filling pressures of the heart were unchanged compared with those in control animals. There was no evidence of hypovolemia or severe congestive heart failure. Despite low systemic vascular resistance, the animals did not become tachycardic. All these responses are compatible with the previously documented interaction of glucocorticoids and catecholamines, suggesting that glucocorticoids mediate catecholamine-induced increases in cardiac contractility and maintenance of vascular tone.

The investigators used a sensitive measure of wound healing by studying hydroxyproline accumulation. All treatment groups, including the group given supraphysiologic doses of glucocorticoids, had the same capacity for wound healing. Furthermore, perioperative administration of supraphysiologic doses of corticosteroids produced no adverse metabolic consequences.

This well-conducted study confirms several long-standing intuitive impressions concerning patients who have inadequate adrenal function, either resulting from underlying disease or secondary to administration of exogenous steroids. Inadequate replacement of corticosteroids perioperatively can lead to addisonian crisis and death. Administration of supraphysiologic doses of steroids for a short time perioperatively caused no discernible complications. However, there are at least theoretical negative consequences when large doses of steroids are given (see later). It is clear that inadequate corticosteroid coverage can cause death. What is not so clear is what dose of steroid for replacement therapy should be recommended. The authors of the previously discussed study on monkeys were reluctant to recommend simple physiologic steroid replacement doses for human patients perioperatively. [110] Our group agrees that a prospective, randomized double-blind trial in patients receiving physiologic doses of steroids is needed before current recommendations are modified. [109] [110] In any case, we never supplement perioperatively with a dose lower than what the patient has already been receiving. [111]

Which patients definitely need supplementation? If in doubt, how can a patient's need for supplementation with glucocorticoids be determined? Because the risk is low, the author normally provides supplementation for any patient who has received steroids within a year. [107] [108] [109] [110] [111] [112] [113] [114] [115] [119] [120] [121] [122] The data indicate that topical application of steroids (even without use of occlusive dressings) can suppress normal adrenal responses for as long as 9 months to 1 year [107] [111] (Table 25-8) .

How can one determine when adrenal responsiveness has returned to normal? The morning plasma cortisol level does not reveal whether the adrenal cortex has recovered sufficiently to ensure that cortisol secretion will increase adequately to meet the demands of stress. Inducing hypoglycemia with insulin has been advocated as a sensitive test of pituitary-adrenal competence but is impractical and probably a more dangerous practice than simply administering glucocorticoids. If the plasma cortisol concentration is measured during acute stress, a value of more than 25 mug/dL assuredly (and a value of >15 mug/dL probably) indicates normal

pituitary-adrenal responsiveness. In another test of pituitary-adrenal sufficiency, the baseline plasma cortisol level is determined. Then, 250 mug of synthetic ACTH (cosyntropin) is given, and plasma cortisol is measured 30 to 60 minutes later. [112] An increase in plasma cortisol of 6 to 20 mug/dL or more is normal. [134] A normal response indicates recovery of pituitary-adrenal axis function. A lesser response usually indicates pituitary-adrenal insufficiency, possibly requiring perioperative supplementation with steroids.

Usually laboratory data defining pituitary-adrenal adequacy are not available before surgery. However, rather than delay surgery or test most patients, the author assumes that any patient who has taken steroids at any time during the preceding year has suppressed pituitary-adrenal functioning and will require perioperative supplementation.

Under perioperative conditions, the adrenal glands secrete 116 to 185 mg of cortisol daily. Under maximum stress, they may secrete 200 to 500 mg/d. Good correlation exists between the severity and duration of the operation and the response of the adrenal gland. "Major surgery" would be represented by procedures such as colectomy, and "minor surgery," by procedures such as herniorrhaphy. In one study of 20 patients during major surgery, the mean maximal concentration of cortisol in plasma was 47 mug/dL (range, 22-75 mug/dL). Values remained above 26 mug/dL for a maximum of 72 hours after surgery. During minor surgery, the mean maximal concentration of cortisol in plasma was 28 mug/dL (range, 10-44 mug/dL).

Although the precise amount required has not been established, I usually administer intravenously the maximum amount of glucocorticoid that the body manufactures in response to a maximal stress (i.e., approximately 200 mg/d of hydrocortisone phosphate/70 kg body weight). [109] [110] [132] [133] For minor surgical procedures, I usually give hydrocortisone phosphate intravenously, 100 mg/70 kg body weight/d. Unless infection or some other perioperative complication develops, I decrease this dose by approximately 25 percent per day until oral intake can be resumed. At this point, the usual maintenance dose of glucocorticoids can be employed.

Risks of Supplementation

Rare complications of perioperative supplementation with steroids include aggravation of hypertension, fluid retention, inducement of stress ulcers, and psychiatric disturbance. Although data are not available to assess the incidences of the following risks, two common complications of short-term perioperative supplementation with glucocorticoids are described in the literature: abnormal wound healing and increased rate of infections. [108] [109] [110] [111] [112] [113] [114] [115] [120] [121] [122] [123] [124] [135] [136] This evidence is inconclusive, however, as it relates to acute glucocorticoid administration and not to chronic administration of glucocorticoids with increased doses at times of stress. Ehrlich and Hunt [122] found that moderate to large

TABLE 25-8 -- Recovery of Hypothalamic-Pituitary Adrenal Function After Withdrawal of Steroids

[b] The diurnal rhythm of the plasma concentrations is qualitatively normal during this stage.

doses of steroids exerted their morphologic effects best within 3 days of injury. They postulated that inhibition of the early inflammatory process by steroids after wounding was responsible for the delay in healing. Vitamin A was found to be somewhat protective against delayed healing, presumably because of its effect on stabilizing lysosomes. [122] In contrast to these studies that suggest a deleterious effect of perioperative glucocorticoid administration on wound healing in rats, a study on primates suggests that high doses of glucocorticoids, administered perioperatively, did not impair sensitive measures of wound healing. [110] Other data provide no better insight into these problems. [108] [109] [110] [111] [112] [113] [114] [115] [120] [121] [122] These data are not conclusive regarding a short-term increase in supplementation. However, an overall assessment of these results suggests that short-term perioperative supplementation with steroids has a small but definite deleterious effect on wound healing that is perhaps partially reversed by topical administration of vitamin A.

Information regarding the risk of infection from perioperative supplementation with glucocorticoids is also unclear. Winstone and Brooke [137] reported four cases of septicemia among 18 surgical patients given perioperative supplementation with glucocorticoids. No similar complications occurred in 17 others who were also taking glucocorticoids but who were not given perioperative supplementation. In a controlled study of 100 patients given perioperative supplementation with glucocorticoids, 11 wound infections occurred in the group treated with steroids, and only one occurred in the control group. [135] Test subjects and controls were not matched for underlying disease. By contrast, Jensen and Elb [136] found no change in the incidence of wound infections or of other infections in an uncontrolled series of 419 patients undergoing surgery and perioperative supplementation with glucocorticoids. Oh and Patterson [130] found only one minor suture abscess in 17 steroiddependent asthmatic patients undergoing 21 surgical procedures. Thus, although the data indicate that the risk of infection to the patient chronically taking steroids is real, these data are inadequate to conclude that perioperative supplementation with steroids increases that risk.

Adrenal Cortex Function in the Elderly

The adrenal gland shows a progressive decrease in production of androgens with age. [138] This decrease in androgen activity has no known implications for anesthesia. Plasma levels of cortisol are unaffected by increasing age. Levels of corticosterone-binding globulin are also unaffected by age; this suggests that a normal fraction of free cortisol (1-5%) is present in elderly patients. Several investigators have noted a progressively impaired ability of the aged patient to metabolize and excrete glucocorticoids. In normal individuals, the quantity of 17-hydroxycorticosteroids excreted is reduced by half by the seventh decade. This decreased excretion undoubtedly reflects reduced renal function that occurs with aging. When excretion of cortisol metabolites is expressed as a function of creatinine clearance, the age difference disappears. Further reductions in cortisol clearance may be due to impaired hepatic metabolism of circulating cortisol.

The rate of secretion of cortisol is 30 percent lower in the elderly. This reduced secretion is an appropriate compensatory mechanism for maintaining a normal level of cortisol in the face of its decreased hepatic and renal clearance. It is important to the anesthesiologist that the reduced cortisol production can be overcome during periods of stress and that the elderly display an entirely normal adrenal response to administration of ACTH and to stresses such as hypoglycemia.

Both underproduction and overproduction of glucocorticoids are generally considered diseases of younger individuals. The highest incidence of Cushing disease, of either pituitary or adrenal origin, occurs during the third decade of life. The most common cause of spontaneous Cushing disease is benign pituitary adenoma. [121] However, in patients older than 60 years in whom Cushing disease develops, the most likely cause is adrenal carcinoma or ectopic ACTH production from tumors usually located in the lung, pancreas, or thymus.

Also see Chapter 61 .

Effect of Etomidate on Adrenal Function

Even a single dose of etomidate used for induction of anesthesia suppresses adrenal function. [139] The clinical significance of adrenal suppression by etomidate is unknown, but there is justifiable concern over continued use of etomidate without steroid supplementation.

Etomidate is an imidazole sedative-hypnotic that induces rapid loss of consciousness with minimal cardiovascular depression even in compromised patients.

Etomidate has been administered in two clinical settings--as a bolus for induction of anesthesia and as a continuous infusion for prolonged sedation in the intensive care unit (ICU) setting. The pattern of adrenal suppression appears to be related to dose and time and differs with the duration of administration. [139]

Etomidate inhibits two essential adrenocortical enzymes, 11beta-hydroxylase and cholesterol side-chain cleavage enzyme, in rats and in humans. [139] I believe that it is important to clarify the difference between the adrenal suppression by etomidate and the stated goal of several anesthesiologists to provide stress-free anesthesia. It appears that providing a level of anesthesia that prevents grimacing, sweating, extreme elevations of blood pressure and heart rate, and an outpouring of the neurohumoral mediators of stress is evidence that we have adequately depressed CNS function and protected our patients from some of the unwanted side effects of surgery. This goal is different from the inhibition of peripheral adrenocortical enzymes of etomidate that occurs as an unwanted side effect of the drug.

Thus, it has been documented that adrenal reserve is compromised for at least 24 hours after a single induction dose of etomidate in most patients. [140] Should hypotension or electrolyte abnormalities associated with adrenal insufficiency (hyponatremia and hyperkalemia) occur in a patient who has recently received etomidate, I agree with previous suggestions [139] that corticosteroids should be administered in stress doses (e.g., cortisol, 100 mg bid) and be tapered as noted in the earlier section, *The Patient Taking Steroids for Other Reasons.*

Adrenal Incidentaloma

Adrenal tumors are found in as many as 9 percent of autopsies, and the increased use of imaging techniques brings many of these tumors to clinical attention before death. Previously, size was used as a discriminator: tumors larger than 6 cm were surgically removed because of the high probability of malignancy. Those smaller than 3 cm were followed up, and those 3 to 6 cm were investigated.

Recent data from three large series [116] [117] [118] and success from laparoscopic removal [141] [142] have called for a reevaluation. The three series found a significant number of adrenal carcinomas and pheochromocytomas (approximately 3% of each), an occasional aldosteronoma (approximately 1%), as well as a not insignificant number of metastases from as yet uncovered primary tumors (approximately 10%). These data may indicate the need for a more aggressive approach to adrenal incidentalomas that are smaller than 6 cm.

Also see Chapter 9 .

Adrenal Medullary Sympathetic Hormone Excess: Pheochromocytoma

Fewer than 0.1 percent of all cases of hypertension are caused by pheochromocytomas, catecholamine-producing tumors derived from chromaffin tissue. [143] Nevertheless, these tumors are clearly important to the anesthetist, as 25 to 50 percent of hospital deaths in patients with pheochromocytomas occur during induction of anesthesia or during operative procedures for other causes. [144] Although usually found in the adrenal medulla, these vascular tumors can occur anywhere, such as in the right atrium, the spleen, the broad ligament of the ovary, or the organs of Zuckerkandl at the bifurcation of the aorta. Malignant spread, which occurs in fewer than 15 percent of pheochromocytomas, usually proceeds to venous and lymphatic channels with a predisposition for the liver. This tumor is occasionally familial and/or part of the pluriglandular-neoplastic syndrome known as multiple endocrine adenoma type IIa or type IIb, manifesting as an autosomal dominant trait on chromosome 10. Type IIa consists of medullary carcinoma of the thyroid, and parathyroid adenoma or hyperplasia and pheochromocytomas. Often, bilateral tumors are found in the familial form. Localization of tumors can be done with magnetic resonance imaging (MRI) or computed tomography (CT) scans, metaiodobenzylguanidine nuclear scanning, ultrasonography, or intravenous pyelography studies (in decreasing order of combined sensitivity and specificity).

Symptoms and signs that may be solicited preoperatively and that are suggestive of pheochromocytoma are excessive sweating; headache; hypertension; orthostatic hypotension; previous hypertensive or arrhythmic response to induction of anesthesia or to abdominal examination; paroxysmal attacks of sweating, headache, tachycardia, and hypertension; glucose intolerance; polycythemia; weight loss; and psychological abnormalities. In fact, the occurrence of combined symptoms of paroxysmal headache, sweating, and hypertension is probably a more sensitive and specific indicator than any one biochemical test for pheochromocytoma [143] [145] [146] (Table 25-9) (Table Not Available) . Despite more than 2,000 articles in the literature about pheochromocytomas, little is known about what factors in care affect perioperative morbidity. [147] [148] [149]

Although no controlled, randomized, prospective clinical studies have studied the value of preoperative use of adrenergic receptor-blocking drugs, the use of such drugs is generally recommended before surgery. These drugs probably reduce the complications of hypertensive crisis, the wide blood pressure fluctuations during manipulation of the tumor (especially until venous drainage is obliterated), and the myocardial dysfunction that occur perioperatively. The reduction in mortality associated with resection of pheochromocytoma (from 40-60% to the current 0-6%) occurred when alpha-adrenergic receptor blockade was introduced as preoperative preparatory therapy for such patients [146] [147] [148] [149] [150] [151] (Table 25-10) .

alpha-Adrenergic receptor blockade with prazosin or phenoxybenzamine restores plasma volume by counteracting the vasoconstrictive effects of high levels of catecholamines. This re-expansion of fluid volume is often followed by a decrease in hematocrit. Because some patients may be very sensitive to the effects of phenoxybenzamine, it should initially be given in doses of 20 to 30 mg/70 kg orally once or twice a day. Most patients usually require 60 to 250 mg/d. Efficacy of therapy should be judged by a reduction in symptoms (especially sweating) and a stabilization of blood pressure. For patients who have carbohydrate intolerance because of inhibition

of insulin release mediated by alpha-adrenergic receptor stimulation, alpha-adrenergic receptor blockade may reduce fasting blood sugar levels. For patients who exhibit ST-T changes on ECG, long-term preoperative alpha-adrenergic receptor blockade (1-6 months) has produced ECG and clinical resolution of catecholamine-induced myocarditis. [147] [148] [149] [150] [151] [152]

beta-Adrenergic receptor blockade with propranolol is suggested for patients who have persistent arrhythmias or tachycardia, [147] [148] [149] [150] [151] [152] because these conditions can be precipitated or aggravated by alpha-adrenergic receptor blockade. beta-Adrenergic receptor blockade should not be used without concomitant alpha-adrenergic receptor blockade, lest the vasoconstrictive effects of the latter go unopposed, thereby increasing the risk of dangerous hypertension.

The optimal duration of preoperative therapy with phenoxybenzamine has not been studied. Most patients require 10 to 14 days, as judged by the time needed to stabilize blood pressure and to ameliorate symptoms. On the basis of my experience, this is a minimal period. [148] [149] [152] Because the tumor spreads slowly, little is lost by waiting until medical therapy has optimized the patient's preoperative condition. Accordingly, I recommend using the following criteria:

1. No in-hospital blood pressure reading higher than 165/90 mm Hg should be evident for 48 hours before surgery. We often measure arterial blood pressure every minute for 1 hour in a stressful environment (our postanesthesia care unit). If no blood pressure reading is greater than 165/90, this criterion is considered satisfied.
2. Orthostatic hypotension should be present, but blood pressure on standing should not be lower than 80/45mm Hg.
3. The ECG should be free of ST-T changes that are not permanent.
4. No more than one premature ventricular contraction should occur every 5 minutes.

Other drugs, including prazocin, calcium channel-blocking drugs, clonidine, and magnesium, have also been used to achieve suitable degrees of alpha-adrenergic blockade prior to surgery.

Although specific anesthetic drugs have been recommended, I believe that optimal preoperative preparation, a gentle induction of anesthesia, and good communication between surgeon and anesthesiologist are most important. Virtually all anesthetic agents and techniques (including isoflurane, sevoflurane, sufentanil, remifentanil, fentanyl, and regional anesthesia) have been used with success. In fact, all agents studied are associated with a high rate of transient intraoperative arrhythmias [148] (Table 25-11) . I have avoided halothane because it sensitizes the myocardium and may increase arrhythmogenic frequency, and desflurane, because it may precipitate nonneurogenic catecholamine release. No good data indicate these biases are appropriate.

Because of ease of use, the author prefers to give phenylephrine hydrochloride (Neo-Synephrine) or dopamine for hypotension and nitroprusside for hypertension. Phentolamine (Regitine) has too long an onset and duration of action. Occasionally (five times in >50 pheochromocytoma resections) I have used a beta-adrenergic blocking agent (esmolol is now the preferred one) for severe tachycardia without hypertension or volume depletion. Painful or stressful events such as intubation often cause an exaggerated stress response in less than perfectly anesthetized patients who have a pheochromocytoma. This response is caused by release of catecholamines from nerve endings that are "loaded" by the reuptake process. Such stresses may cause catecholamine levels of 200 to 2,000 pg/mL in normal patients. For the patient with pheochromocytoma, even simple stresses can lead to blood catecholamine levels of 2,000 to 20,000 pg/mL. However, infarction of a tumor, with release of products onto peritoneal surfaces, or surgical pressure causing release of products, can result in blood levels of 200,000 to 1,000,000 pg/mL--a situation that should be anticipated and avoided. (Ask for a temporary stay of surgery, if at all possible, while the rate of nitroprusside infusion is increased.) Once the venous supply is secured, and if intravascular volume is normal (as measured by pulmonary wedge pressure), normal blood pressure usually results. However, some patients become hypotensive, occasionally requiring massive infusions of catecholamines. On rare occasions, patients remain hypertensive intraoperatively. Postoperatively, about 50 percent remain hypertensive for 1 to 3 days--and initially have markedly elevated but declining plasma catecholamine levels--at which time all but 25 percent become normotensive. It is important to interview other family members and perhaps advise them to inform their future anesthetist about the potential for such familial disease.

Hypofunction or Aberration in Function of the Sympathetic Nervous System (Dysautonomia)

Disorders of the sympathetic nervous system include Shy-Drager syndrome, Riley-Day syndrome, Lesch-Nyhan syndrome, Gill familia dysautonomia, diabetic dysautonomia, and the dysautonomia of spinal cord transection.

Although individuals can function well without an adrenal medulla, a deficient peripheral sympathetic nervous system occurring late in life poses major problems for many facets of life [153] [154] [155] [156] [157] [158] [159] [160] [161] [162] [163] ; nevertheless, a perioperative sympathectomy or its equivalent has been recommended by some. [164] [165] [166] [167] [168] [169] [170] [171] [172] [173] [174] [175] [176] [177] [178] A

primary function of the sympathetic nervous system appears to be the regulation of blood pressure and of intravascular fluid volume during changing of body position. Common features of all the syndromes of hypofunctioning of the sympathetic nervous system are orthostatic hypotension and decreased beat-to-beat variability in

heart rate. These conditions can be caused by deficient intravascular volume, deficient baroreceptor function (as also occurs in carotid artery disease [179]), abnormalities in CNS function (as in Wernicke or Shy-Drager syndrome), deficient neuronal stores of norepinephrine (as in idiopathic orthostatic hypotension [154] and diabetes [15]), or deficient release of norepinephrine (as in traumatic spinal cord injury [153]). Patients with these conditions may have an increased number of available adrenergic receptors (a compensatory response) and an exaggerated response to sympathomimetic drugs. [180] In addition to other abnormalities, such as retention of urine or feces and deficient heat exchange, hypofunctioning of the sympathetic nervous system is often accompanied by renal amyloidosis. Thus, electrolyte and intravascular fluid volume status should be evaluated preoperatively. Because many of these patients have cardiac abnormalities, intravascular fluid volume might be assessed preoperatively using a Swan-Ganz catheter or transesophageal echocardiograph rather than measurement of central venous pressure (Chs. 30 and 31) .

Because functioning of the sympathetic nervous system is not predictable in these patients, I usually employ slow, gentle induction of anesthesia and treat sympathetic excess or deficiency by infusing, with careful titration, drugs that directly constrict (phenylephrine) or dilate (nitroprusside) blood vessels or that stimulate (isoproterenol) or depress (esmolol) heart rate. I prefer these drugs to agonists or antagonists, which may indirectly release catecholamines. A 20 percent perioperative mortality rate for 2,600 patients with spinal cord transection has been reported, [161] indicating that such patients are difficult to manage and deserve particularly close attention.

After reviewing 300 patients with spinal cord injuries, Kendrick et al [181] concluded that autonomic hyperreflexia syndrome does not develop if the lesion is below spinal dermatome T7. If the lesion is above that level (the splanchnic outflow), 60 to 70 percent of patients experience extreme vascular instability. The trigger to this instability, or *mass reflex* involving noradrenergic and motor hypertonus, [155] can be a cutaneous, proprioceptive, or visceral stimulus (a full bladder is a common initiator). The sensation enters the spinal cord and causes a spinal reflex, which in normal persons is inhibited from above. Sudden increases in blood pressure are sensed in the pressure receptors of the aorta and carotid sinus. The resulting vagal hyperactivity produces bradycardia, ventricular ectopia, or various degrees of heart block. Reflex vasodilation may occur above the level of the lesion, resulting in flushing of the head and neck.

Depending on the length of time since spinal cord transection, other abnormalities may occur. Acutely (i.e., <3 wk from the time of spinal injury), retention of urine and feces is common and, by elevating the diaphragm, may impair respiration. Disimpaction of the intestine alleviates this respiratory problem. Hyperesthesia is present above the lesion; reflexes and flaccid paralysis are present below the lesion. The intermediate period (3 d-6 mo) is marked by a hyperkalemic response to depolarizing drugs. [160] The chronic phase is characterized by a return of muscle tone, positive Babinski sign, and frequently, the occurrence of hyperreflexia syndromes (e.g., mass reflex; see previous).

Thus, in addition to meticulous attention to perioperative intravascular volume and electrolyte status, the anesthesiologist should know--by history-taking, physical examination, and laboratory data--the status of the patient's myocardial conduction (as revealed by ECG), the status of renal functioning

TABLE 25-12 -- Biochemical Measurements of Thyroid Function That Account for Variation in Production of Thyroid-Binding Globulin

	EXAMPLES OF NORMAL THYROID STATUS					TSH
	FT_4 E	**=**	***T_4***	**×**	***THBR***	
Normal	0.19 (0.12-0.25)	=	0.6 (0.4-0.9)		31% (25-35%)	0.2 (0.2-0.8)
During use of oral contraceptives	0.19	=	1.3		15%	0.3
During use of corticosteroids	0.18	=	0.3		60%	0.3

Abbreviations: FT_4 E is the free T_4 (thyroxine) estimate. This is usually obtained by multiplying the total thyroxine (T_4) concentration (the free amount and the amount bound to protein) times the thyroid hormone binding ratio (THBR, formerly called the resin T_3 uptake). THBR is a measure of the bound thyroid hormone binding protein. TSH is the thyroid-stimulating hormone secreted by the pituitary in the negative feedback loop. (TSH increases when FT_4 E is low in hypothyroidism.)

(by noting the ratio of creatinine to blood urea nitrogen), and the condition of respiratory muscle (by determining the ratio of forced expiratory volume in 1 s to forced vital capacity [i.e., FEV_1/FVC]) (Ch. 24) . The anesthesiologist may also obtain a chest radiograph, if atelectasis or pneumonia is suspected on the basis of history-taking or physical examination. Temperature control, the presence of bone fractures or decubitus ulcers, and normal functioning of urination and defecation systems must be assessed. Confirmation of the latter prevents postoperative pneumonia or atelectasis caused by high positioning of the diaphragm.

Thyroid Dysfunction

The major thyroid hormones are thyroxine (T_4), a product of the thyroid gland, and the more potent 3,5,3-triiodothyronine (T_3), a product of both the thyroid and the extrathyroidal enzymatic deiodination of thyroxine. Approximately 80 to 85 percent of T_3 is produced outside the thyroid gland. Production of thyroid secretions is maintained by secretion of thyroid-stimulating hormone (TSH) in the pituitary, which in turn is regulated by secretion of thyrotropinreleasing hormone (TRH) in the hypothalamus. Secretion of TSH and TRH appears to be negatively regulated by T_4 and T_3. Whether all effects of thyroid hormones are mediated by T_3, or if T_4 has intrinsic biologic activity, remains unclear.

Thyroid hormones create their effects through several mechanisms. Binding of T_3 to high-affinity nuclear receptors (TR_{alpha} and TR_{beta}) and the subsequent activation of DNA-directed mRNA synthesis may account for the anabolic growth and developmental effects, plus some calorigenic effect, of thyroid hormones. Patients with the syndrome of thyroid hormone resistance have point mutations in the TR_{beta}. Thyroid hormone is also responsible for an increased concentration of adrenergic receptors, which may account for many of its cardiovascular effects.

Because T_3 has a greater biologic effect than does T_4, one would expect the diagnosis of thyroid disorders to be based on levels of T_3. However, this is not usually the case. The diagnosis of thyroid disease is confirmed by one of several biochemical measurements: levels of free T_4 or of total serum concentrations of T_4, and by the "free T_4 estimate." The estimate is obtained by multiplying total T_4 (free and bound) by the thyroid binding ratio (formerly called the resin T_3 uptake) (Table 25-12) . The T_3-binding ratio measures the extra quantity of serum protein binding sites. This measurement is necessary because thyroxine-binding globulin (TBG) is abnormally high during pregnancy, hepatic disease, and estrogen therapy (all of which would elevate the total T_4 level) (Table 25-13) . Reliable interpretation of measurements of the total hormone concentration in serum necessitates data on the percentage of bound hormone. The thyroid hormone-binding ratio test provides this information. In this test, iodine-131-labeled T_3 is added to a patient's serum and allowed to reach an equilibrium binding state. A resin is then added that binds the remaining radioactive T_3. The resin uptake is greater if the patient has fewer TBG binding sites. In normal patients, the resin T_3 uptake (the thyroid hormone-binding ratio) is 25 to 35 percent. When the serum TBG is elevated, the thyroid hormone-binding ratio is diminished (see Table 25-12) . When the serum TBG is diminished, as in the nephrotic syndrome, in conditions in which glucocorticoids are increased, or in chronic liver disease, the thyroid hormone-binding ratio is increased.

The free T_4 estimate and the free T_3 estimate are frequently used as measures of a patient's serum T_4 and T_3 hormone concentration. To obtain these estimates, the concentration of total serum T_4 or total serum T_3 is multiplied by the measured thyroid hormone-binding ratio. The values of these two indices are normal in the event of a primary alteration in binding, but not in secretion, of thyroid hormone.

Hyperthyroidism can be diagnosed by measuring the levels of TSH after administration of TRH. Although administering

TABLE 25-13 -- Factors Influencing Serum Levels of Thyroxine-Binding Globulin

CONDITIONS INCREASING SERUM LEVELS	CONDITIONS DECREASING SERUM LEVELS
Use of oral contraceptives	Testosterone
Pregnancy	Use of corticosteroids
Use of estrogen	Severe illness

Infectious hepatitis	Cirrhosis
Chronic active hepatitis	Nephrotic syndrome
Neonatal state	Inherited conditions
Acute intermittent porphyria	?Phenytoin
Inherited conditions	

TRH normally increases TSH levels in blood, even a small increase in the T_4 or T_3 level in blood abolishes this response. Thus, a subnormal or absent serum TSH response to TRH is a very sensitive indicator of hyperthyroidism. [182] In one group of disorders involving hyperthyroidism, serum TSH levels are elevated in the presence of elevated levels of free thyroid hormone.

Measurement of the alpha-subunit of TSH has been helpful in identifying the rare patients who have a pituitary neoplasm and who usually have increased alpha-subunit concentrations. Some patients are clinically euthyroid in the presence of elevated levels of total T_4 in serum. Certain drugs, notably gallbladder dyes, propranolol, glucocorticoids, and amiodarone, block the conversion to T_3 to T_4 , thereby elevating T_4 levels. Severe illness also slows this conversion. Levels of TSH are often high in situations where the rate of this conversion is decreased. In hyperthyroidism, cardiac function and responses to stress are abnormal; return of normal cardiac function parallels the return of TSH levels to normal values.

Hyperthyroidism

Although hyperthyroidism is usually caused by the multinodular diffuse enlargement in Graves disease (also associated with disorders of the skin and/or eyes), it can also occur with pregnancy, [183] thyroiditis (with or without neck pain), thyroid adenoma, choriocarcinoma, or TSH-secreting pituitary adenoma. Five percent of women have thyrotoxic effects 3 to 6 months postpartum and tend to have recurrences with subsequent pregnancies. Major manifestations of hyperthyroidism are weight loss, diarrhea, warm moist skin, weakness of large muscle groups, menstrual abnormalities, nervousness, jitteriness, intolerance to heat, tachycardia, cardiac arrhythmias, mitral valve prolapse, [184] and heart failure. When the thyroid is functioning abnormally, the entity most threatened is the cardiovascular system. When diarrhea is severe, dehydration should be corrected preoperatively. Mild anemia, thrombocytopenia, increased serum alkaline phosphatase, hypercalcemia, muscle wasting, and bone loss frequently occur in hyperthyroidism. Muscle disease usually involves proximal muscle groups; it has not been reported to cause respiratory muscle paralysis. In the apathetic form of hyperthyroidism (seen most commonly in persons older than 60 years), cardiac effects dominate the clinical picture. [185] These signs and symptoms include weight loss, anorexia, and cardiac effects such as tachycardia, irregular heart rhythm, atrial fibrillation (in 10%), heart failure, and occasionally papillary muscle dysfunction. [184] [185]

Although beta-adrenergic receptor blockade can control heart rate, its use is fraught with hazard in the patient already experiencing congestive heart failure (CHF). However, decreasing heart rate may improve heart pumping function. Thus, hyperthyroid patients who have fast ventricular rates, who are in CHF, and who require emergency surgery are given esmolol guided by changes in pulmonary artery wedge pressure and their condition. If slowing the heart rate with a small dose of esmolol (50 mug/kg) does not aggravate heart failure, the author administers more esmolol. I believe that we should aim to avoid imposing surgery on any patient whose thyroid function is clinically abnormal. Therefore, I believe only "life-or-death" emergency surgery should preclude making the patient pharmacologically euthyroid, a process that can take 2 to 6 weeks. Antithyroid medications include propylthiouracil or methimazole, both of which decrease the synthesis of thyroxine and may enhance remission by reducing TSH-receptor antibody levels (the primary pathologic mechanism in Graves disease). Propylthiouracil also decreases the conversion of T_4 into the more potent T_3 . However, the literature indicates a trend toward preoperative preparation with propranolol and iodides alone. [186] This approach is quicker (i.e., 7-14 d versus 2-6 wk); it shrinks the thyroid gland, as does the more traditional approach; and it treats symptoms but may not correct abnormalities in left ventricular function. [187] Regardless of approach, antithyroid drugs should be administered chronically and on the morning of surgery. If emergency surgery is necessary before the euthyroid state is achieved, if subclinical hyperthyroidism progresses without adequate treatment, [188] or if hyperthyroidism gets out of control during surgery, intravenous administration of esmolol, 50 to 500 mug/kg, should be titrated to restore normal heart rate (assuming the absence of congestive heart failure) (see previous). Also, intravascular fluid volume and electrolyte balance should be restored. However, administering propranolol or esmolol does not invariably prevent "thyroid storm." [189]

No controlled study has demonstrated clinical advantages of any anesthetic drug over another for surgical patients who are hyperthyroid. A review of cases performed at the University of California, San Francisco, from 1968 to 1982 reveals that virtually all anesthetic agents and techniques [190] have been employed without adverse effects being even remotely attributable to agent or technique. Furthermore, although some investigators have recommended that anticholinergic drugs (especially atropine) be avoided because they interfere with the sweating mechanism and cause tachycardia, atropine has been given as a test for adequacy of antithyroid treatment. Because patients are now subject to operative procedures only when euthyroid, the traditional "steal" of the heavily premedicated hyperthyroid patient (so commonly found in the iodine-deficient locales producing the Lahey, Mayo, and Cleveland Clinics) to the operating room has vanished.

The patient having a large goiter and an obstructed airway can be handled in the same way as any other patient having problematic airway management. Preoperative medication should avoid excessive sedation, and an airway should be established, often with the patient awake. A firm armored endotracheal tube is preferable and should be passed beyond the point of extrinsic compression. It is most useful to examine the CT scans of the neck preoperatively to determine the extent of compression. Maintenance of anesthesia usually presents little difficulty. Postoperatively, extubation should be performed under optimal circumstances for reintubation, in the event the tracheal rings have been weakened and the trachea collapses.

Of the many possible postoperative complications (nerve injuries, bleeding, and metabolic abnormalities), "thyroid storm" (discussed later), bilateral recurrent nerve trauma, and hypocalcemic tetany are the most feared. Bilateral recurrent laryngeal nerve injury (by trauma or edema) causes stridor and laryngeal obstruction due to unopposed adduction

of the vocal cords and closure of the glottic aperture. Immediate endotracheal intubation is required, usually followed by tracheostomy to ensure an adequate airway. This rare complication occurred only once in more than 30,000 thyroid operations at the Lahey Clinic. Unilateral recurrent nerve injury often goes unnoticed because of compensatory overadduction of the uninvolved cord. However, we often test vocal cord function before and after this surgery by asking the patient to say "E" or "moon." Unilateral nerve injury is characterized by hoarseness, and bilateral nerve injury, by aphonia. Selective injury of adductor fibers of both recurrent laryngeal nerves leaves the abductor muscles relatively unopposed, and pulmonary aspiration is a risk. Selective injury of abductor fibers leaves the adductor muscles relatively unopposed, and airway obstruction can occur. Bullous glottic edema, an additional cause of postoperative respiratory compromise, has no specific cause or known preventive measure.

The intimate involvement of the parathyroid gland with the thyroid gland can result in inadvertent hypocalcemia during surgery for thyroid disease. Complications relating to hypocalcemia are discussed in the later section, *Hypocalcemia*.

Because postoperative hematoma can compromise the airway, neck dressings and wound dressings are placed in a crossing fashion (rather than vertically or horizontally) and should be examined for evidence of bleeding before a patient is discharged from the recovery room.

Thyroid Storm

Thyroid storm is the name for the clinical diagnosis of a life-threatening illness in a patient whose hyperthyroidism has been severely exacerbated by illness or operation. Thyroid storm is manifested by hyperpyrexia, tachycardia, and striking alterations in consciousness. [191] Thyroid storm can thus present very similarly to malignant hyperthermia, pheochromocytoma, or the neuroleptic malignant syndrome. [150] No laboratory tests are diagnostic of thyroid storm, and the precipitating (nonthyroidal) cause is the major determinant of survival. Therapy can include blocking the synthesis of thyroid hormones by administering antithyroid drugs, blocking the release of preformed hormone with iodine, meticulous attention to hydration and supportive therapy, and correcting the precipitating cause. Blocking the

sympathetic nervous system with reserpine, guanethidine, or alpha- and beta-receptor antagonists may be exceedingly hazardous and requires skillful management and constant monitoring of the critically ill patient.

Hypothyroidism

Hypothyroidism is a common disease, occurring in 5 percent of a large population in Great Britain, in 3 to 6 percent of a healthy older population in Massachusetts, and in 4.5 percent of a medical clinic population in Switzerland. [192] [193] Usually hypothyroidism is subclinical, serum concentrations of thyroid hormones are in the normal range, and only serum TSH levels are elevated. The normal range of TSH being 0.3 to 4.5 mU/L, TSH values of 5 to 15 mU/L are characteristic of this entity. [193] In such cases, hypothyroidism may have little or no perioperative significance. However, a recent retrospective study of 59 mildly hypothyroid patients found that more hypothyroid patients than control subjects required prolonged postoperative intubation (9 of 59 versus 4 of 59) and had significant electrolyte imbalances (3 of 59 versus 1 of 59) and bleeding complications (4 of 59 versus 0 of 59). [194] Because only a small number of charts were examined, these differences did not reach statistical significance. In another study, a high percentage of patients with a history of subclinical hypothyroidism later developed overt hypothyroidism. [195] Thus, a prior history of subclinical hypothyroidism may indicate the need to search for, and be concerned about, the possibility of overt hypothyroidism.

In the less frequent occurrences of overt hypothyroidism, relative lack of thyroid hormone results in slow mental functioning, slow movement, dry skin, arthralgias, carpal tunnel syndrome, periorbital edema, intolerance to cold, depression of the ventilatory responses to hypoxia and hypercarbia, [196] impaired clearance of free water with or without hyponatremia, "hung-up reflexes," slow gastric emptying, and bradycardia. In extreme cases, cardiomegaly, heart failure, and pericardial pleural effusions manifest as fatigue, dyspnea, and orthopnea. [197] Hypothyroidism is often associated with amyloidosis, which may produce an enlarged tongue, abnormalities of the cardiac conduction system, and renal disease. Hypothyroidism decreases anesthetic requirement slightly. [198] The tongue may be enlarged in the hypothyroid patient even in the absence of amyloidosis, and this may hamper endotracheal intubation.

A rising TSH level is a most sensitive indicator of failing thyroid function. Ideal preoperative management of hypothyroidism consists of restoring normal thyroid status: I routinely administer the normal dose of T_3 or T_4 the morning of surgery, even though these drugs have long half-lives (1.4-10 d). Reduced gastrointestinal absorption of levothyroxine may occur with coadministration of cholestyramine or aluminum hydroxide, iron, a high-bran meal, or sucralfate or colestipol. For patients with myxedema coma requiring emergency surgery, T_3 can be given intravenously (with fear of precipitating myocardial ischemia, however) while supportive therapy is undertaken to restore normal intravascular fluid volume, body temperature, cardiac function, respiratory function, and electrolyte balance.

Treating hypothyroid patients having symptomatic coronary artery disease poses special problems and may require compromises in the general practice of preoperatively restoring euthyroidism with drugs. [197] Although both T_4 and esmolol may be given, adequate amelioration of both ischemic heart disease and hypothyroidism may be difficult to achieve. The need for thyroid therapy must be balanced against the risk of aggravating anginal symptoms. One review suggested early consideration for coronary artery revascularization. [199] It advocated initiating thyroid replacement therapy in the ICU soon after the patient's arrival from the operating room and myocardial revascularization surgery. However, several deaths due to arrhythmia and CHF as well as cardiogenic shock with infarction have occurred while patients who were not given thyroid therapy were awaiting surgery. Thus, there is need for consideration of true emergency coronary artery revascularization in patients having

both severe coronary artery disease and significant hypothyroidism.

In hypothyroidism, respiratory control mechanisms do not function normally. [196] However, the response to hypoxia and hypercarbia and the clearance of free water become normal with thyroid replacement therapy. [196] [197] Drug metabolism is anecdotally reported to be slowed, and awakening times from sedatives are reported to be prolonged during hypothyroidism. However, no formal study of the pharmacokinetics and pharmacodynamics of sedatives or anesthetic agents has been published. These concerns disappear when thyroid function is normalized preoperatively. Addison disease (with its relative steroid deficiency) is more common in hypothyroidism, and some endocrinologists routinely treat noniatrogenic hypothyroid patients with stress doses of steroids perioperatively, as both conditions are commonly caused by autoimmune responses. The possibility that this steroid deficiency exists should be considered if the patient becomes hypotensive perioperatively. Body heat mechanisms are inadequate in hypothyroid patients, and temperature should be monitored and maintained, especially in patients requiring emergency surgery. Because there is an increased incidence of myasthenia gravis in hypothyroid patients, it may be advisable to use a peripheral nerve stimulator to guide administration of muscle relaxants (Ch. 36) .

Thyroid Nodules and Carcinoma

Identifying malignancy in a solitary thyroid nodule is a difficult and important procedure. Male patients and patients with previous radiation to the head and neck have an increased likelihood of malignant disease in their nodules. Often, needle biopsy and scanning are sufficient for the diagnosis, but occasionally an excisional biopsy is needed. Papillary carcinoma accounts for more than 70 percent of all thyroid carcinomas. Simple excision of lymph node metastases appears to be as efficacious for patient survival as are radical neck procedures. Follicular carcinoma accounts for about 15 percent of thyroid carcinomas, is more aggressive, and has a less favorable prognosis.

Medullary carcinoma is the most aggressive form of thyroid carcinoma. It is associated with a familial incidence of pheochromocytoma, as are parathyroid adenomas. For this reason, a history might be obtained for patients who have a surgical scar in the thyroid region, so that the possibility of occult pheochromocytoma can be ruled out.

Disorders of Calcium Metabolism

The three substances that regulate the serum concentrations of calcium, phosphorus, and magnesium--parathyroid hormone (parathyrin, PTH), calcitonin, and vitamin D--act on bone, kidney, and gut. PTH stimulates bone resorption and inhibits renal excretion of calcium, two conditions that lead to hypercalcemia. Calcitonin can be considered an antagonist to PTH. Through its metabolites, vitamin D aids in the absorption of calcium, phosphate, and magnesium from the gut and facilitates the bone resorptive effects of PTH. [200]

Hyperparathyroidism and Hypercalcemia

Primary hyperparathyroidism most commonly begins in the third to fifth decades of life and occurs two to three times more frequently in women than in men. Primary hyperparathyroidism usually results from enlargement of a single gland, commonly an adenoma and very rarely a carcinoma. Hypercalcemia almost always occurs.

Calcium is the chief mineral component of the body, providing structure to the skeleton and performing key roles in neural transmission, intracellular signaling, blood coagulation, and neuromuscular functioning. Ninety-nine percent of the 1,000 g of calcium present in the average human body is stored in bone. The normal total serum calcium level is 8.6 to 10.4 mg/dL, as measured in most laboratories. Fifty to sixty percent is bound to plasma proteins or is complexed with phosphate or citrate. The value is dependent on the albumin level, declining 0.8 mg/dL for each 1-g/dL drop in albumin. Calcium binding to albumin is pH dependent: binding decreases with acidic pH and increases with alkaline pH. It should be noted that serum calcium and not ionized calcium decreases with decreases in albumin levels. Although ionized calcium is the clinically significant fraction, the cost and technical difficulties of stabilizing the electrodes used for measurement have limited the available assays. Nevertheless, parathyroid hormone and vitamin D_3 work to keep the level stable within 0.1 mg/dL in any individual.

Many of the prominent symptoms of hyperparathyroidism are a result of the hypercalcemia that accompanies it. Regardless of the cause, hypercalcemia can produce any of a number of symptoms, the most prominent involving the renal, skeletal, neuromuscular, and GI systems--anorexia, vomiting, constipation, polyuria, polydipsia, lethargy, confusion, formation of renal calculi, pancreatitis, bone pain, and psychiatric abnormalities. Free intracellular calcium initiates and/or regulates muscle contraction, release of neurotransmitters, secretion of hormones, enzyme action, and energy metabolism.

Nephrolithiasis occurs in 60 to 70 percent of patients with hyperparathyroidism. Sustained hypercalcemia can result in tubular and glomerular disorders, including proximal (type II) renal tubular acidosis. Polyuria and polydipsia are common complaints.

Skeletal disorders related to hyperparathyroidism are osteitis fibrosa cystica and simple diffuse osteopenia. The rate of bone turnover is five times higher for patients with hyperparathyroidism than for normal controls. Patients may have a history of frequent fractures or complain of bone pain, the latter especially in the anterior margin of the tibia.

Because free intracellular calcium initiates or regulates muscle contraction, neurotransmitter release, hormone secretion, enzyme action, and energy metabolism, abnormalities in these end organs are often symptoms of hyperparathyroidism. Patients may experience profound muscle weakness, especially in proximal muscle groups, as well as muscle atrophy. Depression, psychomotor retardation, and memory impairment may occur. Lethargy and confusion are frequent complaints.

Peptic ulcer disease is more common in these patients than in the rest of the population. Production of gastrin and

gastric acid is increased. Anorexia, vomiting, and constipation may also be present.

Approximately one-third of all hypercalcemic patients are hypertensive; the hypertension usually resolves with successful treatment of the primary disease. Long-standing hypercalcemia can lead to calcifications in the myocardium, blood vessels, brain, and kidney. Cerebral calcifications may cause seizures, whereas renal calcifications lead to polyuria that is unresponsive to vasopressin.

The most useful confirmatory test for hyperparathyroidism is a radioimmunoassay for PTH. In fact, some surgeons follow PTH levels intraoperatively to determine if they have resected the causative adenoma. [201] In hyperparathyroid patients, the hormone levels are abnormal for a given level of calcium. The level of inorganic phosphorus in serum is usually low, but it may be within normal limits. Alkaline phosphatase is elevated if considerable skeletal involvement is present.

Glucocorticoid administration reduces the level of calcium in the blood in many other conditions that cause hypercalcemia but usually not in primary hyperparathyroidism. In sarcoidosis, multiple myeloma, vitamin D intoxication, and some malignant diseases, all of which can cause hypercalcemia, administration of glucocorticoids may lower the serum calcium through an effect on gastrointestinal absorption. This effect occurs to a lesser degree in primary hyperparathyroidism.

Hypercalcemia may also occur as a consequence of secondary hyperparathyroidism in patients who have chronic renal disease. When phosphate excretion decreases as a result of a lower nephron mass, serum calcium levels fall because of deposition of calcium and phosphate in bone. Secretion of PTH subsequently increases, whereas the fraction of phosphate excreted by each nephron increases. Eventually, the chronic intermittent hypocalcemia of chronic renal failure leads to chronically high levels of serum PTH and hyperplasia of the parathyroid glands.

What should be done for asymptomatic patients with primary hyperparathyroidism? This question has become the subject of a major controversy, for which no definitive answer exists. *Symptomatic* primary hyperparathyroidism is usually treated surgically, as is hyperparathyroidism in young patients or in patients with azotemia, bone demineralization, or chronic total calcium elevations greater than 12 mg/dL. If the patient refuses surgery, or if other illnesses make surgery inadvisable, medical management can be difficult. This difficulty occurs when hyperfunctioning parathyroid glands secrete more hormone as the serum calcium is lowered, as if the calcium set point for feedback regulation of PTH secretion had been raised.

Patients with moderate hypercalcemia who have normal renal and cardiovascular function present no special preoperative problems. The electrocardiogram can be examined preoperatively and intraoperatively for shortened PR or QT intervals (Fig. 25-7) (Figure Not Available) . Because severe hypercalcemia can result in hypovolemia, normal intravascular volume and electrolyte status should be restored before anesthesia and surgery are begun.

Management of hypercalcemia can include increasing the urinary calcium excretion by means of hydration and diuresis. Restoration of intravascular volume, augmentation of urinary sodium, excretion, and administration of diuretics

Figure 25-7 (Figure Not Available) Measurement of the QT_c interval (properly termed $Q_E T_c$ to indicate that it begins with the start of the Q wave, lasts throughout the QT interval, ends with the end of the T wave, and is corrected for heart rate). RR is the RR interval in seconds. *(From Hensel and Roizen [200])*

(furosemide is commonly employed) usually increase urinary calcium excretion substantially. Complications of these interventions include hypomagnesemia and hypokalemia.

In emergency situations, vigorous expansion of intravascular volume usually reduces serum calcium to a safe level (<14 mg/dL); administration of furosemide is also often helpful in these situations. Phosphate should be given to correct hypophosphatemia, which decreases calcium uptake into bone, increases calcium, and stimulates breakdown of bone. Hydration and diuresis, accompanied by phosphate repletion, suffice in the management of most hypercalcemic patients. If additional intervention is needed, glucocorticoids, mithramycin, or calcitonin may be given. Corticosteroids inhibit further gastrointestinal absorption of calcium. Mithramycin lowers calcium levels by approximately 2 mg/dL in 36 to 48 hours through its effect on osteoclasts. Its toxic effects include thrombocytopenia, decreased levels of clotting factors, hepatotoxicity, azotemia, proteinuria, hypocalcemia, hypophosphatemia, and hypokalemia. Most of these side effects can be reversed simply by discontinuation of the drug. Consultation with an endocrinologist or oncologist is advisable before mithramycin is given, because it has a narrow therapeutic-to-toxic ratio.

Calcitonin lowers serum calcium levels through direct inhibition of bone resorption. It can decrease serum calcium levels within minutes after its intravenous administration. Calcitonin is less effective than phosphate or mithramycin, however, for patients with hypercalcemia caused by hyperparathyroidism. Side effects include urticaria and nausea.

It is especially important to know whether hypercalcemia has been chronic, because serious cardiac, renal, or CNS abnormalities may have resulted.

Hypocalcemia

Hypocalcemia (caused by hypoalbuminemia, hypoparathyroidism, hypomagnesemia, or chronic renal disease) is not usually accompanied by a clinically evident cardiovascular disorder. However, myocardial contractility does

vary directly with levels of blood ionized calcium, although contractility decreased only 20 percent when ionized calcium levels changed from 1.68 to 1.34 mmol/L. [202] The clinical signs of hypocalcemia are clumsiness; convulsions; laryngeal stridor; depression; muscle stiffness; paresthesia (oral and perioral); parkinsonism; tetany; Chvostek sign; dry, scaly skin, brittle nails, and coarse hair; low serum concentrations of calcium; prolonged QT intervals; soft tissue calcifications; and Trousseau sign.

Hypocalcemia delays ventricular repolarization, hence increasing the QT_c interval (normal, 0.35-0.44 seconds). With electrical systole prolonged, the ventricles may fail to respond to the next electrical impulse from the sinoatrial node, causing 2:1 heart block. Prolongation of the QT interval is a moderately reliable ECG sign of hypocalcemia, not for the population as a whole, but for the individual patient. [203] Thus, following the QT interval as corrected for heart rate (see Fig. 25-7) (Figure Not Available) is a useful but not always accurate means of monitoring hypocalcemia in any one patient. CHF may also occur with hypocalcemia, but this is rare. Because CHF in patients with coexisting heart disease is reduced in severity when calcium and magnesium ion levels are restored to normal, these levels might be normal before surgery in the patient with impaired exercise tolerance or signs of cardiovascular dysfunction. [200] [202] Sudden decreases in blood levels of ionized calcium (as with chelation therapy) can result in severe hypotension.

Patients with hypocalcemia may have seizures. These may be focal, jacksonian, petit mal, or grand mal in appearance, indistinguishable from such seizures in the

absence of hypocalcemia. Patients may also have a type of seizure called cerebral tetany, which consists of generalized tetany followed by tonic spasms. Therapy with standard anticonvulsants is ineffective and may even exacerbate these seizures (by an anti-vitamin D effect). In long-standing hypoparathyroidism, calcifications may appear above the sella, representing deposits of calcium in and around small blood vessels of the basal ganglia. These may be associated with a variety of extrapyramidal syndromes.

The most common cause of *acquired hypoparathyroidism* is surgery of the thyroid or parathyroid glands. Other causes include therapy with iodine-131, hemosiderosis, neoplasia, and granulomatous disease. *Idiopathic hypoparathyroidism* has been divided into three categories: an isolated persistent neonatal form, branchial dysembryogenesis, and multiple endocrine deficiency autoimmune candidiasis.

Pseudohypoparathyroidism and pseudopseudohypoparathyroidism are rare hereditary disorders characterized by short stature, obesity, rounded face, and shortened metacarpals. Patients with pseudohypoparathyroidism have hypocalcemia and hyperphosphatemia despite high serum levels of PTH. These patients have a deficient end-organ response to PTH because of abnormalities in G-protein function.

Because treatment of hypoparathyroidism is not surgical, hypoparathyroid patients who come to the operating room are those who require surgery for an unrelated condition. Their calcium, phosphate, and magnesium levels should be measured both preoperatively and postoperatively. Patients with symptomatic hypocalcemia might be treated with intravenous calcium gluconate before surgery. Initially, 10 to 20 mL of 10 percent calcium gluconate may be given at a rate of 10 mL/min. The effect on serum calcium levels is of short duration, but a continuous infusion with 10 mL/min of 10 percent calcium gluconate in 500 mL of solution over 6 hours helps keep serum calcium at adequate levels.

The objective of therapy is to bring the symptoms under control before surgery and anesthesia. For patients with chronic hypoparathyroidism, the objective is to keep the serum calcium level in the lower half of the normal range. A preoperative ECG is useful for maintaining the QT_c interval. The preoperative QT_c value may be used as a guide to the serum calcium level if rapid laboratory assessment is not possible.

The intimate involvement of the parathyroid gland with the thyroid gland can result in unintentional hypocalcemia during surgery for diseases of either organ. Because of the affinity of their bones for calcium, this relationship is crucial for patients having advanced osteitis. Internal redistribution of magnesium and/or calcium ions may occur (into "hungry bones") after parathyroidectomy, causing either hypomagnesemia or hypocalcemia, or both. Because the tendency to tetany increases with alkalosis, hyperventilation is usually assiduously avoided. The most prominent manifestations of acute hypocalcemia are distal paresthesias and muscle spasm (tetany). Potentially fatal complications of severe hypocalcemia include laryngeal spasm and hypocalcemic seizures. The clinical sequelae of magnesium deficiency include cardiac arrhythmias (principally ventricular tachyarrhythmias), hypocalcemic tetany, and neuromuscular irritability independent of hypocalcemia (tremors, twitching, asterixis, and seizures).

In addition to monitoring total serum calcium or ionized calcium postoperatively, one can test for Chvostek sign and Trousseau sign. (Note that serum calcium, and not ionized calcium, is dependent on albumin level, declining about 0.8 mg/dL for each 1-g/dL drop in serum albumin level.) Because Chvostek sign can be elicited in 10 to 15 percent of patients who are not hypocalcemic, an attempt should be made to elicit it preoperatively to ensure its appearance is meaningful. Chvostek sign is a contracture of the facial muscles produced by tapping the ipsilateral facial nerves at the angle of the jaw. Trousseau sign is elicited by applying a blood pressure cuff at a level slightly above the systolic level for a few minutes. The resulting carpopedal spasm, with contractions of the fingers and inability to open the hand, stems from the increased muscle irritability in hypocalcemic states, aggravated by ischemia produced by the blood pressure cuff.

Osteoporosis

Fifty percent of women older than 65 years suffer an osteoporotic fracture. (Because men are living longer, osteoporosis will probably become an increasing problem for them, too.) Osteoporosis is the thinning of bone that causes low bone mass and thus weakening of this living tissue to the point of breakage. Known risk factors include age, relative lifetime estrogen deficiency (late menarche, amenorrhea, early menopause, nulliparity), deficiency of dietary calcium, tobacco usage, increased aerobic exercise in combination with decreased weight-bearing exercise, decreased weight-bearing

exercise by itself, soft drink usage, and Asian or caucasian ancestry. Although therapy for osteoporosis (use of biphosphates, bone mineral depositors, weight-bearing exercises, calcium, vitamin D, estrogen--and now designer estrogens that may be useful for men, such as Evista) does not have major known implications for anesthesia care, bone fractures in such patients have occurred on movement to and from an operating table. Thus, the precautions mentioned earlier for hyperparathyroid patients relative to self-positioning and careful positioning may be useful.

Pituitary Abnormalities

Anterior Pituitary Hypersecretion

The anterior pituitary gland consists of five identifiable types of secretory cells (and the hormones they secrete): somatotrophs (growth hormone [GH]), corticotrophs (ACTH), lactotrophs (prolactin), gonadotrophs (luteinizing hormone [LH] and follicle-stimulating hormone), and thyrotrophs (TSH). The secretion of these pituitary hormones is regulated largely by a negative feedback loop by hypothalamic regulatory hormones and by signals that originate from the target site of pituitary action. Six hypothalamic hormones have been characterized: dopamine, the prolactin-inhibiting hormone; somatostatin, the GH release-inhibiting hormone; GH-releasing hormone; corticotropin-releasing hormone; gonadotropin-releasing hormone (or LH-releasing hormone); and thyrotropin-releasing hormone. Most pituitary tumors (>60 percent) are hypersecretory and are classified according to the excess production of a specific anterior pituitary hormone.

The three most common disorders of pituitary hypersecretion are those related to excesses of prolactin (amenorrhea, galactorrhea, and infertility), ACTH (Cushing syndrome), or GH (acromegaly). In addition to knowing the pathophysiologic processes of the disease involved, the anesthesiologist must determine whether the patient recently underwent air pneumoencephalography. If so, nitrous oxide should not be used; this practice lessens the risk of intracranial hypertension from gas collection. CT or MRI scanning of the sella has largely replaced neuroencephalography, but the latter is still performed.

Acromegaly is a syndrome that presents with characteristic facies, weakness, enlargement of the hands (often to the point of rendering the usual oximeter probes difficult to use) and feet, thickening of the tongue (often to the point of making endotracheal intubation difficult), and enlargement of the nose and mandible with spreading of the teeth (often to the point of requiring larger than normal laryngoscopic blades). [204] [20] The patient may even appear myxedematous. Other findings include abnormal glucose tolerance and osteoporosis. The most specific test for acromegaly is measurement of GH before and after glucose administration. The typical acromegalic has very elevated fasting levels of GH (usually >10 g/mL), and the levels do not change appreciably after oral administration of glucose. In the normal state, glucose markedly suppresses the GH level. A few patients with active acromegaly have normal levels of fasting GH, and GH levels are not suppressed by glucose. In addition, an elevated plasma insulin-like growth factor-I (IGF-I), also known as somatomedin-C, is pathognomonic of growth hormone excess. The drug L-dopa, which normally causes an elevation of GH in normal subjects, in the acromegalic either has no effect or lowers GH levels. More than 99 percent of cases of acromegaly are attributable to pituitary adenoma. Thus, the primary treatment of acromegaly is trans-sphenoidal surgery. If the pituitary tumor is not totally removed, patients are often offered external pituitary irradiation. In the case of suprasellar extension, conventional transfrontal hypophysectomy is often employed. The dopaminergic agonist bromocriptine can lower GH levels, but long-term follow-up with this drug is not favorable. Octreotide, a long-acting analogue of somatostatin, is an effective palliation in 50 percent of patients.

The effects of excessive GH stem from both direct actions of the hormone on tissue and stimulation of the production of somatomedins. Excessive GH often results in retention of sodium and potassium, inhibition of the peripheral action of insulin (which can result in diabetes mellitus), and premature atherosclerosis (often associated with cardiomegaly). Exertional dyspnea may be related to either heart failure or respiratory insufficiency due to kyphoscoliosis. Cardiac arrhythmias are common. The incidence of these problems in elderly men now being treated with or receiving GH (recombinant) for the possible improvement of functional status is not known. Preoperative evaluation of the patient who has acromegaly or who is receiving GH might begin by determining whether significant cardiac, hypertensive, pulmonary, or diabetic problems exist. If so, preoperative evaluation should proceed along the lines described in sections discussing those topics. In addition, difficulty with endotracheal intubation should be anticipated in the acromegalic patient; lateral neck films or CT scans of the neck and direct or indirect visualization can identify the patient who has subglottic stenosis or an enlarged tongue, mandibles, epiglottis, or vocal cords. [205] [206] If placement of an arterial line is necessary, a brachial or

femoral site may be preferable to a radial site. [207]

Prolactin has been one of the most interesting markers to identify patients with pituitary tumors. Elevated prolactin levels are often but not invariably associated with galactorrhea. Females commonly present with amenorrhea, and males present with impotence. Optimal therapy for prolactin-secreting tumors is now believed to be the dopamine agonist bromocriptine. This drug, which is extremely effective in controlling the prolactin level and restoring gonadotropin function, is used when fertility is desired. When normal menses, contraception, and skeletal integrity are desired, birth control pills are the treatment. [208] The side effects of bromocriptine include orthostatic hypotension, gastroparesis (possible increased risk of aspiration), constipation, and nasal congestion (possible need for oral intubation). [208] With large prolactin-secreting tumors (macroadenomas), loss of other pituitary function is common, and evaluation of thyroid and adrenocortical status is indicated. Preoperative preparation of patients with Cushing syndrome is discussed in the section on ACTH excess.

Anterior Pituitary Hypofunction

Anterior pituitary hypofunction results in deficiency of one or more of the following hormones: GH, TSH, ACTH,

prolactin, or gonadotropin. Preoperative preparation of those patients who are chronically deficient in ACTH and TSH was discussed previously. No special preoperative preparation is required for the patient deficient in prolactin or gonadotropin; deficiency in GH can result in atrophy of cardiac muscle, a condition that may necessitate preoperative cardiac evaluation. However, anesthetic problems have not been documented in patients with isolated GH deficiency. Acute deficiencies are another matter.

Acute pituitary deficiency is often caused by bleeding into a pituitary tumor. In surgical specimens of resected adenomas, as many as 25 percent show evidence of hemorrhage. Patients with this condition often present with acute headache, visual loss, nausea or vomiting, ocular palsies, disturbances of consciousness, fever, vertigo, or hemiparesis. In such patients, rapid transsphenoidal decompression should be accompanied by consideration of replacement therapy, including glucocorticoids and treatment for increased intracranial pressure.

The obstetrical anesthesiologist is often aware of these pituitary failure problems: Sheehan's syndrome is the clinical manifestation of pituitary infarction associated with hypotension after or during obstetric hemorrhage. Conditions that strongly suggest this diagnosis are failure to start postpartum lactation, increasing fatigue, cold intolerance, and especially hypotension unresponsive to volume replacement and pressors.

Posterior Pituitary Hormone Excess and Deficiency

The secretion of vasopressin, or antidiuretic hormone (ADH), is increased by increased serum osmolality or the presence of hypotension. Inappropriate secretion of vasopressin, without relation to serum osmolality, results in hyponatremia and fluid retention. This inappropriate secretion can result from a variety of CNS lesions; from drugs such as nicotine, narcotics, chlorpropamide, clofibrate, vincristine, vinblastine, and cyclophosphamide; and from pulmonary infections, hypothyroidism, adrenal insufficiency, and ectopic production from tumors. Preoperative management of the surgical patient with inappropriate secretion of vasopressin includes appropriate treatment of the causative disorders and restriction of water. Occasionally, drugs that inhibit the renal response to ADH (e.g., lithium or demeclocycline) should be administered preoperatively to restore normal intravascular volume and electrolyte status.

Most of the clinical features associated with the syndrome of inappropriate ADH (SIADH) secretion are related to hyponatremia and the resulting brain edema; these features include weight gain, weakness, lethargy, mental confusion, obtundation, and disordered reflexes and may progress, finally, to convulsions and coma. This form of edema rarely leads to hypertension.

SIADH should be suspected in any patient with hyponatremia who excretes urine that is hypertonic relative to plasma. The following laboratory findings further support the diagnosis:

1. Urinary sodium >20 mEq/L
2. Low serum levels of BUN, creatinine, uric acid, and albumin
3. Serum sodium <130 mEq/L
4. Plasma osmolality <270 mOsm/L
5. Urine hypertonic relative to plasma

Noting the response to water loading is a useful way of evaluating the patient with hyponatremia. Patients with SIADH are unable to excrete dilute urine even after water loading. Assay of ADH in blood can confirm the diagnosis. Too vigorous treatment of chronic hyponatremia can result in disabling demyelination. [209] [210] The increase in serum sodium should not be greater than 1 mEq/L/h. [209] [210] (See the discussion of hyponatremia in the later section, *Electrolyte Disorders*.)

Patients with mild to moderate symptoms of water intoxication can be treated with restriction of fluid intake to about 500 to 1,000 mL/d. Patients with severe water intoxication and CNS symptoms may need vigorous treatment, with intravenous administration of 200 to 300 mL of 5 percent saline solution over several hours, followed by fluid restriction.

Treatment should be directed at the underlying problem. If SIADH is drug induced, the drug should be withdrawn. Inflammation should be treated with appropriate measures, and neoplasms should be managed with surgical resection, irradiation, or chemotherapy, whichever is indicated.

No drugs are available that can suppress release of ADH from the neurohypophysis or from a tumor. Dilantin and narcotic antagonists such as naloxone and butorphanol have some inhibiting effect on physiologic ADH release but are clinically ineffective in patients with SIADH. Drugs blocking the effect of ADH on renal tubules include lithium, which is rarely used because its toxicity often outweighs its benefits, and demethylchlortetracycline in doses of 900 to 1,200 mg/d. The latter drug interferes with the ability of the renal tubules to concentrate urine, causing excretion of isotonic or hypotonic urine and thereby lessening hyponatremia. Demethylchlortetracycline can be used for ambulatory patients with SIADH when it is difficult to restrict fluids.

When a patient with SIADH comes to the operating room for any surgical procedure, fluids are managed by measuring the central volume status by central venous pressure, pulmonary artery lines, or cross-sectional left ventricular area at end-diastole on transesophageal echocardiography, and by frequent assays of urine osmolarity, plasma osmolarity, and serum sodium, including during the period immediately after surgery. Despite the common impression that SIADH is frequently seen in elderly patients in the postoperative period, studies have shown that the patient's age and the type of anesthetic used have no bearing on the postoperative development of SIADH. It is not unusual to see many patients in the neurosurgical intensive care unit suffering from this syndrome. The diagnosis is usually one of exclusion. Patients with SIADH usually require only fluid restriction; very rarely is hypertonic saline needed.

Lack of ADH, which results in diabetes insipidus, is caused by pituitary disease, brain tumors, infiltrative diseases such as sarcoidosis, head trauma (trauma after neurosurgery), or lack of renal response to ADH. The last can occur with such diverse causes as hypokalemia, hypercalcemia, sickle cell anemia, obstructive uropathy, or renal insufficiency. Preoperative treatment of diabetes insipidus consists of restoring normal intravascular volume by replacing urinary losses, by using nasal desmopressin, and by giving daily fluid requirements intravenously.

Perioperative management of patients with diabetes insipidus is based on the extent of the ADH deficiency. Management of a patient with complete diabetes insipidus and a total lack of ADH usually does not present any major problem as long as side effects of the drug are avoided and the presence of the condition is known before surgery. Just before surgery, the patient is given the usual dose of desmopressin acetate intranasally or an intravenous bolus of 100 mU of aqueous vasopressin, followed by constant infusion of 100 to 200 mU/h. [211] The dose is usually adjusted to permit daily breakthrough polyuria that avoids the iatrogenic syndrome of SIADH. We have found it useful to continue that dosing regimen perioperatively in all ambulatory patients who can take fluid orally in the postoperative period. All the

intravenous fluids given intraoperatively should be isotonic, to reduce the risk of water depletion and hypernatremia. Plasma osmolality should be measured every hour, both intraoperatively and immediately after surgery. If plasma osmolality rises well above 290 mOsm/L, hypotonic fluids can be administered; the rate of the intraoperative vasopressin infusion can be increased to more than 200 mU/h.

For patients who have a partial deficiency of ADH, it is not necessary to use aqueous vasopressin perioperatively unless plasma osmolality rises above 290 mOsm/L. Nonosmotic stimuli, for example, volume depletion, and stress of surgery usually cause the release of large quantities of ADH perioperatively. Consequently, these patients require only frequent monitoring of plasma osmolality during this period.

Because of side effects, the dose of vasopressin should be limited to that necessary for control of diuresis. [212] The oxytoxic and coronary artery-constricting properties of vasopressin make this limit especially applicable to patients who are pregnant or who have coronary artery disease. [210]

Another problem for anesthesiologists is the care of patients who come to the operating room with a vasopressin drip for treatment of bleeding from esophageal varices. This treatment is less common since the advent of laser therapy for varices. However, when vasopressin is given, the vasoconstrictive effect of vasopressin on the splanchnic vasculature is used to decrease bleeding. Such patients are often volume depleted and may have concomitant coronary artery disease. Because vasopressin has been shown to decrease oxygen availability markedly, primarily because of a decreased stroke volume and heart rate, monitoring of tissue oxygen delivery may be useful. In 1982, Nikolic and Singh [213] described a patient with a history of angina pectoris who received a combination of cimetidine and vasopressin for esophageal varices. Bradyarrhythmias and AV block occurred, necessitating placement of a pacemaker. On two occasions, discontinuation of either of these drugs alleviated the symptoms. This effect indicates that the combination of cimetidine and vasopressin could be deleterious to the heart because of the combined negative inotropic and arrhythmogenic effects of the two drugs.

DISEASES INVOLVING THE CARDIOVASCULAR SYSTEM

Hypertension

Analysis of the perioperative treatment of hypertension is important because of the prevalence of the condition (25% of the general population in the United States), the great risk in perioperative care of the hypertensive patient (Ch. 22) , and the high cost of unnecessary delays in surgery. The controversy centers around two issues. Does inadequate control of hypertension result in complications that could be prevented with some control? How much control of blood pressure is needed, and for how long? That is, does overzealous control just create unnecessary postponements of elective surgery or, worse, predispose the patient to exaggerated adverse drug reactions and greater hemodynamic instability than not-so-zealous control?

Because of the controversy regarding the appropriateness of preoperative treatment of hypertension, the original articles that stimulated this controversy are evaluated here. Smithwick and Thompson [214] and Brown [215] reported overall mortality rates of 2.5 to 3.6 percent, respectively, for hypertensive patients undergoing sympathectomy between 1935 and 1947. These values were five or six times higher than values for normotensive patients undergoing similar operations. Obviously, these patients were not randomly assigned to treatment or nontreatment groups, and no attempt was made to ensure that end-organ disease was equivalent for the two groups. In 1929, Sprague [216] analyzed the records of 75 patients with hypertensive cardiac disease and found that 24 (32%) died during or shortly after operations employing general anesthesia.

In the early 20th century, severely ill patients did not do well perioperatively; however, whether *pre*operative treatment would have improved surgical outcome is unknown. The evolution of drug therapy for hypertension was hampered in the late 1950s and early 1960s by the publication of case reports of severe hypotension and bradycardia in patients given antihypertensive drugs before surgery. The tailoring of anesthetic dose to patient condition and the realization that sympatholytic antihypertensive drugs decreased anesthetic requirement [217] caused such case reports to disappear from the literature.

A more recent prospective controlled double-blind study by the Department of Veterans Affairs provided a rationale for lifelong treatment of hypertension: Such treatment decreased the incidence of stroke, CHF, and progression to renal insufficiency and to accelerated (malignant) hypertension [218] [219] (Table 25-14) . Many other studies have confirmed the beneficial effect of treating hypertension, even for patients with diastolic pressures of 90 to 104 mm Hg. [220] [221] [222] One study has indicated caution in adding

TABLE 25-14 -- Effect on Morbidity of Treating Hypertension (Average Diastolic Blood Pressure 90-114 mm Hg)

	CONTROL GROUP	TREATMENT GROUP
5-y morbidity	55%	18%
Death	19/194	8/186

Data from Veterans Affairs Cooperative Study Group on Antihypertensive Agents [219]

TABLE 25-15 -- Effect on Morbidity of Treating Isolated Systolic Hypertension [a]

(Not Available)

Modified from the Systolic Hypertension in the Elderly Program (SHEP) study [224]

[a] Systolic blood pressure >160 mm Hg

diuretics to therapeutic limits in therapy for the patient with an abnormal ECG whose blood pressure does not decrease after administration of the usual doses of diuretic drugs (see the section, *Hypokalemia,* which follows). [223] Substantial benefit has also been shown for treatment of isolated systolic hypertension (systolic blood pressure [BP] >160 mm Hg and diastolic BP <90 mm Hg) in the elderly [224] (Table 25-15) (Table Not Available) and in diabetics. [225] However, overvigorous treatment of hypertension can result in a "J curve" for morbidity, especially for patients with coronary artery stenosis (i.e., if BP is reduced too much, morbidity starts to increase again) [221] [226] (Fig. 25-8) (Figure Not Available) . Other studies in experimental models of hypertension and in humans indicate even more than prophylactic benefit: Treatment results in a regression of cardiac hypertrophy and in autonomic nerve alterations of hypertension. U.S. government statistics reveal significant decreases (>50%) in the death rate from stroke from 1969

Figure 25-8 (Figure Not Available) Studies that stratified cardiac events by treated diastolic blood pressure levels. Ischemic Heart Disease Events is a combination of morbidity and mortality. Summary curve was calculated using a systematic decrease of 10 mm Hg in diastolic blood pressure levels. Surrounding dashed curves show the 95 percent confidence intervals. *(From Farnett et al [226])*

to 1992 and a 40 percent overall decrease in age-adjusted cardiovascular mortality. Deaths related to hypertensive cardiovascular disease and to myocardial infarction have decreased dramatically since 1974, accounting for most of the decrease in cardiovascular death in this time period. This decrease (at least in localized communities) correlates with successful control of hypertension. This strong evidence from Veterans Affairs studies and the epidemiologic data have led to the belief that all patients with a diastolic blood pressure above 90 mm Hg should be treated, regardless of age.

Although the median blood pressure in the United States is 129/86 mm Hg, the ideal blood pressure for the prevention of arterial aging is 115/76 mm Hg. [22] Furthermore, as the Framingham studies have shown, we gain approximately 20 mm Hg in systolic BP and 10 mm Hg in diastolic BP as we age from 30 to 65. This is important because every 10-mm Hg increase in systolic BP and every 8-mm Hg increase in diastolic BP age the arteries the equivalent of 4 years. Therefore,

preventing these increases would make the average 65-year-old person only 52 years old physiologically. [22] If 115/76 mm Hg is the ideal, why, then, do we accept 130 or even 140/85 or 90 mm Hg before treatment? Arterial aging could be greatly mitigated if we advocated a more aggressive approach to treating blood pressure that exceeds 115/76 mm Hg.

The Framingham data also indicate that one should prevent elevations in both systolic and diastolic BP. [221] In fact, investigations of the Framingham study show there is nothing to suggest a greater impact of diastolic BP on aging of the arteries.

However, the question is, should elective surgery be postponed and patient and physician schedules disrupted so that treatment can be instituted and stabilized, even for systolic hypertension alone? Several schools of thought exist, the two oldest represented by the study conducted by Prys-Roberts et al [227] in 1971 and by Goldman and Caldera [228] in 1979. Several other studies (Bedford and Feinstein, [229] Asiddao et al, [230] Stone et al, [165] Flacke et al, [167] Ghignone et al, [168] Tuman et al, [172] Ellis et al, [231] Charlson et al, [8] Mangano et al, [166] [232] Stone et al, [233] Wolfsthal, [234] and Pasternack et al [235]) also have been cited. Unfortunately, each of these studies has deficiencies that prevent the establishment of a definitive answer to this question. However, I now believe that the weight of evidence from these studies taken together compels an answer.

Critical Analysis of the Data of Prys-Roberts and Colleagues

The followers of Prys-Roberts et al [227] believe that preoperative treatment of hypertension lowers the incidence of perioperative morbidity and mortality. This study compared three groups: a control group consisting of seven elderly normotensive patients having an average mean arterial BP of 89.5 mm Hg; a group of seven hypertensive patients whose high BP was not treated preoperatively (four were being treated not for high BP but for its complications) who had an average mean arterial BP (MABP) of 129.5 mm Hg; and a group of 15 hypertensive patients whose high BP was treated preoperatively and who had an average MABP of

129.9 mm Hg. The same doses of thiopental and halothane were given to all groups of patients, and measurements were made of absolute change in MABP, cardiac arrhythmias, and ECG evidence of ischemia. Patients with untreated hypertension had the greatest absolute fall in BP and the highest percentage of arrhythmias and ischemia.

Several flaws in study design create serious doubt as to whether the relationship between preoperative treatment of hypertension and perioperative morbidity has been evaluated objectively in this investigation. First, the wisdom of administering the same dose of anesthetic to both groups of patients should be questioned. If the anesthetic dose had been titrated to the anesthetic needs of the patient, would the results have been different? Second, BP did not differ between the treated and untreated groups. In addition, at least four of the seven hypertensive patients who were not treated for high BP were "sicker" than any of the hypertensive patients who were treated. Why some patients were treated for hypertension and others were not was not explained; selection definitely did not occur on a random basis. Finally, it was not stated whether surgery was similar for all groups.

This study does indicate that patients who are sick preoperatively have more problems perioperatively than do healthy patients. This has been shown many times. (See refs. [12] and [236] for reviews.) However, from these data, the efficacy of preoperative treatment of hypertension cannot be established. This study and others by the same group provide useful data regarding the hemodynamic consequences of anesthesia when a standard technique is used on patients who have untreated hypertension.

Critical Analysis of the Data of Goldman and Caldera

The school of thought represented by Goldman and Caldera [228] advocates that preoperative treatment of hypertension does not affect outcome. Goldman and Caldera state that their study is a prospective one. However, the only prospective aspect of their study appears to be that patients were examined preoperatively. These investigators compared surgical outcome for three groups: sick hypertensive patients whose high BP was treated preoperatively; less sick hypertensive patients whose high BP was "undertreated" preoperatively; and less sick, only moderately hypertensive patients who received no treatment preoperatively. No differences in outcome between groups were found.

This study has several flaws in design. Patients were not randomly assigned regarding preoperative treatment, undertreatment, or nontreatment of hypertension. Also, sicker patients were allocated to the treated hypertensive group (Table 25-16) , thus biasing study results toward favoring nontreatment of hypertension.

Other flaws concern statistical methods. Only 117 hypertensive patients were studied, and only 34 of the 117 patients who were hypertensive at surgery had diastolic BP of at least 100 mm Hg (see Table 25-14) . If morbid complications were assumed to be 20 percent in the untreated group, and if treatment was assumed to reduce morbidity 50 percent, then, by power analysis, [237] Goldman and Caldera [228] would have had to compare approximately 237 patients to have an 80 percent chance of finding a difference at a confidence level of 0.05 percent. If a lower rate of morbidity in the untreated group (e.g., 15%) and a lesser reduction in the rate of morbidity (e.g., 33%) were assumed, substantially more patients would have to be studied to be 80 percent sure no difference occurred, even at the 0.05 confidence level. For example, if morbid complications were assumed to be 15 percent in the untreated group, and if treatment were assumed to reduce morbidity 33 percent, 764 patients would have had to be studied in each group to be 80 percent certain no difference occurred, the confidence level being 0.05. These major flaws in study design make it impossible to ascertain whether preoperative treatment of hypertension decreased perioperative morbidity.

Critical Analysis of the Data of Bedford and Feinstein and of Wolfsthal

Bedford and Feinstein [229] and Wolfsthal [234] and their supporters believe that instability of BP is the condition most frequently predicting morbid perioperative complications. In the Bedford-Feinstein study, [229] the responses of three groups to rapid-sequence induction were compared prospectively. Patients were allocated to groups based on the initial admitting room BPs and the average presurgical

TABLE 25-16 -- Analysis of Treatment Groups Used by Goldman and Caldera [228] to Evaluate Effectiveness of Preoperative Treatment of Hypertension in Surgical Patients

PREOPERATIVELY HYPERTENSIVE PATIENTS	n	PREOPERATIVELY			
		DIASTOLIC BP > 100 MM HG (n)	*BUN > 30 MG % (n)*	*ANGINA OR CHF (%)*	*TIAS (%)*
Treated successfully [a]	79	0	8	47	13
Treated unsuccessfully	40	34	13	40	18
Not treated	77		1	26	4

Abbreviations: BP, blood pressure; BUN, blood urea nitrogen; CHF, congestive heart failure; TIAs, transient ischemic attacks

[a] These data demonstrate that the patients who were the sickest before surgery were allocated to this group, thereby biasing results toward nontreatment.

in-hospital BP: group I (30 patients) had a BP of less than 140/90 mm Hg during and after admission (normal BP group); group II (12 patients) had a BP of greater than 140/90 mm Hg on admission but less than 140/90 mm Hg during hospitalization (labile BP group); group III (eight patients) had a BP greater than 140/90 mm Hg during and after admission (hypertensive BP group). Whether any of the patients in the labile or hypertensive BP groups were under treatment for hypertension, had end-organ complications of hypertension (e.g., ischemic heart disease), or were told they were hypertensive was not stated. Patients were given standard (i.e., not tailored to the patient's condition) premedication (morphine, diazepam, and atropine) and a standard rapid-sequence induction (thiopental, 3-4 mg/kg intravenously;

succinylcholine, 1.5 mg/kg intravenously). After intubation, heart rate and BP increased significantly in all three groups. The increase was greatest in the labile BP group, rising from a mean BP of 102 ± 5 to 152 ± 4 mm Hg. Eight of 12 patients in that group required additional thiopental and/or vasodilating drugs to normalize BP, and 2 of 12 developed transient ST segment depression in lead II. No patient in either of the other two groups required similar treatment or had ST segment changes as seen on ECG.

Thus, this study does indicate that patients with labile BP may require more careful titration of anesthetic drugs than those whose BP is either normal or high but stable. However, whether the results would have been different if the anesthetic had been titrated to the anesthetic needs of the individual patient is not known. Nor do we know whether the groups had equivalent baseline end-organ disease. We do not even know how many patients were being treated for hypertension. Similar deficiencies are present in retrospective analyses of the effect of hypertension on perioperative hemodynamic lability (Wolfsthal [234]) and perioperative outcomes (Mangano studies [7] [232] and Charlson et al [8] [238] [239] [240]). Although such deficiencies mean that we do not know whether preoperative treatment lessened the perioperative risk for those particular hypertensive patients, the deficiencies do not decrease the importance of preoperative hypertension as a marker predicting increased perioperative cardiovascular and renal risk.

Critical Analysis of the Data of Asiddao and Colleagues

The study conducted by Asiddao et al [230] is cited by those advocating preoperative treatment of hypertension. In this study, records of 166 cases of unilateral carotid endarterectomy were reviewed to investigate the association of preoperative and intraoperative factors with perioperative complications. Asiddao and coworkers found that postoperative hypertension (i.e., systolic BP >200 mm Hg or diastolic BP >110 mm Hg) and transient postoperative neurologic deficits occurred more commonly in the 21 patients with poor preoperative control of BP (BP >170/95 mm Hg) (52 and 23.8%, respectively) than in the 79 patients with adequate BP control (BP <170/95 mm Hg) (35 and 2.5%, respectively) or in the 66 normotensive patients (17 and 1.5%, respectively). No statistically significant difference was found between the groups regarding permanent neurologic sequelae of surgery or the rate of myocardial ischemia.

The study by Asiddao et al [230] does not indicate whether postoperative hypertension caused the transient neurologic deficits or whether these deficits resulted in a compensation of postoperative hypertension. We also do not know whether the three groups were equivalent in end-organ manifestations of preoperative disease. Nor does the study indicate why BP was not controlled preoperatively in some patients or whether preoperative normalization of high BP would have reduced the rate of postoperative complications. This study does tell us that patients who have high BP before surgery are likely to have high BP after surgery.

Critical Analysis of the Data of Stone and Colleagues

Stone et al [165] [233] gave one of a variety of beta-adrenergic- blocking drugs or a placebo as preoperative medication to a group of mildly hypertensive patients, and, knowing to which group the patients were assigned, the investigators then looked for ischemic episodes. They observed a significantly greater incidence of brief ischemic episodes during induction and emergence in the untreated patients than in patients given a beta-adrenergic-blocking drug as premedication (Table 25-17) . Although, on the surface, the results seem to establish clearly the efficacy of beta-blocking drugs in reducing perioperative ischemic episodes in patients who are mildly hypertensive preoperatively, two limitations might temper enthusiasm. First, there seems to be a problem with the randomization. Although characteristics of the groups are not statistically different, they are numerically different. One wonders, therefore, whether bias was introduced by the fact that the control group underwent more vascular operations and had more pre-existing coronary artery disease than did the treatment groups. Second, the observers' awareness of which patients belonged to which treatment group could introduce insidious and subtle differences in management, such as provision of inadequate anesthesia, a closer search for myocardial ischemia, or a more lengthy sampling of ECG strips from the control group. Although one wishes one could perform a double-blind study in such a situation, and maybe it is possible to do so, the effect on heart rate induced by beta-adrenergic blockade may make this difficult. Stone et al [165] clearly note the limitations

Modified from Mangano et al [166]

of their study and should be congratulated for not extrapolating or expanding their conclusions beyond that allowed by the data.

Some may comment that the tachycardia that was allowed to occur was severe, indicating inadequate anesthesia, and that the authors have merely demonstrated that betaadrenergic blockade takes the place of a skillful anesthesiologist. I hesitate to come to that conclusion, as I believe that these investigators really tried to provide the best anesthesia care possible. I doubt that even the subtle bias of an unblinded study could have caused this degree of inadequate anesthesia, but one must consider that possibility. Nevertheless, this study and several other published papers, [166] [167] [168] [172] [231] [234] demonstrating that clonidine or other techniques depressed sympathetic nervous system responses during anesthesia, all imply that modifying the response of the sympathetic nervous system, whether on the alpha-adrenergic side with clonidine or on the beta-adrenergic side with one of the beta-adrenergic-blocking drugs used by Stone et al, [165] or with deep general anesthesia [170] or with regional anesthesia, [169] may be all that is needed preoperatively in the mildly hypertensive patient. Data from the McSPI group (see following review) substantiate this point of view. [166]

Critical Analysis of the Data of the McSPI Group

Mangano and coworkers in the McSPI group [166] evaluated patients at risk of coronary artery disease who were undergoing

TABLE 25-19 -- Protocol for Administration of Atenolol in Patients at Risk of Coronary Artery Disease Who Were Undergoing Noncardiac Surgery: The McSPI Study

(Not Available)

Modified from Mangano et al [166]

noncardiac surgery. Those meeting the inclusion criteria listed in Table 25-18 (Table Not Available) were randomly assigned to receive atenolol or placebo for 7 days, as outlined in Table 25-19 (Table Not Available) . Although no difference in morbidity occurred in the first 2 weeks, atenolol produced significantly higher survival rates at 1 and 2 years (Table 25-20) . The difference was so great that administering atenolol was the equivalent of making the average 69-year-old man 3.7 years younger physiologically than the same patient not given atenolol. [22] Even though these data did not pertain solely to hypertensive patients (about 65% did relate to such patients), the results speak clearly about the benefit of controlling BP and "hemodynamic stress" in similar patients. Thus, the author believes the weight of evidence provides a clear answer to the question. The long-lasting benefit from even short-duration therapy indicates that prevention of plaque disruption may be the mechanism of benefit. [241]

Recommendations

Although preoperative systolic BP has been found to be a significant predictor of postoperative morbidity, [165] [197] [212] [213] [214] [215] [216] [217] [218] [219] [220] [222] [223] [224] [226] [227] [228] [229] [230] [231] [232] [233] [234] [238] [239] [240] [242] [249] [250] [251] no data establish definitively whether preoperative treatment of hypertension reduces perioperative risk. Until a definitive study is performed (and that would be, unfortunately, extremely difficult to do), I recommend letting the weight of evidence guide preoperative treatment of the patient with

TABLE 25-20 -- Benefits of Administration of Atenolol for 1 Week in Patients at Risk of Coronary Artery Disease Who Were Undergoing Noncardiac Surgery: The McSPI Study

	PLACEBO GROUP (n = 101; %)	ATENOLOL GROUP (n = 99; %)	*P* VALUE

1-y survival rate	86	97	.005
2-y survival rate	79	91	.019

Data from Mangano et al [166]

hypertension. Such treatment would be based on three general beliefs: (1) The patient should be educated as to the importance of the lifelong treatment of hypertension, [166] [218] [219] [221] [222] [223] [224] [225] [244] even isolated systolic hypertension; (2) perioperative hemodynamic fluctuations occur less frequently in treated than in untreated hypertensive patients (as demonstrated by Prys-Roberts et al [227] and confirmed by Goldman and Caldera, [228] Mangano et al, [232] and Wolfsthal [234]); and (3) hemodynamic fluctuations have some relationship to morbidity. The data of Stone et al, [165] Pasternack et al, [235] and the McSPI group [166] imply that rapid correction of BP or prevention of increases in heart rate may be all that is needed. However, data from animals that had declining renal function with acute reductions in arterial BP accentuate the risks of such reductions. [245] Even though other epidemiologic data confirm these risks, [226] the hazards of BP fluctuations and acute hypertension may be serious in the untreated hypertensive subject. [246] Modern drug therapy for hypertension appears to reduce these risks but does so with a decrement in quality of life that causes many patients to avoid such medications. [247] Specific racial differences need to be considered before treatment (African-Americans respond less well to beta-adrenergic receptor-blocking drugs and angiotensin-converting enzyme inhibitors but as well to calcium channel antagonists as do Caucasians). [248]

In addition to deciding whether a hypertensive patient needs treatment and ensuring that none of the complications of antihypertensive drugs is present, preoperative management should include a search for end-organ damage secondary to hypertension--that is, changes in the CNS and coronary arteries, myocardium, aorta, carotid arteries, kidneys, and peripheral blood vessels. This type of injury may affect perioperative management. For example, the presence of renal disease may alter the choice and dosage of anesthetic drugs. Similarly, recent myocardial ischemia may warrant a delay in elective surgery. Knowing the location of myocardial ischemia would indicate which ECG lead should be monitored intraoperatively (Ch. 32) . Also, to guide intraoperative regulation of BP and to judge the effects of therapy, I obtain multiple BP readings in both arms while the patient is in various positions. I do this even if these readings are obtained in the preoperative holding area, in the preprocedure evaluation clinic (Ch. 23) , or the operating room rather than on a ward the night before surgery. It is possible that patients admitted the morning of surgery do not receive as good care, but the difference in outcome is small. I try to minimize that difference by being especially careful.

I use such preoperative data to determine the individualized range of values I consider tolerable by a particular patient during and after surgery. That is, if BP is 180/100 mm Hg and heart rate 96 beats/min on admission with no signs or symptoms of myocardial ischemia, I feel confident that the patient can tolerate these levels during surgery. If during the night, BP decreases to 80/50 mm Hg and heart rate to 48 beats/min and the patient does not wake with signs of a new cerebral deficit, I believe he or she can tolerate safely such levels during anesthesia. Therefore, on the basis of preoperative data, I derive an individualized set of values for each patient. I then try to keep cardiovascular variables within that range and, in fact, plan prior to induction what therapies to use to accomplish that goal (e.g., administration of more or less anesthesia, nitroglycerin or nitroprusside/dopamine, dobutamine, phenylephrine, or propranolol/isoproterenol, atropine) (Fig. 25-9) . I believe this sort of planning is especially important for the patient with suspected cardiovascular disease and relatively unimportant for the totally healthy patient. I do not know for certain that keeping cardiovascular variables within an individualized

Figure 25-9 Window of acceptable values for cardiovascular variables during and after surgery. This hypothetical range of "safe" cardiovascular values for one patient illustrates possible therapies that might be employed if actual perioperative values approached the high or low end of that range. The range of safe values, variables treated, and therapies are tailored to the patient and surgical situation. SBP, systemic blood pressure; NTG, nitroglycerin; NTP, nitroprusside; HR, heart rate; PCWP, pulmonary capillary wedge pressure; NEO, Neo-Synephrine; DOPI ISUP, dopamine or Isuprel.

range of acceptable values improves surgical outcome, but I do believe that such a plan reduces morbidity. For example, in several studies, major intraoperative deviations in BP and/or heart rate from the preoperative level have correlated with the occurrence of myocardial ischemia. [227] [228] [229] [230] [239] [240] [249] [250] [251] [252] [253]

Preoperative Administration of All Antihypertensive Drugs

I routinely administer all antihypertensive drugs preoperatively, except angiotensin-converting enzyme (ACE) inhibitors. For these, I convert to intravenous preparations, which I administer after establishing hemodynamic stability. Coriat and colleagues [254] found that ACE inhibitors were associated with hypotension in 100 percent of patients during induction versus about 20 percent in whom ACE inhibitors were withheld on the morning of surgery. Although the long-term adverse effects from withholding therapy on the morning of surgery were not assessed, I withhold therapy until either oral fluid is able to be consumed (ambulatory patients), or until I can convert to intravenously or nasogastrically administered alternatives (patients who receive nothing by mouth postoperatively). I even administer the patient's chronic diuretics on the morning of surgery, as the major effect of diuretics after 1 week of therapy is arteriolar vasodilation, and assessment of urine output may be inaccurate if the diuretic is abruptly discontinued on the morning of surgery.

Ischemic Heart Disease

Identifying Ischemic Heart Disease

Any of the following conditions may indicate the presence of ischemic heart disease: a history of viselike chest pain, with or without radiation to the inner arm or neck; dyspnea on exertion, on exposure to cold, with defecation, or after eating (especially in postmenopausal women who do not take estrogen); orthopnea; paroxysmal nocturnal dyspnea; nocturnal coughing; nocturia; previous or current peripheral or pulmonary edema; history of myocardial infarction (MI); family history of coronary artery disease; diagnosis of MI by ECG or elevated levels of enzymes; and cardiomegaly. Other patients who should be suspected of having ischemic heart disease include those who have diabetes, hypertension (especially if they are cigarette smokers or hyperlipemic [Lichtor JL, et al, personal communication] [31] [32] [255]), left ventricular hypertrophy on ECG or echocardiogram, [79] [80] [256] [257] peripheral vascular disease (Lichtor JL, et al, personal communication), [257] [258] [259] [260] [261] [262] [263] [264] carotid bruits, [261] [262] [263] [264] [265] [266] [267] asymptomatic carotid artery occlusion, [261] [262] or unexplained tachycardia or fatigue.

The more difficult question to answer is, how common is ischemic heart disease in asymptomatic patients or in patients having a normal ECG but predisposing conditions? The history appears to be the best indicator of coronary artery disease. Tomatis et al [258] recorded coronary angiograms for "nearly all patients" who presented for aortoiliac reconstruction or resection of an abdominal aortic aneurysm. Of those having normal ECG results and histories not suggestive of coronary artery disease, 38 percent had stenosis of at least 50 percent in one or more coronary arteries, and 14 percent had stenosis of at least 75 percent in one or more coronary arteries. The percentages of patients with stenosis were the same for asymptomatic patients having abnormal ECG findings. However, a normal ECG result was not sensitive in ruling out significant stenosis when vascular disease was present: 44 percent of patients having normal ECGs and peripheral vascular disease had stenosis of at least 50 percent in one or more coronary arteries, and 30 percent had stenosis of at least 75 percent.

Hertzer et al [259] [260] found angina and a history of myocardial disease to be reliable indicators of coronary artery disease. These investigators studied 1,000 patients having peripheral vascular disease. Of the 500 patients having normal ECG results and no history of myocardial disease, 37 percent had narrowing of at least 70 percent in one or more coronary arteries. By contrast, of those suspected of coronary artery disease because of history and/or ECG results, 78 percent had narrowing of this same degree. Also, patients who currently had angina had a 66 percent incidence of either severe correctable or severe inoperable coronary artery disease, whereas those who had peripheral vascular disease but no angina had an incidence of only 22.5 percent. For women, knowing the estrogen status appears crucial to interpreting other aspects of their cardiovascular history. [268] Thus, in addition to the symptoms listed previously that are sought by routine questioning, [269] information about age, smoking, history of diabetes, cholesterol level, exercise tolerance, and estrogen status can all help predict the likelihood of coronary artery disease.

Are these data from 15 and 25 years ago still valid today? I believe so. Even though the average age of the typical surgical patient in America is now about 7 years higher than it was 20 years ago (Lichtor JL, et al, personal communication), the physiologic age (i.e., the RealAge) of the patients now being operated on is probably similar to that of patients 20 years ago. [22] Therefore, although the age-adjusted mortality rates for coronary artery disease have decreased by approximately 40 percent and the age-adjusted mortality rate for all in-hospital surgical procedures has fallen by over 40 percent, the aging of the surgical population has caused us to face the same risks we faced two decades ago.

Although more than 80 percent of all episodes of myocardial ischemia are "silent," [270] [271] patients with myocardial ischemia are *not* "silent." For example, although the episodes of myocardial ischemia may have been silent, for all 165 patients studied by Rabkin and Horne [269] [272] who had ECG evidence of coronary artery disease, the patient's history gave an indication of the risk of coronary artery disease. This has also been the finding of our own studies [269] [273] and several others when physiologic age of 74 years or older has been added to the factors in a clinical history that would indicate myocardial ischemia. These indicators consist of the following: chest pain, typical or atypical; dyspnea on exertion or exposure to cold, with defecation, or after eating; nocturnal coughing; nocturia; previous or current peripheral or pulmonary edema; history of myocardial infarction; a family history (especially sibling history) of coronary artery disease; cardiomegaly; abnormal ECG results; diabetes, hypertension; hyperlipemia; left ventricular hypertrophy; peripheral

vascular disease; cigarette smoking; carotid artery bruits; peripheral vascular surgery; and unexplained tachycardia.

Several studies of asymptomatic carotid artery disease have shown very high perioperative mortality rates and life risk from associated ischemic heart disease. [261] [265] [266] [267] Barnes and Marszalek [262] found perioperative mortality rates of 18.2 and 15 percent, respectively, for patients having an asymptomatic carotid bruit or occlusive disease but a rate of only 2.1 percent for patients undergoing similar peripheral vascular procedures who did not have a carotid bruit. Whereas the existence of asymptomatic carotid bruits did not predict the site of stroke or greatly influence the incidence of perioperative stroke, [212] [213] [214] it did predict mortality from ischemic heart disease (Table 25-21) . Another point of view is found in the retrospective case-controlled review of strokes after CABG surgery. [267] In that review, strokes after CABG surgery were 3.9 times more likely to occur if carotid bruit was present preoperatively than if such was not present. The group was too small to determine whether site of bruit predicted site of stroke. As few as 15 percent of patients with triple-vessel coronary artery disease have abnormal resting ECGs. [257] Transient ischemic attacks are even more predictive. The 5 to 6 percent annual mortality rate after transient ischemic attacks in a 60-year-old individual is due mainly to myocardial infarction; this rate is similar to the 4 percent annual mortality rate for the 60 year old with stable angina pectoris. [274]

The important point to remember is that the history is the best indicator of coronary artery disease. In most series, the sensitivity and specificity of the history in indicating coronary artery disease range from 80 to 91 percent (Lichtor JL, et al, personal communication). [255] [257] [258] [259] [267] [272] [273] [275] [276] The history has higher sensitivity and specificity than most tests in indicating such disease (also see Ch. 23 for the definition of sensitivity and specificity). However, one test is gaining in popularity, as it has been demonstrated to be easy to perform and to accurately predict perioperative morbidity.

One Easy Noninvasive Test and Two Easy Measures: But Does Preoperative Treatment Improve Outcome?

Fowkes and colleagues, [79] Leng et al, [277] and Kornitzer and associates [278] are testing a simple-to-measure index that would predict the degree of subclinical arterial aging that exists and the likelihood of subsequent cardiovascular events and death: the ratio of systolic BP in the posterior tibial artery of the ankle (as measured by Doppler) to systolic BP in the brachial artery (as measured by cuff). This index has predicted 8- and 10-year cardiovascular mortality in patients who did not undergo surgery: The incidence of cardiovascular death was 85 percent higher among those having an index of less than 0.7. The index is made even more powerful when combined with other historical factors. Patients who had an index of less than 0.9, were hypertensive, and currently smoked had a 43.8 percent risk of cardiovascular events in the next 5 years, as opposed to the 15.6 percent risk for those who had identical conditions but an index of 1.0 or higher.

TABLE 25-21 -- Carotid Artery Bruits and the Risk of Stroke in Elective Surgery

STUDY	INCIDENCE OF STROKE IN PATIENTS	
	WITH BRUITS	*WITHOUT BRUITS*

CABG; 54 strokes	13/54 [b]	4/54 [b]

Abbreviation: CABG, coronary artery bypass graft.

[a] All patients included in this study were undergoing vascular surgery. These 85 patients also had either a bruit or significant carotid artery obstruction or both.
[b] Case-control study. These investigators examined the incidence of carotid bruit in patients who had strokes after CABG surgery.

The exercise index of Older et al [279] [280] ("aerobic threshold") seems to have the same goal--to predict the degree of subclinical arterial aging. The RealAge system attempts to do the same thing with its measurements but uses a much broader range of modifiable factors. [22]

However, the key payoff would be the demonstration that using such tests would motivate patients to modify health-related habits, which would, in turn, improve their index values. This result would then have to be correlated with beneficial effects on perioperative cardiovascular events. (Examples of changes in health-related habits include food choices, smoking and smoke inhalation, increased physical activity, consumption of antioxidants, use of aspirin, use of beta-blocking drugs, weight reduction, BP control, and flossing of teeth.) Although an increasing body of data [22] [264] [281] [282] seems to predict that such changes would occur, they have not yet been confirmed. Such a study would be incredibly difficult to execute successfully, but would any study be more worthwhile?

Perioperative Morbidity

The presence of coronary artery disease, its severity, the time of most recent myocardial tissue death, the arteries affected, and the complications and treatment of the disease are important information to the anesthesiologist. These variables influence the manner in which anesthesia is given and, in fact, may determine whether anesthesia and surgery should be postponed.

Previous Myocardial Infarction

Numerous epidemiologic studies [129] [243] [251] [283] [284] [285] [286] [287] [288] [289] [290] [291] [292] (Table 25-22) (but none in the past 5 years) have shown that if a previous MI and subsequent surgery are separated by less than 6 months, the perioperative reinfarction rate is 5 to 86 percent (1.5-10 times higher than the value when previous MI

and subsequent surgery are separated by more than 6 months), and the mortality rate is 23 to 86 percent. After 6 months, the perioperative reinfarction rate seems to stabilize at 2 to 6

[a] Mortality was not stated.

Abbreviations: MI, myocardial infarction; Mort, mortality; Reinf, reinfarction

percent. An investigation by Schoeppel et al [290] studying a small number of patients produced a 0 percent mortality rate in the first year after infarction but a perioperative reinfarction rate of 16.7 percent and a mortality rate of 67 percent for patients experiencing perioperative reinfarction. Because the incidence and timing of perioperative reinfarction in the study by Schoeppel et al differ so much from those variables in the other studies listed in Table 25-22 , I have placed little emphasis on that study. However, for all 12 of the studies listed in Table 25-22 , the overall reinfarction rates are similar. [129] [238] [239] [240] [243] [249] [250] [251] [273] [275] [276] [283] [284] [285] [286] [287] [288] [289] [290] [291] [292] [293] These data do not include patients who have had immediate angiography, clot dissolution therapy, angioplasty, or stents therapy.

The study conducted by Rao et al [129] deserves special comment because it proposes to show a vast decrease in perioperative reinfarction rate attributable to the use of modern monitoring techniques. The rates of perioperative reinfarction and mortality were compared for two groups of patients who had previous MIs operated on at two different time periods: 364 patients between 1973 and 1976; and 733 patients between 1976 and 1982. Rao and coworkers attribute the reduction in overall perioperative reinfarction rate (from 7.7 to 1.9%) and in each time period (i.e., from 36 to 5.8% when surgery occurs within 3 months of a previous MI) to invasive monitoring and rapid treatment of cardiovascular variables when values deviated from normal values. These two practices apply to both the intraoperative period and the first 72 postoperative hours. (The 72-hour period may be critical, as virtually all 12 studies and others showed that reinfarction was most likely to occur 24-96 hours after surgery [129] [243] [251] [283] [284] [285] [286] [287] [288] [289] [290] [291] [292] [293] [294] [295] [296] [297] [298] [299] [Table 25-23].) Most of the reduction in the perioperative reinfarction rate applied to patients older than 65 years. (An MI makes the physiologic age or risk of death equivalent to that of someone 3-17 years older, depending on the location of the infarction and the decrease in the left ventricular ejection fraction. [22])

The editorial evaluating the study by Rao et al stated that the use of historical controls may have biased the conclusions. Also, a different patient mix, improved skills of the surgeon and anesthetist, and other unidentified or unmeasured changes over time may have contributed to the reduction in reinfarction rate.

Normalization of hemodynamics using pulmonary artery catheter monitoring and 3 days in an ICU also appears to reduce perioperative morbidity in vascular surgery patients, a group at high risk of postoperative cardiac morbidity. In a randomized controlled trial, Berlauk et al [299] examined that intervention scheme, which was similar to that investigated by Rao et al, [129] for patients undergoing vein graft bypass for limb salvage from 1986 to 1990. Forty-five patients were randomly assigned to group 1 (i.e., pulmonary artery catheterization performed 12 hours before surgery, followed by treatment for hemodynamic optimization). The 44 other patients were randomly assigned to either group 2 (23 patients; i.e., pulmonary artery catheterization within 3 hours of surgery, followed by a shorter treatment for hemodynamic optimization); or to group 3 (21 control patients; i.e., no preoperative catheterization or hemodynamic optimization, treatment via central venous pressure lines, and minimal or no stay in the ICU).

Berlauk and colleagues [299] reported that patients undergoing less intensive treatment (group 3) were significantly more likely to have intraoperative complications (tachycardia, hypotension, arrhythmia) than were patients in group 1. The overall incidence of postoperative complications (renal failure, CHF, myocardial infarction, graft thrombosis, death) was 18 percent for group 1, 13 percent for group 2, and 43 percent for group 3. One-half of the complications in group 3 were attributable to early graft thrombosis and accounted for most of the difference in complication rates. The authors conjectured that the increased incidence of thromboses was due to poor cardiac output. No significant difference in mortality existed between groups. Although Berlauk and coworkers reported a higher incidence of postoperative cardiac morbidity in the control group, this conclusion is difficult to follow, as discrepancies exist between their calculations and data provided elsewhere in the paper. For example, their Table 5 reports three postoperative cardiac complications for group 1, two for group 2, and five for group 3. However, their Table 4 says only three patients in group 3 (1, 7, and 8) experienced these complications. Simple explanations for these discrepancies may exist but were not evident to me or to the Task Force on Pulmonary Artery Catheterization of the ASA. [300]

This study had other deficiencies that preclude definitive advice on ways of reducing morbidity for the patient with a prior MI: outcome did not differ significantly between the groups undergoing "normalization" of hemodynamics more than 12 hours before surgery versus less than 3 hours before surgery. Furthermore, the rationale for group assignments in this study is unclear. Rather than randomly assign the 89 patients to three groups of equal size, the investigators created two randomly selected groups and then subdivided the second group in a separate randomization that created imbalanced sample sizes. Group assignments may not have been truly random, as there were significant preoperative

differences between groups regarding the incidence of angina, CHF, and hemodynamic indices. Berlauk et al [299] explained that "although the randomization sequence was performed at the beginning of the study, actual patient entry into the study was finalized the evening before surgery. Bias of the chief surgical resident, who determined the operating room schedule, may account for the lack of patients with angina...." Furthermore, the role of pulmonary artery catheterization and hemodynamic control using aggressive management in reducing perioperative morbidity in a patient with a previous MI is unclear. [301] [302]

Other workers have pointed out that certain surgical procedures (e.g., ophthalmic operations) have low perioperative reinfarction rates, [288] [289] [290] [301] whereas others (e.g., vascular operations [289] [296] [297] [298] [299] [303] [304] [305] [306] [307] [308]) have high reinfarction rates. The study by Rao et al [129] does confirm that the perioperative reinfarction rate is higher in the first 6 months after a previous MI. Postponement of surgery for patients who have had an MI less than 6 months earlier should reduce mortality associated with anesthesia. Again, however, we are lacking data analyzing whether such risk changes with preoperative segregation by clinical criteria or provocative testing. The guidelines promulgated by the American College of Cardiology and the American Heart Association seem to indicate a liberalization of surgery to 6 weeks after infarction in "low risk patients." The less severe the coronary artery disease, the more similar the patient's anticipated survival curve to that of patients who do not have coronary artery disease [309] and probably the less the perioperative risk. [299] [310] [311]

Preoperative Testing: Analyses of Benefit Versus Risk and Versus Cost

Treadmill exercise testing, bicycle ergometer, dipyridamole-thallium imaging, dobutamine stress echocardiography, preoperative Holter monitoring, noninvasive imaging, ankle-brachial pressure index (see the earlier section, *One Easy Noninvasive Test* ....), and cardiac catheterization also add information to the history, increasing our knowledge about the likelihood of cardiac disease and perioperative cardiac function. [275] [296] [297] [298] [304] [305] [306] [307] [308] [312] Mantha et al [308] performed a meta-analysis to determine which preoperative noninvasive test was most predictive of the risk of adverse cardiovascular outcome after vascular surgery. They concluded that the search for wall-motion abnormalities during dobutamine stress echocardiography was not only successful in predicting risk but also the most cost-effective of the tests (Table 25-24 and Fig. 25-10) (Figure Not Available) .

The ECG criteria for myocardial ischemia during or after exercise consist of at least 1 mm of J-point depression with downsloping or horizontal ST segments; slowly upsloping ST-segment depression, defined as being 2 mm of ST depression, measured at 80 ms from the J point; and STsegment elevation [267] (Fig. 25-11) . Other responses to treadmill testing predictive of severe multivessel or of left main stem coronary artery disease include ST-segment depression exceeding 2.5 mm; serious ventricular arrhythmias at low heart rates, or early (first 3 minutes) onset of ischemic ST-segment depression; and/or prolonged duration of the ischemic ST-segment depression in the posttest recovery period (>8 minutes). [275]

TABLE 25-24 -- Adverse Cardiac Events After Abnormal Preoperative Tests: Relative Risks (Combined) and Costs of Tests

TEST	STUDIES (N)	RR (95% CI)	COST (U.S. $)
DTS	11	6.3 (3.0-13.1)	1,200-1,400
RNV	5	3.8 (1.5-9.4)	500-600
AECG	6	3.7 (2.0-7.1)	300-550
DSE	3	19.0 (5.9-60.8)	1,000-1,200

Abbreviations: RR, relative risks; CI, confidence intervals; DTS, dipyridamole-thallium scintigraphy; RNV, estimation of ejection fraction by radionuclide ventriculography; AECG, ambulatory electrocardiography; DSE, dobutamine stress echocardiography.

Data from Mantha et al [308]

Non-ECG responses to treadmill testing that predict severe coronary artery disease include low achieved heart rates (
120 beats/min), systolic hypotension (decrease of >10 mm Hg) in the absence of hypovolemia or antihypertensive medications, rise in diastolic BP to higher than 110 mm Hg, and inability to exercise beyond 3 minutes. The treadmill test responses predictive of severe multivessel and/or left main stem coronary artery disease are listed in Table 25-25 (Table Not Available) . Clearly, however, the response to the test must be interpreted in light of the patient's history and with knowledge that it is more predictive for men than for women [275] (Table 25-26) (Table Not Available) .

Inability to increase heart rate (cardiac risk index [CRI]) above 90 beats/min after supine bicycle exercise for 2 minutes at 50 rpm has been shown to predict perioperative myocardial infarction with 80 percent sensitivity. This test is claimed by its investigators to have better sensitivity (80%) with a small sacrifice in specificity (53%) than the Goldman CRI (sensitivity 60%, specificity 64%). This same group recommended this test for geriatric patients at low risk (according to the Goldman CRI) to identify the "false negatives" of the Goldman CRI or for geriatric patients at risk of perioperative MI. Limitations to this test, however, are recognized in patients with impaired joint mobility, dementia, muscle weakness, claudication, or exertional angina. [298] Ejection fractions of more than 50 percent (and normal left ventricular size on plain chest radiograph) predict good perioperative cardiac function and survival. [311] [312]

For dipyridamole-thallium scanning, patients received dipyridamole (0.56 mg/kg) intravenously over 4 minutes while their heart rate, BP, and ECG were monitored. After an additional 2 minutes, when the effect of dipyridamole was considered maximal, 2 mCi of thallium-201 was administered intravenously. Five minutes after administration of thallium, initial images were taken for 8 consecutive minutes. Delayed images were obtained 3 hours later. The anterior, 45-degree, and 70-degree left anterior oblique projections were taken each time. Dipyridamole causes vasodilation and increase in coronary blood flow. Because stenotic vessels cannot dilate normally, areas of myocardium supplied by them will take up less thallium during scanning than will areas supplied by normal vessels and will show up as filling defects on immediate image. On the late images, after vasodilation has resolved, thallium redistributes to these previously underperfused areas.

Dipyridamole infusion resulted in an increase in heart

Figure 25-10 (Figure Not Available) Relative risks and confidence intervals resulting from use of four preoperative tests to predict adverse outcome after vascular surgery, as reported by various studies. Names at left refer to first author of studies reviewed by Mantha et al. [308] Broken vertical lines represent combined relative risks, as assessed by each test. DTS, dipyridamole-thallium scintigraphy; RNV, estimate of ejection fraction by radionuclide ventriculography; AECG, ambulatory electrocardiography; and DSE, dobutamine stress echocardiography. *(Adapted from Mantha et al [308])*

Figure 25-11 Electrocardiographic criteria for myocardial ischemia consist of 1mm of J-point depression with downsloping or horizontal ST segments; slowly upsloping ST-segment depression, defined as 2 mm of ST depression measured 80 ms from the J point; and ST-segment elevation. Whereas STsegment depression indicates nontransmural ischemia, ST-segment elevation often connotes more severe degrees of ischemia reflecting transmural injury. The structure of the ST-segment slope is predictive of the severity of coronary disease shown angiographically, with downsloping ST depression indicating severe two- and three-vessel coronary artery disease more often than does either horizontal and slowly upsloping ST depression, and ST-segment elevation indicating high-grade, usually proximal, arterial obstruction in patients without previous myocardial infarction. *(From Goldschlager [275])*

TABLE 25-25 -- Treadmill Test Responses Predictive of Severe Multivessel and/or Left Main Coronary Artery Disease

(Not Available)

Modified from Goldschlager [275]

rate of 17 beats/min, a decrease in systolic BP of 17 mm Hg, and chest pain in 30 percent of patients, which was reversible with 125 mg of aminophylline intravenously. ECGs were examined for ischemic changes defined as 1-mm horizontal or downsloping ST-segment depression. Myocardial regions on initial and delayed images were graded as being normal, as showing fixed deficits (without redistribution), or as showing one or more segments with thallium redistribution (with or without evidence of fixed deficits). Initial studies [304] [305] [313] (reviewed by Mantha et al [308]) have shown this test to be valuable in further stratifying high risk, as assessed by five clinical factors (CHF, diabetes mellitus, history of ventricular ectopy, angina, and history of MI). Of patients with thallium redistribution, 45 percent had a perioperative MI, whereas 7 percent of patients without redistribution had a perioperative MI (*P* = .001). Dipyridamole-thallium scanning has been suggested to be valuable in stratifying patients with intermediate risk, as assessed by five clinical factors (Q waves on resting ECG, history of ventricular ectopy, diabetes, age >70 years, and angina) that were identified by logistic regression on several clinical findings and Goldman CRIs and Dripp classes. Fletcher et al [313] found the test superior to clinical assessment in identification of high-risk patients for further angiographic study, prophylactic CABG surgery, or intensive intraoperative and postoperative management. Dipyridamole-thallium scanning may reveal redistribution when coronary narrowing is only 40 to 60 percent. This process may aid in the management of higher-risk patients by initiating invasive monitoring, with prompt medication of hemodynamic changes. These actions may have artificially decreased the incidence of perioperative MI in the studies of thallium scanning cited. Because the results of thallium scans in all these studies were made known to the caretakers, those patients with positive scans may have received more invasive monitoring, as well as coronary angiography, angioplasty, medications, and CABG surgery. The discriminating capacities of this test may improve with further classification of redistribution segment by size and number and by additional projections (see Fig. 25-10 (Figure Not Available) . and Table 25-24)

Twenty-four to 48-hour Holter monitoring of intermediate-risk patients has recently been shown to be effective in detecting asymptomatic ischemia and has an excellent negative predictive value and a fair positive predictive value for postoperative cardiac complications (see Fig. 25-10 (Figure Not Available) and Table 25-24.) Preoperative ischemia increases the risk of intraoperative ischemia 3- to 4-fold. Raby and colleagues [306] studied 176 vascular surgery patients who were asymptomatic for ischemic cardiac disease and found preoperative ischemia on Holter monitoring to be an independent factor with high correlation for significant postoperative cardiac complications (e.g., infarction, unstable angina, and ischemic pulmonary edema). In this series, 24- to 48-hour Holter monitoring detected two of three patients with positive stress test results and four patients with postoperative cardiac complications who did not have a history suggestive of ischemic heart disease. With an overall sensitivity of 92 percent, specificity of 88 percent, positive predictive value of 38 percent, and negative predictive value of 99 percent, Holter monitoring may be the test of choice for evaluating intermediate-risk patients who have no suggestive history or for those patients who are unable to undergo an exercise stress test. Limitations of this method are seen in patients with left bundle branch block, left ventricular hypertrophy, with strain, and ST-T changes with digoxin because of the difficulties in analyzing ST-segment changes.

Studies of visual interpretation of the coronary angiogram suggest that the physiologic effects of most coronary artery obstruction cannot be determined accurately by conventional angiographic approaches.

Dobutamine stress echocardiography has also been tested recently for its ability to predict adverse cardiac outcome in patients undergoing vascular surgery. [308] [314] [315] [316] [317] For this test, an abnormal result or a positive result consists of new regional

[a] To calculate a patient's score, the number of points from all factors he or she possesses are summed.
[b] Patients are further segregated into class I (0-5 points), with a risk of 4-7% of major complications: class II 6 - 12 points), risk 7-11 % ;class III (13- 25 points), risk 14 -38 % and class IV (26 points), risk 30 -100 %.

wall motion abnormalities or worsening of existing regional wall motion abnormalities on echocardiography during infusion of dobutamine. A negative result consists of absence of any change on echocardiography during dobutamine infusion. This test has high predictive value for adverse cardiac events (although the findings of Mantha and coworkers [308] are limited to only three studies of dobutamine stress echocardiography for this purpose). The relative risk (95% confidence intervals) of adverse outcome predicted by the test was 19 (5.9-60.8) (see Fig. 25-10 (Figure Not Available) and Table 25-24) , which suggests that this test is very "effective." It is interesting to note that unlike the other studies, the Mantha et al [308] study found that the predictive value increased over the time period the test was available.

Recent studies have concentrated on the identification and stratification of risks in the intermediate-risk group of patients who would benefit most from a preoperative cardiac workup and risk assessment. Goldman et al [289] prospectively studied 1,001 patients older than 40 years undergoing a broad variety of emergency and elective surgery. Multiple regression analysis of the data showed that nine factors correlated independently with development of life-threatening or fatal cardiac complications: (1) the presence of an S_3 gallop, jugular vein distention, or CHF; (2) history of MI in the preceding 6 months; (3) a cardiac rhythm other than sinus; (4) the occurrence of more than five premature ventricular contractions (PVCs)/min; (5) performance of intraperitoneal, intrathoracic, or aortic surgery; (6) patient age above 70 years; (7) significant valvular aortic stenosis; (8) emergency surgery; and (9) poor general medical condition. On the basis of this study, the investigators developed a method of computing a CRI (Table 25-27) (Table Not Available) . This study suggests that history and physical examination account for 29 of 53 points in assessing cardiac risk of the general surgical population and that initial history and physical examination permit selection of intermediate-risk patients for further evaluation. Eagle and colleagues [304] studied 200 vascular surgery patients, a population with a high incidence of cardiovascular disease, and, using logistic regression, found independent risk factors to be as follows: Q waves on resting ECG, history of ventricular ectopy, diabetes, age above 70 years, angina, and CHF. Again, multiple regression studies suggest that initial clinical evaluation suffices for selecting patients for further evaluation.

The Cleveland Clinic group has established a clinical severity scoring system to characterize risk prior to coronary artery bypass surgery [318] (Table 25-28 (Table Not Available) and Fig. 25-12.) (Figure Not Available) This system predicts cardiovascular morbidity and gives stratification points for risk of adverse cardiovascular outcome for preoperative renal insufficiency, diabetes, age, anemia, chronic obstructive lung disease, mitral valve insufficiency, aortic valve stenosis, cerebrovascular disease, and surgery performed on an emergency basis--many factors found by Goldman and colleagues to affect outcome adversely. Therefore, diseases that

impinge on the cardiovascular system, such as renal insufficiency and diabetes, have important effects in predicting cardiovascular morbidity.

The American College of Cardiology/American Heart Association Task Force on Perioperative Cardiovascular Evaluation for Noncardiac Surgery used data such as that above, combined with expert opinion, to propose a series of algorithms for preoperative evaluation of such patients (Tables 25-29 (Table Not Available) 25-30 (Table Not Available) ; 25-31 (Table Not Available) ; . Fig. 25-13) (Figure Not Available) . [10]

TABLE 25-28 -- Use of Preoperative Factors to Predict Risk of Adverse Outcome After CABG: Clinical Severity Scoring System of the Cleveland Clinic

(Not Available)

Modified from Higgins et al. [318]

Figure 25-12 (Figure Not Available) The observed morbidity after coronary artery bypass surgery versus the morbidity predicted by a clinical severity scoring system that evaluated various pertinent preoperative conditions. Morbidity was lower than the predicted 99.4 percent confidence interval at scores 2, 5, 6, and 7 to 9. Model may not validate prospectively because of changes in clinical management resulting in complications. Vertical lines at top of bars indicate confidence intervals. *(From Higgins et al [318])*

They did this, realizing the importance of a surgical event to a patient's long-term prognosis and realizing that surgery may present the first opportunity for long-term evaluation, risk management, and motivation of the patient.

Thus, the major signposts of perioperative myocardial function that we can obtain before surgery are the risk factors for arterial aging and the history of ischemic pain (and its relationship to exercise), CHF, diabetes, and renal insufficiency. The value of this information is slightly enhanced by a 6-minute walk test, determination of the ankle-brachial pressure index, ECG and non-ECG responses to bicycle or treadmill exercise, determination of ejection fraction, and the use of an ECG, radionuclide imaging, radionuclide imaging after dipyridamole, wallmotion changes during dobutamine infusion, or angiogram. [232] [238] [239] [240] [275] [296] [297] [298] [304] [305] [306] [307] [308] [312] [313] [314] [315] [316] [317] [319] [320]

Relationship to Previous Coronary Artery Bypass Graft or to Percutaneous Transluminal Coronary Artery Angioplasty

Much of the information on which altered perioperative anesthetic management of ischemic heart disease is based derives from studies of patients undergoing aortic and CABG procedures. Although CABG relieves angina and increases exercise tolerance (as did many placebo operations and medications before it), [321] improved survival occurs only for patients having significant left main coronary artery disease [307] [322] and for those with mild to moderate impairment of left ventricular function. [323] However, a potential additional benefit of CABG surgery or percutaneous transluminal coronary angioplasty (PTCA) has been documented. Reduced perioperative morbidity during subsequent noncardiac surgical procedures may be an additional benefit of surviving CABG or PTCA. [10] [259] [260] [310] [323] [224] [325]

To provide definitive data for this hypothesis, a randomized controlled study would be necessary: CABG surgery may constitute a "survival test." That is, it may cause reinfarction or death, or both, in those patients who would have sustained an MI or who would have died after the noncardiac surgery. [310] This appears to be a likely conclusion, as those patients who do poorly during and after CABG surgery are those with poor left ventricular function and increased left ventricular end-diastolic pressure. [325] Patients with these same cardiovascular conditions also have increased perioperative risk after noncardiac surgery. [238] [240] [259] [260] [289] [296] [297] [298] [304] [305] [306] [307] [308] [311] [313] Therefore, one proposal to decrease perioperative risk in patients severely disabled with angina (or ischemic heart disease) is to study the coronary arteries and to perform PTCA or CABG, if indicated, prior to their noncardiac surgery.

Hertzer et al [259] [260] did just this. Knowing that survival after vascular surgery depends mainly on preserving myocardial function, these investigators obtained coronary angiograms from, and proposed CABG surgery (when appropriate) for, 1,001 consecutive patients needing peripheral vascular surgery (regardless of the degree of suspicion of coronary artery disease prior to angiogram). CABG was believed to be indicated in 251 patients, of whom 226 underwent CABG with 12 (5.13%) operative deaths; of those,

(Not Available)

From Eagle et al. [10]

130 subsequently underwent peripheral vascular procedures with only one death.

Do these figures imply that mortality was decreased or increased by the CABG procedure? Did some patients not undergo their initially indicated vascular procedure because of morbidity associated with CABG? (The report did not indicate why 26 patients who initially were scheduled for peripheral vascular procedures did not undergo those procedures after CABG.) The long-term prognosis for the patients of Hertzer et al [259] [260] was better for those who underwent CABG prior to their noncardiac surgery than for those who did not: The 5-year cardiac survival rate was 82.5 versus 74 percent. In fact, in the Coronary Artery Surgery Study series, prior CABG or PTCA (versus medical therapy) reduced the risk to that of someone 4 years younger (Fig. 25-14) (Figure Not Available) . This was the equivalent risk reduction found by the McSPI group for beta-adrenergic receptor-blocking therapy for the day of surgery and seven subsequent days. [166] [326]

Are these therapies additive? We do not have an answer. Again, Hertzer and associates describe a nonrandomized series. [259] [260] Huber and colleagues [325] try to make the point that vascular surgery after PTCA is safer than without PTCA, but their series had a rate of serious complications (failed PTCA, MIs, death) from PTCA of more than 10 percent. Thus, perhaps these studies serve to reemphasize the point made by Goldman et al [9] and Higgins et al [318] in their risk indices (see Tables 25-27 (Table Not Available) and 25-28) (Table Not Available) that current vascular disease should call forth a warning about the risk of perioperative cardiovascular morbidity.

Therefore, the hypothesis that CABG or PTCA decreases morbidity and mortality in patients undergoing subsequent noncardiac surgery remains a hypothesis. (Although prior CABG or PTCA reduces risk, does the combination lead to better outcome?) This hypothesis warrants study in a randomized clinical trial.

Summary of Preoperative and Intraoperative Factors That Correlate with Perioperative Morbidity

Summarizing a large number of studies, I list the following preoperative findings as conditions that correlate with perioperative morbidity and that can be corrected prior to operation: (1) recent MI (within 6 months), [129] [250] [283] [284] [285] [286] [287] [288] [289] [290] [291] [292] [293] (2) severe CHF (i.e., sufficiently severe to produce rales, an S_3 gallop, or distention of the jugular vein), [129] [232] [238] [240] [287] [289] [296] [297] [298] [299] [300] [302] [303] [304] [305] [306] [307] [311] [318] [327] (3) severe angina (see Table 25-32 for classification of the severity of angina), [289] [296] [307] [311] [327] (4) heart rhythm other than sinus, [287] [289] [296] [297] [298] (5) premature atrial contractions, [289] (6) more than five PVCs/min, [287] [289] and (7) blood urea nitrogen (BUN) levels higher than 50 mg/dL or potassium levels below 3.0 mEq/L. [289] [318]

Preoperative factors that correlate with perioperative risk but that cannot be altered include: (1) old physiologic or chronologic age (perioperative risk increases with age), [22] [236] [289] [296] [297] [298] [299] [308] [328] [329] (2) significant aortic stenosis, [289] [318] [330] (3) emergency operation, [129] [236] [283] [289] [296] [297] [298] [311] [318] (4) cardiomegaly, [240] [289] [296] [297] [298] [311] [318] (5) history of CHF, [129] [238] [240] [287] [289] [296] [297] [298] [299] [300] [302] [303] [304] [305] [306] [307] [311] [313] [318] (6) angina (or history of angina or ischemia) on ECG, [129] [232] [275] [287] [289] [296] [297] [298] [299] [300] [302] [303] [304] [305] [306] [307] [311] (7) abnormal ST-segment or inverted or flat T waves on ECG, [9] [289] [296] [298] abnormal QRS complex on ECG, [289] and (8) significant mitral regurgitant murmur. [289] [318]

Significant intraoperative factors that correlate with perioperative risk and that may be avoided or altered are as follows: (1) unnecessary use of vasopressors [331] [332] ; (2) unintentional hypotension [239] [251] [286] [289] (this point is controversial, however, as some investigators have found that unintentional hypotension does not correlate with perioperative morbidity [329] [332]); (3) hypothermia [333] ; (4) too low or too high a hematocrit level [334] [335] and (5) lengthy operations. [256] [283] [288] [289]

Significant intraoperative factors that correlate with perioperative morbidity and probably cannot be avoided are emergency surgery and thoracic or intraperitoneal surgery or above-the-knee amputations. [256] [287] [288] [289] [296] [297] [298] [299] [300] [302] [303] [304] [305] [306] [307] [308] [309] [310] [311] [313] [318] [328]

Although the evidence for these factors is fairly substantial, virtually no data are derived from prospective randomized studies indicating that treatment of the above conditions reduces the perioperative risk to patients with ischemic

III. Marked limitation of ordinary physical activity. Walking one or two blocks on the level and climbing one flight of stairs under normal conditions and at a normal pace. "Comfortable at rest."	III. Marked limitation of ordinary physical activity. Walking one to two blocks on the level and climbing more than one flight under normal conditions.
IV. Inability to carry on any physical activity without discomfort--anginal syndrome may be present at rest.	IV. Inability to carry on any physical activity without discomfort--anginal syndrome *may be* present at rest.

heart disease. Nevertheless, all logic dictates that such treatment does reduce risk. Thus, the goal in giving anesthesia to patients with ischemic heart disease is to achieve the best preoperative condition obtainable, by treating those conditions that correlate with perioperative risk. The next step is to monitor intraoperatively for those conditions that correlate with perioperative risk and, by careful attention to detail, avoid those circumstances that lead to perioperative risk. Although local anesthesia may reduce perioperative risk. [287] [301] epidemiologic studies do not indicate significant differences in perioperative morbidity for patients with ischemic heart disease who are given local anesthesia as opposed to general anesthesia.

Preoperative Evaluation

Preoperative evaluation of the patient with ischemic heart disease should include a review of the clinical course of any previous myocardial infarctions and a review of studies made subsequent to those events. Because the patients most likely to benefit are those who have severe coronary artery disease (i.e., multivessel left main stem coronary artery disease) and ejection fractions of 21 to 50 percent, some strategies have been devised to limit routine exercise testing, dipyridamole-thallium scanning, Holter monitoring, dobutamine stress echocardiography, and angiographic testing to only such patients (Figs. 25-15 25-16 (Figure Not Available) 25-17 (Figure Not Available)) [10] [336] That these studies have been or are being performed implies something about the patient's cardiac function.

The preoperative evaluation should also include a review of the results of exercise studies, Holter monitoring, other noninvasive tests such as dobutamine-stress echocardiography, and coronary angiography, to determine which ECG lead to monitor for ischemia. Although in theory the ECG lead that first indicates ischemia or best represents the stenosed artery on exercise should be the first to reveal ischemia in the operating room, no study has confirmed this

Figure 25-15 Assessment of cardiac risk in a patient about to undergo vascular surgery. If the clinical index is high, coronary arteriography (CATH) is recommended with subsequent coronary artery bypass grafting (CABG) or percutaneous transluminal coronary angioplasty (PTCA) for those with correctable lesions and patient (PT) consent. An equivocal history is followed by Holter monitoring and, if Holter monitoring is abnormal, by dobutamine stress echocardiography. *(See text and data of Fig. 25-9 for analyses by Mantha et al. [305])*

Figure 25-16 (Figure Not Available) Strategy for identifying patients who should undergo cardiac catheterization after acute myocardial infarction. This strategy is based on clinical assessment, evaluation of left ventricular (LV) function by radionuclide angiography (RNA) or echocardiography, analysis of arrhythmias, and stress testing. MI, acute myocardial infarction; CHF, overt congestive heart failure; EF, ejection fraction. *(From Epstein et al [891])*

assumption. If no exercise or coronary angiographic study has been performed, precordial lead V_5 is preferred. [8] [232] [337] [338]

The only known way to increase oxygen supply to the myocardium of patients with coronary artery stenosis is to maintain diastolic BP, hemoglobin concentration [318] [339] [340] (Fig. 25-18) , and oxygen saturation. The main goal of anesthesia practice for these patients has been to decrease the determinants of myocardial oxygen demand (Gibby GL, et al personal communication), heart rate, ventricular wall tension, and contractile performance. [233] [235] [303] [339] [340] [341] Thus, medical management designed to preserve all viable myocardial tissue may include (1) administration of beta-adrenergic receptor-blocking drugs (propranolol, atenolol, esmolol, or metoprolol) to decrease contractility and heart rate; and (2) vasodilation (with nitroglycerin [or its "long-acting" analogues nitroprusside, hydralazine, or prazosin]) to decrease ventricular wall tension. [165] [166] [167] [168] [231] [233] [235] The goal of anesthesia management should be the same, although only one prospective controlled study has documented a decrease in perioperative morbidity by reducing preload, afterload, or heart rate. [166] However, keeping cardiovascular variables within an acceptable range and the rate-pressure product below the threshold for angina appears to be an appropriate objective. [129] [166] [235] [252] [353] [341] [342] The use of Swan-Ganz catheters [300] [343] and transesophageal echocardiography for

Figure 25-17 (Figure Not Available) First-year mortality rates for patients with acute myocardial infarction, according to subgroup. Clear areas represent patients with ejection fractions of more than 30 percent; dotted area represents patients with ejection fractions of less than 30 percent. (The percentages are, by necessity, rough approximations.) MI, acute myocardial infarction; CHF, overt congestive heart failure. *(From Epstein et al [891])*

this type of patient is described in Chapters 30 and 31 , and the intraoperative management of ischemic heart disease patients is discussed in further detail in Chapters 49 through 51 .

Briefly, the author believes that drugs given chronically (e.g., antihypertensive medications and some ACE inhibitors) should be continued through the morning of surgery (see previous section). The topic of chronic drug therapy is discussed in more detail in the last section of this chapter. Finally, a patient with a subendocardial MI has been assumed to be at less perioperative risk than a patient with a transmural MI. This assumption is probably wrong. Thus, patients with a subendocardial MI should be treated no differently than those with a transmural MI.

Valvular Heart Disease

Major alterations in the preoperative management of patients with valvular heart disease have been made regarding the use of anticoagulant therapy and are now based on the causes of disease. Preoperative and intraoperative management of patients with valvular heart disease is discussed in Chapter 49 ; nevertheless, a few important points concerning preoperative care are emphasized here. Of prime importance is realizing that stenotic lesions are managed in a fashion exactly opposite that for regurgitant lesions. Therefore, the type of lesion that exists should be determined preoperatively.

Figure 25-18 Relationship of postoperative myocardial ischemia (solid bars) and morbid cardiac events (shaded bars) to hematocrit for 27 high-risk patients undergoing infrainguinal arterial bypass. *(Data from Nelson et al [340])*

Although the causes of various forms of valvular heart disease have not changed, the relative frequency has. Rheumatic valvulitis is much less common today than it was in the 1970s, and syphilitic aortitis has all but disappeared. Now common are congenital bicuspid aortic stenosis, mitral valve prolapse, hypertrophic cardiomyopathy (also called asymmetric septal hypertrophy or subvalvular aortic stenosis), and mitral valve insufficiency due to calcification, and to drug therapy.

The prognosis and, presumably, the perioperative risk for patients with valvular heart disease depend on the stage of the disease. [319] [330] Although stenotic lesions progress faster than regurgitant lesions, regurgitant lesions secondary to infective endocarditis, rupture of chordae tendineae, or ischemic heart disease can be rapidly fatal. Left ventricular dysfunction is common in the late stage of valvular heart disease. Once again history and physical examination appear to be the most sensitive and specific indicators of disease and disease stage [344] [345] (Table 25-33) (Table Not Available) .

Preoperative maintenance of drug therapy can be crucial: The patient with aortic stenosis can deteriorate rapidly with the onset of atrial fibrillation or flutter, as the atrial contribution to left ventricular filling can be critical in maintaining cardiac output. One of the most serious complications of valvular heart surgery and of valvular heart disease prior to surgery is cardiac arrhythmia. Conduction disorders and chronic therapy with antiarrhythmic and inotropic drugs are discussed elsewhere in this chapter. The reader is referred elsewhere in this book (Chs. 49 and 50) or to other sources [346] [347] for discussion of the management of the child with congenital heart disease who is undergoing noncardiac surgery.

Mitral Valve Prolapse

Mitral valve prolapse, perhaps the most frequent valvular abnormality, occurs in 5 to 17 percent of otherwise healthy people. It is associated with atrioseptal secundum defects, [348] [349] thoracic skeletal abnormality (due to time of development of these structures), and, for unknown reasons, migraine anxiety neurosis and autonomic dysfunction. Hereditary transmission has been proposed as occurring through autosomal dominance with reduced expressivity in humans. Mitral valve prolapse is also associated with von Willebrand syndrome and polycystic kidney disease, and the presence of one condition requires a search (by at least history and physical examination) for the other.

Mitral valve prolapse presents either asymptomatically or with palpitations, dyspnea, atypical chest pain, dizziness, syncope, or sudden death. Supraventricular arrhythmias (associated

TABLE 25-33 -- Bedside Diagnosis of Systolic Murmurs: Sensitivity, Specificity, and Predictive Value of Diagnostic Maneuvers

(Not Available)

Modified from Lembo et al. [344]

with atrioventricular bypass tracts and the preexcitation syndrome) occur in more than 50 percent of patients with mitral valve prolapse. Ventricular arrhythmias (usually in surgery) occur in 45 percent of such patients, bradyarrhythmias in 25 percent, and sudden death in 1.4 percent. [348] [349] The frequent occurrence of transient cerebral ischemia has resulted in the chronic use of aspirin or anticoagulants in patients with mitral valve prolapse, and the potential for endocarditis has led to the recommendation for prophylaxis with antibiotics prior to known bacteremic events, [348] [349] [350] and the avoidance of head-up positions and decreased afterload in such patients.

Valvular Heart Disease

Preoperative Antibiotic Prophylaxis for Endocarditis

Patients who have any form of valvular heart disease, as well as those with intracardiac (ventricular septal or atrial septal defects) or intravascular shunt, should be protected against endocarditis at the time of known bacteremic events. Endocarditis has occurred in a sufficiently significant number of patients with hypertrophic cardiomyopathy (subvalvular aortic stenosis, asymmetric septal hypertrophy) and mitral valve prolapse to warrant the inclusion of these two conditions in the prophylaxis regimen.

Is endotracheal intubation a bacteremic event? Bacteremia occurs after the following events at these rates: dental extraction, 30 to 80 percent; brushing of teeth, 20 to 24 percent; use of oral irrigation devices, 20 to 24 percent; barium enema, 11 percent; transurethral prostate resection, 10 to 57 percent; upper gastrointestinal endoscopy, 8 percent; nasotracheal intubation, 16 percent (4 of 25 patients); and orotracheal intubation, 0 percent (0 of 25 patients). [351] [352] Thus, although bacteremia from orotracheal intubation is rare, I believe that prophylaxis should be given to patients with valvular heart disease before instituting instrumentation of the gallbladder, GI tract, oropharynx, or genitourinary tract. The choice of antibiotic for prophylaxis should be aimed at the most commonly occurring (i.e., most numerous) pathogen [353] (Table 25-34) . Note that these prophylactic regimens should be altered to prevent sepsis after specific surgical procedures [354] (Table 25-35) (Table Not Available) . Guidelines of the American Heart Association state that all antimicrobial prophylaxis should be started 30 minutes to 1 hour, rather than 24 hours, before a known bacteremic event, so as to reach therapeutic levels without superinfecting the patient with unusual pathogens. [353] [354]

TABLE 25-34 -- Endocarditis Prophylaxis: Recommended Antibiotic Regimens[a]

	DOSAGE FOR ADULTS	DOOSAGE FOR CHILDREN (IN NO CASE TO EXCEED ADULT DOSE)
DENTAL AND UPPER RESPIRATORY PROCEDURES LIKELY TO PRODUCE BACTEREMIA (I.E., TONSILLOADENOIDECTOMY, BRONCHOSCOPY, NASAL INTUBATION, NASOGASTRIC TUBE PLACEMENT)		
Oral		
Amoxicillin	3 g 1 h before procedure and 1.5 g 6 h later	50 mg/kg
Amoxicillin, penicillin allergy:		
Erythromycin ethylsuccinate	800 mg	20 mg/kg 1 h before procedure and 10 mg/kg 6 h later
or		
Erythromycin sisarate	1 g PO 2 h before procedure and half the initial dose 6 h later	
or		
Clindamycin	300 mg orally 1 h before procedure and 150 mg 6 h after initial dose	10 mg/kg and 5 mg/kg 6 h later
Parenteral		
Ampicillin	2 g IM or IV 30 min before procedure	50 mg/kg IM or IV 30 min before procedure
Penicillin allergy: Clindamycin	300 mg IV 30 min before procedure	10 mg/kg IV 30 min before procedure
GASTROINTESTINAL AND GENITOURINARY PROCEDURES (I.E., GI OR GU SURGERY, OR INSTRUMENTATION OR SURGERY INVOLVING A TISSUE POSSIBLY CONTAMINATED WITH GI OR GU ORGANISMS)		
Parenteral		
Ampicillin	2 g IM or IV 30 min before procedure	50 mg/kg IM or IV 30 min before procedure
Plus gentamicin	1.5 mg/kg (not to exceed 80 mg) IM or IV 30 min before procedure	2.0 mg/kg IM or IV 30 min before procedure
Plus amoxicillin	1.5 g PO 6 h after ampicillin and gentamicin or repeat ampicillin and gentamicin after initial dose	50 mg/kg
Penicillin, amoxicillin allergy: Vancomycin	1 g IV infused slowly over 1 h beginning 1 h before procedure	20 mg/kg IV infused slowly over 1 h beginning 1 h before procedure
Plus gentamicin	1.5 mg/kg (not to exceed 80 mg) IM or IV 30 min before procedure	2.0 mg/kg IM or IV 30 min before procedure
Oral		
Amoxicillin	3 g 1 h before procedure and 1.5 g 6 h after initial dose	50 mg/kg 1 h before procedure and 25 mg/kg 6 h after initial dose

Data from Dajani et al [353]

[a] The frequently used cephalosporins are not recommended. A single dose of the parenteral drugs is probably adequate, because bacteremias after most oral cavity and diagnostic procedures are of short duration. However, one or two follow-up doses may be given at 8- to 12-h intervals in selected patients, such as hospitalized patients judged to be at higher risk.

Cardiac Valve Prostheses and Anticoagulant Therapy, and Prophylaxis for Deep Venous Thrombosis

Prothrombin time (PT) or international ratio should be within 20 percent of control international ratio of time at the time of operation or an appreciable risk is incurred. [355] Therefore, to produce a normal PT on the day of surgery, chronic anticoagulant therapy should be suspended in surgical patients with cardiac valve prostheses. This can be done with safety several days before surgery if the prosthesis is an aortic valve. However, because the risk of thromboembolism is greater with mitral valve prostheses (5%) than with aortic valve prostheses (1-3%), patients having mitral valve prostheses should have rapid reversal of oral anticoagulation with vitamin K the day before surgery or fresh frozen plasma on the day of surgery. For resumption of anticoagulant therapy after surgery, rapid anticoagulation with heparin 12 hours postoperatively has proved successful in patients with mitral valve prostheses. [356] In patients with new aortic valve prostheses, resumption of anticoagulant therapy can start 2 days after surgery. Regional anesthetic techniques might be avoided, although controversy exists on this issue. [357] [358] [359] [360] [361] [362] [363] [364] [365] [366] [367] [368] [369] [370] [371] [372] Many practitioners do not hesitate to use regional anesthesia in the face of prophylaxis for deep venous thrombosis. [361] [364] [366] [368] However, many reports of epidural hematoma have been associated with anticoagulant therapy. Large retrospective reviews of outcome after epidural and/or spinal anesthesia during or shortly before initiation of anticoagulant therapy with heparin have not reported neurologic dysfunction relating to hematoma formation in any patient. [361] [362] [363] [364] This paucity of epidemiologic data, while reassuring, does not reduce the need for frequent evaluation of neurologic function and search for back pain in the perioperative period after regional anesthesia for any patient receiving any clotting function inhibitor, including aspirin. [369] [370] [371] [372] The risk of regional anesthesia concurrent with prophylaxis for deep venous thrombosis with heparin is greater with the use of the low-molecular-weight heparin. (Heparin-induced thrombocytopenia has been treated successfully with intravenous immunoglobulin. [366])

Deep venous thromboses are so common in postoperative patients that almost 1 percent of postsurgical patients die of fatal pulmonary embolism [373] (Table 25-36) . Because of this high mortality risk, prophylaxis against deep venous thrombosis has attained widespread acceptance; thus, prophylaxis often begins with 5,000 units of heparin given subcutaneously 2 hours prior to surgery. [373] [374] [375] Other trials have shown equal effect with external pneumatic compression. [374] [376] Persuading surgeons to use this technique may provide greater assurance in using regional anesthesia. Such an option, however, is not available for the patient with a prosthetic valve.

Another problem that can arise is managing the pregnant patient with a prosthetic valve during delivery. It is recommended that warfarin be replaced by subcutaneous heparin during the peripartum period. During labor and delivery, elective induction is advocated with discontinuance of all anticoagulant therapy, as indicated for the particular valve prosthesis (discussed previously). [377]

Auscultation of the prosthetic valve should be performed preoperatively to verify normal functioning [378] (Fig. 25-19) (Figure Not Available) . Abnormalities in such sounds warrant preoperative consultation and verification of functioning.

Cardiac Conduction Disturbances

Cardiac Arrhythmias

Bradyarrhythmias, especially if profound or associated with dizziness or syncope, are generally managed with pacemakers. However, on rare occasion, chronic bifascicular block (right bundle branch block with left anterior or posterior hemiblock or left bundle branch block with combined left anterior and posterior hemiblocks), even when only first-degree heart block is present, progresses to complete heart block and sudden perioperative death. This is a rare occurrence. In six studies, fewer than 2 percent of the approximately 266 patients with bifascicular block progressed to complete heart block perioperatively. [379] [380] [381] [382] [383] [384] On the other hand, these patients have a high 5-year mortality rate (160 of 554 patients, or 35%). Most of the deaths were related to tachyarrhythmias or MI--events usually not preventable by pacemakers. [385] Thus, the presence of bifascicular block on ECG should make the anesthesiologist more worried about associated coronary artery disease or left ventricular dysfunction. Nevertheless, these patients rarely have complete heart block perioperatively. Therefore, prophylactic preoperative insertion of temporary pacing wires for bifascicular block does not seem warranted. However, a central route can be established in advance in the event a temporary pacemaker needs to be inserted. (Most operating rooms do not rely on transthoracic pacing, although such might be attempted if available.) [386] The actual pacemaker equipment and appropriate personnel should be immediately available and tested regularly, because symptomatic heart block does occur perioperatively in more than 1 percent of patients. [379] [380] [381] [382] [383] One study appears to have confirmed this rate of at least 1 percent for patients undergoing cardiac surgery. [387] One percent of patients who had no preoperative insertion of a pacing pulmonary artery catheter subsequently required pacing prior to cardiopulmonary bypass. By contrast, 19 percent of patients who had such a catheter in place had cardiac pacing prior to cardiopulmonary bypass. Predictors of the need for pacing included prior symptomatic bradyarrhythmias, a history of transient complete atrioventricular block, and aortic valve disease.

Premature ventricular contractions (PVC) of more than five per minute on preoperative examination correlate with perioperative cardiac morbidity. [289] [297] [298] [311] To the classic criteria for treating PVCs (the presence of R-on-T couplets, the occurrence of more than three PVCs per minute, and multifocality of PVCs) must be added frequent (>10/h over a 24-h period) and repetitive ventricular beats. Electrophysiologic and programmed ventricular stimulation studies are being used to indicate and guide treatment for patients with ischemic heart disease or recurrent arrhythmias and for survivors of out-of-hospital cardiac arrest. [388] Although such patients are often treated with antiarrhythmic therapy, attention to their underlying condition should be a focus of our preoperative management. Chronic antiarrhythmic therapy

is discussed in the last section of this chapter. Torsades de pointes is an arrhythmia characterized by episodes of alternating electrical polarity such that the major vector of the QRS complex seems to alternate around an isoelectric line. The hallmark enabling differential diagnosis from ventricular tachycardia is the unusual response of this arrhythmia to commonly used antiarrhythmic drugs. That is, the use of drugs that prolong the QT interval (e.g., quinidine, procainamide, and disopyramide and the antipsychotic phenothiazines) may well make the arrhythmia more frequent or of longer duration. The report of the sudden occurrence of torsades de pointes during surgery has been rare in the anesthesia literature. Immediate therapy consists of administration of magnesium or electrical cardioversion, followed by overdrive cardiac pacing or administration of beta-adrenergic agonists and discontinuation of drugs that prolong the QT interval.

Premature atrial contractions and cardiac rhythm other than sinus also correlate with perioperative cardiac morbidity. [289] [297] These arrhythmias may be more a marker of poor cardiovascular reserve than a specific cause of perioperative cardiac complications.

Preexcitation syndrome is the name for supraventricular tachycardias associated with atrioventricular bypass tracts. [389] Successful treatment, which is predicated on an understanding of the clinical and electrophysiologic manifestations of the syndrome, consists of either catheter ablation techniques [385] or surgery using preoperative and intraoperative techniques that avoid release of sympathetic substances and other vasoactive substances and therefore

tachyarrhythmias. [390] [391] [392] (Anesthesia for electrophysiologic procedures is discussed in Chs. 40, 49, and 66.)

Pacemakers (Control of Arrhythmias)

The types of pacemakers available and the indications for their use have changed significantly since 1980. More than 90 percent of pacemakers are inserted for the treatment of bradyarrhythmias occurring either after tachycardia (brady-tachy syndrome) or by themselves (that is, in sick sinus syndrome or AV conduction disorders). Physiologic pacing is an attempt to increase the patient's hemodynamic response to increased metabolic demands. An increase in heart rate provides greater augmentation of cardiac output than does maintenance of atrioventricular synchrony. The rate of pacemaker insertion has also declined by more than 50 percent since 1980; in 1984 a publication by the American College of Cardiology and the American Heart Association on the indications for pacemaker insertion codified these changes in practice patterns. The most common pacemaker for this type of dysfunction is the ventricular R-wave inhibited (demand) type (VVI). (Letter codes are described later and in Table 25-37.) More complex pacemakers are now being employed to provide better cardiac output in stressful situations and to decrease myocardial wall stress [393] or to treat ventricular or supraventricular tachyarrhythmias. Lithium batteries now give a pacemaker a 5- to 10-year life span. Programmable pacemakers are adjustable for sensitivity and rate. Currently available atrial pacemakers fired by an outside radiofrequency source permit termination of re-entrant or pre-excitation atrial arrhythmias; similarly, ventricular pacemakers can be used to terminate supraventricular tachycardia and recurrent ventricular tachycardia. [394] Thus, in addition to learning about the patient's underlying disease, current condition, and drug therapy, the anesthesiologist must learn, preoperatively, the following information about any implanted pacemaker [394]:

TABLE 25-37 -- The NASPE/BPEG Generic (NBG) Five-Letter Code for Pacemaker Systems

FIRST LETTER: CHAMBER PACED	SECOND LETTER: CHAMBER SENSED	THIRD LETTER: MODE OF RESPONSE	FOURTH LETTER (IF USED): PROGRAMMABLE FEATURES	FIFTH LETTER (IF USED): ARRHYTHMIA TREATMENT
A = atrium	A = atrium	T = triggered	P = programmable (single)	O = none
V = ventricle	V = ventricle	I = inhibited	M = multiprogrammable	P = Pacing (antitachyarrhythmia)
D = dual	D = dual	D = dual (T & I)	O = not programmable	S = shock
O = none	O = none	O = not applicable	R = rate modulated	D = dual (P & S)
			C = communicating	

Note: Positions I-III are used exclusively for antibradyarrhythmia function.

1. The indication for placement of the pacemaker and the default rhythm (i.e., what rhythm occurs if the pacemaker does not capture).
2. The type of pacemaker (demand, fixed, or radiofrequency), the chamber paced, and the chamber sensed. Pacemakers have traditionally been given a five-letter code (Table 25-37) . However, most pacemakers implanted since 1980 have codes consisting of only the first three letters. The *first* letter indicates the chamber paced (i.e., V = ventricle, A = atrium, D = dual or both). The *second* letter indicates the chamber sensed (i.e., V = ventricle, A = atrium, D = dual, 0 = none). The

third letter indicates the sensing pattern (i.e., 0 = no sensing, fixed mode; I = inhibited, demand pacer; T = triggered, meaning that the sensing of an electrical impulse triggers a pacemaker spike; D = dual, i.e., both T and I.). For example, a V00 pacemaker paces the ventricle, does not sense, and is in a fixed mode. In other words, it is a fixed-rate ventricular pacemaker. A VVI pacemaker paces the ventricle, senses the ventricle, and is inhibited. It is a ventricular-inhibited demand pacemaker. A DVI pacemaker

paces both atrium and ventricle, senses only the ventricle, and is inhibited. Thus, it is a sequential AV demand pacemaker that fires when it does not sense intrinsic ventricular activity. Rate-modulated pacemakers increase the heart rate in response to increased demand. They have special sensors and are placed in patients who may have abnormal sinus node function. These pacemakers have an R in the fourth position of the pacemaker letter code [393] (e.g., VVIR; see Table 25-37) . A DDDCP pacemaker has multiprogrammable "physiologic" dual chamber pacing, with telemetry and antitachyarrhythmia-pacing capability. An OOOPS is a simple, programmable cardioverter, defibrillator, or cardioverter-defribrillator. It cannot be overemphasized that no generic code can describe every antiarrhythmic device in a comprehensive and unambiguous fashion. It seems to me beneficial to consult with an electrophysiologist/cardiologist before anesthetizing any patient who has a pacemaker.

3. How to detect deterioration in battery function (increased rate or decreased rate).
4. How to change the mode or to fire the pacemaker if it is of the radiofrequency type. (These procedures should not only be learned by the anesthesiologist but also be demonstrated to him or her. Also, the magnet and/or programming device should be in or near the operating room at the time of surgery.)
5. The current rate and sensitivity settings of the pacemaker.
6. Whether the pacemaker is currently functioning and how well.

Because demand pacemakers can sense electrocautery, which sometimes inhibits pacemaker firing, asystole can occur in the pacemaker-dependent patient during electrocautery. Most pacemakers can be converted to a fixed rate, and the anesthesiologist should take the following precautions: (1) have the cardiologist demonstrate how this is done and (2) have the necessary magnet and/or programming device available in the operating room. In addition, the ground plate should be as far from the pulse generator and lead as possible, a bipolar form of electrocautery should be used, and, if possible, some measure of blood flow should be monitored (i.e., Doppler detector, pulse oximetry unaffected by electrocautery, or intra-arterial line). The rationale for the last measure is that electrocautery temporarily affects the accuracy of ECG results; because asystole could occur during this period, a measure of blood flow is necessary. Currently, at least eight manufacturers produce a total of more than 80 types of pacemakers, with a variety of default programs. A default program is the secondary program (i.e., the generator circuit) to which the primary program will revert if it senses problems in the initial circuit. Because default programs differ, pacemaker malfunction will present differently depending on the brand and model. Thus, it is necessary to learn before surgery how problems will manifest with each pacemaker during surgery. [394]

The most common cause of temporary pacemaker malfunction is lack of contact between the electrode wire and the endocardium. Pacemaker spikes continue to exist on the ECG oscilloscope, even when no myocardial contractions propel blood. This situation has occurred with muscular exertion, blunt trauma, cardioversion, and positive-pressure ventilation. [395] Treatment consists of advancing the electrode until it captures, administering isoproterenol (if that worked in the past), external pacing, or, failing that, cardiopulmonary resuscitation.

During the preoperative examination, the anesthesiologist can also assess the progression of underlying disease (e.g., CHF, electrolyte disorders, and the condition of all systems related to the underlying disease). Antiarrhythmic therapy and its implications are discussed in the last section of this chapter.

Also see Chapters 30 and 32 regarding detection and monitoring of cardiac arrhythmias.

DISORDERS OF THE RESPIRATORY AND IMMUNE SYSTEMS

General Preoperative Considerations

Although little may seem to have changed in preoperative preparation of the patient with respiratory disease, this impression is not true. Major changes in drug therapy have occurred, and appreciation has increased regarding the effects of smoking on perioperative and chronic care. [396] [397] [398] [399] [400] [401] [402] [403] [404] [405] [406] [407] [408] [409]

The main purpose of preoperative testing is to identify patients at risk of perioperative complications and to institute appropriate perioperative therapy. Preoperative assessment can also establish baseline function and the feasibility of surgical intervention. Whereas numerous investigators have used pulmonary function tests that define inoperability or high-risk versus low-risk groups for pulmonary complications, few have been able to demonstrate that the performance of any specific preoperative or intraoperative measure reliably decreases perioperative pulmonary morbidity or mortality. Because routine preoperative pulmonary testing and care are discussed extensively in Chapters 24 and 72 , the current discussion is limited to an assessment of the effectiveness of this type of care.

In fact, only four randomized prospective studies indicate an outcome benefit of preoperative preparation; a few more imply a benefit of intraoperative and postoperative pain therapy techniques [410] (usually planned preoperatively; see Ch. 23) . Stein and Cassara [411] randomly allocated 48 patients to undergo preoperative therapy (cessation of smoking, use of antibiotic treatment for purulent sputum, and use of bronchodilating drugs, postural drainage, chest physiotherapy, and ultrasonic nebulizer) or no preoperative therapy. The no-treatment group had mortality of 16 percent and morbidity of 60 percent, as opposed to the 0 and 20 percent rates, respectively, for the treatment group. In addition, the treatment group spent an average of 12 postoperative days in the hospital, compared with 24 days for the 21 survivors in the no-treatment group.

Collins et al [412] prospectively examined the benefits of preoperative antibiotics, perioperative chest physiotherapy and therapy with bronchodilating drugs, and routine postoperative analgesia (morphine) on postoperative respiratory complications in patients with chronic obstructive pulmonary disease (COPD). Of those therapies, only preoperative treatment with antibiotics had a beneficial effect.

Warner and colleagues [413] collected data retrospectively about smoking history and prospectively (concurrently) about pulmonary complications for 200 patients undergoing

CABG. These investigators documented that 8 weeks or more of smoking cessation was associated with a 66 percent reduction in postoperative pulmonary complications. Smokers who stopped for less than 8 weeks actually had an increase (from 33% for current smokers to 57.1% for recent quitters) in the rate of one or more of the six complications surveyed: purulent sputum with pyrexia; need for respiratory therapy care; bronchospasm requiring therapy; pleural effusion and/or pneumothorax necessitating drainage; segmental pulmonary collapse, as confirmed by radiograph; or pneumonia necessitating antibiotic therapy. Although others have found both shorter and longer periods of cessation of smoking prior to cardiovascular benefits [414] [415] [416] and hematologic benefits, [417] this is one of the few studies that show both harmful and beneficial outcomes for pulmonary status from the same maneuver--cessation of smoking. The fact that anesthesiologists rarely see their patients 8 weeks or more before surgery presents a dilemma: If one is unable to advise the patient to stop smoking 8 weeks or more before surgery, is it preferable for the patient to continue smoking? Perhaps these data will further support the implementation of preoperative assessment clinics in which anesthesiologists are able to advise and counsel patients about risk reduction. When Skolnick and coworkers [409] studied 602 children prospectively, exposure to passive smoking (as measured by urinary cotinine, the major metabolite of nicotine) correlated directly with airway complications. Children with the least exposure to passive smoke had the fewest complications.

Celli and coworkers [418] performed a randomized prospective controlled trial of intermittent positive-pressure breathing (IPPB) versus incentive spirometry and versus deep-breathing exercises in 81 patients undergoing abdominal surgery. The groups exposed to a respiratory therapist (regardless of treatment given) had both shorter hospital stays and an incidence of clinical complications that was more than 50 percent lower (30-33% versus 88%) than the control group. Thus, this third prospective study indicates that outcome improves when there is any concern about lung function on the part of someone knowledgeable in maneuvers designed to clear lung secretions.

Bartlett et al [419] randomly assigned 150 patients undergoing extensive laparotomy to one of two groups. One group received preoperative instruction in and postoperative use of (10 times/h) incentive spirometry. The other group received similar medical care but no incentive spirometry. Only 7 of 75 patients using incentive spirometry had postoperative pulmonary complications, as opposed to 19 of 75 in the control group. However, other studies have not shown a benefit for specific treatments or have been too contaminated with bias to have a clear result emerge. Lyager et al [420] randomly assigned 103 patients undergoing biliary or gastric surgery to receive either incentive spirometry with preoperative and postoperative chest physiotherapy or only preoperative and postoperative chest physiotherapy. No difference in postoperative course or pulmonary complications was found between the two groups. Other studies have shown a specific benefit (i.e., above that provided by routine care) for chest physiotherapy and IPPB. These studies are usually poorly controlled, not randomized, and/or retrospective in design; these deficiencies probably substantially bias the results toward finding a benefit in reducing postoperative pulmonary complications. [421] [422] [423] [424] Although randomized prospective studies showed no benefit or actual harm from chest physiotherapy and IPPB on the resolution of pneumonia, [425] [426] or postoperative pulmonary complications, [412] [418] [423] [426] [427] [428] [429] the four studies cited previously [411] [412] [418] [419] and numerous retrospective studies [413] [421] [422] [423] strongly suggest that preoperative evaluation and treatment of patients with pulmonary disease actually decrease perioperative respiratory complications, even if only by causing a change in anesthetic techniques. [410]

The evaluation of dyspnea is especially useful and so warrants discussion here. (For a review of the specific pulmonary function tests that identify high-risk groups, see Ch. 24) . Boushy et al [429] found that grades of preoperative dyspnea correlated with postoperative survival. (The grades of respiratory dyspnea are provided in Table 25-38.) (Table Not Available) Mittman [430] demonstrated an increased risk of death after thoracic surgery from 8 percent in patients without dyspnea to 56 percent in patients who were dyspneic. Similarly, Reichel [431] found that no patients died after pneumonectomy if they were able to complete a preoperative treadmill test for 4 minutes at the rate of 2 mph on level ground. Other studies have found that history and physical examination of the asthmatic subject can also predict the need for hospitalization. [398] [432] Wong and colleagues [433] found that the risk index (Table 25-39) (Table Not Available) correlated with postoperative pulmonary complications.

Other than dyspnea, what preoperative conditions make postoperative respiratory complications more likely [424] [433] [434] [435] (Ch. 72) ? The important information and conditions to search for during the history-taking and physical examination are as follows:

TABLE 25-38 -- Grade of Dyspnea Caused by Respiratory Problems (Assessed in Terms of Walking on the Level at a Normal Pace)

(Not Available)

Modified from Boushy et al. [429]

1. Dyspnea (see Table 25-38) (Table Not Available) .
2. Coughing and production of sputum. Sputum, if present, should undergo Gram staining and culturing, and appropriate antibiotic treatment should be instituted.
3. Recent respiratory infection. Viral respiratory infections affect respiratory function, giving rise to increased airflow obstruction that may persist for as long as 5 weeks. [436] [437] These infections also adversely affect respiratory mechanisms responding to bacteria. However, whether the incidence of complications in normal children is lessened by waiting 5 weeks until the symptoms of respiratory infections have disappeared is open to question. [438] [439] [440] [441] [442] [443] For all children (and possibly adults), it appears appropriate to

delay surgery that requires tracheal intubation for 5 weeks after the presence of an upper respiratory infection.
4. Hemoptysis.
5. Wheezing and prior use of bronchodilating drugs and corticosteroids (systemic or inhaled). Wheezing often suggests potentially reversible airway obstruction but is a notoriously poor indicator of the degree of obstruction. In addition, not all wheezing is caused by bronchospasm. Cardiac and other pulmonary causes must be differentiated from asthma. [444] Drug therapy for asthma should be ascertained and optimized if possible. Asthmatics have a 4-fold increase in perioperative respiratory complications. Holleman and Simel [398] found that auscultated audible wheezing on nonforced expiration (along with a 70-pack-year history of smoking and patient sensation of wheezing) was a reliable sign of severe airflow limitation.
6. Pulmonary complications from previous surgery. Prolonged endotracheal intubation after surgery can be required by many conditions, most probably respiratory and neuromuscular disorders.
7. A history of smoking. The incidence of respiratory complications is higher among tobacco smokers than among nonsmokers. [413] [421] [422] [445]
8. Age, general history of the patient, and any other significant physical findings. Although other disease conditions probably increase respiratory risk, the documentation on this hypothesis is barely adequate. [433] Old age definitely increases respiratory and cardiac risk. [413] [420] [445] [446] Cardiovascular history and examinations are obviously important in themselves but are also especially helpful in revealing signs of pulmonary hypertension, such as right ventricular lift (i.e., lift over the lower sternum), fixed and widely split second heart sound, and S_4 gallop at the left sternal border.
9. Breathing frequency and form. Pursed lips, cyanosis, and use of accessory muscles should be noted. Vocal cord dysfunction occurs commonly from both psychosocial illness and the attempt to increase end-expiratory pressure. [447]
10. Body habitus:
    a. Abnormalities of the chest wall, trauma, kyphoscoliosis with restrictive lung disease. Development of a barrel chest is a late manifestation of obstructive lung disease.
    b. Obesity. A weight 30 percent over ideal weight doubles the incidence of respiratory complications (Amalraj S, personal communication). [88] [89] [90] [91] [92] [93] [425] [445]
11. Adequacy of upper airway, presence of tracheal deviation, ease of face mask application, ease of endotracheal intubation.
12. Presence of rales, rhonchi, wheezing (especially on nonforced expiration), diaphragmatic excursion, and air movement and the ratio of expiratory to inspiratory times. [398]
13. Site of proposed surgery. Upper abdominal surgery increases the incidence of perioperative pulmonary complications. [410] [411] [422] [433] [434] [448]
14. Surgery performed on an emergency basis. Wong and colleagues [433] found that surgery performed on an emergency basis increased the risk of perioperative pneumonia 13-fold for patients with severe COPD.

TABLE 25-39 -- Classification of Risk of Pulmonary Complications for Thoracic and Abdominal Procedures

(Not Available)

Modified from Shapiro et al. [602]

Chapters 24 and 72 review the value of chest radiographs and pulmonary function tests in identifying patients with preoperative pulmonary disease as well as which tests should be ordered and for whom. Any patient who will require postoperative ventricular support should be considered for preoperative testing. Although we have yet to find the ideal pulmonary function test that guarantees success or that predicts a poor outcome that could be improved by therapy, the following conditions are relatively good predictors of complications associated with resection of a lung: a maximum breathing capacity of less than 40 or 50 L/min/70 kg, an FEV_1/FVC of less than 40 percent of predicted, an FEV_1 of less than 1.2 L, or a maximum midexpiratory flow rate of less than 50 L/min. [421] [424] [430] [431] [432] [433] [434] [449] [450] [451]

To these is now added the diffusing capacity of the lung for carbon monoxide (DLCO). [312] [450] [451] DLCO decreases with fixed obstructive lung disease (i.e., emphysema) but remains normal in bronchospastic disease. In one study, when preoperative DLCO was less than 60 percent of predicted, the mortality rate was 25 percent and pulmonary morbidity rate was 45 percent, whereas a DLCO of 100 percent or greater of predicted was associated with a 0 percent mortality rate and an 11 percent pulmonary morbidity rate. A subsequent study confirmed these findings. [451] Although I have always tried to reduce laboratory studies, these may prove useful in the patient with COPD who requires pulmonary surgery. Further analysis is necessary to determine whether the finding of a normal DLCO may allow expansion of the usual spirometric criteria to permit successful pulmonary resection in patients who are currently excluded as candidates for such operations. The author conducts such tests on any patient with dyspnea of grade II or higher or on any patient

who shows significant abnormalities or risk on the first 13 factors listed previously. Wong and colleagues [433] found that the Shapiro score (see Table 25-39) (Table Not Available) and ASA physical status independently predicted adverse outcome after surgery for patients with severe obstructive pulmonary disease. Although this score depends heavily on abnormal pulmonary function tests for grading risk, abnormalities in the cardiovascular, neuromuscular, and central nervous systems, plus restrictions in ambulation, can also increase the risk score. A Shapiro score of 5 points or more was associated with a 17-fold higher risk of perioperative death and a 14-fold higher risk of postoperative bronchospasm after nonthoracic surgery. [433]

Despite the lack of definitive data establishing the efficacy of preoperative pulmonary testing and therapy, I recommend the following approach:

1. Eradicate acute infections and suppress chronic infections by using appropriate diagnostic measures and antibiotic treatment.
2. Relieve bronchospasm by using inhaled corticosterodis and bronchodilating drugs and document such relief with measurements of FEV_1 (Chs. 24 and 72).
3. Institute measures to improve sputum clearance and to familiarize the patient with respiratory therapy equipment (incentive spirometry) and postural drainage maneuvers. Initiate practice coughing and deep-breathing exercises (Chs. 24 and 72) .
4. Treat uncompensated right ventricular heart failure with digoxin, diuretics, oxygen, and drugs that decrease pulmonary vascular resistance (e.g., hydralazine). [452]
5. Use low-dose heparin prophylactically to decrease the incidence of venous thrombosis (and pulmonary emboli). [373] [374] [375] [453]
6. Encourage reduction or cessation of smoking 8 weeks or more prior to surgery. [413] Although the debate about cessation of smoking includes more than pulmonary risk, cardiovascular, hematologic, and aspiration risks also have not been shown to be responsive to short-term cessation. [413] [414] [415] [416] [417] Perhaps the benefit of using a major life event--an operation--to promote cessation of smoking is worth the increased short-term risk that encouraging cessation within a day or two of surgery would entail; the latter hypothesis remains to be tested. Even young people who smoke only one-half to one pack of cigarettes per day exhibit abnormalities in respiratory function. [454] Avoiding passive smoking also appears beneficial. [409]

Specific Diseases

Pulmonary Vascular Diseases

Pulmonary vascular diseases include pulmonary hypertension secondary to heart disease (postcapillary disorders), parenchymal lung disease (pulmonary precapillary disorders), pulmonary embolism, and cor pulmonale from chronic obstructive pulmonary disease. [455] Optimal preoperative management of these conditions requires treatment of the underlying disease. [455] [456] Because pulmonary embolism can be especially difficult to diagnose, it is crucial to be especially alert to the possibility of this disease. The clinical findings of pulmonary emboli are not always present or specific for the diagnosis. The history may include tachypnea, dyspnea, palpitations, syncope, chest pain, or hemoptysis. Physical examination can reveal a pleural rub, wheezing, rales, a fixed and split second heart sound, right ventricular lift, or evidence of venous thromboses, none of which is present in most patients. If the ECG shows an S_1-Q_3 pattern, lung perfusion scans can be obtained to rule out the diagnosis of pulmonary emboli. A high degree of suspicion is necessary to warrant angiography and anticoagulation or fibrinolytic therapy. If possible, the reactivity of the pulmonary vasculature should be determined, for it may be enhanced or decreased by such agents as nifedipine, hydralazine, nitroglycerin, prazosin, tolazoline, phentolamine, and nitric oxide. Monitoring of pulmonary artery pressure is often required; preoperative measures should be undertaken to ensure that the patient is not exposed to conditions that elevate pulmonary vascular resistance (i.e., hypoxia, hypercarbia, acidosis, lung hyperinflation, hypothermia) [457] or that decrease blood volume (prolonged restriction of fluid intake) or systemic vascular resistance.

Infectious Diseases of the Lung

Preoperative evaluation and treatment should follow the basic guidelines outlined in the introduction to this section; treatment of the underlying disease should be completed before all but emergency surgery is performed. It bears repeating that viral respiratory infections do affect respiratory function, giving rise to increased airflow obstruction (especially in the small airways) that may persist for at least 5 weeks. Viral respiratory infections also adversely affect the respiratory mechanisms that defend against bacteria. Within 5 weeks of an upper respiratory tract infection, children may have an increased incidence of perioperative respiratory tract complications after intubation. [438] [439] [440] [441] [442] [443] It appears appropriate to delay surgery that requires tracheal intubation for all children (and possibly all adults) for 5 weeks after an upper respiratory infection. [438] [439] [440] [441] [442] [443]

Even though elective surgery should be postponed whenever infectious diseases of the lung are present, patients undergoing emergency surgery often have nosocomial infections and immunocompromised systems. The predominant pathogens for nosocomial pneumonia are gram-negative bacilli, *Staphylococcus aureus, Haemophilus influenzae,* anaerobes, and pneumococci. Furthermore, tuberculosis has been increasing since 1985, probably because of reactivation in patients infected with human immunodeficiency virus (HIV). Tuberculosis leads to chronic pulmonary and systemic symptoms. Affected patients may have malaise, headache, fever, hemoptysis, and extrapulmonary diseases affecting the skin, cervical lymph nodes, kidneys, pericardium, and meninges. Active disease is treated with isoniazid and rifampin for 9 months. Therapy should probably be started before surgery; for patients coming from countries having a high incidence of resistance to isoniazid, initial therapy might include more than two drugs. Administration of treatment before these emergency patients (many of whom have adult respiratory distress syndrome) are brought to the operating room might include initiation of antiinfective therapy, optimization of fluid status and gas exchange,

and therapy for the underlying pathophysiologic process. [456] [457] [458] [459] [460] [461]

Chronic Obstructive Pulmonary Disease

Treatment of COPD (reactive airways) may include the use of beta-adrenergic drugs, parasympatholytic agents (especially for exercise-induced asthma), systemic or inhaled corticosteroids, and leukotriene antagonists. [396] [397] [398] [399] [400] [401] [402] [403] [404] [405] [406] [407] [408] [462] An estimated 5 percent of the population has bronchospasm. Some investigators recommend using inhaled bronchodilators as first-line drugs and reducing the dose of inhaled steroids, such as beclomethasone dipropionate, budesonide, mometasone, or fluticasone, which are inactivated after absorption. However, in large doses, these "inhaled" steroids can suppress adrenal function, and supplemental systemic corticosteroids may be needed at times of stress. (See earlier discussion under the section on adrenocortical malfunction.) Preoperative assessment must include gaining knowledge of drug regimens and their effects and education of the patient regarding proper use of an inhaler (Table 25-40) , as these drugs can interact dangerously with anesthetic agents (see last section of this chapter) or can be used inappropriately and therefore produce side effects without maximum benefit. [396] [397] [398] [399] [400] [401] [402] [403] [404] [405] [406] [407] [408] No known interaction between the inhaled anticholinergic ipratropium bromide and muscle relaxants has been reported. It is important to note that patients can feel fine at rest but must be tested with exercise or spirometry to document the degree of current bronchospasm. Furthermore, symptomatic response to bronchodilators in the asymptomatic patient may not predict whether the patient responds to bronchodilator therapy. An estimated 10 percent of asthmatic patients exhibit sensitivity to aspirin and may react not only to compounds containing aspirin but also to tartrazine, yellow dye number 5, indomethacin, and aminopyrine. [463]

COPD takes several forms. Bronchial asthma, which occurs in 3 to 5 percent of the population, is characterized by reversible airway obstruction. When airway obstruction is partially reversible (by steroids or adrenergic mediators), it is often accompanied by chronic bronchitis. Some of the drugs may improve aspects of lung function other than bronchial muscle tone. [385] [441] Most patients with a history of chronic cough and production of sputum on most days for 3 months a year for at least 2 years have chronic bronchitis. These patients are (or almost always have been) smokers, although

TABLE 25-40 -- Procedures for Correct Use of a Metered-Dose Inhaler

Remove the cap and hold the inhaler upright.
Shake the inhaler.
Tilt the head back slightly and exhale steadily to functional residual capacity.
Position the inhaler using a spacer between the actuator and the mouth.
Press down on the inhaler while taking a slow, deep breath (3-5 s).
Hold the full inspiration for at least 5 s and up to 10 s, if possible, to allow medication to reach deeply into the lungs.
Repeat inhalations as directed; waiting 1 min after inhalations of the bronchodilator may permit subsequent inhalations to penetrate more deeply into the lungs and is necessary to ensure proper dose delivery.
Rinse the mouth and expectorate after using the inhaler.

environmental and occupational or genetic predisposition may contribute to hypertrophy of mucous glands in major airways, to hyperplasia of goblet cells, and to edema and inflammation of the airways. These patients will have a decreased DLCO, whereas patients with pure bronchospasm will have a normal DLCO. Hyperinflation of airspaces, abnormal dilation, and destruction of acinar units distal to the terminal bronchiole define emphysema. The destruction of alveolar membranes is believed to be related to an imbalance favoring destructive proteases (the most important of which are neutrophil-derived) over protective circulating antiproteases (the most important of which is $alpha_1$-antitrypsin). Cigarette smoking increases the protease-to-antiprotease ratio. The destruction of alveolar structures limits expiratory air flow by decreasing both elastic lung recoil and radial lung traction, and the loss of alveolar capillary blood volume results in a decreased DLCO. Cystic fibrosis is characterized by dilation and hypertrophy of bronchial glands, mucous plugging of peripheral airways, and often bronchitis, bronchiectasis, and bronchiolectasis. For all these conditions, the measures recommended earlier in this section, as well as appropriate hydration to allow for mobilization of secretions, should be followed.

Interstitial and Immune Lung Diseases

Included in this heterogeneous group of diseases are the hypersensitivity lung diseases, environmental exposure diseases, the inorganic dust diseases, radiation-induced lung disease, sarcoidosis, the collagen vascular disorders (systemic lupus erythematosus, polymyositis, dermatomyositis, Sjogren syndrome, rheumatoid arthritis, systemic sclerosis), Goodpasture syndrome, idiopathic pulmonary hemosiderosis, Wegener's granulomatosis, and the autoimmune diseases. [464] CT scans localize pulmonary inflammation and have become the primary decision-making tool in diagnosing infiltrative lung disease. [465] [466] Many of these disorders affect not only the lungs but also the blood vessels, the conduction system of the heart, the myocardium, the joints (including those of the upper airway and larynx), and the renal, hepatic, and/or central nervous systems. The reader is referred to a textbook of internal medicine to aid in understanding the pathophysiologic

processes and full preoperative assessment of these conditions. Therapy for these conditions includes the use of anti-inflammatory drugs, corticosteroids, and immunosuppressive drugs.

Neoplasms

Solitary nodules consist of tumors that are less than 6 cm in diameter, surrounded by lung parenchyma, and not associated with adenopathy or pleural effusion. The cure rate for bronchogenic carcinoma presenting as a solitary nodule is 50 percent--much better than the "cure" rate for other presentations. [467] (It should be remembered that tuberculosis can mimic cancer so closely that surgery has even been performed.) Blood studies including calcium and alkaline phosphatase levels and liver function studies help confirm that the neoplasm has not disseminated. If these studies and history and physical examination show no abnormal findings, it

is unlikely that bone, brain, or hepatic MRI or CT scanning techniques will indicate metastasis. Surgery need not await the results of these tests, as few patients not found to have metastatic disease by simple blood tests, history, and physical examination will prove to have such disease detected by these scans. Survival depends on stage of the tumor and age of the patient. [468]

Surgical resection is the primary therapy for non-small-cell carcinomas (e.g., adenocarcinoma, squamous cell carcinoma, and large-cell carcinoma). These carcinomas constitute 75 percent of all lung carcinomas, 12 percent of all malignant tumors, and 20 percent of all cancer deaths in the United States. [468] Success of surgery can be predicted by stage of the tumor. The most widely accepted staging system for these carcinomas is the tumor-node-metastasis (TNM) classification. In this system, T1 lesions are smaller than 3 cm in diameter, T2 lesions are larger than 3 cm, T3 lesions invade chest wall mediastinum or diaphragm, and T4 lesions invade heart or great vessels. The designation N0 indicates no lymph node involvement; N1, tracheobronchial or hilar lymph node involvement; and N3, contralateral or supraclavicular lymph node involvement. M0 connotes no metastases; and M1, systemic metastases.

Patients in stage I who have small primary tumors (T1N0M0) usually undergo lobectomy and have a 5-year survival rate of 50 percent. Those surgical procedures that spare pulmonary parenchyma--wedge resection or bronchial sleeve resection--are reserved for patients with COPD and heart disease, although thoracoscopic resections may radically improve localization and tolerance of procedures. Patients in stage II (T1N1M0 or T2N1M0) also undergo total resection and have a 5-year survival rate of 30 percent. Patients in stage IIIa (T3N0M0, or T1 or T2N2M0) are resected for cure but currently have a 5-year survival rate of only 17 percent. [468] Postresection radiotherapy does not improve survival, and mass screening programs do not lead to better prognosis (see Ch. 23 sections on lead- and length-time biases). Diagnostic typing and staging often involve percutaneous transthoracic aspiration, which is associated with a 30 percent incidence of pneumothorax. [468]

The combination of chemotherapy and radiation therapy is the current treatment of choice for small-cell carcinomas of the lung. [469] Oat-cell (small-cell) carcinomas of the lung and bronchial adenomas are known for their secretion of endocrinologically active substances, such as ACTH-like hormones. Squamous cell cancers in the superior pulmonary sulcus produce Horner syndrome, as well as a characteristic pain in the areas served by the eighth cervical nerves and first and second thoracic nerves. These tumors are now treated with preoperative radiation; surgical resection leads to an almost 30 percent "cure" rate.

Anaphylaxis, Anaphylactoid Responses, and Allergic Disorders Other Than Those Related to Lung Diseases and Asthma

Anaphylactic and Anaphylactoid Reactions

Anaphylaxis is a severe life-threatening allergic reaction. *Allergic* applies to immunologically mediated reactions, as opposed to those caused by pharmacologic idiosyncrasy, by direct toxicity or drug overdosage, or by drug interaction. [466] [470] [471] Anaphylaxis is the typical immediate hypersensitivity reaction (type 1). Such reactions are produced by the immunoglobulin E (IgE)-mediated release of pharmacologically active substances. These mediators in turn produce specific end-organ responses in the skin (urticaria), the respiratory system (bronchospasm and upper airway edema), and the cardiovascular system (vasodilation, changes in inotropy, and increased capillary permeability). Vasodilation occurs at the level of the capillary and postcapillary venule, leading to erythema, edema, and smooth muscle contraction. This clinical syndrome is called *anaphylaxis.* By contrast, *anaphylactoid reaction* denotes an identical or very similar clinical response that is not mediated by IgE or (usually) an antigen-antibody process. [472]

In anaphylactic reactions, an injected substance can serve as the allergen itself. Low-molecular-weight agents are believed to act as haptens that form immunologic conjugates with host proteins. The offending substance, whether hapten or not, may be the parent compound, a nonenzymatically generated product, or a metabolic product formed in the patient's body. When an allergen binds immunospecific IgE antibodies on the surface of mast cells and basophils, histamine and eosinophilic chemotactic factors of anaphylaxis are released from the storage granules in a calcium- and energy-dependent process. [470] Other chemical mediators are rapidly synthesized and subsequently released in response to cellular activation. These mediators include slow-reacting substance of anaphylaxis, which is a combination of three leukotrienes; other leukotrienes [473] ; kinins; plateletactivating factors; adenosine; chemotactic factors; heparin tryptase; chymase; and prostaglandins, including the potent bronchoconstrictor prostaglandin D_2 , eosinophil growth and -activating factors, mast-cell growth factors, and proinflammatory and other factors that contribute to the IgE isotype switch.

The end-organ effects of the mediators produce the clinical syndrome of anaphylaxis. Usually a first wave of symptoms, including vasodilation and a feeling of impending doom, is quickly followed by the second wave as the cascade of mediators amplifies the reactions. In a sensitized patient, the onset of the signs and symptoms caused by these mediators is usually immediate but may be delayed 2 to 15 minutes or, in rare instances, as long as 2.5 hours after the parenteral injection of antigen. [473] [474] After oral administration, manifestations may occur at unpredictable times.

Mast-cell proliferation, together with severe progressive inflammation, contributes to the worsening of symptoms that occurs even after there is no longer an allergen load. Both activated mast cells and the antigen present in cells and lymphocytes start to make cytokines. These proinflammatory cytokines recruit more inflammatory cells, which promotes tissue edema and mediates a second wave of mast-cell degranulation. This second wave can promote recurrence of severe symptoms 6 to 8 hours later and necessitates, some believe, at least 8 hours of continued ICU-like observation.

In addition, there are multiple effector processes by which biologically active mediators can be generated to produce an anaphylactoid reaction. Activation of the blood coagulation and fibrinolytic systems, of the kinin-generating sequence, or of the complement cascade can produce the

same inflammatory substances that result in an anaphylactic reaction. The two mechanisms known to activate the complement system are called classic and alternate. The classic pathway can be initiated through IgG or IgM (transfusion reactions) or plasmin. The alternate pathway can be activated by lipopolysaccharides (endotoxin), drugs (Althesin [472]), radiographic contrast media, [475] membranes (nylon tricot membranes for bubble oxygenators [476]), cellophane membranes of dialyzers, [477] vascular graft material, [478] latex or latex-containing products, [479] and perfluorocarbon artificial blood. In addition, histamine can be liberated independent of immunologic reactions. [480] Mast cells and basophils release histamine in response to chemicals or drugs. Most narcotics can release histamine, [480] producing an anaphylactoid reaction, as can radiographic contrast media, [475] *d*-tubocurarine, [481] and thiopental. What makes some patients susceptible to histamine release in response to drugs is unknown, but hereditary and environmental factors may play a role.

Intravenous contrast material is probably the most frequently used agent causing anaphylactoid reactions. Because diagnostic (skin and other) tests are helpful only in IgE-mediated reactions, pretesting is not useful in contrast reactions. Pretreatment with diphenhydramine, cimetidine (or ranitidine), and corticosteroids has been reported to be useful in preventing or ameliorating anaphylactoid reactions to intravenous contrast material [475] [482] and perhaps to narcotics and chymopapain. [483] [484] Unfortunately, very large doses of steroids (1 g of methylprednisolone intravenously) may be necessary to obtain a beneficial effect. [485] The efficacy of large-dose steroid therapy has not been confirmed. Other common substances associated with anaphylactic or anaphylactoid reactions that might merit preoperative therapy include antibiotics, volume expanders, and blood products [470] [486] [487] (Table 25-41) (Table Not Available) . The anesthesiologist should be prepared preoperatively to treat an anaphylactic or anaphylactoid response.

In some cases, a patient with a history of anaphylactic or anaphylactoid reaction must receive a substance suspected of producing such a reaction (e.g., iodinated

contrast material). Also, some patients have a higher-than-average likelihood of having a reaction, warranting well-planned pretreatment and therapy for possible anaphylactic and anaphylactoid reactions. [470]

TABLE 25-41 -- Incidence of Anaphylactic or Anaphylactoid Reactions to Some Common Agents

(Not Available)

Data modified from Ring and Messmer. [486] Levy et al. [470] and Moss et al [483]

Minimizing the Risks Preoperatively

Although virtually all evidence on these subjects is merely anecdotal, enough consistent thought recurs through the literature to justify proposing an optimal approach to these problems. First, predisposing factors should be sought; the patient with a history of atopy or allergic rhinitis should be suspected as being at risk. Because anaphylactic and anaphylactoid reactions to contrast media occur five to ten times more frequently in patients with a previously suspected reaction, consideration should be given to administration of both H_1 - and H_2 -receptor antagonists for 16 to 24 hours before exposing these patients to a suspected allergen. The H_1 -receptor antagonist appears to require this much time to act on the receptor. Volume status should be optimized, [470] and perhaps large doses of steroids (2 g of hydrocortisone) should also be administered before exposing patients to agents associated with a high incidence of anaphylactic or anaphylactoid reactions. [485] [486] [488] Older patients and patients taking beta-adrenergic-blocking drugs present special problems; they are at higher risk of having complications from both pretreatment (especially vigorous hydration) and therapy for anaphylactic reactions and are less responsive to treatment regimens. [489] One approach is to avoid drugs likely to trigger anaphylactic or anaphylactoid reactions or to alter the treatment protocol for this group. Drawing blood for later analysis, especially of tryptase, can be useful in clarifying the diagnosis. [490]

Primary Immunodeficiency Diseases

The primary immunodeficiency diseases usually present early in life with recurrent infections. Along with survival achieved with antibiotic and antibody treatment have come new prominent features: cancer and allergic and autoimmune disorders. Heredity angioneurotic edema is an autosomal dominant genetic disease characterized by episodes of angioneurotic edema involving the subcutaneous tissues and submucosa of the GI tract and the airway and often presenting as abdominal pain. These patients have a functionally impotent inhibitor or a deficiency of an inhibitor to the complement component C1. Treatment of an acute attack is supportive because epinephrine, antihistamines, and corticosteroids often fail to work. Plasma transfusions have been reported to resolve attacks or to make them worse (theoretically by supplying either C1 esterase inhibitor or previously depleted complement components). The severity of attacks can be prevented or decreased by drugs that are either plasmin inhibitors (e.g., epsilon-aminocaproic acid and tranexamic acid) or androgens (e.g., danazol). Because trauma can precipitate acute attacks, prophylactic therapy with danazol, intravenous epsilon-aminocaproic acid, plasma, or all three, is recommended prior to elective surgery. Reports have also described the successful use of a partially purified C1esterase inhibitor in two patients. [491] [492]

Most of the 1 in 700 persons who have selective IgA deficiency (i.e., <5 mg/dL) have repeated serious infections or connective tissue disorders. [493] These infections commonly involve the respiratory tract (e.g., sinusitis, otitis) or GI tract (presenting as diarrhea, malabsorption, or both). If the patient has rheumatoid arthritis, Sjogren syndrome, or systemic

lupus erythematosus, the anesthetist should consider the possibility of isolated IgA deficiency. However, patients with this disorder can be otherwise healthy. Because these patients may develop antibodies to IgA if previously exposed to IgA (as might occur from a previous blood transfusion), subsequent blood transfusions can cause anaphylaxis, even when they contain washed erythrocytes. Transfusion should therefore consist of blood donated by another IgA-deficient patient.

Many immunomodulators are now being given to augment cancer treatments [494] ; no interactions between these modulators, or effects on the incidence of immune reactions during anesthesia, or interactions with anesthetic effects have been reported except regarding immune-suppressing agents. (See last section of this chapter.)

DISEASES OF THE CENTRAL NERVOUS SYSTEM, NEUROMUSCULAR DISEASES, AND PSYCHIATRIC DISORDERS

Taking the history and performing the physical examination suggested in Chapter 23 should help identify almost all significant neurologic or mental disease. Information gathered from the history that would warrant further investigation includes the previous need for postoperative ventilation in a patient without inordinate lung disease, indicating the possibility of metabolic neurologic disorders such as porphyria, alcoholic myopathy, other myopathies, neuropathies, and neuromuscular disorders such as myasthenia gravis. Other historical information warranting further investigation would be the use of drugs such as steroids; guanidine; anticonvulsant, anticoagulant, and antiplatelet drugs; lithium; tricyclic antidepressant drugs; phenothiazines; and butyrophenones.

Although preoperative treatment of most neurologic disorders has not been reported to lessen perioperative morbidity, knowledge of the pathophysiologic characteristics of these disorders is important in planning intraoperative and postoperative management. Thus, preoperative knowledge about these disorders and their associated conditions (e.g., cardiac arrhythmias with Duchenne muscular dystrophy or respiratory and cardiac muscle weakness in dermatomyositis) may reduce perioperative morbidity. A primary goal of neurologic evaluation is to determine the site of the lesion in the nervous system. Such localization is essential for accurate diagnosis and appropriate management. (Disorders accompanied by increased intracranial pressure and cerebrovascular disorders are discussed in Ch. 52 .)

Coma

Little is known about anesthesia for the comatose patient, but, as for all other conditions, it is imperative to know the cause of the coma, so as to avoid drugs that might worsen the condition or that might not be metabolized because of organ dysfunction. First, the patient should be observed. Yawning, swallowing, or licking of the lips implies a "light" coma with major brain stem function intact. If consciousness is depressed but respiration, pupillary reactivity to light, and eye movements are normal and no focal motor signs are present, metabolic depression is likely. Abnormal pupillary responses may indicate hypoxia, hypothermia, local eye disease, or drug intoxication with belladonna alkaloids, narcotics, or glutethimide; pupillary responses may also be abnormal, however, after the use of eyedrops. Other metabolic causes of coma include uremia, hypoglycemia, hepatic coma, alcohol ingestion, hypophosphatemia, myxedema, and hyperosmolar nonketotic coma. Except in extreme emergencies, such as uncontrolled bleeding or perforated viscus, care should be taken to render the patient as metabolically normal as possible before surgery. This practice and documenting the findings on the chart preoperatively lessen any confusion regarding the cause of intraoperative and postoperative problems. However, too-rapid correction of uremia or hyperosmolar nonketotic coma can lead to cerebral edema, a shift of water into the brain due to a reverse osmotic effect caused by the dysequilibrium of urea concentration.

The physical examination can be extremely helpful preoperatively in assessing the prognosis. [495] [496] [497] [498] [499] Flexion of the arms at the elbow (i.e., decorticate posture) implies bilateral hemisphere dysfunction but intact brain stem, whereas extension of legs and arms (bilateral decerebrate posture) implies bilateral damage to structures at the upper brain stem or deep hemisphere level. Seizures are often seen in uremia and in other metabolic encephalopathies. Hyperreflexia and upward-pointing toes suggest a structural CNS lesion or uremia, hypoglycemia, or hepatic coma; hyporeflexia and downward-pointing toes with no hemiplegia generally indicate no structural CNS lesion.

Epileptic Seizures

Epileptic seizures result from paroxysmal neuronal discharges of abnormally excitable neurons. Seizures can be generalized (arising from deep midline structures in the brain stem or thalamus, usually without aura or focal features during the seizure), partial focal motor, or sensory seizures (the initial discharge comes from a focal unilateral area of brain, often preceded by an aura). As with cerebrovascular accidents and coma, knowing the origin may be crucial to understanding the pathophysiologic processes of the disease and to managing the intraoperative and postoperative course.

Epileptic seizures can arise from discontinuation of sedative hypnotic drugs or alcohol, use of narcotics, uremia, traumatic injury, neoplasms, infection, congenital malformation, birth injury, drug usage (e.g., amphetamines, cocaine), hypercalcemia or hypocalcemia, blood in the ventricle or hypoxia, and vascular disease and vascular accidents. Thirty percent of epileptic seizures have no known cause. Most partial seizures are caused by structural brain abnormalities (secondary to tumor, trauma, stroke, infection, and other causes).

The epileptic patient requires no special anesthetic management other than that for the underlying disease. Most authorities believe anticonvulsant medications should be given in the therapeutic range [500] [501] [502] and continued through the morning of surgery; they should also be given postoperatively.

Appropriate treatment of status epilepticus may include general anesthesia. [502] In one controlled trial, phenobarbital was more rapidly effective at controlling status epilepticus than was diazepam followed by phenytoin. [502] The frequencies of side effects and required tracheal intubation were similar for both regimens. High concentrations of enflurane (especially with hyperventilation) can be associated with electroencephalographic evidence of epileptic activity and tonic-clonic movements. [503] [504] These seizures, however, do not appear to have serious sequelae. [505] Enflurane anesthesia does not appear to increase seizure activity in patients with a history of convulsive disorders and even suppresses seizures induced by electroshock, pentylene-tetrazole, strychnine, picrotoxin, or bemegride. [504] [505] [506] Thus, other than the use of current drug therapy and heeding precautions taken for the underlying disease, no known changes in perioperative management seem indicated.

Infectious Diseases and Degenerative Disorders of the Central Nervous System, and Headache

Many degenerative CNS disorders have been traced to slowly developing viral diseases or even the presence of certain proteins or viral particles ("prions"). No special perioperative anesthetic considerations appear to apply for infectious disorders of the CNS other than those for increased intracranial pressure and avoiding occupational exposures. (Also see Ch. 52 .) The appropriate prophylactic measures to take if one comes into contact with meningococcal disease or other infectious CNS disease are still not well established. The use of *H. influenzae* type b vaccine has made meningitis an adult disease. [507]

Parkinson disease is a degenerative disorder of the CNS that may or may not be caused by a virus. Clinically, Parkinson disease, chronic manganese intoxication, phenothiazine or butyrophenone toxicity, Wilson disease, Huntington chorea, traumatic boxing injury, the effects of street drug toxins such as methylphenyltetrahydropyridine, and carbon monoxide encephalopathy all present with similar features: bradykinesia, muscular rigidity, and tremor. The substantia nigra and nerve terminals in the striatum (caudate nucleus and putamen) degenerate, and the clinical signs presumably result from decreased production of dopamine in the neurons of the basal ganglia leading to the putamen and caudate nucleus. The effects of this dopaminergic deficiency may be compounded by the unopposed effects of cholinergic neurons bordering the basal ganglia. The resulting clinical syndrome (parkinsonism) includes tremor, rigidity, akinesia, and postural instability.

Newer therapies have been developed to arrest or even reverse the progression of this disease. Therapy is directed at (1) increasing the neuronal release of

dopamine or the receptor's response to dopamine, (2) stimulating the receptor directly with bromocryptine and lergotrile, (3) implanting dopaminergic tissue, or (4) decreasing cholinergic activity. The new therapies using the monoamine oxidase inhibitor deprenyl or adrenal medullary transplants to slow the progression of disease appear promising. [508] [509] There is insufficient experience with deprenyl in the perioperative milieu to make proscriptions about its use. Anticholinergic agents have been the initial drugs of choice, as they decrease tremor more than muscle rigidity. Because dopamine does not pass the blood-brain barrier, its precursor, L-dopa (levodopa) is used. Unfortunately, L-dopa is decarboxylated to dopamine in the periphery and can cause nausea, vomiting, and arrhythmia. These side effects are diminished by administration of alpha-methylhydrazine (Carbidopa), a decarboxylase inhibitor that does not pass the blood-brain barrier. Refractoriness to L-dopa develops; it is now debated if the drug should be used only when symptoms cannot be controlled with other anticholinergic medications. "Drug holidays" have been suggested as one means of restoring the effectiveness of these compounds, but cessation of such therapy may result in a marked deterioration of function and the need for hospitalization. Therapy for Parkinson's disease should be initiated before surgery and continued through the morning of surgery; such treatment seems to decrease drooling, the potential for aspiration, and ventilatory weakness. [510] [511] [512] [513] Reinstituting therapy promptly after surgery is crucial, [501] [508] [509] [510] [511] [512] [513] [514] as is avoiding such drugs as phenothiazines and butyrophenones (droperidol) that inhibit release of dopamine (and perhaps alfentanil) or that compete with dopamine at the receptor. [510] [514] Clonapine (a benzodiazepine) appears not to worsen the movement disorders of Parkinson disease and has been used postoperatively to stop levodopa-induced hallucinations.

Dementia, a progressive decline in intellectual function, can be caused by treatable infections (e.g., syphilis, cryptococcosis, coccidioidomycosis, Lyme disease, tuberculosis), myxedema, vitamin B_{12} deficiency, chronic drug or alcohol intoxication, metabolic causes (liver and renal failure), neoplasms, partially treatable infections (HIV), untreatable infections (Creutzfeldt-Jakob syndrome), or decreased acetylcholine in the cerebral cortex (Alzheimer disease). This last condition occurs in more than 0.5 percent of Americans. [498] [515] [516] [517] Although these patients are often given cholinergic agonists, controlled trials of these drugs have not as yet shown major significant benefits. [515] [516] [518] Gingko has been advertised and has improved the subjective symptoms in 37 percent of patients versus 23 percent of patients given placebos. However, the commonness of Alzheimer disease and the desperateness of the patients and their families have now widened such therapies. These families often desire surgery, but the interactions with perioperative analgesic and anesthetic drug therapies are not well established. Most reversible dementias are either drug-induced deliriums or depression. [515] [516] [519] Creutzfeldt-Jakob disease has been transmitted inadvertently by surgical instruments and corneal transplants; the causative virus is not inactivated by heat, disinfectants, or formaldehyde.

More than 90 percent of patients with chronic recurring headaches are diagnosed as having migraine, tension, or cluster headaches. The mechanism of tension or cluster headaches may not differ qualitatively from that for migraine headaches; all may be manifestations of labile vasomotor regulation. [520] A headache is said to be migraine if it is characterized by four of the following five " *POUND*ing" conditions: if it is *P*ulsating; if it lasts *O*ne day or more; if it is *U*nilateral; if there is *N*ausea; and if it *D*isturbs daily activities. [521]

Treatment for cluster and migraine headaches centers on the use of serotonin agents such as sumatriptan or ergotamine and its derivatives. [520] [521] [522] Other drugs that may be effective are propranolol, calcium-channel inhibitors, cyproheptadine, prednisone, antihistamines, tricyclic antidepressant drugs, phenytoin, and diuretic drugs, as well as biofeedback. Giant-cell arteritis, glaucoma, and all the meningitides, including Lyme disease, are other causes of headache that might benefit from treatment before surgery. [523] No other special treatment is indicated preoperatively for the patient who has a well-delineated cause for headaches. Acute migraine attacks can sometimes be terminated by ergotamine tartrate aerosol or by injection of sumatriptan or dihydroergotamine mesylate intravenously; general anesthesia has also been used. I normally continue all prophylactic headache medicine, except aspirin (because of the potential for bleeding), through the morning of surgery.

Back Pain, Neck Pain, and Spinal Canal Syndromes

Acute spinal cord injury is discussed earlier in the section on autonomic dysfunction. Although it is a common problem, little is written about the anesthetic management of syndromes related to herniated disc, spondylosis (usually of advancing age), and the congenital narrowing of the cervical and lumbar canal that gives rise to symptoms of nerve root compression. [524] [525] One report stresses the importance of the vascular component in the mechanism of damage to the spinal cord and, hence, the theoretical desirability of slight hypertension perioperatively. [526] Another report suggests the use of awake intubation, a fiberoptic bronchoscope, and evoked potential monitoring. [524] The preoperative management of the patient about to undergo chemonucleolysis is discussed earlier in the section on anaphylaxis. Other than the commonsense approach of seeking neurologic consultation or, if necessary, using awake positioning of patients in a comfortable position prior to emergency root-decompression procedures, no special procedures appear to be necessary.

Demyelinating Diseases

Demyelinating diseases constitute a diffuse group of diseases ranging from those with uncertain causes (e.g., multiple sclerosis, where genetic epidemiologic and immunologic factors are probably all involved and beta-interferon appears to be a promising treatment [527]) to those that follow infection, vaccination (e.g., Guillain-Barre syndrome), or antimetabolite treatment of cancer. Therefore, demyelinating disease can present with very diverse symptoms. Apparently, there is a risk of relapse of these diseases immediately after surgery. [528] Because relapse may occur because of rapid electrolyte changes in the perioperative period, such changes might be avoided. Also, perioperative administration of steroids has been advocated as a protective measure. [209] Thus far, no mode of treatment has been shown to alter most of these disease processes, although ACTH, steroids, beta-interferon, and plasmapheresis may ameliorate or abbreviate a relapse, especially of multiple sclerosis and (if started within 2 weeks of onset) of Guillain-Barre syndrome. [529] Such an effect is consonant with the hypothesis of an immunologic disorder as the cause of these diseases.

Sleep apnea may be considered a demyelinating or degenerative CNS disease or a peripheral disease of obesity, depending on etiology. Both types (central and peripheral etiologies) appear to be increasingly common and are present in more than 5 percent of elderly African-Americans. Because sleep apnea poses many problems for postoperative pain control, I now recommend using only nonsteroidal anti-inflammatory drugs for pain relief if I cannot monitor these patients in a second-stage recovery unit. [530] [531] [532]

Metabolic Diseases

Included in the category of metabolic diseases is nervous system dysfunction secondary to porphyrias, alcoholism, uremia, hepatic failure, and vitamin B_{12} deficiency. The periodic paralysis that can accompany thyroid disease is discussed under neuromuscular disorders (see later).

Alcoholism or heavy alcohol intake is associated with acute alcoholic hepatitis (Ch. 54) (the activity of which declines as alcohol is withdrawn), myopathy and cardiomyopathy that can be severe, and withdrawal syndromes. The best questions to ask in seeking a history of alcohol intake are, "Have you ever had a drinking problem?" and "Have you had a drink in the last 24 hours?" These questions have a higher sensitivity and specificity than many other longer series of questions about alcoholism [533] (Ch. 23) . Within 6 to 8 hours of withdrawal, the patient may become tremulous, a state that usually subsides within days or weeks. Alcoholic hallucinosis and withdrawal seizures generally occur within 24 to 36 hours. These seizures are generalized grand mal attacks; when focal seizures are manifest, other causes should be sought. Delirium tremens usually appears within 72 hours of withdrawal and is often preceded by tremulousness, hallucinations, or seizures. These three occurrences, combined with perceptual distortions, insomnia, psychomotor disturbances, autonomic hyperactivity, and, in a large percentage of cases, another potentially fatal illness (e.g., bowel infarction or subdural hematoma), comprise delirium tremens. This syndrome is now treated with benzodiazepines. Nutritional disorders of alcoholism include alcoholic hypoglycemia and hypothermia, alcoholic polyneuropathy, Wernicke-Korsakoff syndrome, and cerebellar degeneration. In alcoholic patients (i.e., those who drink at least two six-packs of beer, one pint of whiskey, or the equivalent per day), emergency surgery and anesthesia (despite alcoholic hepatitis) are not associated with worsening abnormalities of liver enzymes. [533] In addition, about 20 percent of alcoholic patients also have COPD. The patient who has a history of alcohol abuse therefore warrants careful examination of many systems for quantification of preoperative physical status.

Although hepatic failure can lead to coma with highoutput cardiac failure, unlike uremia, it does not lead to chronic polyneuropathy. Uremic polyneuropathy is a distal symmetric sensorimotor polyneuropathy that may be improved by dialysis. The use of depolarizing muscle relaxants has been questioned in polyneuropathies (Ch. 12) . I believe

that patients who have a neuropathy associated with uremia should not be given succinylcholine because of a possible exaggerated hyperkalemic response.

Pernicious anemia caused by vitamin B_{12} deficiency may result in subacute combined degeneration of the spinal cord; the signs are similar to those of chronic nitrous oxide toxicity. Both pernicious anemia and nitrous oxide toxicity are associated with peripheral neuropathy and disorders of the pyramidal tract and posterior column (which governs fine motor skills and the sense of body position). Combined system disease can also occur without anemia, as can nitrous oxide toxicity in dentists and nitrous oxide abusers. Patients with B_{12} deficiency and anemia, if treated with folate, improve hematologically but progress to dementia and severe neuropathy. It may thus be prudent to give an intramuscular administration of 100 mug of vitamin B_{12} before giving folate to the patient who has signs of combined system degeneration. [534]

The porphyrias are a constellation of metabolic diseases that result from an autosomally inherited lack of functional enzymes active in the synthesis of hemoglobin. Figure 25-20 depicts schematically the abnormalities that result from these enzyme deficits. It is important to note that types 1, 3, and 4 porphyrias can cause life-threatening neurologic abnormalities. These conditions are characterized by the presence of aminolevulinic acid (ALA) and/or porphobilinogen in urine, substances that do not occur in porphyria cutanea tarda, a disease that does not incur neurologic sequelae. [535] In acute intermittent porphyria, the typical pattern consists of acute attacks of colicky pain, nausea, vomiting, severe constipation, psychiatric disorders, and lesions of the lower motor neuron that can progress to bulbar paralysis. Certain drugs can induce the enzyme ALA synthetase, exacerbating the disease process. [536] [537] [538] These sensitizing drugs include barbiturates, meprobamate, chlordiazepoxide, glutethimide, diazepam, hydroxydione, phenytoin, imipramine, pentazocine, birth control pills, ethyl alcohol, sulfonamides, griseofulvin, and ergot preparations. Patients often have attacks during infection, fasting, or menstruation. Administration of glucose suppresses ALA synthetase activity and prevents or ablates acute attacks. Drugs used in anesthetic management that are reported to be safe for patients with porphyria include neostigmine (Prostigmin), atropine, gallamine, succinylcholine, *d*-tubocurarine, pancuronium, nitrous oxide, procaine, propofol, propanidid, etomidate, meperidine, fentanyl, morphine, droperidol, promazine, promethazine, and chlorpromazine. [536] [537] [538] Although ketamine has been used, postoperative psychoses attributed to the disease may be difficult to distinguish from those possibly caused by ketamine. In addition, although ketamine and etomidate are reported to be safe in humans, they seem to be porphyrinogenic in rats. Propofol has been used without provoking porphyria in at least two susceptible patients. [536] [537]

Figure 25-20 Schematic depiction of the functional enzyme deficits that occur in some of the porphyrias. ALA, aminolevulinic acid; PBG, porphobilinogen.

Neuromuscular Disorders

Neuromuscular disorders consist of conditions affecting any major component of the motor unit: motor neuron, peripheral nerve, neuromuscular junction, and muscle. Neuropathies may involve all components of the nerve, producing sensory, motor, and autonomic dysfunction, or only one component. Myopathies may involve only proximal or distal muscles, or both.

Myasthenia gravis (Ch. 12) is a disorder of the muscular system caused by partial blockade or destruction of nicotinic acetylcholine receptors by IgG antibodies. This syndrome is characterized by fluctuating ophthalmoplegia, ptosis, and bulbar, respiratory, or limb weakness and is confirmed by a beneficial response to cholinergic drugs. [539] [540] These patients often have other autoimmune diseases, including rheumatoid arthritis and hypothyroidism. Thirty-three percent of patients with myasthenia gravis have bulbar symptoms (and are therefore subject to problems with disposing of secretions) at presentation, and more than 60 percent of people with myasthenia gravis will have bulbar symptoms at some time during their life. This symptom should not be confused with respiratory muscle weakness, which occurs much less commonly.

The severity of the disease correlates with the ability of the antibodies to decrease the number of available acetylcholine receptors. [539] Treatment of myasthenia is usually begun with anticholinesterase agents but, in moderate and severe disease, progresses to steroids and thymectomy. [539] [540] Immunosuppressive drugs and plasmapheresis are begun if the more conservative measures fail. [539] [540]

One major problem for the anesthesiologist involves the use of muscle relaxants and their reversal. [541] [542] Because much of the care of myasthenia gravis patients involves tailoring the amount of anticholinesterase medication to the maximal muscle strength of the patient, derangement of the course of the patient during surgery could necessitate reassessment of the drug dosage. For that reason, several researchers recommend withholding all anticholinergic drugs for 6 hours before surgery and reinstituting medicine postoperatively with extreme caution, as the sensitivity of these patients to such drugs may have changed. In addition, there has been some concern that anticholinergic drugs may facilitate a high incidence of bowel anastomotic leaks in those patients who have undergone bowel anastomoses. Small doses of succinylcholine can be used to facilitate endotracheal intubation; tiny doses of nondepolarizing drugs can be used for intraoperative relaxation not obtained by regional anesthesia or volatile agents. Controlled ventilation is usually required for at least 24 to 48 hours postoperatively. [540] [541] [542] [543] This practice is especially important in cases involving myasthenia gravis of more than 6 years' duration, chronic obstructive lung disease, daily pyridostigmine requirement of 750 mg in association with significant bulbar weakness, and vital capacity of less than 40 mL/kg. [542] [543]

Eaton-Lambert syndrome (myasthenic syndrome) is characterized by proximal limb muscle weakness. Strength or reflexes may increase with repetitive effort. Affected patients have a decreased release of acetylcholine at the neuromuscular junction. Guanidine therapy enhances the release of acetylcholine from nerve terminals and improves strength. Men who have this syndrome generally have small-cell carcinoma of the lung or other malignancy, whereas women often have malignancy, sarcoidosis, thyroiditis, or a collagen-related vascular disease. In addition, these patients have increased sensitivity to both depolarizing and nondepolarizing muscle relaxants. [544] [545] Eaton-Lambert syndrome is also associated with an autonomic nervous system defect characterized by gastroparesis, orthostatic hypotension, and urinary retention. [544]

Dermatomyositis and polymyositis are characterized by proximal limb muscle weakness with dysphagia. These conditions are associated with malignancy or collagen-related vascular disease, often involving respiratory and cardiac muscle.

Periodic paralysis is another disease in which sensitivity to muscle relaxants increases. Periodic weakness starts in childhood or adolescence and is precipitated by rest after exercise, sleep, cold, surgery, or pregnancy. Hypokalemic and hyperkalemic forms exist and are associated with cardiac arrhythmias. Like thyrotoxic periodic paralysis, these hypokalemic and hyperkalemic forms usually spare the respiratory muscles. Anesthetic management consists of minimizing stress and maintaining normal fluid and electrolyte states and body temperature. [544] [545] [546] [547]

Muscular dystrophy patients now survive into their late 20s or early 30s. Complicating their disease are respiratory infections, kyphoscoliosis, muscle contractions, and cardiac abnormalities. Duchenne muscular dystrophy is a sex-linked recessive disease, at the Xp21 locus, the most common of the muscular dystrophies. [548] It occurs after 2 years of age, at which time patients experience a rapid progression of muscle disease that leads to incapacity in their teens. Cardiac involvement is common when the disease affects proximal and pelvic muscles, and respiratory failure is a common cause of death. Limb-girdle muscular dystrophy is not as severe as Duchenne muscular dystrophy; it occurs later in life, has cardiac involvement, and is transmitted as an autosomal recessive trait. Facioscapulohumeral muscular dystrophy is a disease of autosomal dominant inheritance that has a mild clinical form in adolescence. Patients with this disorder have a normal life-span without an increased risk of cardiac complications; however, postoperative respiratory deaths have been recorded. Myotonic dystrophy is a disease in which continued active contraction of the muscles persists after voluntary effort or stimulation has ceased. This autosomal dominant inherited disease begins at 20 to 40 years of age and is associated with cardiomyopathy, baldness, testicular atrophy, cataracts, intellectual and emotional abnormalities, and premature death in the 50- to 60-year age range. The facial, sternocleidomastoidal, distal, and pharyngeal muscles become weak and atrophy. Because the disease involves the muscles themselves and not their innervation, conduction anesthesia cannot produce adequate relaxation of tonic muscles. Gastric dilation has also been reported to be a problem, as has malignant hyperthermia. As with the other forms of muscular dystrophies, most problems in myotonic dystrophy arise from cardiac arrhythmias and inadequacies of the respiratory muscles. [549] For all the forms of muscular dystrophy, as for all the neuropathies (discussed earlier), there have been problems related to exaggerated serum potassium release after administration of depolarizing muscle relaxants (Ch. 12) .

Malignant hyperthermia (Ch. 27) in the patient or in a

relative of the patient merits careful history-taking and at least consideration of performing a test for susceptibility to the condition (Ch. 23) . Prophylaxis with intravenous dantrolene sodium (Dantrium) may also be warranted (Ch. 27) . In some cases, malignant hyperthermia has been associated with recognizable musculoskeletal abnormalities such as strabismus, ptosis, myotonic dystrophy, hernias, kyphoscoliosis, muscular dystrophy, central core disease, and marfanoid syndrome. The appropriate preparation for the patient with previous masseter spasm, or trismus, is a matter of considerable debate. I prepare for malignant hyperthermia (e.g., I ensure a contaminant-free machine, use nontriggering agents, and have a malignant hyperthermia cart in the room) but do not routinely perform muscle biopsy or prescribe dantrolene prophylaxis. [550] [551] Malignant hyperthermia occurs most frequently among children and adolescents, the incidence being 1 in 14,000 administrations of anesthetic. The incidence increases to 1 in 2,500 among patients requiring squint surgery. Questions to ask the parents during the preoperative evaluation include the following: Does your child become rigid when upset? Does your child sweat profusely when upset? However, the sensitivity and specificity of such questions in predicting malignant hyperthermia have not been confirmed. The reader is referred to Chapters 23 and 27 for a complete discussion of the screening procedure to use.

Down Syndrome

Down syndrome (trisomy 21) occurs 1.5 times in 1,000 live births. It is associated with congenital cardiac lesions, such as endocardial cushion defects (40%), ventricular septal defects (27%), patent ductus arteriosus (12%), and tetralogy of Fallot (8%), necessitating prophylactic antibiotics prior to predictable bacteremic events. Down syndrome is also associated with upper respiratory infections; with atlanto-occipital instability (in about 15% of patients, [552] [553] in which it is asymptomatic in most cases) and laxity of other joints; with thyroid hypofunction (50%); with an increased incidence of subglottic stenosis; and with enlargement of the tongue. [554] No abnormal responses to anesthetics or anesthetic adjuvants have been substantiated. A reported sensitivity to atropine has been disproved, although administration of atropine to any patient given digoxin for atrial fibrillation should be done with extreme care. [554] Examination for the conditions associated with Down syndrome should precede surgery.

Preoperative Prediction of Patients Having Increased Intracranial Pressure During Neurosurgery

Symptoms and signs of increased intracranial pressure include morning headache or headache made worse by coughing, nausea, vomiting, disturbances of consciousness, history of large tumors, tumors involving the brain stem, neck rigidity, and papilledema. Patients having theses signs, large ventricles (as seen on radiography or images of the brain), or edema surrounding supratentorial tumors should be considered at risk of intraoperative intracranial hypertension. These patients may benefit from preoperative treatment or anesthetic management that assumes this possibility [555] (Ch. 52) .

Other preoperative considerations for patients with neurologic disease that can cause intracranial hypertension are the associated hypoventilation and hypoxia in patients who have severe hemiplegia and the presence of subarachnoid bleeding or other forms of intracranial hemorrhage (especially likely in women given heparin who have two or more cerebral infarcts on CT scan). [556] Many strokes or transient ischemic attacks have a possible cardiac origin (59 of 184 patients). [557] [558] The drugs used to prevent cerebral arterial spasm, calcium channel blockers, are discussed in the last section of this chapter.

Mental Disorders

Perhaps the most important preoperative consideration for patients with mental disorders, in addition to developing rapport, is understanding their specific drug therapy and its effects and side effects. Lithium, tricyclic antidepressants, selective serotonin reuptake inhibitors, phenothiazines, butyrophenones, and monoamine oxidase inhibitors are used in these patients. [559] These drugs have potent effects and side effects that are discussed in the last section of this chapter.

RENAL DISEASE, INFECTIOUS DISEASES, AND ELECTROLYTE DISORDERS

One may ask why preoperative preparation of the patient with renal disease is discussed in the same section as preoperative preparation of the patient with an infectious disease. Although it is commonly recommended that no surgery except emergency or curative (e.g., drainage of an abscess) be performed in patients with infectious disease, it has become evident that renal insufficiency can be caused by antimicrobial agents [560] and that sepsis, not shock, is probably the leading cause of acute postoperative renal failure. [561] The anesthesiologist has an important role to play in preventing the onset and consequences of renal failure and its initiators. [562] [563] The linking of renal failure to electrolyte disorders is more obvious: the kidney is the primary organ for regulating body osmolality and fluid volume and has a major role in the excretion of the end products of metabolism. In performing these functions, the kidney becomes intimately involved in the excretion of electrolytes.

The patient with renal insufficiency whose own kidneys are still functioning is distinct not only from the patient with end-stage renal disease whose renal functions are provided by a dialysis machine, but also from the patient who has a transplanted kidney. These three groups of patients require very different preoperative preparation. In addition, acute changes in renal function present quite a different problem than do chronic alterations in function. [562] [563] Certain renal diseases require different preoperative preparation than others, but generally renal disease of any origin presents the same preoperative problems (Chs. 18 , 34 , and 53) .

Renal Disease

Causes and Systemic Effects of Renal Disorders

The nephrotic syndrome may develop in patients with glomerular diseases without disturbing tubular function. The soundness of tubular function is an important consideration, as tubular dysfunction with attendant uremia presents quite different problems than does glomerular disease with only the nephrotic syndrome. This is not to minimize the adverse effects of glomerular disease; the nephrotic syndrome consists of massive proteinuria and consequent hypoalbuminemia. The resulting reduction in plasma oncotic pressure diminishes plasma volume; this calls forth compensatory mechanisms that result in retention of sodium and water. As a result, a common clinical finding in nephrotic syndrome is edema. Thus, patients with the nephrotic syndrome may have excess total body water and decreased intravascular volume. In addition, diuretics are often given in attempts to decrease edema. Although serum creatinine and creatinine clearance have limitations as indices of glomerular filtration rate (GFR) (inulin clearance is still the gold standard), these measurements are, for now, the most readily available to the anesthesiologist. [563] Plasma creatinine levels reflect endogenous muscle catabolism and dietary intake, as well as urinary excretion. Urinary excretion depends on both filtration and secretion by the kidney. Drugs that are commonly used in the preoperative and perioperative periods can distort this measure of glomerular filtration: Cimetidine and trimethoprim interfere with secretion, increasing plasma creatinine and decreasing creatinine clearance without altering filtration. [563] It should also be remembered that the commonly used methods for measuring creatinine have a 95 percent confidence limit of more than 20 percent for GFR greater than 30 mL/min. Thus, a normal creatinine level of 1.3 mg/dL might give a measured value ranging from 1.0 to 1.5 mg/dL. [563]

Furthermore, in patients with the nephrotic syndrome in whom renal tubular function has been preserved, hypovolemia appears to be a significant cause of deteriorating tubular renal function. [563] [564] [565] [566] [567] Consequently, I advocate the same intense preoperative, intraoperative, and postoperative fluid management for patients with the nephrotic syndrome as I do for patients with diminished tubular function. Admittedly, no randomized study shows that close control of intravascular volume status in these groups of patients preserves renal tubular function (or any other measure of perioperative morbidity) to a greater degree than does less rigid control.

Uremia, the end result of renal tubular failure (i.e., failure of the concentrating, diluting, acidifying, and filtering functions), presents in many ways. Changes occur in the cardiovascular, immunologic, hematologic, neuromuscular, pulmonary, and endocrine systems, as well as in bone. These alterations are ascribed either to the toxic end products of protein metabolism or to an imbalance in the functioning of the kidney. As the number of functioning nephrons diminishes, the still-functioning nephrons attempt to increase some solute and body composition preservation functions at the expense of other functions, such as the excretion of phosphate. The accumulation of phosphate increases parathormone levels, which in turn produces osteodystrophy. Osteodystrophy can be managed by (1) restriction of dietary phosphate, (2) the use of gels (e.g., aluminum hydroxide or carbonate) that bind with intestinal phosphate, (3) calcium supplementation, or (4) parathyroidectomy. [568]

Certain alterations in uremia, such as neuropathy, are most logically attributed to an accumulation of toxic metabolites. Peripheral neuropathy is most often sensory and of the lower extremities but may also be motor; peripheral neuropathies are often improved with hemodialysis and can be dramatically reversed with transplantation. The use of depolarizing muscle relaxants in patients with peripheral neuropathy is controversial; it is discussed in the section on neuropathies (Ch. 12) . Tubular function is commonly assessed by acidifying and concentrating capabilities. [569] Although these are crude tests, these capabilities are usually readily assessed by measuring urine pH level and specific gravity. Better assessment of renal blood flow, for the purpose of improving renal blood flow and its distribution, is promised by the use of contrast ultrasound in the operating room. [570] Along with the altered volume states and cardiac complications in uremic patients, autonomic neuropathy may contribute to hypotension during anesthesia. Atherosclerosis is often accelerated in uremic patients; hypertension, with its attendant consequences, is very common.

Cardiac failure (especially episodic) frequently occurs in uremic patients because of the presence of many adverse conditions: anemia with increasing myocardial work, hypertension, atherosclerosis, and altered volume states. Pericarditis can present with pericardial rub alone or with pain (with or without hemorrhage). Cardiac tamponade should be ruled out on the basis of clinical features and by echocardiography if this diagnosis is seriously suspected preoperatively. Also, cardiac tamponade should be treated or planned for preoperatively.

If anemia is present, its severity generally parallels the degree of uremia; chronically uremic patients seem to adapt well to anemia. No hard data substantiate the need to give a preoperative blood transfusion to a chronically uremic patient, even when preoperative hematocrit is as low as 16 or 18 vol percent. One of the major historical reasons for not transfusing blood in patients having end-stage renal disease has been disproved: Data show that the more blood transfusions a transplant recipient receives before transplant, the greater the chance that the transplant will function successfully. [571] This immunosuppressive effect of transfusions is now routinely used in transplantation. However, the development of recombinant human erythropoietin may obviate the need for transfusions in chronically uremic patients in the future. Administration of recombinant human erythropoietin to patients in chronic and progressive renal failure showed an average increase in hematocrit level of 10 percent above baseline within 3 weeks, with no serious side effects. [572] The balancing of the immunosuppressive uses of blood transfusions versus the benefits of erythropoietin and risks of transfusion remains to be determined. In uremic patients, coagulation and platelet adhesiveness may be abnormal and factor III activity decreased. Even those uremic patients not given corticosteroids or immunosuppressive drugs may demonstrate abnormal immunity, perhaps meriting increased attention regarding the procedures that lessen patient cross-contamination.

Uremic patients exhibit a wide variety of metabolic and endocrinologic disorders, in addition to hyperparathyroidism, [568] including impaired carbohydrate tolerance, insulin resistance, type IV hyperlipoproteinemia, autonomic insufficiency, hyperkalemia, and anion-gap acidosis (caused by the inability of the kidneys to reabsorb filtered bicarbonate and to excrete sufficient ammonium into the urine). [573] Also, the excretion and pharmacokinetics of drugs are different in uremic patients than in normal patients. In addition, the complications of hemodialysis include hepatitis B (and persistent hepatitis B antigenemia), nutritional deficiencies, electrolyte and fluid imbalances, and mental disorders. Because these conditions can lead to serious perioperative morbidity, they should be evaluated before surgery. No data, however, substantiate the hypothesis that preoperative optimization of these metabolic and endocrinologic disorders reduces perioperative risk in the uremic patient.

As with uremic patients, preoperative optimization of volume status is paramount in patients with kidney stones. [574] Seventy-five percent of all kidney stones are composed of calcium oxylate. Patients with these stones often take diuretic drugs, avoid calcium-rich foods, or restrict salt intake. Prevention of dehydration by institution of intravenous fluid therapy along with restricted oral intake of protein may be as important for these patients as it is for patients with struvate or uric acid stones. Struvate stones often result from urinary infection. Uric acid stones can be prevented by treatment with allopurinol, by preoperative hydration, or by alkalization of the urine. Acidosis may contribute to stone formation. Again, optimal intravascular volume status is important in preventing stones and preserving renal function. More thorough discussion of renal function and physiology is provided in Chapter 18 . Chapter 53 deals with the complexities of managing patients for renal surgery and other urologic procedures.

Creatinine clearance in conjunction with free water clearance appears to be the most accurate way of quantifying, for pharmacokinetic purposes, the degree of decreased renal function [575] [576] [577] (Ch. 34) . For the patient with stable renal function, creatinine clearance, which is a rough estimate of GFR, can be approximated by noting the serum creatinine levels: A doubling of creatinine level represents a halving of GFR. Thus, a patient with a stable serum creatinine level of 2 mg/dL would have a GFR of approximately 60 mL/min. A stable serum creatinine level of 4 mg/dL would accompany a GFR of approximately 30 mL/min, and a stable serum creatinine of 8 mg/dL would accompany a GFR of 15 mL/min or less. When pregnancy and considerable edema are not present and the serum creatinine level is stable, the following formulas can be used to estimate creatinine clearance and free water clearance [575] [576] [578]

Note that renal function must be stable. Unstable renal function often is associated with changes in serum creatinine levels that lag by several days. Although knowing the serum creatinine level is more useful than knowing the blood urea nitrogen level, the latter provides some information, as discussed in the next section.

Free water clearance is a measure of renal concentrating ability and is normally -25 to -100 mL/h, becoming more positive in renal insufficiency states. It may also become more positive in patients who have head injury or high blood alcohol levels, or who are undergoing aggressive fluid infusion or administration of diuretics. [577]

The Patient With Insufficient but Functioning Kidneys

One of the greatest challenges for the anesthesiologist is presented by patients with insufficient renal function whose renal function must be preserved during surgery. The many uremic symptoms and great perioperative morbidity associated with uremia can probably be avoided by attention to detail in the preoperative and perioperative management of patients with insufficient but still functioning kidneys. [561] [562] [563] [564] [565] [566] [567] [568] First, studies demonstrate that acute postoperative renal failure is associated with an extremely high mortality rate. Moreover, acute perioperative renal failure is most likely to occur in patients who have renal insufficiency before surgery, are older than 60 years, and have preoperative left ventricular dysfunction. [579] Proper hydration before surgery probably decreases mortality following acute renal failure due to radiocontrast agents. [566] [567] [568] Clues as to the presence of hypovolemia or hypervolemia should be sought from the history and physical examination (e.g., weight loss or gain, thirst, edema, orthostatic hypotension and tachycardia, flat neck veins, dry mucous membranes, decreased skin turgor). In seriously ill patients, insertion of a pulmonary arterial catheter will permit more precise monitoring of intravascular fluid volume. To preserve normal renal function, infusion of saline, mannitol, furosemide, or low-dose dopamine has been recommended. [580] [581] [582] [583] [584] [585] [586] These therapies should be initiated with caution because saline infusions and mannitol can lead to fluid overload and myocardial damage; also, diuretic drugs given intraoperatively can produce postoperative hypovolemia, which worsens renal function. Maintaining normal intravascular fluid volume can be guided by pulmonary capillary wedge pressure. Maintaining normal intravascular fluid volume has prevented impairment of renal function after abdominal aortic reconstruction, even when urinary volumes were low. [587] Other causes of deterioration in function in chronic renal insufficiency are low cardiac output or low renal blood flow (in prerenal azotemia, whether because of cardiac failure or because of fluid depletion from diuretic drugs, BUN often increases disproportionately to increases in creatinine), urinary tract infection, use of nephrotoxic drugs, hypercalcemia, and hyperuricemia. These conditions and drugs should be avoided; if any of these conditions exists, it should be treated preoperatively.

The Patient Undergoing Dialysis

Because the patient undergoing dialysis has already lost natural renal functioning, the emphasis in preoperative assessment

shifts toward protecting other organ systems and toward optimally maintaining vascular access sites for cannulation. Usually this does not require invasive monitoring. Emphasis is placed on intravascular fluid volume and electrolyte status, which can be ascertained by knowing when the patient last underwent dialysis, how much weight was normally gained or lost with dialysis, whether fluid loss was peritoneal or intravascular, and what electrolyte composition the blood was dialyzed against. Although preoperative dialysis may benefit patients who have hyperkalemia, hypercalcemia, acidosis, neuropathy, and fluid overload, the resulting dysequilibrium between fluid and electrolytes can cause problems. Because hypovolemia induced by dialysis can lead to intraoperative hypotension, I try to avoid weight and fluid reduction when giving preoperative dialysis. Also, hypopnea has been found to occur during and after dialysis when the dialysate contained acetate. [588] Avoiding an acetate bathing solution may prevent this cause of hypoventilation.

The Patient Who Has Had a Renal Transplant

More than 100,000 patients have received renal transplants (compared with 65,000 currently undergoing dialysis in the United States). Approximately 55 percent are still alive, although one-third must undergo dialysis. The advantages, in addition to increased survival, include improvement of the anemia, the endocrine and sexual functions, and the fatigue that inhibit employment and enjoyment for the dialysis patient. The disadvantages are the cost and risks of the transplant operation and of the chronic use of immunosuppressants. When these patients have subsequent surgery, the state of their renal function must be determined (i.e., whether they have normal renal function, insufficient but still functioning kidneys, or end-stage renal disease requiring hemodialysis). Descriptions of side effects from immunosuppressive drugs should also be sought. Drugs used preoperatively and intraoperatively to prevent acute rejection themselves have serious side effects that encourage close monitoring of blood glucose and cardiovascular function. [571] [589] [590] Because renal transplant greatly increases the risk of infection, it is very important to avoid invasive monitoring and prevent patient cross-contamination.

Drugs in Renal Failure

Patients with renal azotemia have a 3-fold or higher risk of an adverse drug reaction than do those with normal renal function. [591] [592] [593] [594] [595] Risk is increased by two conditions. (1) *Excessive pharmacologic effects* result from high levels of a drug or its metabolite (e.g., the metabolite of meperidine) in the blood because of physiologic changes in target tissues induced by the uremic state. An example would be excessive sedation in the uremic patient having standard blood levels of sedative hypnotic drugs. (2) *Excessive administration of electrolytes with drugs* also increases the risk of an adverse drug reaction. For example, the standard dose of

penicillin contains 1.7 mEq of potassium/1 million units. [591] [592] [593] [594] [595] Administration of standard doses of drugs that depend on renal excretion for their elimination can result in drug accumulation and enhanced pharmacologic effect. Bennett et al [591] and Gibson [594] have provided dosing guidelines for many drugs used by anesthesiologists for patients with and without renal failure.

Infectious Disease

Because it is commonly recommended that no surgery except emergency or essential surgery (e.g., drainage of an abscess) be performed when an acute infectious disease is present, and because renal insufficiency can be caused by antimicrobial agents, [560] [565] [566] renal function and organ damage due to renal insufficiency should be assessed preoperatively when infectious disease is present. Prophylactic administration of antibiotics (see Tables 25-34 and 25-35) (Table Not Available) helps prevent sepsis from bacteremic interventions. [596] [597] If therapeutic levels of an antibiotic are given and a reduction in fever occurs (presumably because of decreased levels of released interleukin-2, spinal anesthesia might be considered (using benefit-to-risk judgments) by the anesthesiologist when an acute infectious disease is present. [598]

Sepsis is a leading cause of postoperative morbidity, [561] [562] [566] [567] probably through a decrease in systemic vascular resistance related to activation of the complement system and other mediators. Thus, attention to the effects of antibiotic drugs must be supplemented by attention to intravascular volume status. [564] [565] [566] [567] [599] [600] The degree of impairment of the infected organ and its effect on anesthesia should be assessed. For instance, endocarditis merits examination of volume status; antibiotic and other drug therapy and side effects [601] ; myocardial function; and renal, pulmonary, neurologic, and hepatic function--those organ systems that can be affected by endocarditis.

Although all surgery except emergency or essential is proscribed when an acute infectious disease is present [436] [437] [438] [439] [440] [441] [442] [443] [444] [445] [446] [448] [449] [450] [451] [602] (also see section on upper respiratory infections in the pulmonary section of this chapter), many such diseases (e.g., influenza and pneumococcal pneumonia) are becoming less frequent because of successful immunization recommendations and programs. [603] [604] Whether the preoperative clinic can or should be used to increase use of preventive vaccines is currently being studied (Table 25-42) (Table Not Available) , but it is unclear whether vaccination during the 48 hours before surgery is effective or risky. [605] Furthermore, even though acute infections are less common, surgery for patients with chronic viral diseases such as hepatitis and HIV is more frequent. Many of these patients may also harbor opportunistic infections such as tuberculosis or may have other systemic problems. Whether anesthesia and/or surgery exacerbates these infections or their systemic manifestations is not clear. [606]

At least two other considerations merit preoperative consideration: patient isolation to prevent contamination of the patient and health-care providers. Both concerns are real and are the focus of at least several published volumes. Nosocomial infection is a major source of postsurgical morbidity. [607] [608] [609] [610] [611] [612] [613] Acquired immunodeficiency syndrome [614] and many forms of hepatitis (A, B, and C) appear to be due to viral infections but require direct contact with blood or body fluids. Screening for specific viruses or for the chronic end-organ effects of these viruses [615] [616] [617] is now being done to reduce

TABLE 25-42 -- Estimated Potential Benefit of Full Use of Vaccines Currently Advocated for Adults, in General, and if Immunization Were Encouraged During the Perioperative Period

(Not Available)

Modified from Gardner and Schaffner [604]

the risk of infection to both recipients and health-care personnel during blood transfusions. The usual precautions appear to be largely effective, [618] but the risk is considerable if these precautions are not followed meticulously. [619]

Electrolyte Disorders

Disorders of calcium, magnesium, and phosphate balance were discussed in the section on diseases involving the endocrine system and disorders of nutrition. (Also see Chs. 34 , 38 , and 45.)

Hyponatremia and Hypernatremia

Electrolyte disorders are usually detected by determining the levels of electrolytes in serum. These concentrations reflect the balance between water and electrolytes. The osmolality of all body fluids is normally maintained within the narrow physiologic range of 285 to 290 mOsm/kg H_2O by integration of three key processes: thirst, ADH release, and responsiveness of the medullary collecting ducts to ADH. Because of the permeability of biologic membranes, intracellular and extracellular osmolality are almost always equal and can be estimated by the following formula:

This formula will become easier to calculate when we convert fully to the Systeme International d'Unites (metric system), as millimoles (mmol) can be substituted for mg/(factor) in this formula to read

with concentrations expressed in millimoles per liter (mmol/L). Although secretion of ADH is tightly controlled by osmotic stimuli at 285 to 290 mOsm/kg, the osmotic threshold for thirst is high (300 mOsm/kg), making this sign an important guide to volume deficiency.

Hyponatremia is perhaps the third most common fluid-electrolyte abnormality in hospitalized patients. (Magnesium deficiency occurs in as many as 25% [Ch. 23] ; and potassium deficiency, discussed later in this section, in as many as 10%.) Hyponatremias can occur in isotonic, hypertonic, or hypotonic forms. For example, isotonic hyponatremia can occur in protein or liquid accumulation states such as myeloma. Hypertonic hyponatremia can be present with hyperglycemia or with infusions of glycine (as in the transurethral resection of the prostate syndrome [620]). Hypotonic hyponatremia is the largest classification and is subdivided according to the state of the extracellular fluid into hypovolemic, isovolemic, or hypervolemic hypotonic hyponatremia. All three types require that excretion of renal water be impaired despite continued intake of dilute fluid. Common causes of *hypovolemic* hypotonic hyponatremia (Table 25-43) are GI losses [621] (vomiting, diarrhea), third-space losses (diuretics or salt-wasting nephropathy), or

TABLE 25-43 -- Causes of Hypotonic Hyponatremias[a]

TYPE OF HYPOTONIC HYPONATREMIA, AND CAUSES
HYPOVOLEMIC
Gastrointestinal losses
Vomiting
Diarrhea
Skin losses
Third-space losses

Lung losses
Renal losses
  Diuretics

  Urinary tract obstruction
Adrenal insufficiency
ISOVOLEMIC
Syndrome of inappropriate secretion of antidiuretic hormone
Renal failure
Water intoxication
Hypokalemia
Dysfunctional osmostat
HYPERVOLEMIC
Congestive heart failure
Nephrosis
Liver dysfunction
*Serum osmolality <280 mOsm/L

adrenal insufficiency. *Hypervolemic* hypotonic hyponatremic states complicate severe cardiac failure, [622] cirrhosis, nephrotic syndrome, or renal failure and are characterized by retention of sodium with disproportionately larger amounts of water.

The more common *isovolemic* hypotonic hyponatremia is caused by retention of water without sodium. Because edema is usually not clinically apparent, such patients appear isovolemic. Edema is most often caused by the syndrome of inappropriate ADH secretion. SIADH may be caused by CNS or pulmonary tumors or dysfunction. Secretion of ADH increases with age, rendering the elderly more prone to hyponatremia. Drugs that potentiate the secretion of ADH (tricyclic antidepressants and vincristine) or its effects on the medullary collecting duct system in the kidney (nonsteroidal anti-inflammatory drugs and chlorpropamide), or that have similar effects (oxytocin), may be more likely to cause hyponatremia in the elderly. To establish the diagnosis of SIADH, the physician should determine that the patient is free of renal and cardiac dysfunction, has normal adrenal and thyroid function, and is normovolemic. Urine osmolality would then be found to exceed 100 mOsm/kg, serum osmolality would be low, and urine sodium excretion would be higher than 20 mEq/L (20 mOsm/L).

Therefore, disturbances in serum sodium reflect alterations in glucose metabolism, renal function, or accumulation of body water. The last can be affected by disturbances in thirst, ADH release, and renal function. Thus, hyponatremia reflects a relative excess of free water and can occur when total body sodium increases (as in edematous disorders), when total body sodium is normal (as in excesses of free water because of SIADH), or when total body sodium decreases (as occurs with too-aggressive use of diuretic drugs). Definition of the cause defines treatment. For instance, water restriction is the mainstay of therapy for SIADH. Administration of demeclocycline is another option that corrects SIADH by inducing a reversible nephrogenic diabetes insipidus. The anesthesiologist is faced with the question: What levels of electrolytes require treatment prior to anesthesia? Although slowly developing hyponatremia usually produces few symptoms, the patient may be lethargic and apathetic. Chronic hyponatremia is better tolerated than acute hyponatremia because of mechanisms regulating intracellular fluid volume that alleviate brain edema; the loss of other solutes from the cell decreases the osmotic movement of water into cells. Despite this, severe chronic hyponatremia (i.e., serum sodium levels <123 mEq/L) can cause brain edema. [623] [624] By contrast, acute hyponatremia may manifest with severe symptoms requiring emergency treatment: profound cerebral edema with obtundation, coma, convulsions, and disordered reflexes and thermoregulatory control. [623] [624] Depending on the cause and relative total sodium and water content, treatment can range from administration of hypertonic saline or mannitol (with or without diuretic drugs) to restriction of fluids or administration of other drugs. [210] [623] [624] Because neurologic damage may develop if the serum sodium concentration is increased too rapidly, the rate of increase should not exceed 1 mEq/L/h. [209] [210] [624] After the serum sodium concentration has reached 125 mEq/L, therapy may consist of water restriction; more rapid correction may result in CNS demyelination. [209] [210] [624] In hyponatremic patients who have excess total body water secondary to SIADH, serum levels can be corrected by giving furosemide, 1 mg/kg, and hypertonic saline to replace loss of electrolytes in urine. [209] [623] [624] The diagnosis of SIADH is discussed earlier in this chapter *(Pituitary Abnormalities).*

Neither acute nor chronic hyponatremia necessitates the restoration of serum sodium levels to their normal levels; brain swelling usually disappears at a serum sodium level of 130 mEq/L. This leaves us with the question: What levels of serum sodium make anesthesia more risky? Because no data exist to answer this question, to allow for some error in caring for patients, I have arbitrarily chosen a flexible concentration of 131 mEq/L as the lower sodium limit for elective surgery. A discussion of intraoperative hyponatremia in patients undergoing transurethral prostatectomy [620] is in Chapter 53 .

Hypernatremia occurs much less commonly than hyponatremia. It is often iatrogenic in origin (e.g., it can be caused by failure to provide sufficient free water to the patient who is unconscious or who has had a recent stroke-induced deficit of the thirst mechanism) and can occur in the presence of low, normal, or excess total body sodium. The primary symptoms of hypernatremia relate to brain cell shrinking. Because too-rapid correction of hypernatremia can lead to cerebral edema and convulsions, correction should be made gradually. Again, with no data to support this stance, I believe that all patients undergoing surgery should have serum sodium concentrations of less than 150 mEq/L prior to anesthesia.

Hypokalemia and Hyperkalemia

Hypokalemia and hyperkalemia are also discussed in Chapters 34 , 36 , 38 , and 45 . The relationship between the measured potassium concentration in serum and the total body potassium stores can best be described using a scattergram. [126] [625] Only 2 percent of total body potassium is stored in plasma (4,200 mEq in cells and 60 mEq in extracellular fluid). In normal persons, 75 percent of the 50 to 60 mEq/L of total body potassium is stored in skeletal muscle, 6 percent in red blood cells, and 5 percent in the liver. Thus, a 20 to 25 percent change in potassium levels in plasma could represent a change in total body potassium of 1,000 mEq or more if the change were chronic, or as little as 10 to 20 mEq if the change were acute.

As with serum sodium levels, [623] [624] acute changes in serum potassium levels appear to be less well tolerated than chronic changes. Chronic changes are relatively well tolerated because of the equilibration of serum and intracellular stores that takes place over time to return the resting membrane potential of excitable cells to near-normal levels.

Hyperkalemia can result from factitious elevation of potassium (as in red blood cell hemolysis); excessive exogenous potassium from sources such as salt substitutes or, in large amounts, bananas; cellular shifts in potassium (owing to metabolic acidosis, tissue and muscle damage after burns, use of depolarizing muscle relaxants, or intense catabolism of protein); and decreased renal excretion (as occurs in renal failure, renal insufficiency with trauma, and therapy with potassium-sparing diuretic drugs, especially when combined with the angiotensin-converting inhibiting drugs or mineralocorticoid

deficiency). [625] [626] [627] [628] [629] [630] [631] Factitious hyperkalemia can occur when a tourniquet is left on for too long or even by simple fist clenching. [632]

The major danger in anesthetizing patients who have disorders of potassium balance appears to be abnormal cardiac function--that is, both electrical disturbance [626]

[627] [628] [629] and poor cardiac contractility. [627] [628] Hyperkalemia lowers the resting membrane potential of excitable cardiac cells and decreases the duration of the myocardial action potential and upstroke velocity. This decreased rate of ventricular depolarization, plus the beginning of repolarization in some areas of the myocardium while other areas are still undergoing depolarization, produces a progressively widening QRS complex that merges with the T wave into a sine wave on ECG.

Above a potassium level of 6.7 mEq/L, the degree of hyperkalemia and the duration of the QRS complex correlate well. [626] This correlation is even better than the correlation between the serum potassium level and T-wave changes. Nevertheless, the earliest manifestations of hyperkalemia are narrowing and peaking of the T wave. Although not diagnostic of hyperkalemia, T waves are almost invariably peaked and narrow when serum potassium levels are 7 to 9 mEq/L. When serum potassium levels exceed 7 mEq/L, atrial conduction disturbances appear, as manifested by a decrease in P-wave amplitude and by an increase in the PR interval. Supraventricular tachycardia, atrial fibrillation, PVCs, ventricular tachycardia, ventricular fibrillation, or sinus arrest may all occur.

The ECG and cardiac alterations of hyperkalemia are potentiated by low serum levels of calcium and sodium. Intravenous administration of saline, bicarbonate, glucose with insulin (1 U/2 g glucose), and calcium can reverse these changes by shifting some extracellular potassium into the cell.

beta-Adrenergic stimuli also cause redistribution of potassium into the cell. Indeed, the plasma potassium concentration measured in samples immediately before surgery is usually 0.2 to 0.8 mEq/L lower than that measured during the less stressful period 1 to 3 days before surgery. [633] beta-Adrenergic receptor-blocking drugs such as propranolol can be used to prevent such an effect preoperatively. A beta- adrenergic receptor-stimulating agent (20 mg of nebulized albuterol for a 70-kg patient) can be used to treat hyperkalemia when it occurs; it decreases potassium levels 1.0 mEq/L within 30 minutes, and its effect lasts 2 hours. [634] Although nebulized $beta_2$ -agonists effectively lower plasma potassium concentrations by stimulating sodium- and potassium-dependent adenosine triphosphatase, this therapy should be used as an adjunct to, rather than as a substitute for, more established measures. Kayexalate (sodium polystyrene sulfonate) enemas can be given to bind potassium in the gut in exchange for sodium. Dialysis against a hypokalemic solution will also decrease serum potassium levels. However, in the hyperkalemic patient, hypoventilation can be dangerous during anesthesia, [529] [533] [635] [636] because each 0.1 change in pH level can produce a 0.4 to 1.5 mEq/L change in serum potassium levels in the opposite direction. For example, if pH level decreases from 7.4 to 7.3, serum potassium levels could increase from 5.5 to 6.5 mEq/L. [629]

Hypokalemia can be caused by inadequate intake of potassium, excessive GI losses (through diarrhea, vomiting, nasopharyngeal suctioning; chronic use of laxatives; or ingestion of cation-exchange resins, as in certain wines), excessive renal losses (because of use of diuretic drugs, renal tubular acidosis, chronic chloride deficiency, metabolic alkalosis, mineralocorticoid excess, excessive ingestion of licorice, use of antibiotics, ureterosigmoidostomy, and diabetic ketoacidosis), and shifts of potassium from extracellular to intracellular compartments (as occur in alkalosis, insulin administration, beta-adrenergic agonist administration or stress, barium poisioning, and periodic paralysis). As with hyperkalemia, knowledge of the cause of potassium deficiency and the appropriate preoperative evaluation and treatment of that cause may be as important as treatment of the deficiency itself. Also like hyperkalemia, hypokalemia may reflect small or vast changes in total body potassium. Acute hypokalemia may be much less well tolerated than chronic hypokalemia. The major worrisome manifestations of hypokalemia pertain to the circulatory system, both the cardiac and peripheral components. In addition, chronic hypokalemia results in muscle weakness, hypoperistalsis, and nephropathy.

The cardiovascular manifestations of hypokalemia include autonomic neuropathy (which results in orthostatic hypotension and decreased sympathetic reserve), impaired myocardial contractility, and electrical conduction abnormalities that can result in sinus tachycardia, atrial and ventricular arrhythmias, and disturbances of intraventricular conduction that can progress to ventricular fibrillation. That these are real concerns for the hypokalemic patient has been shown far too often. [626] [627] [628] [634] [637] [638] [639] In addition to arrhythmias, the ECG shows widening of the QRS complex, ST-segment abnormalities, progressive diminution of the T-wave amplitude, and progressive increase in the U-wave amplitude. [640] Surawicz [626] found these changes to be present invariably when serum potassium levels decreased to below 2.3 mEq/L. Although U waves are not specific to hypokalemia, they are sensitive indicators of the condition. Replenishing the total body potassium deficit for a depletion reflected by a serum deficit of 1 mEq/L (e.g., from 3.3 to 4.3 mEq/L) may require 1,000 mEq of potassium. Even if this amount could be given instantaneously (and it should not be replenished at a rate exceeding 250 mEq/d), it would take 24 to 48 hours to equilibrate in all tissues. [127] [128] The potassium-depleted myocardium is unusually sensitive to digoxin, calcium, and, most important, potassium. Rapid potassium infusion in the hypokalemic patient can produce arrhythmias as severe as those produced by hypokalemia itself. [128] [641] [642] [643]

Thus, the decision to proceed with surgery and anesthesia in the face of acute or chronic depletions or excesses of potassium depends on many factors. [644] [645] [646] [647] [648] One must know the cause and treatment of the underlying condition creating the electrolyte imbalance and the effect of that imbalance on perioperative risk and physiologic processes. The urgency of the operation, the degree of electrolyte abnormality, the medications given, the acid-base balance, and the suddenness or persistence of the electrolyte disturbance are all considerations.

Retrospective epidemiologic studies attribute significant risk to administration of potassium (even chronic oral administration). [645] [646] In one study, 1,910 of 16,048 consecutive

hospitalized patients were given oral potassium supplements. Of these, hyperkalemia contributed to death in seven, making the incidence of complications of potassium therapy one in 250 patients. Armed with such data, many internists do not prescribe oral potassium therapy for patients given diuretic drugs. Yet these patients frequently become moderately hypokalemic. [649] [650] Modest hypokalemia occurs in 10 to 50 percent of patients given diuretic drugs. Should surgery be delayed to subject such patients to the risks of potassium therapy?

Two studies investigated whether modest hypokalemia was a problem by prospectively seeking arrhythmias on the ECGs of patients who had various preoperative levels of potassium. [647] [648] No difference in the incidence of arrhythmias occurred among 25 normokalemic (K >3.4 mEq/L) patients, 25 moderately hypokalemic (K = 3-3.4 mEq/L) patients, and 10 severely hypokalemic (K <2.9 mEq/L) patients. [647] The inability of the eye in picking up these changes--or of even Holter recordings for short periods [651] (which seem not to have been obtained in this study)--points to the need for confirming studies.

Other studies indicate that modest hypokalemia can have severe consequences. [650] [652] [653] Holland and coworkers [653] treated 21 patients with 50 mg of hydrochlorothiazide twice a day for 4 weeks. These patients had a history of becoming hypokalemic during diuretic therapy; none of them had cardiac disease or was taking other medication. Before and after diuretic therapy, 24-hour ambulatory ECGs were recorded. This study is also subject to the limitations of Holter monitoring. [651] Seven of the 21 patients (33%) developed ventricular ectopy, including complex ventricular ectopy (multifocal PVCs, ventricular couplets, ventricular tachycardia). Potassium repletion decreased the number of ectopic ventricular beats per patient from 71.2 to 5.4/h. Apparently, some patients are sensitive to even minor potassium depletion. In the Multiple Risk Factor Intervention Trial involving 361,662 patients, more than 2,000 of whom were treated for hypertension with diuretics, the reduction in serum potassium after diuretic therapy was greater for those with PVCs. [650] Although I recommend that hypokalemic patients be given potassium supplements, the merit of this practice is unclear.

My personal criteria for preoperative potassium therapy are as follows. As a rule, all patients undergoing elective surgery should have normal serum potassium levels. However, I do not recommend delaying surgery if the serum potassium level is above 2.8 mEq/L or below 5.9 mEq/L, if the cause of potassium imbalance is known, and if the patient is in otherwise optimal condition. This range of safe potassium levels is arbitrary and has changed from 3.3 in 1979, to 3.1 in 1986, to 2.9 in 1990 on the lower side and from 5.6 in 1979, to 5.7 in 1986, and to 5.9 in 1990 on the upper side as more data have become available on the safety of preoperative hypokalemia and the dangers of replacing potassium in a hospital environment. [645] [646] (See Table 23-5.) I subject all patients with end-stage renal failure to dialysis (using the same arbitrary safe range) before all surgical procedures except truly emergency ones (as in the instances of imminent exsanguination). In studies on dogs in 1978, Tanifuji and Eger [654] determined the relationships between electrolyte status and anesthetic requirement that may represent intraoperative considerations: Hyponatremia and hypo-osmolality decreased minimum alveolar concentration (MAC), hypernatremia increased MAC, and hyperkalemia did not affect anesthetic requirement.

GASTROINTESTINAL AND LIVER DISEASES

The reader should also see the discussion of porphyrias in the section on neurologic disease; the discussion of nutritional deficiencies in the section on disorders of nutrition; and pediatric disorders, such as transesophageal fistula, in Chapters 58 , 59 , and 73 .

Gastrointestinal Disease

Preoperative Search for Diverse Associated Disorders in Gastrointestinal Disease

Although preoperative preparation of the GI tract is usually the responsibility of the surgeon, and although the GI tract frequently does not need to be extensively evaluated by the anesthesiologist, GI disease can, and often does, cause derangements in many or all other systems. Such disturbances can affect the safety of anesthesia for the patient. Thus, the anesthesiologist may need not only to optimize the patient's condition through extensive preoperative preparation but also to have knowledge of disease processes and their effects to guide the patient smoothly through the perioperative period. The major advances of correcting fluid and electrolyte disorders and of optimizing nutritional status before surgery now allow surgery to be performed in patients with GI disease previously deemed to be at too great a risk and may have lessened the risk for others. [101] [102] [103] [104] [655] [656] Still, in patients with GI disease, a thorough evaluation of intravascular fluid volume and electrolyte concentrations and nutrition is essential, including an evaluation of the supervening side effects of these therapies (e.g., hypophosphatemia from parenteral nutrition, hyperkalemia or cardiac arrhythmias from too-vigorous treatment of hypokalemia, and CHF from too-rapid or too-vigorous treatment of hypovolemia).

In addition to vast alterations in fluids, electrolytes, and nutrition that can occur with such diverse GI diseases as neoplasms and pancreatitis, patients with GI disorders can have reflux disease, [657] bowel obstruction, vomiting, or hypersecretion of acid. These effects may merit rapid induction of anesthesia with application of cricoid pressure or awake endotracheal intubation, preoperative nasogastric suctioning, or preoperative use of histamine receptor-blocking agents (Ch. 39) . Clotting abnormalities may need to be corrected, because the fat-soluble vitamin K (often malabsorbed) is necessary for synthesis of factors V, VII, IX, and X in the liver (Ch. 54) . Liver disease is often associated with GI disease and, if severe enough, can also result in deficiency of clotting factors synthesized by the liver.

Other factors should be remembered in any preoperative evaluation of the patient with GI disease. First, closed spaces containing gas expand by absorbing nitrous oxide.

This expansion can lead to ischemic injury and/or GI viscus rupture. [658] Second, GI surgery predisposes the patient to sepsis; sepsis and decreased peripheral vascular resistance can lead to massive fluid requirements, cardiac failure, and renal insufficiency. Recently, the wound infection rate has been declining. This decrease may be attributable to the use of better technique, to more appropriate prophylactic use of antibiotics, to better nutrition, to less invasive (laparoscopic and endoscopic) surgery, or to surgical resection of even solid tumors. [354] [658] [659] [660] [661] [662] Third, patients with GI disease may have many other associated disorders not directly related to the GI tract. For example, they may be anemic from deficiencies in iron, intrinsic factor, folate, or vitamin B_{12} . They may also manifest neurologic changes from combinedsystem disease. Respiration may be impaired because of heavy cigarette smoking, peritonitis, abscess, pulmonary obstruction, previous incisions, aspirations, or pulmonary embolism (as occurs with ulcerative colitis or with thrombophlebitis in the bedridden). [663] These patients may also have hepatitis, cholangitis, or side effects from antibiotic drugs or other medications, massive bleeding with anemia and shock, or psychologic derangements.

Because GI disease can be accompanied by so many diverse associated disorders, the clinician clearly must search for other system involvement and preoperatively assess and treat such disorders appropriately. Discussion of two specific diseases, ulcerative colitis and carcinoid tumors, will highlight the importance of involvement of other systems in GI disease.

Ulcerative Colitis and Carcinoid Tumors as Examples of Gastrointestinal Disease Affecting Other Systems

Patients with ulcerative colitis often have psychologic problems. They may also have phlebitis; deficiencies in iron, folate, or vitamin B_{12} ; anemia; or clotting disorders caused by malabsorption. They may be malnourished or dehydrated or have electrolyte abnormalities. In addition, ulcerative colitis can be accompanied by massive bleeding; bowel obstruction or perforation or toxic megacolon, causing respiratory compromise; hepatitis; arthritis; iritis; spondylitis; or diabetes; secondary to pancreatitis.

The site of origin of carcinoid tumors in more than 75 percent of patients is the GI tract. [664] Within the GI tract, carcinoid tumors have been documented to occur from the esophagus to the rectum. The most frequent site is the appendix, but carcinoids in this location rarely, if ever, metastasize or produce the carcinoid syndrome. Tumors arising in the ileocecal region have the highest incidence of metastases. Carcinoid tumors originating from other than the GI tract have been reported in other sites, such as the head and neck, lung, gonads, thymus, breast, and urinary tract. Cardiac involvement, although frequently reported, is usually limited to right-sided valvular and myocardial plaque formation.

Not all patients with carcinoid tumors have symptoms attributable to secretion of hormone by the tumor. The most comprehensive series in the literature indicates that only 7 percent of patients have the carcinoid syndrome, which consists of flushing, diarrhea, and valvular heart disease. Of those with the syndrome, approximately 74 percent have cutaneous flushing; 68 percent, intestinal hypermotility; 41 percent, cardiac symptoms; and 18 percent, wheezing. Factors influencing symptoms include location of the tumor and the specific hormones produced and secreted. Although it is generally believed that if patients do not exhibit the carcinoid syndrome, the tumors are not producing serotonin (5-hydroxytryptamine [5-HT]), this may not be the case. Approximately 50 percent of patients with carcinoid tumors of the GI tract demonstrate evidence of 5-HT production, as manifested by elevated levels of 5-hydroxyindoleacetic acid (5-HIAA), a metabolic product of 5-HT, in urine. The carcinoid syndrome is usually associated with ileal carcinoid tumors that have metastasized to the liver. Presumably, the liver clears mediators released from the tumor. Impairment of this clearing ability by the metastatic tumor results in the carcinoid syndrome.

Most patients with carcinoid tumors and increased urinary 5-HIAA have typical carcinoid tumors originating from the midgut (ileum or jejunum). These patients excrete only small amounts of 5-hydroxytryptophan (5-HTP). Patients with atypical carcinoid tumors that originate in the foregut (bronchus, stomach, and pancreas) excrete large amounts of 5-HT and 5-HTP as well as moderately higher amounts of 5-HIAA.

Although there is general agreement that 5-HT is responsible for the diarrhea experienced by patients with carcinoids, other neurohumoral agents may contribute to the flushing and hypotension. [664] [665] [666] These include dopamine, histamine, and some of the neuropeptides, such as substance P, neurotensin, vasoactive intestinal peptide, and somatostatin.

The net physiologic effect of circulating 5-HT represents a composite of both direct action (mediated by 5-HT receptors) and indirect action (mediated through the modulation of adrenergic neurotransmission). The existence of several subtypes of 5-HT receptors may account for the different effects of 5-HT on various serotonin-sensitive tissue beds. Indirect actions are effected through alterations in catecholamine release and depend on the level of circulating 5-HT.

5-HT has little, if any, direct effect on the heart. With elevated levels, however, positive chronotropic and inotropic myocardial effects may occur, mediated by the release of noradrenaline (norepinephrine). Effects of serotonin on the vasculature include both vasoconstriction and vasodilation.

Alterations in GI function attributed to 5-HT include increased motility and net secretion of water, sodium chloride, and potassium by intestine. 5-HT reportedly causes bronchoconstriction in many animals but rarely in humans. Asthmatics are a possible exception. Carcinoid tumors frequently present as diarrhea with fluid and electrolyte abnormalities. Because these tumors secrete vasoactive substances, patients can exhibit hypotension or hypertension with the flush of vasoactive substance release. Vasoactive substances can be released from the tumor by any number of substances, including catecholamines. Thus, the anesthesiologist must tread the fine line between avoiding substances known to release 5-HT (e.g., *d*-tubocurarine and morphine) and creating anesthesia so light that painful stimuli

activate a sympathetic stress response. [667] [668] The anesthesiologist must also be ready and able to treat hypotension, decreased peripheral vascular resistance, bronchospasm, and hypertension. alpha-Adrenergic receptor blockade with the phenothiazines, butyrophenones, or phenoxybenzamine and beta-adrenergic receptor blockade with propranolol have been advocated to prevent catecholaminemediated release of vasoactive substances. These practices, however, can lead to hypotension. In fact, somatostatin is now such a powerful inhibitor of release of peptides from carcinoid tumors and an inhibitor of peptic effects on receptor cells that it is the therapy of choice for preoperative, intraoperative, and postoperative management of carcinoid symptoms and crises. [664] [667]

If severe hypotension occurs that is not treatable with somatostatin, the drug of choice is either angiotensin or vasopressin. (Angiotensin is not commercially available in the United States but is an approved drug that is available by contacting CIBA-GEIGY.) However, the vasoactive substances released by carcinoid tumors cause fibrosis of heart valves, often resulting in pulmonic stenosis or tricuspid insufficiency. To increase cardiac output in the patient with tricuspid insufficiency, the anesthesiologist should avoid drugs or situations that increase pulmonary vascular resistance (e.g., angiotensin, vasopressin, acidosis, hypercarbia, hypothermia) (Chs. 49 and 50) . In addition, the production of large amounts of 5-HT (equal to 200 mg/d of 5-HIAA) can lead to the development of niacin deficiency with pellagra (as occurs with diarrhea, dermatitis, and dementia).

Acute elevation of plasma kinin activity in carcinoid patients has been postulated for many years as the explanation for the symptoms of carcinoid syndrome. Physiologic effects of kinins are known to include vasodilation of smaller resistance vessels and stimulation of release of histamine from mast cells. The latter action potentiates their own vasodilating properties and further reduces systolic and diastolic blood pressure. In addition, increases in vascular permeability may lead to edema. Kinins are not known to affect the myocardium directly.

Steroids have been effective in treating the symptoms of bronchial carcinoid tumors. Although prophylactic preoperative administration and intraoperative therapeutic uses have been described, controlled studies of beneficial effects are lacking. Aprotinin, like steroids, inhibits the kallikrein cascade. This agent is believed to be capable of blocking the proteinase activity of kallikrein. Some reports have described a dramatic clinical response.

A subset of patients with symptoms of the carcinoid syndrome excrete histamine at increased levels in their urine. Histamine causes vasodilation of small blood vessels, leading to flushing and decreased total peripheral resistance. Histamine is known to cause bronchoconstriction, particularly in patients with bronchial asthma and other pulmonary diseases. Its role in carcinoid bronchospasm, if any, is uncertain. Histamine receptor-blocking drugs have been used with some success in alleviating the flushing associated with carcinoid syndrome. H_2 -antagonism alone was found to be just as effective as combination therapy in preventing symptoms; pure H_1 -antagonism, however, was ineffective. These therapies have been relegated to a second-line defense since the use of somatostatin.

Catecholamines aggravate the symptoms of carcinoid syndrome, presumably by stimulating hormone release by the tumor. The mechanism by which this occurs remains obscure. Adrenergic receptors have not been demonstrated in carcinoid tumors, nor do these tumors usually have neural innervation. Perhaps adrenergic stimuli work through their mechanical effects on the gut and vessels to stimulate the release of tumor products. Treatment of patients with carcinoid tumors by means of alpha- and beta-adrenergic antagonists has been beneficial in ameliorating flushing in some instances but ineffective in others.

Results of prospective studies on somatostatin used to ameliorate symptoms of the carcinoid syndrome have been dramatic. In several case reports involving a total of 46 patients, all but two patients had rapid, dramatic improvement in flushing. [664] [665] [666] [667] [669] [670] [671] [672] Similar results have been obtained in patients with diarrhea. Somatostatin appears to be a major advancement in the treatment of carcinoid syndrome.

It might logically be concluded that preoperative preparation of the patient with carcinoid syndrome would be similar to that for the patient with pheochromocytoma, titrating adrenergic, histaminic, and serotonergic receptor-blocking drugs to maximum effect while monitoring intravascular volume status and adding somatostatin prior to surgery. Although this approach is logical, preoperative symptoms do not correlate with perioperative symptoms, and only the last two therapeutic options (optimization of intravascular fluid status and administration of somatostatin) are most effective.

Many patients also develop bronchospasm with or without flushing when vasoactive substances are released. Thus, a patient with a carcinoid tumor may be well or may be severely incapacitated by pulmonary, neurologic, nutritional, fluid, electrolytic, or cardiovascular disturbances. [664] [667] Therefore, although the GI system in itself may not require extensive preoperative preparation, GI disease can cause disturbances in any or all other systems that require both extensive preoperative preparation to optimize the patient's condition, plus preoperative knowledge of physiology and effects of diseases in order to guide patients through the perioperative period smoothly. In addition, the anesthesiologist's understanding of the nature of the surgery probably aids in determining the system involvement caused by GI disorder.

Another preoperative consideration is that patients with GI diseases (perhaps even more so than those with other diseases) have had to endure the psychosocial trauma of having to live with their disease for long periods or to face such a prospect. [673] They need emotional support and holistic kindnesses as much as, if not more, than others, without sacrificing scientific rigor in the treatment of their condition. Obtaining relevant psychologic data while gathering medical information, sitting (not standing) while taking the history, and empathizing with the patient as to how difficult it must be to accomplish tasks with this disease (stressing accomplishments, I have found) legitimize the physician's interests in, and support of, the patient's pain and other psychosocial issues. The time spent sitting and talking with the patient also allows the anesthesiologist to discuss options for pain therapy with the patient, why systemic morphine might be avoided in the patient with a fresh bowel anastomosis, [674] and other issues that show the anesthesiologist to be both a competent physician and particularly concerned with that

patient's well-being. In addition to an appreciation of the organic effects of their disease, attention to emotional support of these patients perioperatively presents opportunities to use one's full skills as a physician to bring about healing.

Liver Disease

What are the risks of giving anesthesia to patients with acute liver disease who require emergency surgery? What are the risks of giving anesthesia to patients with chronic impairment of liver function? What can be done to minimize these risks? Although one might think that the experiences gained from providing anesthesia for liver transplantation would answer many of these questions, there is a substantial difference between optimizing cardiovascular function to meet the needs of a new liver (e.g., supply of nutrients) and maintaining liver function in a diseased liver. Because hepatic function and physiology are discussed in Chapter 54 , I will mention only that the liver performs many functions: it synthesizes (e.g., proteins, clotting factors), detoxifies the body of both drugs and the products of normal human metabolism, excretes waste products, and stores and supplies energy. Tests of liver function assess synthesis (cholesterol levels, PT, albumin levels), cellular integrity (aspartate transaminase and alanine aminotransferase, lactate dehydrogenase, alkaline phosphatase), the liver's ability to detoxify the body (e.g., ammonia,

direct bilirubin, or lidocaine levels), and the liver's ability to excrete certain substances (bromosulphthalein retention, total bilirubin levels).

In examining the effects of anesthesia (with or without surgery) on liver function, and in examining ways to reduce risk in patients with pre-existing liver disease, investigators have often looked at one or more of these tests or, more commonly, at major end points of morbidity (jaundice) or mortality. The evidence can be summarized as follows: Without anesthesia or surgery, approximately 1 in 700 to 800 patients who are otherwise healthy and scheduled for surgery will have abnormal preoperative results for liver function tests; of these patients, one in three will develop jaundice. [675] [676] (Also see Ch. 23 for these studies.) In our preliminary study, *every* patient with abnormal liver function tests was symptomatic preoperatively. [273] Therefore, the risk may be less than described (Ch. 23) .

All anesthetics tested (general, narcotic-nitrous oxide, and regional) have caused transient abnormalities in liver function tests. These abnormalities were magnified by upper intra-abdominal surgery and occurred regardless of preexisting liver disease. [635] [677] [678] [679] [680] [681] [682] [683] [684] [685] [686] Patients whose preoperative liver function tests are abnormal will obviously have a higher incidence of abnormal results on postoperative liver function tests. [635] [679] [680] [681] [683] [684] Lacking in the literature are investigations that studied patients with compromised hepatic function to determine how to decrease the risk of surgery and anesthesia. Also lacking are comparisons of outcome after various perioperative management strategies, based on the different causes of hepatic dysfunction (i.e., viral [or even one virus versus another virus], toxic, or drug induced). In addition to pre-existing hepatic disease and the operative site, hypokalemia, hypotension, sepsis, and the need for blood transfusion all contribute to postoperative hepatic dysfunction. Thus, anesthesia and surgery probably exacerbate hepatic disease, clearly increasing morbidity and mortality. [635] [678] [679] [680] [683] [684] Only one study, on alcoholic liver disease, has implied otherwise. [635]

The main goal of the anesthesiologist is to avoid making the hepatic disease (with perhaps its metabolic and CNS toxicity) worse and thereby increase the chance of renal failure, coma, and death. [687] Studies of portal hypertension have shown that mortality can be 50 percent when preoperative serum albumin concentrations are lower than 3 g/dL, preoperative serum bilirubin levels are greater than 3 mg/dL, and ascites and encephalopathy are present; mortality can be even higher when PT is grossly abnormal. By contrast, mortality decreases to 10 percent when preoperative serum albumin levels are 3 to 3.5 g/dL, preoperative serum bilirubin levels are 2 to 3 mg/dL, PT is normal, and encephalopathy is absent. The risks of anesthetizing a patient with chronic liver disease not requiring portacaval shunt are detailed only sporadically but appear to be greater than those associated with anesthetizing a healthy patient. [675] [676] [677] [678] [679] [680] [681] [682] [683] [684] [685] [686] [687] [688] [689] [690] [691]

Should halothane be given to patients with hepatitis or biliary tract disease? The National Halothane Study did not find halothane to cause massive hepatic necrosis or any other hepatic abnormality more frequently than any other anesthetic agent [574] and, in fact, demonstrated its safety in biliary tract surgery. Prospective studies have been contradictory at best as to whether repeat exposures to halothane within a short time elevate liver enzyme levels to a greater degree than do other anesthetic agents. [692] [693] [694] [695] Because the incidence of hepatitis attributable only to halothane would be very low, very large groups would have to be studied. The incidence of postoperative jaundice and hepatitis not attributable to halothane is much greater than the incidence of hepatitis attributable only to halothane, and the absence of differentiating pathologic features makes halothane hepatitis difficult to exclude as a possibility. Newer tests imply an immunologic basis to the continuation of either the hepatitis or liver dysfunction after the initial mechanism (e.g., if hypoxia begets the injury, the immune mechanism continues it) and are supported by resolution of the prolonged case of halothane hepatitis after treatment. [696] Although other cases that have resolved after steroid therapy have been presented, those cases did not, in fact, allow a long enough time before the beginning of their resolution when the disease was stable to conclude that the steroids made a difference and that this was not the natural course of the disease. One case is inconclusive but certainly implies that a controlled trial should be instituted. This subject is perhaps even more important now that several forms of viral hepatitis (acute and chronic) are now treatable: Left untreated, hepatitis C evolves to chronic type C hepatitis in 50 percent of patients and to cirrhosis in 20 percent of those developing chronic hepatitis. Treatment with alpha-(leukocyte) interferon appears to reduce the risk of these consequences substantially. [615] [616]

More sensitive tests of hepatocellular dysfunction after anesthesia and surgery, such as glutathione- *s*-transferase, reveal impairment more frequently. [697] One is left to conclude that both metabolic and immunologic mechanisms can contribute to hepatocellular dysfunction after anesthesia and surgery. Are these related to anesthesia or surgery? Internists almost always point to anesthesia and must be educated to shed light on their bias, although this need is reduced

with better diagnostic tests [615] [617] and with the possibility of treatment of some forms of hepatitis. [615] [616]

Thus, the strong bias of internists makes anestheticinduced hepatitis ("halothane hepatitis") a popular diagnosis, despite the higher incidence of viral and drug hepatitides. [635] [695] [696] [697] [698] [699] [700] [701] [702] [703] [704] [705] [706] [707] [708] [709] Another factor producing possible bias is the fact that animal models of halothane hepatitis incorporate liver hypoxia or pretreatment with polyvinylchlorides, conditions that can themselves adversely affect liver function. No irrefutable evidence exists implicating halothane as being better or worse than any other anesthetic for the patient with pre-existing liver disease. However, should liver disease worsen postoperatively, the tendency is to blame halothane. Anesthesia is certainly less likely than hypoxia, trauma, viral hepatitis, drug-induced hepatitis, or sepsis to cause serious hepatic injury. [675] [708] No one has yet determined whether a time limit exists within which repeat exposure to an anesthetic is more dangerous than exposure to various anesthetics, or after which repeat anesthesia is as safe as a first exposure to anesthetic. The common consistent feature of many forms of chronic liver disease is a vulnerability to decreased oxygen delivery to the hepatic artery. This vulnerability occurs because of increased resistance to portal vein blood flow. Many stimuli, including surgical palpation, appear to decrease oxygen delivery to the hepatic artery. Thus, anesthesia and surgery may affect hepatic well-being after surgery in the patient with an already compromised liver.

What should physicians do to prevent contracting hepatitis from patients--or giving it to them? It is cost-effective for anesthesia personnel to be given the vaccine. [709] [710] [711] How the physician with hepatitis B can prevent infecting patients is discussed in detail elsewhere. [712]

Liver disease severe enough to affect hepatic synthesis can impair the detoxification of many drugs, [696] [697] [708] [713] [714] [715] [716] including muscle relaxants [713] [714] [715] [716] (Ch. 12) , and can disturb coagulation (Ch. 46) but may or may not affect anesthetic requirements greatly. [717] [718] Administration of fresh-frozen plasma may be needed to correct coagulation disorders.

HEMATOLOGIC DISORDERS AND ONCOLOGIC DISEASE

Hematologic Disorders

Anemia and Polycythemia

Chapter 23 presents the evidence that normovolemic anemia or polycythemia increases perioperative morbidity. The results indicate that knowledge and pretreatment of polycythemia might decrease perioperative morbidity and mortality.

Except for patients with ischemic heart disease (see later), no such evidence exists for normovolemic anemia. [339] [340] (This is also reviewed in Chapter 23.) Thus, there are no specific preoperative routines for anemia itself, except regarding patients who have or are likely to have ischemic heart disease (as determined by risk factors). [719] [720] [721] [722] [723] [724] For these patients, hematocrit levels above or below 29 to 34 percent were found in two separate studies to be associated with increased episodes of myocardial ischemia after vascular surgery [339] [340] (see Fig. 25-18) . For patients at risk of current ischemic heart disease, the data indicate that transfusion to a hematocrit level of 29 to 34 percent may be appropriate. It should be remembered that anemia is the reduction in circulatory erythrocyte mass below the range of values considered normal for persons of the same gender at the same location. (Age over 6 months, race, and ethnic background do not explain anemia.) Each erythrocyte lives for approximately 120 days; therefore, replacement of 15 to 20 mL of senescent cells needs to be accomplished in the absence of diseases that destroy or cause loss of blood cells. Furthermore, the symptoms of anemia--headache, weakness, exertional dyspnea, and loss of endurance--do not provide much information about the severity, rapidity of onset, and cardiorespiratory effects of the underlying cause of anemia.

Furthermore, because anemia can be a hallmark of many other diseases possibly affecting perioperative anesthetic management, the preoperative presence of anemia requires a search for, and treatment of, the underlying cause. For instance, anemia could indicate renal insufficiency or a drug reaction, both of which could alter anesthetic management. For this reason, the cause of anemia should be known preoperatively. Similarly, polycythemia can be a primary disease (e.g., polycythemia vera) or it can be secondary to smoking, to the use of diuretic drugs, to chronic use of androgens, to hypoxia, or to other forms of chronic lung or heart disease. Phlebotomies are quite effective for patients with mild polycythemia. Cerebral blood flow improves when the hematocrit level is kept below 45 percent. [721] [722] No prospective controlled study has been performed on humans regarding a possible decrease in perioperative morbidity or wound healing [339] [340] [719] [720] [721] [722] [723] [724] from perioperative treatment of anemia or polycythemia. The time of most danger to the patient may be the early recovery room period, during which time oxygen delivery to the lungs is perhaps at its worst. [339] [340] (Also see Chs. 68 and 72.) When religious convictions prohibit blood transfusion and the patient is anemic or may become anemic, therapeutic options include autotransfusion with the salvaged or removed blood always connected to (or in contact with) the patient, and use of blood substitutes. Although perfluorocarbons have fallen into disrepute because of effects on reticuloendothelial function, other substitutes may become available, and synthetic erythropoietin will find greater use in preoperative prophylaxis and preoperative predeposit blood programs. [669] [725] This subject is discussed in greater detail in Chapters 46 and 47 .

Erythropoietin is one of the substances necessary for the normal production of red blood cells. The production and secretion of erythropoietin from the peritubular cells of the kidney are stimulated by tissue hypoxia. Signal transduction of this hypoxic stimulus depends on a heme-containing oxygen-sensing protein that mediates changes in the stability of mRNA from chromosome 7 in erythropoietinproducing cells. Erythropoietin triggers quiescent early erythroid progenitor cells into cycle, acting like a mitogen and facilitating differentiation into late committed erythroid progenitor cells. In normoxic individuals, erythropoietin synthesis is not stimulated until the concentration of hemoglobin falls below 10.5 g/dL. In severe anemia, erythropoietin levels can increase more than 1,000-fold. Iron, folic acid, and vitamin B_{12} are also needed for normal maturation of erythrocytes. Several forms of anemia present special situations,

such as sickle cell anemia, hereditary spherocytosis, and the autoimmune hemolytic anemias.

Sickle Cell Anemia and Related Hemoglobinopathies

The sickle cell syndromes comprise a family of hemoglobinopathies caused by abnormal genetic transformation of amino acids in the heme portion of the hemoglobin molecule. [726] The sickle cell syndromes arise from a mutation in the beta-globin gene that changes the sixth amino acid from valine to glutamic acid. A major pathologic feature of sickle cell disease is the aggregation of irreversibly sickled cells in blood vessels. The molecular basis of sickling is aggregation of deoxygenated hemoglobin B molecules along their longitudinal axis. [726] This abnormal aggregation distorts the cell membrane, producing a sickle shape. Irreversibly sickled cells become dehydrated and rigid and can cause tissue infarcts by impeding blood flow and oxygen to tissues. [726] [727] [728] [729] [730] Some other abnormal hemoglobins interact with hemoglobin S to various degrees, giving rise to symptomatic disease in patients heterozygous for hemoglobin S and one of the other hemoglobins such as the hemoglobin of thalassemia (hemoglobin C).

Three-tenths of 1 percent of the African-American population has sickle cell-thalassemia disease (hemoglobin SC); these patients also have end-organ disease and symptoms suggestive of organ infarction. For these patients, perioperative considerations should be similar to those for patients with sickle cell disease (hemoglobin SS), discussed later.

Whereas 8 to 10 percent of black Americans have the sickle cell trait (hemoglobin AS), 0.2 percent are homozygous for the sickle cell hemoglobin and have sickle cell anemia. Sickle cell trait is a heterozygous condition in which the individual has one betaS-globin gene and one betaA-globin gene, resulting in the production of both hemoglobin S and hemoglobin A, with a predominance of hemoglobin A. The sickle cell trait should not be considered a disease, because hemoglobin AS cells begin to sickle only when oxygen saturation of hemoglobin is below 20 percent. No difference has been found between normal persons (those with hemoglobin AA) and those with hemoglobin AS regarding survival rates or incidence of severe disease, with one exception: Patients with hemoglobin AS have a 50 percent increase in pulmonary infarction. However, single case reports of a perioperative death and a perioperative brain infarct in two patients with hemoglobin AS disease do exist, [730] [731] as does a report of death believed due to aortocaval compression during general anesthesia that resulted in a sickling crisis. [732] Frequent measurement of oxygen saturation (pulse oximetry) in multiple areas of the body is recommended, including ear and toe in pregnant patients. [732] A recent retrospective review of exercise in military recruits showed that soldiers with sickle cell trait had a higher risk of sudden death following extreme exertion during basic training than did black soldiers with only hemoglobin A--32 per 100,000 versus 1 per 1,000,000. [733] Although this magnitude of increase may not seem great, the vasoactive responses of the perioperative period can be similar to those of moderate to extreme exertion.

The pathologic end-organ damage that occurs in sickle cell states is attributable to three processes: the sickling of cells in blood vessels, which causes infarcts and consequent tissue destruction secondary to tissue ischemia; hemolytic crisis secondary to hemolysis; and aplastic crises that occur with bone marrow exhaustion, which can rapidly result in severe anemia. Logic dictates that patients currently in a crisis should not undergo surgery except for extreme emergencies and then only

after the performance of exchange transfusion. [728] [730] [731] [732] [733] [734]

Because sickling is increased with lowered oxygen tensions, acidosis, hypothermia, and the presence of more desaturated hemoglobin S, current therapy includes keeping the patient warm and well hydrated, giving supplemental oxygen, maintaining high cardiac output, and not creating areas of stasis with pressure or tourniquets. Meticulous attention to these practices in those periods when we usually do not pay most careful attention (i.e., waiting in the preinduction area) or when gas exchange may be most unmatched to cardiovascular-metabolic demands (early postoperative period) may be important in lessening morbidity. Even following these measures routinely, with no special emphasis placed on the periods described, researchers have succeeded in reducing mortality to 1 percent in several series of patients with sickle cell syndromes. [731] [732] [733] [734] [735] Retrospective review of patient charts led the authors of those studies to conclude that, at most, a 0.5 percent mortality rate could be attributed to the interaction between sickle cell anemia and anesthetic agent.

Can this rate be decreased? [727] [735] [736] [737] Several investigators have advocated using partial exchange transfusions perioperatively. In children with sickle cell anemia and acute lung syndromes, partial exchange transfusion improved clinical symptoms and blood oxygenation. Also, serum bilirubin levels decreased in patients with acute liver injury. Clinical improvement of pneumococcal meningitis and cessation of hematuria in papillary necrosis also accompanied exchange transfusion. [727] [738] The goal of exchange transfusion is to increase the concentration of hemoglobin A to 40 percent and the hematocrit to 35 percent. The 40 percent figure is an arbitrary one, as no controlled studies have established the threshold ratio of hemoglobin A to S that would render blood unable to sickle in vivo. To achieve the 40 percent ratio in a 70-kg adult, about 4 units of washed erythrocytes would have to be exchanged; the system is inexpensive but efficient.

The possible decrease in preoperative morbidity after partial exchange transfusion has not been compared with the risks of exchange, except in two studies, [729] [735] [739] in which the risks of exchange were found to exceed the benefits. In the first study, a retrospective review of 82 surgical procedures performed between 1978 and 1986 in 60 patients, no advantage was noted in preoperative exchange transfusion, as measured by a decrease in postoperative complications. [739] (However, only the sickest may have received exchange, as patients were not randomly allocated to exchange or nonexchange groups.) A slight increase in postoperative atelectasis requiring treatment was seen in those patients given preoperative transfusions. More than 50 percent of patients given transfusions had a postoperative complication. Patients who began with a hematocrit level of more than 36 percent had a lower rate of complications. [739] In the second study, a randomized comparison of aggressive

versus conservative transfusion practices in 551 patients (604 operations), perioperative sickling complications were *not* different between groups, and transfusion-related complications were substantially less in the conservative group. [729] Therefore, my recommendation is to pay meticulous attention to preventing conditions that increase sickling or that cause infection and to limit exchange transfusion to crisis situations. Perhaps giving higher concentrations of enriched oxygen to patients undergoing laparoscopic procedures should also become routine. Induction of hyponatremia has been shown to abort acute sickle cell crisis; however, this treatment has not gained widespread acceptance. Other conditions are common in sickle cell syndromes: pulmonary dysfunction with increased shunt, renal insufficiency, gallstones, small MIs, priapism, stroke, aseptic necrosis of bones and joints, ischemic ulcers, retinal detachments from neovascularization, and complications of repeated transfusions.

In thalassemia, globin structures are normal, but, because of gene deletion, the rate of synthesis of either the alpha- or beta-chains of hemoglobin (alpha- and beta-thalassemia, respectively) decreases. [740] [741] [742] Two copies of the gene that codes for the alpha-globin chain are located on chromosome 16. Deletion of all four of these genes causes cell death in utero, and three deletions cause severe chronic hemolysis and a shortened life span. "alpha-Thalassemia-1 [trait]" occurs when two genes have been deleted, leading to a mild anemia; "alphathalassemia-2 [silent]" occurs when the two genes have been deleted, but no mild anemia or microcytosis occurs. In alpha-thalassemia trait, the hemoglobin A_2 level is normal. beta-Thalassemia is associated with an excess of alpha-chains, which denature developing erythrocytes, leading to their premature death in the marrow or to shortened survival in the circulation. An elevated hemoglobin A_2 level is the hallmark of beta-thalassemia trait, a common cause of mild anemia and microcytosis. Bone marrow transplantation and pharmacologic manipulation of hemoglobin F synthesis are being tried in these hemoglobinopathies, as is direct gene replacement therapy. These syndromes are common in Southeast Asia, India, and the Middle East and in people of African descent.

In thalassemia, facial deformity from erythropoietinstimulated ineffective erythropoiesis (ineffective secondary to genetic inability to produce useful hemoglobin) has been reported to make endotracheal intubation difficult. [740] [741] [742] This one case report [741] has not been amplified, and there are no reports of this complication for patients with sickle cell anemia. However, the anemia associated with these syndromes often produces a compensatory hyperplasia of the erythroid marrow, which in turn is associated with severe skeletal abnormalities. [740] [741] [742]

Cytoskeletal Anemias (Hereditary Spherocytosis and Elliptocytosis), Enzyme-Deficient Anemias, and Autoimmune Hemolytic Anemias

Congenital abnormalities of the erythrocyte membrane are becoming better understood. In elliptocytosis and hereditary spherocytosis, the membrane is more permeable to cations and more susceptible to lipid loss when cell energy is depleted than is the membrane of the normal red blood cell. Both hereditary spherocytosis (present in 1 in 5,000 people) and hereditary elliptocytosis are inherited as autosomal dominant traits. In both disorders, defects in the membrane are thought to result from mutation of spectrin, a structural protein of the membrane cytoskeleton. [743] Although the therapeutic role of splenectomy in these diseases is not fully defined, in severe disease, splenectomy is known to improve the shortened life span of the red blood cell 100 percent (from 20-30 days to 40-70 days). Because splenectomy predisposes the patient to grampositive septicemia (particularly pneumococcal), perhaps patients should be given pneumococcal vaccine preoperatively prior to predictable bacteremic events. No specific problems relating to anesthesia have been reported for these disorders.

Glucose-6-phosphate dehydrogenase (G6PD) deficiency (a gender-linked recessive trait) is also reported to occur in approximately 8 percent of African-American men. [744] Young cells have normal activity, but older cells are grossly deficient compared with normal cells. A deficiency in this enzyme results in hemolysis of the erythrocyte and formation of Heinz bodies. Red cell hemolysis can also occur with intercurrent infections or after administration of drugs that produce substances requiring G6PD for detoxification (e.g., methemoglobin, gluthathione, and hydrogen peroxide). Drugs to be avoided are sulfa drugs, quinidine, prilocaine, lidocaine, antimalarial drugs, antipyretic drugs, non-narcotic analgesics, vitamin K analogues, and perhaps sodium nitroprusside.

The autoimmune hemolytic anemias include cold antibody anemia, warm antibody anemia (idiopathic), and drug-induced anemias. [745] [746] [747] The cold antibody hemolytic anemias are mediated by immunoglobulin M or G antibodies, which, at room temperature and below, cause red blood cells to clump. When these patients are given blood transfusions, the cells and all fluid infusions must be warm, and body temperature must be maintained meticulously at 37°C if hemolysis is to be prevented. Warm antibody (or "idiopathic") hemolytic anemia is a difficult management problem characterized by chronic anemia, the presence of antibodies active against red blood cells, positive Coombs test, and difficulty in cross-matching blood. For patients undergoing elective surgery, autologous transfusions, predeposit of blood with or without erythropoietin stimulation, [725] and blood from rare Rh-negative red blood cell donors and/or the patient's first-degree relatives can be used. In emergency situations, the possibility of autotransfusions, splenectomy, or corticosteroid treatment should be discussed with a hematologist knowledgeable in this area.

Drug-induced anemias have three mechanisms. In receptor-type hemolysis, a drug (e.g., penicillin) binds to the membrane of the red blood cell, and the complex stimulates formation of an antibody against the complex. In "innocent bystander" hemolysis, a drug (e.g., quinidine, sulfuramide) binds to a plasma protein, thereby stimulating an antibody (IgM) that cross-reacts with an erythrocyte. In autoimmune hemolysis, the drug stimulates production of an antibody (IgG) that cross-reacts with the erythrocyte. Drug-induced hemolytic anemias generally cease when drug therapy ends. In emergency situations, the least incompatible cells available should be used for blood transfusion.

Granulocytopenia

Granulocyte mechanisms have undergone experimental elaboration in the past decade, partly because of the molecular biologic revolution: In addition to erythropoietin (discussed previously), more than 14 hemolymphopoietic growth factors or cytokines have been characterized biochemically and cloned genetically. These growth factors interact with cell-surface receptors to produce their major actions [748] (Table 25-44) (Table Not Available) . The use of the colony-stimulating

factors has permitted more intense oncologic treatment. The few reports relating to their perioperative effects detail the adverse consequences such therapies can have on gas exchange when adverse immunologic effects occur. [749]

In patients who have fewer than 500 granulocytes/mL blood and established sepsis, use of growth factor and granulocyte transfusion has been shown to prolong life. [750] [751] [752] Although bone marrow transplantation is being used increasingly, complications usually occur after transplantation, not on harvesting of cells (at which time the anesthesiologist who is not involved in critical care is most frequently involved). Abnormal results on pulmonary function testing prior to bone marrow transplantation seem to predict complications after transplantation but not so strongly as to preclude transplantation. [753]

Platelet Disorders

Although *inherited* platelet disorders are rare, *acquired* disorders are quite common. Both conditions cause skin and mucosal bleeding, whereas defects in plasma coagulation produce deep-tissue bleeding or delayed bleeding. [754] Perioperative treatment of inherited platelet disorders (e.g., Glanzmann thrombasthenia, Bernard-Soulier syndrome, Hermansky-Pudlak syndrome) consists of platelet transfusion. epsilon-Aminocaproic acid (EACA) has recently been used successfully (experimentally, 1 g/70 kg qid) to decrease perioperative bleeding in thrombocytopenic patients. The much more common acquired disorders may respond to one of several therapies. Immune thrombocytopenias, such as those associated with lupus erythematosus, idiopathic thrombocytopenic purpura, uremia, hemolytic-uremic syndrome, platelet transfusions, heparin, and thrombocytosis may respond to steroids, splenectomy, platelet pheresis, or alkylating agents or may require platelet transfusions, plasma exchange, whole blood exchange, or transfusion; sometimes these disorders do not respond to anything. [366] [754] [755] [756] [757]

Thrombotic thrombocytopenic purpura is a rare disorder of unknown cause. Despite various therapies, this disorder carries a very high mortality rate. However, the introduction of plasmapheresis has improved response rates dramatically for patients with this disease. One uncontrolled study implies that the benefit lies not only in improvement of the hematologic picture but also in the prevention of adult respiratory distress syndrome, a leading cause of death in these patients. [757] In that study, the early institution of plasmapheresis improved oxygenation.

By far, the largest number of platelet abnormalities consists of drug-related defects in the aggregation and release of platelets. Aspirin irreversibly acetylates platelet cyclooxygenase, the enzyme that converts arachidonic acid to prostaglandin endoperoxidases. Because cyclo-oxygenase is not regenerated in the circulation within the life span of the platelet, and because this enzyme is essential for the aggregation of platelets, one aspirin may affect platelet function for a week. All other drugs that inhibit platelet function (e.g., vitamin E, indomethacin, sulfinpyrazone, dipyridamole, tricyclic antidepressant drugs, phenothiazines, furosemide, steroids) do not inhibit cyclo-oxygenase function irreversibly; these drugs disturb platelet function for only 24 to 48 hours. If emergency surgery is needed before the customary 8-day period for platelet regeneration after aspirin therapy, or if the 2-day period for other drugs has not elapsed, administration of 2 to 5 units of platelet concentrates will return platelet function to a 70-kg adult to an adequate level and platelet-induced clotting dysfunction to normal. [754] [758] Only 30,000 to 50,000 normally functioning platelets/mm^3 are needed for normal clotting. Because low-dose aspirin therapy (<650 mg/d) allows aspirin to be gone from the body 24 hours after the last dose, and because the body makes 70,000 platelets/mL blood per day, a 48-hour period after the last aspirin in minidose therapy should be sufficient time for platelet aggregation to become normal. This may be the time that must pass to avoid the need for platelet transfusions and their associated risks. One platelet transfusion will increase the platelet count from 4,000 to 20,000/mL blood; platelet half-life is about 8 hours. [754] [758] Although designer aspirin that affects only one part of the cyclo-oxygenase tree may soon be available, the form that is most likely to be used may cause clotting disturbances (without the GI effects, however) that are equal to those caused by the currently available form of aspirin.

Hemophilia and Related Clotting Disorders

Abnormalities in blood coagulation owing to defects in plasma coagulation factor are either inherited or acquired. Inherited disorders include X-linked hemophilia A (a defect in factor VIII activity), von Willebrand diseases (defect in von Willebrand component of factor VIII), hemophilia B (a sex-linked deficiency of factor IX activity), and other less common disorders. The sex-linked origin of some of these disorders means that hemophilia occurs almost exclusively in male offspring of female carriers; men do not transmit the disease to their male offspring.

In elective surgery, levels of the deficient coagulation factor should be assayed 48 hours before surgery and the level restored to 40 percent of normal before surgery. One unit of factor concentrate per kilogram of body weight normally increases the factor concentration by 2 percent. Thus, in the individual essentially devoid of activity, administration of 20 U/kg body weight would be required as an initial dose. Because the half-life is 6 to 10 hours for factor VIII and 8 to 16 hours for factor IX, approximately 1.5 U/h/kg of factor VIII or 1.5 U/2h/kg of factor IX should be given. Additional administration of factors VIII and IX should be guided by the activity of the clotting factors for about 6 to 10 days postoperatively. [759] [760] [761]

These factors are available in various preparations: The newer genetically engineered von Willebrand factor, cryoprecipitate,

TABLE 25-44 -- Major Effects of Hemolymphopoietic Growth Factors/Cytokines

(Not Available)

Modified from Quesenberg et al [745]

which contains 20 U/mL, is obtained from regular donors (the risk of hepatitis being 1:200 for 5-mL lots) or from fresh-frozen plasma (which contains 1 U/mL). Some risk of transmitting hepatitis and acquired immunodeficiency syndrome (AIDS) accompanies transfusion, but, with better testing, the risk is much lower than formerly. [762] [763] [764] [765] [766] Current screening of blood for aspartate transaminase or alanine aminotransferase levels is believed to result in a much lower risk of hepatitis C and even AIDS from transfusion. Theoretically, antigenic testing for the HIV viruses should further decrease the risk of their transmission by blood products. Heat treatment is also reported to reduce these risks substantially. Factor IX, but not factor VIII, is contained in prothrombin complex concentrates; however, these concentrates may contain activated clotting factors, leading to disseminated intravascular coagulation (DIC) and a high risk of hepatitis. In addition, although EACA or tranexamic acid (0.5 mg/kg) is sometimes administered as a fibrinolytic inhibitor, these substances carry with them a significant risk of DIC. Additional hazards of modern therapy include acute and chronic hepatitis, AIDS, hypersensitivity reactions, psychic trauma, chronic pain with narcotic addiction, and inhibition of factors, especially VIII.

Approximately 10 percent of patients with either hemophilia A or B develop an antibody that inactivates factor VIII or IX (fresh-frozen plasma fails to increase clotting factor activity after incubation with the patient's plasma). These acquired anticoagulants are usually composed of immunoglobulin G, are poorly removed by plasmapheresis, and are variably responsive to immunosuppressive drugs. The use of prothrombin complex concentrates can be life saving but carries the risk of DIC and hepatitis.

Vitamin K deficiency is discussed in the section on liver disease. To review, vitamin K-dependent clotting factors (II, VII, IX, and X) require vitamin K for the postsynthetic addition of gamma-carboxyl groups to glutamate residues; administration of vitamin K or fresh-frozen plasma can correct these deficiencies.

Patients who come to the operating room having received many units of blood (as in massive GI bleeding) may have deficient clotting. This impaired clotting is initially caused by depletion of platelets (which occurs after approximately 10-15 units of blood have been given) and later, by depletion of coagulation factors [767] [768] (Ch. 46) . Treatment of these deficiencies can be corrected with platelet concentrates--each concentrate is normally suspended in 50 mL of fresh plasma; thus, coagulation factors are also replaced.

Urokinase, streptokinase, and tissue plasminogen activator have been used to treat pulmonary embolism, deep venous thrombosis, stroke, and arterial occlusive disease. These drugs accelerate the lysis of thrombi and emboli, in contrast to heparin, which may prevent but not dissolve a thrombus. Bleeding complications associated with these fibrinolytic agents result from dissolution of hemostatic plugs and can be quickly reversed by discontinuing the medication and replenishing

plasma fibrinogen with cryoprecipitate or plasma. However, cryoprecipitate and plasma are seldom needed preoperatively because the fibrinolytic activity of urokinase and streptokinase usually dissipates within 1 hour of discontinuing their administration. However, insufficient data have accumulated to prescribe ideal preoperative preparation and intraoperative management of hemostasis in patients recently treated with urokinase, streptokinase, or tissue plasminogen activator. Postponing surgery for three half-lives of the drug (increases in plasmin activity in blood can be assayed for
4-8 hours) may not be possible, and observing the operative field for meticulous attention to hemostasis may not suffice. [769] [770] The process may be even more complex in the vascular or cardiac patient who requires heparin administration intraoperatively. To correct fibrinogen deficiency in these patients, some clinicians administer fibrinogen before surgery and EACA at heparin administration. I usually delay or avoid giving EACA until heparin is administered, in an effort to minimize the risk of thrombosis.

Desmopressin is now being tried in high-blood-loss operations as a routine measure to decrease bleeding and transfusion requirements. Desmopressin therapy began as a treatment for platelet dysfunction in von Willebrand disease but has since expanded to routine use in patients undergoing cardiovascular surgery and frequent use in other high-blood-loss operations. This increased use was prompted by the finding that desmopressin decreased bleeding and transfusion requirements. [771] Whether the side effects of desmopressin exceed the benefits remains to be determined and will probably influence how routine its administration becomes.

The problems of patients on oral anticoagulants are discussed in the cardiovascular section of this chapter. [358] [359] [360] [361] [362] [363] [364] [365] [366] [367] [368] [369] [370] [371] [373] [374] [375] [376] Regional anesthetic techniques might be avoided in patients given anticoagulant drugs. [358] [359] [360] [361] [362] [363] [364] [365] [366] [367] [368] [369] [370] [371] [373] [374] [375] [376] Whether these regional techniques should also be avoided in patients treated prophylactically with low-dose subcutaneous heparin has not been studied. The effects of heparin sulfate can be reversed by titrating protamine, using activated clotting time as a guide. Our group usually gives approximately 1 mg of protamine per 3 to 4 mg of heparin administered within the past 8 hours. Pharmacologic research is searching for specific molecular subtypes of heparin that have different anticoagulant potencies, binding affinities for antithrombin III, antithrombotic effects, and plateletaggregating effects. (See pulmonary section in this chapter on deep-venous thrombosis prophylaxis.) The search is for a "new" heparin preparation that will block thrombosis without causing clinical bleeding. (See previous.) Such a development might change our ways of monitoring clotting function. As of now, the new heparins appear to increase the risk of epidural hematoma. Determining bleeding time, platelet count, partial thromboplastin time, and PT will identify almost all problems in the patient with a suspected clotting or bleeding disorder (Ch. 46) . As explained in Chapter 23 , these screening tests probably should not be obtained for asymptomatic patients.

Oncologic Disease

Patients with malignant tumors may be otherwise healthy or may be desperately ill with nutritional, neurologic, metabolic, endocrinologic, electrolyte, cardiac, pulmonary, renal, hepatic, hematologic, or pharmacologic disabilities. Thus, determining the other disabilities accompanying malignant tumors requires evaluation of all systems. Abnormalities frequently accompanying such tumors include hypercalcemia

either by direct bone invasion or by ectopic elaboration of parathyroid hormone or other bone-dissolving substance, uric acid nephropathy, hyponatremia (especially with small-cell, or oat-cell, carcinoma of the lung), nausea, vomiting, anorexia and cachexia, fever, tumor-induced hypoglycemia, intracranial metastases (10-20% of all cancers), peripheral nerve or spinal cord disorders, meningeal carcinomatosis, toxic neuropathies secondary to anticancer therapy, and paraneoplastic neurologic syndromes (dermatomyositis, Eaton-Lambert syndrome, myopathies, and distal neuropathies).

Many patients with malignant tumors are given large doses of analgesics and should be kept comfortable during the perioperative period. Avoiding drug dependence is of no practical importance in terminally ill patients. [772] [773] Marijuana (tetrahydrocannabinol) depresses the CNS vomiting center and may be more effective than the phenothiazines or butyrophenones in suppressing nausea associated with cancer and its therapy; marijuana decreases anesthetic requirements 15 to 30 percent. [774] Immunomodulators, stimulating factors or cytokines, gene identification, [775] [776] and agents for treating side effects (e.g., midazolam or ondansetron) have given new hope for safer, more effective therapy, with fewer limiting side effects. The effect of ondansetron in preventing vomiting and the effect of midazolam in preventing "memory-stimulated vomiting" have been important additions.

The toxicity of cancer chemotherapy relates to the agents used and the dose. For radiation therapy, damage occurs when the following doses are exceeded: lungs, 1,500 rad; kidneys, 2,400 rad; heart, 3,000 rad; spinal cord, 4,000 rad; intestine, 5,500 rad; brain, 6,000 rad; and bone, 7,500 rad. The toxicities of biologic therapy and immunomodulating therapies relate to the change in immune function they cause. [494] [748] [749] [751] Alkylating agents cause bone marrow depression, including thrombocytopenia, alopecia, hemorrhagic cystitis, nausea, and vomiting. The alkylating agents including cyclophosphamide and mechlorethamine can act as anticholinesterase and prolong neuromuscular blockade. [777] The antineoplastic alkaloids vincristine and vinblastine produce, respectively, peripheral neuropathies and SIADH, and myelotoxicity. Cisplatin also produces peripheral neuropathies and severe nausea. Nitrosoureas can produce severe hepatic and renal damage, as well as bone marrow toxicity, myalgias, and paresthesia. Folic acid analogues such as methotrexate produce bone marrow depression, ulcerative stomatitis, pulmonary interstitial infiltrates, GI toxicity, and occasionally severe liver dysfunction. Fluorouracil and floxuridine, both pyrimidine analogues, cause bone marrow toxicity, megaloblastic anemia, nervous system dysfunction, and hepatic and GI alterations. Purine analogues (mercaptopurine, thioguanine) have bone marrow depression as their primary toxic effect. Anthracycline antibiotics (doxorubicin, daunorubicin, mithramycin, mitomycin C, bleomycin) can all cause pulmonary infiltrates; cardiomyopathies (especially doxorubicin and daunorubicin); myelotoxicity; and GI, hepatic, and renal disturbances.

The wisdom of anesthetizing patients given bleomycin has been questioned. A retrospective study by Goldiner et al [778] reported postoperative deaths in five consecutive patients given bleomycin. All five patients died of postoperative respiratory failure. Using the same anesthetic technique, Goldiner et al [778] then anesthetized 12 patients, limited the inspired oxygen concentration to 22 to 25 percent perioperatively, and replaced much of the blood loss with colloids, rather than crystalloids. None of the 12 patients died. These investigators postulated that bleomycin caused epithelial cell edema that progressed to necrosis of type I alveolar cells, fluid leakage into the alveolar space, and the formation of "hyaline membranes" similar to that associated with oxygen toxicity. [779] Goldiner et al [778] believe that this pathophysiologic similarity indicates a possible synergistic relationship between oxygen and bleomycin. However, LaMantia and coworkers [780] retrospectively analyzed the changes in 16 patients undergoing surgery after bleomycin therapy. Thirteen patients were given oxygen at inspired concentrations of 37 to 45 percent. No instances of postoperative respiratory failure occurred. Animal data do not support this effect of bleomycin in altering the toxicity of hyperoxia. [781] Thus, data are currently available to support all practices regarding oxygen administration to patients given bleomycin. I prefer to keep inspired oxygen concentrations at the lowest level providing adequate tissue oxygenation. When in doubt about side effects in patients undergoing cancer chemotherapy, my practice is to seek advice from two experts.

PATIENTS GIVEN DRUG THERAPY FOR CHRONIC AND ACUTE MEDICAL CONDITIONS

A steadily increasing number of potent drugs are being used to treat disease; the average hospitalized patient receives more than ten drugs. Many drugs have side effects that might make anesthesia more risky or patient management more difficult. Knowing the pharmacologic properties and potential side effects of commonly used drugs helps the anesthesiologist avoid pitfalls during anesthesia and surgery.

The first step in avoiding these pitfalls is to obtain a drug history (including vitamins, herbs, and supplements) [22] [782] from the patient. Then, for every drug, medicine, and over-the-counter preparation the patient is using, the anesthesiologist should know the name, classification of drug, diseases, conditions for which it is prescribed, and common side effects. Having this knowledge before surgery helps the anesthesiologist avoid making mistakes that might turn minor side effects into life-threatening situations. If necessary, the anesthesiologist should return to the patient's bedside to search for signs or symptoms of these effects. Unnecessary drugs should be discontinued for at least three and preferably five half-lives of the drugs. This period should be longer if metabolites of the drug have activity and longer half-lives. For essential or beneficial drugs, the optimal dose should be determined in consultation with the treating physician; the optimal dose is that maximizing the ratio of therapeutic value to risk of drug toxicity. Side effects should be sought and either corrected preoperatively or at least planned for in anesthetic management. For instance, if a patient is made hypokalemic with diuretic drugs, hypokalemia might be corrected before surgery; an even better approach would be to avoid hyperventilation during surgery. (See earlier section on hypokalemia.) This line of reasoning and planning is best

done at least 1 week before surgery. Ideally, the surgeon, internist, primary care practitioner, and anesthesiologist should communicate regarding these topics well in advance of surgery. Understanding the side effects of chronic drug therapy that affect the sympathetic nervous system requires some knowledge of the basic pharmacologic characteristics of the sympathetic nervous system. [669] [670]

Pharmacologic Processes in the Sympathetic Nervous System

The autonomic nervous system is discussed in detail in Chapter 14 . Although that review is comprehensive, it is important to remember several points related to the pharmacology of the sympathetic nervous system when considering chronic drug therapy.

Norepinephrine, dopamine, and epinephrine exert their physiologic effect by interacting with an appropriate receptor at the target tissue. The primary receptor acts through intermediary messenger systems (including cyclic 3
,5
-adenosine monophosphate and/or G-stimulatory or Ginhibitory proteins) and/or can change conformation (hence affinity for ligands) of bordering or neighboring receptors. These bordering or neighboring receptor effects may account for many of the multitude of effects associated with catecholamines. The three major kinds of catecholamine receptors are alpha-adrenergic, beta-adrenergic, and dopaminergic. These receptors are subdivided as follows:

1. alpha$_1$ -*Receptor:* Stimulation constricts vascular smooth muscle and thus increases peripheral vascular resistance.
2. alpha$_2$ -*Receptor:* Stimulation inhibits the release of norepinephrine itself (constituting negative feedback to the sympathetic neuron). These are largely presynaptic, although postsynaptic vasoconstricting alpha $_2$ -receptors exist on blood vessels.
3. beta$_1$ -*Receptor:* Stimulation increases heart rate and the strength of cardiac contractions.
4. beta$_2$ -*Receptor:* Stimulation causes dilation of smooth muscles of the blood vessels and airway, relaxation of uterine smooth muscle, and a variety of endocrine effects, including secretion of renin.
5. beta$_3$ -*Receptor:* Stimulation results in a greater release of norepinephrine from the sympathetic neuron (constituting positive feedback to the sympathetic neuron).
6. *Dopamine-1 receptor:* Stimulation causes dilation of vascular smooth muscle, notably of renal and mesenteric blood vessels.
7. *Dopamine-2 receptor:* Stimulation inhibits release of norepinephrine (presynaptic) and may also inhibit, via its ganglionic actions, the release of acetylcholine. The class of dopamine receptors involved in locomotion, inhibition of intestinal motility (the antagonism of which accounts for the increase in gastric emptying by metoclopramide), and vomiting is not known. These different effects may be caused by slight differences in receptor conformations.

The action of sympathomimetic substances is terminated through an unusual process: The nerve ending uses an active reuptake system to recapture most of the norepinephrine from the target tissue (Ch. 14) . Obviously, blockage of this system permits more norepinephrine to remain free to produce physiologic effects. In addition to this reuptake system, two enzymes transform catecholamines metabolically: monoamine oxidase (MAO) and catechol- *o*-methyltransferase (Ch. 14) .

Antihypertensive Drugs

Many antihypertensive agents and almost all mindaltering drugs affect sympathetic neuronal storage, uptake, metabolism, or release of neurotransmitters. For instance, the antihypertensive drug reserpine depletes the granules of norepinephrine, epinephrine, and dopamine in both the brain stem and the periphery. The depletion of transmitters in sympathetic nerve endings renders drugs such as ephedrine and metaraminol ineffective, as these drugs act primarily by releasing catecholamines (Fig. 25-21) . Guanethidine and guanadrel deplete granular norepinephrine and affect only the peripheral sympathetic system. In amounts used clinically, reserpine decreases the MAC by 20 to 30 percent, whereas guanethidine has no effect on anesthetic requirements. [217] In addition to causing a lack of response to indirect-acting vasopressors, reserpine can cause a denervation supersensitivity and hyperresponsiveness (with hypertension and/or tachycardia) to the usual doses of direct-acting sympathetic amines, such as phenylephrine (Neo-Synephrine), isoproterenol, norepinephrine, epinephrine, and dopamine. [781] [783] [784] [785] [786] Thus, in patients who have been treated with drugs that alter sympathetic neurotransmitter release, uptake, metabolism, or receptor function, some problems may occur: Hypotension, hypertension,

Figure 25-21 Antihypotensive drugs such as metaraminol (Aramine), tyramine, and ephedrine create their effect by releasing catecholamines from the granules of the nerve terminal. Therefore, when treatment with drugs such as methyldopa, reserpine, or guanethidine depletes the store of norepinephrine (NE) in the granules, little norepinephrine remains for release, and the antihypotensive drugs have been rendered ineffective.

and/or bradycardia should be treated by titrating doses of direct-acting vasoconstrictors, such as phenylephrine (Neo-Synephrine); vasodilators, such as nitroprusside; or chronotropic drugs, such as atropine, isoproterenol, or dopamine.

Another group of antihypertensive agents are the "false neurotransmitters." False neurotransmitters replace norepinephrine in the granules at the nerve ending. alpha-Methyldopa (Aldomet) becomes alpha-methyldopamine, which is further metabolized to alpha-methylnorepinephrine (Fig. 25-22) . In some nerve endings and for some receptors, alpha-methyldopamine or alpha-methylnorepinephrine is more potent than dopamine or norepinephrine as dopaminergic or alpha-adrenergic receptor stimulants. However, at most nerve endings, the false neurotransmitters are less potent stimulants; this lower degree of stimulation is one means by which their antihypertensive action is produced. Alternately, alpha-methyldopa may act by stimulating the brain-stem sympathetic nervous system. When this system antagonizes the peripheral sympathetic nervous system, the activity of the latter decreases and blood pressure is reduced. Through its central effect, alpha-methyldopa decreases anesthetic requirements 20 to 40 percent. [217]

In addition to altering the response to exogenously administered vasopressors, these neurotransmitter-depleting drugs can also produce side effects: psychic depression, nightmares, drowsiness, nasal stuffiness, diarrhea, bradycardia, and orthostatic hypotension with impotence (reserpine). [786] [787] Guanethidine and guanadrel can cause orthostatic hypotension, bradycardia, asthma, diarrhea, and inhibition of ejaculation. alpha-Methyldopa is associated with drowsiness, orthostatic hypotension, bradycardia, diarrhea, acute or chronic hepatitis, cirrhosis, and autoimmune hemolytic anemia (i.e., positive Coombs test result). [786] Because of these side effects, ACE inhibitors (captopril, enalapril, lisinopril, enalaprilat, and ramipril) are being used increasingly as first-line drugs and appear to improve the quality of life for the patient taking antihypertensive drugs. [247] However, ACE inhibitors may be associated with more peripheral vasodilation and hypotension on induction of anesthesia than are sympatholytics. [788] Added to this group are the ACE receptor-blocking agents. These last two

Figure 25-22 In the granules of the nerve terminal, alpha-methyldopa (Aldomet) is converted enzymatically to alpha-methyldopamine by the same enzyme that converts dopa to dopamine. alpha-Methyldopamine is converted to alpha-methylnorepinephrine by the same enzyme that converts dopamine to norepinephrine.

classes of drugs are associated with such severe hypotension with standard anesthetic induction that I discontinue those drugs preoperatively. [254] (See previous.)

Catecholamine or sympathetic receptor-blocking drugs affect the three major types of catecholamine receptors: alpha-adrenergic, beta-adrenergic, and dopaminergic. The existence of subdivisions (e.g., $beta_1$ and $beta_2$) suggested the possibility that some drugs would be found to affect only one set of receptors. For example, terbutaline is used more frequently than isoproterenol because terbutaline is said to exert a preferential effect on $beta_2$-receptors (i.e., to dilate bronchial smooth muscle), thereby avoiding the cardiac stimulation produced by drugs that stimulate $beta_1$-receptors. In fact, selectivity is dose-related. At a certain dose, a direct $beta_2$-receptor stimulating drug will affect only those receptors, but at a higher dose will stimulate both $beta_1$- and $beta_2$-receptors. The effect of a given dose varies with each patient. A certain dose may stimulate $beta_1$- and $beta_2$-receptors in one patient but neither receptor in another patient. More and more selective blocking drugs are being developed in hopes of widening the margin between $beta_1$- and $beta_2$- and alpha-adrenergic effects. Ultimately, however, more selectivity is desired than even this. It would be advantageous to be able to decrease heart rate without changing myocardial contractility or to increase contractility without changing heart rate. Such is the goal of much drug research and of the development of dobutamine (Chs. 14 and 16) . However, to date, all such selectivity appears to be dose-related, even for dobutamine. [789]

Metoprolol (Lopressor) and atenolol (Tenormin) (both $beta_1$-adrenergic receptor-blocking drugs) and propranolol, betaxolol, timolol, esmolol, pindolol, oxprenolol, acebutolol, carteolol, penbutolol, and nadolol are widely available beta-adrenergic receptor-blocking drugs used for chronic therapy in the United States. Because nadolol has poor lipid solubility, it has a long elimination half-life (17-24 hours) and does not cross the blood-brain barrier readily. Although nadolol should be associated with fewer CNS side effects, such as fatigue, nightmares, and depression, we do not know that definitely. The ability to use nadolol on a once-daily basis should increase patient compliance. Although selective beta-adrenergic receptor-blocking drugs should be more appropriate in patients with increased airway resistance or diabetes, this advantage is apparent only when low doses are used. The use of beta-adrenergic receptor-blocking drugs has become widespread, as these drugs treat everything from angina and hypertension to priapism and stage fright. These drugs appear to decrease morbidity and mortality in patients who have initially survived myocardial infarction [176] [790] [791] and to increase perioperative survival. [166] [235] [241]

Propranolol is the current standard for beta-adrenergic receptor-blocking drugs. Smulyan et al [792] studied the problems of long-term propranolol hydrochloride therapy on adult patients who must undergo abdominal surgery. Because these patients cannot take oral medications postoperatively for many days, they must be protected against perioperative sympathetic stimulation and the propranolol withdrawal syndrome. A continuous intravenous infusion of propranolol (3 mg/h, regardless of the patient's weight) given postoperatively accomplished these goals: Postoperative serum propranolol levels and beta-adrenergic receptor blockade returned to their "usual" preoperative levels. The hypotensive and bradycardic effects of propranolol and general

anesthesia appear to be additive. [793] Because of its shorter half-life (3-10 min), esmolol is quickly replacing propranolol in critical care (including anesthesia) settings, as errors in therapy or side effects, such as increased airway resistance, vanish much more quickly than if propranolol were administered. [794] Propranolol does not affect anesthetic requirements, [795] and one would expect the same lack of effect from other "pure" beta-adrenergic receptor-blocking drugs. The regimen for atenolol was presented earlier. (See Tables 25-18 (Table Not Available) and 25-19.) (Table Not Available)

alpha-Adrenergic receptor-blocking drugs include phentolamine, prazosin, terazosin, doxazosin, phenoxybenzamine, the phenothiazines, and the butyrophenones (e.g., droperidol). Dopaminergic receptor antagonists include the antischizophrenic drugs (phenothiazines and butyrophenones) and metoclopramide. The receptor-blocking drugs inhibit the action of sympathomimetic drugs at the receptor in a dose-related fashion. Thus, propranolol lowers blood pressure by blocking the tendency of norepinephrine and epinephrine to increase the rate and force of the contractions of the heart (and perhaps their tendency to increase the secretion of renin as well). To overcome this blockade, one need only provide more beta-receptor-stimulating drug. Thus, high doses of vasopressors may be needed to increase BP in a patient given large doses of propranolol.

When administration of beta-adrenergic receptor-blocking drugs is terminated, sympathetic stimulation often increases, as if the body had responded to the presence of these drugs by increasing sympathetic neuron activity. Thus, propranolol and nadolol (to name just two) withdrawal can be accompanied by the hyper-beta-adrenergic condition that increases myocardial oxygen demands. Administering propranolol or metoprolol can cause bradycardia, CHF, fatigue, dizziness, depression, psychoses, bronchospasm, and Peyronie disease. [786] [787] Side effects of the dopaminergic receptor-blocking drugs are discussed later in this chapter. Prazosin (Minipress), terazosin, and oxazocin are $alpha_1$-adrenergic receptor-blocking drugs used to treat both hypertension and ischemic cardiomyopathy because they dilate both veins and arteries. These agents are associated with vertigo, palpitations, depression, dizziness, weakness, and anticholinergic effects.

Brain-stem sympathomimetic drugs stimulate alpha-adrenergic receptors in the brain stem. Clonidine (Catapres), a drug with a half-life of 12 to 24 hours; guanabenz; and guanfacine (Tenex) are $alpha_2$-adrenergic receptor stimulants. Presumably, $alpha_2$-adrenergic agonists, including clonidine, guanabenz, and guanfacine, lower BP through the central brain-stem adrenergic stimulation referred to previously. They may also be used to treat opiate, cocaine, food, and tobacco withdrawal. Occasionally, withdrawal from clonidine can precipitate a sudden hypertensive crisis, analogous to that occurring on withdrawal from propranolol, causing a hyper-beta-adrenergic condition. The degree of hypertensive crisis following clonidine withdrawal is now being debated. (Although intravenous clonidine is not yet available in the United States, a skin patch of clonidine has been approved and is being used preoperatively to ablate sympathomimetic responses perioperatively.) Tricyclic antidepressant drugs and, presumably, phenothiazines and the butyrophenones interfere with the action of clonidine. Although administration of a butyrophenone (e.g., droperidol) to a patient given clonidine or guanabenz or guanfacine chronically could theoretically precipitate a hypertensive crisis, none has been reported. Clonidine administration can be accompanied by drowsiness, dry mouth, orthostatic hypotension, bradycardia, and impotence. In dogs, acute clonidine administration decreases anesthetic requirements by 40 to 60 percent; chronic administration decreases requirements by 10 to 20 percent. [167] [168] [231] [796] Because of the relative safety of these drugs and their ability to decrease anesthetic requirements, to block narcotic-induced muscle rigidity, and to provide pain relief, their popularity preoperatively is increasing. [167] [168] [231] [796] [797] [798] [799] [800] [801] [802]

Three other classes of antihypertensive drugs affect the sympathetic nervous system indirectly: diuretics, arteriolar dilators, and slow (calcium) channel-blocking agents. Thiazide diuretic drugs are associated with hypochloremic alkalosis, hypokalemia, hyperglycemia, hyperuricemia, and hypercalcemia. The potassium-sparing diuretic drug spironolactone is associated with hyperkalemia, hyponatremia, gynecomastia, and impotence. All diuretic drugs can cause dehydration. The thiazide

diuretics and furosemide appear to prolong neuromuscular blockade. [803] The arteriolar dilator hydralazine can cause a lupus-like condition (usually with renal involvement), nasal congestion, headache, dizziness, congestive heart failure, angina, and GI disturbances. Such a syndrome is nonexistent with the other direct vasodilator on the U.S. market, minoxidil.

The slow-channel calcium ion antagonists ("calcium channel-blocking drugs") inhibit the transmembrane influx of calcium ions into cardiac and vascular smooth muscle. Such inhibition reduces heart rate (negative chronotropy); depresses contractility (negative inotropy); decreases conduction velocity (negative dromotropy); and dilates coronary, cerebral, and systemic arterioles [804] (Fig. 25-23) (Figure Not Available) . Verapamil, diltiazem, and nifedipine all produce such effects, but to varying degrees and apparently by similar but different mechanisms. [804] [805] These mechanisms relate to the three different classes of calcium channel antagonists they represent: the phenylalkylamines, the benzothiazepines, and the dihydropyridines, respectively. [804] [805] Nifedipine is the most potent of the three as a smooth-muscle dilator, whereas verapamil and diltiazem have negative dromotropic and inotropic effects and vasodilating properties. Diltiazem has weak vasodilating properties as compared with nifedipine and has less atrioventricular conduction effect than does verapamil. Thus, verapamil and diltiazem can increase the PR interval and produce AV block. In fact, reflex activation of the sympathetic nervous system may be necessary during administration of diltiazem and especially during verapamil therapy to maintain normal conduction. Clearly, verapamil and diltiazem must be titrated very carefully when a patient is already taking a beta-adrenergic receptor-blocking drug or when adding beta-blocking drugs to verapamil or diltiazem. Although the increased death rate among patients taking calcium channel-blocking drugs as antihypertensive treatment (versus other agents) has cast doubt on their utility, calcium channel-blocking drugs are still widely prescribed.

The use of calcium channel-blocking drugs has several important implications for anesthetic management. [804] [806] [807] [808] [809] [810] [811] [812] [813] [814] [815] [816] First, the effects of inhalational and narcotic anesthetic agents and of nifedipine in decreasing systemic vascular resistance,

Figure 25-23 (Figure Not Available) Schematic drawing of smooth muscle cell showing calcium flux and possible sites of interference by halothane and nifedipine. The concentration of calcium (Ca^{2+}) in the cytoplasm increases (black arrows) because of entry through the plasma membrane (PM) and release from surface vesicles (SV) or the sacroplasmic reticulum (SR). When the concentration of cytoplasmic Ca^{2+} is sufficiently high, adenosine triphosphate (ATP) is activated. The splitting of ATP by adenosinetriphosphatase (ATPase) into phosphatidylinositol (Pi) and ADP (adenosine diphosphate) provides the interaction and contraction of actin filaments and myosin particles constituting muscle fibers. The concentration of cytoplasmic Ca^{2+} decreases (white arrows) with the return of Ca^{2+} to cellular stores and the extracellular transport of Ca^{2+}. Both halothane and nifedipine probably (1) inhibit the entry of Ca^{2+} and (2) may also interfere with cytoplasmic Ca^{2+} flux by reducing the release of Ca^{2+} by the SR, by (3) reducing storage and reuptake, or by (4) blocking ATPase and/or the contractile mechanism. *(From Tosone et al [892])*

BP, and contractility may be additive. [804] [807] [808] [809] [810] Similarly, verapamil and anesthetics (inhalational anesthetics, nitrous oxide, and narcotics) increase atrioventricular conduction times and additively decrease blood pressure, systemic vascular resistance, and contractility. [808] [809] [810] [813] [816] Second, verapamil and presumably the other calcium channel-blocking drugs have been found to decrease anesthetic requirements by 25 percent. [806] These agents can produce neuromuscular blockade, potentiate both depolarizing and nondepolarizing neuromuscular blocking drugs, and in at least one type of myopathy (Duchenne muscular dystrophy) even precipitate respiratory failure. [811] [812] [814] Finally, because slow channel activation of calcium is necessary to cause spasms of cerebral and coronary vessels, bronchoconstriction, and normal platelet aggregation, these drugs may have a role in treating ischemia of the nervous system, bronchoconstriction, and unwanted clotting disorders perioperatively. [811] All three drugs are highly protein bound and may displace or be displaced by other drugs that are also highly protein bound (e.g., lidocaine, bupivacaine, diazepam, disopyramide, and propranolol). Adverse consequences can be minimized by titrating inhalational or narcotic agent to hemodynamic and anesthetic effects. By monitoring for side effects, the anesthetist can prevent side effects from becoming serious (Slogoff S, et al, personal communication). Hemodynamic, but not electrophysiologic, changes usually can be reversed by administering calcium. [815] Reversal of electrophysiologic effects may occur if "industrial" doses of beta-adrenergic agonists are given.

Mood-Altering Drugs

Mood-altering drugs are the most frequently prescribed medications in the United States. They include MAO inhibitors (MAOI), selective serotonin reuptake inhibitors (SSRI), phenothiazines, tricyclic antidepressant drugs, and drugs of abuse such as cocaine. MAOIs, which include isocarboxazid (Marplan), phenelzine (Nardil), pargyline (Eutonyl), tranylcypromine (Parnate), and deprenyl, bind irreversibly to the enzyme MAO, thereby increasing intraneuronal levels of amine neurotransmitters (serotonin, norepinephrine, dopamine, epinephrine, octopamine). This increase is associated with an antidepressant effect, an antihypertensive effect, an antinarcoleptic effect, liver enzyme elevation, and delayed onset of Parkinson disease (deprenyl). [508] Because two forms of the enzyme (MAO-A and MAO-B) are selective in vitro for substrate (MAO-A is selective for serotonin, dopamine, and norepinephrine; MAO-B for tyramine and phenylethylamine), presumably MAOIs selective for MAO-A or MAO-B would have different effects. [817] This is not known for certain, as deprenyl (selegiline, Eldepryl), an MAOI-B-selective drug, improves a dopamine deficiency state, parkinsonism. [508]

Interactions between MAOIs and a variety of foods and drugs containing indirect-acting sympathomimetic substances such as ephedrine or tyramine (found especially in aged cheeses) can occur for as long as 2 weeks after the last dose of MAOI is given. The most serious effects of this interaction are convulsions and hyperpyrexic coma (particularly after narcotics).

Anesthetic management of a patient given an MAOI can be chaotic: For this reason it is widely accepted practice to discontinue MAOIs at least 2 to 3 weeks before any planned operation. [818] [819] [820] [821] [822] [823] [824] [825] [826] [827] [828] An alternate point of view has recently been expressed regarding severely psychotic patients or emergency surgery. [817] [829] [830] Clearly, the risk of discontinuing MAOIs must be weighed against the risk of suicidal tendencies in some patients deprived of MAOIs. There are no reported experiences of interactions between narcotics and deprenyl, so judgments about possible worsening of Parkinson disease and continuing MAOIs have no basis in data. It should be noted that severe reactions have occurred when too short an interval existed between administration of MAOIs and tricyclic antidepressants. [705] Emergency surgery on patients given MAOIs can be punctuated by hemodynamic instability. Regional block can be attempted as treatment for postoperative pain to avoid having to give narcotics. Case reports of hyperpyrexic coma following administration of most narcotics exist for humans, and animal studies document a 10 to 50 percent incidence of hyperpyrexic coma in animals pretreated with MAOIs and then given a variety of narcotics. [818] [819] [820] [821] [822] [823] [824] [825] [826] [827] [828] These reactions appear to be best treated using therapy supporting vital functions.

Alternate drugs for the treatment of severe depression include the tricyclic antidepressant drugs: amitriptyline (Elavil, Endep), imipramine (Imavate, Tofranil, Presamine), despiramine (Norpramine), doxepin (Adapin, Sinequan), nortriptyline (Aventyl), fluoxetine (Prozac), trazodone (Desyrel), and bupropion (Wellbutrin). [823] Tricyclic antidepressant drugs also block the reuptake of neurotransmitters and cause their acute release. Given chronically, these drugs decrease the stores of noradrenergic catecholamines. Tricyclic antidepressant drugs also produce side effects similar to those of atropine (dry mouth, tachycardia, delirium, urinary retention) and can cause changes on ECG (changes in T wave, prolongation of the QRS complex, bundle branch block or other conduction abnormalities, or premature ventricular contractions). Although arrhythmias induced by tricyclic antidepressants have been treated successfully with physostigmine, bradycardia has sometimes occurred. [823] Drug interactions with tricyclic antidepressants include those related to blockade of the reuptake of norepinephrine (such as interference with the action of guanethidine) and fatal arrhythmias after halothane and pancuronium. [831] [832] [833] Such interactions, although predictable for a population of patients, may not alter a patient's threshold for arrhythmias. The newer antidepressants (the SSRIs) also have serious side effects. Fluoxetine, a tricyclic that also has an SSRI effect, causes nausea, vomiting, headaches, nervousness, and possibly paranoia and ideas of suicide more commonly than do the other tricyclics [823] but is less likely to cause anticholinergic effects or orthostatic hypotension. Bupropion may cause nausea, vomiting, seizures, agitation, tremor, excitement, and increased motor activity but only rarely causes anticholinergic effects or orthostatic hypotension. Switching between drugs for depression can cause hyperpyrexia and coma. Thus, switching prior to surgery should not be requested casually. [823]

The effectiveness of phenothiazines and butyrophenones in schizophrenia suggests a dopamine receptor-blocking action. In addition, these drugs possess varying degrees of parasympathetic stimulation and ability to block alpha-adrenergic receptors. The phenothiazines include chlorpromazine (Thorazine, Chlor-PZ), promazine (Sparine), triflupromazine (Vesprin), fluphenazine (Prolixin), trifluoperazine, prochlorperazine (Compazine), and many others. The butyrophenones include droperidol and haloperidol (Haldol). Both phenothiazines and butyrophenones produce sedation, depression, and antihistaminic, antiemetic, and hypothermic responses. They are also associated with cholestatic jaundice, impotence, dystonia, and photosensitivity. Other side effects associated with phenothiazines include orthostatic hypotension (partly due to alpha-adrenergic blockade) and ECG abnormalities, such as prolongation of the QT or PR intervals, blunting of T waves, depression of the ST segment, and, on rare occasion, PVCs and torsades de pointes. [823] [832] [833] Although few data are available on the antidepressant drugs selective for serotonin (the SSRIs), occasional case reports of severe hypotension and cardiac arrest with severe bradycardia have been presented in abstract form.

Several important drug interactions are noteworthy for the phenothiazine derivatives. The effects of CNS depressants (especially narcotics and barbiturates) are enhanced by concomitant administration of phenothiazines. Also, CNS seizure threshold is lowered by administration of phenothiazines, which should be avoided in patients who are epileptic or withdrawing from any drug that depresses the CNS. The antihypertensive effects of guanethidine and guanadrel are blocked by tricyclic antidepressant drugs and phenothiazines. [786] Lithium carbonate is used to treat manic depression; it is more effective in preventing mania than in relieving depression. In excitable cells, lithium mimics sodium, decreasing the release of neurotransmitters both centrally and peripherally. Lithium prolongs neuromuscular blockade [834] and may decrease anesthetic requirements because it blocks brain-stem release of norepinephrine, epinephrine, and dopamine.

Psychoactive drugs such as amphetamines (including methamphetamines and their smokable derivative in crystal form, known as "ice") and cocaine acutely release norepinephrine, epinephrine, and dopamine and block their reuptake. Taken chronically, they deplete the nerve endings of these neurotransmitters.

Drugs that appear to increase central alpha-adrenergic release increase anesthetic requirement, whereas drugs that appear to decrease central alpha-adrenergic release decrease anesthetic requirements. (This may not be the mechanism by which they alter anesthetic requirement, but it is a convenient way of remembering the alteration.) Drugs that affect only the beta-adrenergic receptors do not alter anesthetic requirements. [167] [168] [217] [795] [796] [835] [836]

Sympathomimetic Drugs

Many antiasthmatic drugs (bronchodilators) such as terbutaline, aminophylline, and theophylline are sympathomimetic

drugs that can interact with the volatile anesthetics to cause cardiac arrhythmias. Halothane (and to some degree, most other volatile anesthetics) sensitizes the myocardium to exogenous catecholamines. [837] [838] [839] [840] Sensitization means that the minimum dose of exogenous epinephrine administered intravenously needed to produce premature ventricular contractions would be lower in patients anesthetized with halothane than in awake patients.

How much epinephrine is safe to give when halothane is the anesthetic? Katz and Bigger [837] reported that administration of 0.15 mL/kg of a 1/100,000 epinephrine solution per 10-min period (not to exceed 0.45 mL/kg of a 1/100,000 solution/h) was safe. Several studies have shown that lidocaine given with epinephrine affords extra protection and that enflurane and isoflurane are less sensitizing than halothane. [838] [839] [840] Because halothane is a potent bronchodilator, [841] it may be the best choice for anesthetizing patients with asthma. [842] However, this may not be the case; many asthmatic patients are already taking exogenous catecholamines such as xanthines as chronic bronchodilator therapy.

Xanthines are effective bronchodilators because they produce beta-adrenergic stimulation in two ways: They cause release of norepinephrine [843] [844] and also inhibit the breakdown of cyclic adenosine monophosphate (cAMP), [845] the mediator of many of the actions of beta-adrenergic receptor agonists. [434] Phosphodiesterase catalyzes the breakdown of cAMP. Thus, inhibition of phosphodiesterase by theophylline increases the concentration of cAMP. Marcus et al [843] and Westfall and Flemming [844] showed that at least 40 percent of the inotropic effects of aminophylline are due to its ability to release norepinephrine directly. Experimentally, aminophylline decreases the threshold for ventricular fibrillation. [846]

Plasma theophylline levels of 5 mg/L are needed to reduce abnormally high airway resistance. No further beneficial effects are obtained when levels exceed 20 mg/L; instead, toxic effects appear. [847] Theophylline (aminophylline is a combination of 85% theophylline and 15% ethylenediamine) is metabolized largely by the liver, less than 10 percent being excreted unchanged in the urine. The average half-life is 4.4±1.15 hours in adults, and clearance is 1.2 mL/min/kg. [847] Significant liver disease or pulmonary edema can decrease clearance of the drug by one-half and by one-third, respectively. [848] Cigarette smokers clear aminophylline more rapidly than do nonsmokers. [849]

An interaction between aminophylline and halothane appears to be a frequent, predictable occurrence: Of 16 dogs anesthetized with 1 percent halothane and given high-dose bolus injections of aminophylline, 12 had ventricular arrhythmias and 8 had ventricular tachycardia or fibrillation. [850] [851] [852] Thus, it is advisable to wait three drug half-lives after the last dose of aminophylline is given (i.e., approximately 13 hours in normal individuals) before using halothane to anesthetize an asthmatic patient. Using another anesthetic that is a bronchodilator [841] but that is less likely to predispose the patient to catecholamine-induced arrhythmias [838] [839] [840] (e.g., enflurane or isoflurane) or using inhaled or systemic steroids started several days in advance might be alternatives for patients requiring aminophylline or other exogenous sympathomimetic drugs before or during surgery. [853]

Other Drugs

Drugs other than those discussed earlier in this chapter have implications for anesthetic management. The therapies that have been discussed include anticoagulants and fibrinolytics (in hematologic section), endocrinologic preparations excluding birth control pills but including corticosteroids (in the section on endocrinologic disease), antihypertensive drugs (earlier in this section and in cardiovascular diseases), anticonvulsant drugs (in the section on neurologic disorders), and cancer chemotherapeutic agents (in the section on oncology).

Antiarrhythmic Drugs

Antiarrhythmic drugs include local anesthetics (lidocaine, procaine), anticonvulsant (phenytoin) or antihypertensive (propranolol) drugs, calcium channel-blocking agents, or primary antiarrhythmic drugs. These drugs are classified into five major categories: local anesthetics that alter phase 0 and phase 4 depolarization (quinidine, procainamide, and flecainide); local anesthetics that affect only phase 4 depolarization (lidocaine, tocainide, phenytoin, encainide); beta-adrenergic receptor antagonists; antiadrenergic drugs (bretylium, disopyramide, amiodarone); and calcium-entry blockers. These drugs are discussed elsewhere in this chapter and in Chapter 14 . A useful reference with suggestions about drug therapy for cardiac arrhythmias and monitoring of side effects was published by the *Medical Letter on Drugs and Therapeutics.* [854] Lack of adverse reports does not indicate that all these drugs should be continued through the time of surgery; pharmacokinetic studies have not yet determined whether anesthesia (or anesthesia with specific agents) alters the volume of distribution or clearance of these drugs to an extent sufficient to warrant changing the dosage or dosage schedule in the perioperative period. The dearth of reports on this subject may be due to a lack of significant drug interaction or to a lack of awareness that untoward events could be caused by such an interaction.

The pharmacologic characteristics of the various antiarrhythmic drugs can affect anesthetic management. Disopyramide is similar to quinidine and procainamide in its antiarrhythmic effectiveness. Disopyramide is mainly excreted by the kidneys, but hepatic disease increases its half-life. This drug often produces anticholinergic effects, including tachycardia, urinary retention, and psychosis. Hepatitis has also been reported to have occurred after its use. [854] Little is known of the interaction of bretylium with anesthetic agents. Because bretylium blocks the release of catecholamines, chronic therapy with this drug has been associated with hypersensitivity to vasopressors. [854] Quinidine is dependent on the kidneys for excretion, can have vagolytic effects that can decrease AV block, and is associated with blood dyscrasias and GI disturbances. [854] Most of the antiarrhythmic agents enhance a nondepolarizing neuromuscular blockade. Reports confirm this enhancement for quinidine, phenytoin, lidocaine, procainamide, and propranolol. [855] [856] [857] [858] [859] [860] [861] [862] [863] Amiodarone, an antiadrenergic drug used to treat recurrent supraventricular and ventricular tachycardias, causes a peripheral neuropathy and has been associated with hypertension, bradyarrhythmias, and reduced cardiac output during

anesthesia. [864] The drug has a half-life of 29 days, and pharmacologic effects persist for over 45 days after its discontinuance. [865] No data document such an effect for depolarizing muscle relaxants.

Antibiotics

Many antibacterial agents are nephrotoxic and/or neurotoxic, and many prolong neuromuscular blockade. [857] [858] [859] [860] [861] [862] [863] (Also see Ch. 12.) The only

antibiotics devoid of neuromuscular effects appear to be penicillin G and the cephalosporins. [862] Most enzyme-inducing drugs do not increase the metabolism of enflurane or isoflurane. However, isoniazid appears to induce the microsomal enzymes responsible for the metabolism of at least enflurane, increasing the possibility of fluorine-associated renal damage after enflurane. [866] Appropriate antibiotic prophylaxis for surgery (see Tables 25-34 and 25-35) (Table Not Available) requires a knowledge of the probability of infection for that type of surgical procedure and whether the incidence of infection warrants use of a drug regimen directed against the most likely infecting organisms. [354]

Digitalis

Digitalis preparations have a limited margin of safety, the risk of toxicity increasing with hypokalemia. [867] Although there is good rationale for administering digoxin prophylactically prior to surgery, [452] [868] I generally avoid doing so because potassium concentrations can fluctuate widely during anesthesia due to fluid shifts, ventilatory acid-base derangements, and adjuvant treatments, [596] [632] [633] [634] and because intraoperative arrhythmias caused by digitalis toxicity may be difficult to differentiate from those having other sources. Digitalis intoxication can present with such diverse cardiac arrhythmias as junctional escape rhythm, PVCs, ventricular bigeminy or trigeminy, junctional tachycardia, paroxysmal atrial tachycardia with or without block, sinus arrest, sinus exit block, Mobitz type I or II blocks, or ventricular tachycardia. [867] However, anesthetic agents appear to protect against digitalis toxicity, at least in animal studies. [869] [870] [871] [872] A titrated cardioversion technique, using at first 10-, and then 20-, 30-, 40-, 50-, 75-, 100-, 150-, and 200-joule doses, resulted in safe cardioversion in the presence of digitalis and propofol or midazolam hypnosis. [873] For patients in atrial fibrillation, the ventricular response should guide the choice of dose of digitalis.

Medications for Glaucoma

Medications for glaucoma include two organophosphates: echothiophate and isoflurophate. These drugs inhibit serum cholinesterase, which is responsible for hydrolysis and inactivation of succinylcholine and the ester-type local anesthetics, such as procaine, chloroprocaine, and tetracaine. [874] [875] These ester-type local anesthetics should be avoided in patients treated with eyedrops containing organophosphate. Table 25-45 lists other medications related to anesthesia and their side effects (from the National Registry for Drug-Induced Ocular Side Effects, Oregon Health Sciences University, 3181 SW Sam Jackson Park Road, Portland, Oregon 97201; 503-279-8456).

Also see Chapter 63 .

Magnesium, Cimetidine, and Oral Contraceptives

Magnesium is given to treat eclampsia; it can cause neuromuscular blockade by itself and potentiates neuromuscular blockade by both nondepolarizing and depolarizing muscle relaxants. [876] [877] Cimetidine reduces hepatic blood flow and inhibits enzymatic degradation of drugs by the liver. Thus, higher blood levels and prolonged elimination half-lives may result when drugs that are metabolized by the liver (e.g., lidocaine, procaine, some narcotics, and propranolol) are given to patients taking cimetidine chronically or acutely. [878] [879] The risk of postoperative venous thrombosis increases when oral contraceptives are used preoperatively. [880] [881] Although some authorities recommend changing from oral contraceptives to topical methods of birth control 2 to 4 weeks before surgery, [882] no controlled study has determined whether birth control pills should be discontinued before surgery, or the resulting incidence of pregnancy. Other authorities recommend preventing venous thromboembolism by using low-dose heparin, guided by a determination of efficacy and cost-effectiveness. [373] [374] [375] Because estrogens greatly decrease the incidence of cardiovascular disease and osteoporosis, their use in the elderly is being encouraged. [268] Thus, the uncertainty surrounding prophylaxis for heart disease (created by the dilemma of long-term benefit versus short-term risk of thromboembolism) makes necessary better data for resolution.

Interrupting a Drug Regimen Before Surgery

If a drug is needed for treatment preoperatively, it should be continued through surgery. It often must be specifically requested, as many patients and nurses perceive the nothing-by-mouth directive to include drugs. [883] [884] The only exception to this general rule of not altering preoperative drug therapy might pertain to (1) MAOIs; (2) anticoagulants and fibrinolytic agents if surgical hemostasis is needed; (3) nicotinic acid; (4) dosage adjustments for insulin and corticosteroids; and (5) ACE inhibitors and receptor antagonists. These recommendations require that the anesthesiologist be aware of the pharmacologic characteristics, interactions, and anesthetic implications of drugs described earlier in this chapter. [254] [512] [885] [886]

When in doubt about a disease or a drug, I consult the following textbooks: *Harrison' s Principles of Internal Medicine; Anesthesia and Uncommon Diseases; Pathophysiologic and Clinical Correlations; Anesthesia and Co-Existing Disease; To Make the Patient Ready for Anesthesia: Medical Care of the Surgical Patient; Anesthetic Implications of Congenital Anomalies in Children; Pharmacology and Physiology in Anesthetic Practice; Medical Care of the Surgical*

TABLE 25-45 -- Common Ophthalmologic Agents and Their Anesthetically Important Interactions

GLAUCOMA: PRIMARY GOAL IS TO REDUCE IOP BY-- MITOTICS AND EPINEPHRINE: INCREASE OUTFLOW OF AQUEOUS HUMOR beta -BLOCKADE AND CARBONIC ANHYDRASE INHIBITORS: REDUCE PRODUCTION OF AQUEOUS HUMOR OSMOTIC AGENTS: TRANSIENTLY DECREASE VOLUME	
AGENT (TRADE NAME)	***TOXICITIES AND SPECIFIC TREATMENTS***
Miotics	
Parasympathomimetics	
Pilocarpine (Adsorbocarpine, Isopto Carpine, Pilocar, Pilocel)	
Carbachol	
Acetylcholinesterase inhibitors	*Tox:* hypersalivation, sweating, N/V, bradycardia, hypotension, bronchospasm, CNS effects, coma, respiratory arrest, death
Physostigmine	
Demecarium	
Isoflurophate (Floropryl)	*Rx:* atropine, pralidoxime (Protopam)
Echothiophate (Echodide, Phospholine)	*Ix:* succinylcholine--prolonged apnea (agents must be discontinued 4 wk prior)
Epinephrine (Epitrate, Murocoll, Mytrate, Epifrin, Glaucon, Epinal, Eppy)	*Tox:* (rare) tachycardia, PVCs, hypertension, headache, tremors *Ix:* Avoid agents that sensitize to catecholamines, e.g., halothane.
beta -Blockers	
Timolol (Timoptic)	*Tox:* J-blockade with bradycardia, exacerbation of asthma, CNS depression, lethargy, confusion
Betaxolol (Betopic (?beta-1 selective))	
Levobunolol (Betagan)	Synergy noted with systemic agents
Carbonic anhydrase inhibitors	
Acetazolamide (Diamox)	*Tox:* Anorexia, GI disturbances,"general miserable feeling" and malaise, paresthesias, diuresis, hypokalemia (transient), renal colic and calculi, hyperuricemia, thrombo-cytopenia, aplastic anemia, acute respiratory failure in patients with COPD
Dichlorphenamide (Daranide, Oratrol)	

Ethoxzolamide (Cardrase, Ethamide)	
Methazolamide (Neptazane)	
Osmotic agents	
Glycerin (Glyrol, Osmoglyn)	*Tox:* Dehydration, hyperglycemia, nonketotic hyperosmolar coma (rare). Fatalities with mannitol secondary to CHF or intracranial bleeding
Isosorbide (Ismotic)	
Urea (Urevert, Ureaphil)	Urea may cause thrombosis
Mannitol (Osmitrol)	
Intraocular acetylcholine (Miochol)	*Tox:* hypotension, bradycardia *Rx:* atropine

MYDRIATICS AND CYCLOPLEGICS: PROVIDE PUPILLARY DILATATION AND PARALYSIS OF ACCOMMODATION-- ANTICHOLINERGICS BLOCK MUSCARINIC RECEPTORS; PARALYZING IN IRISalpha -ADRENERGICS CONTRACT THE DILATOR OF THE IRIS

AGENT (TRADE NAME)	***TOXICITIES AND SPECIFIC TREATMENTS***
Anticholinergics	
Atropine (Atropisol, Bufopto, Isopto Atropine)	*Tox:* dry mouth, flushing, thirst, tachycardia seizure, hyperactivity, transient psychosis, rare coma, and death
Cyclopentolate, alone (Cyclogyl) or with phenylephrine-homatropine (Cyclomydril)	*Rx:* physostigmine
Scopolamine tropicamide (Homatrocel, Isopto Homatropine, Isopto Hyoscine, Murocoll #19, Mydriacyl)	
alpha-Adrenergics	
Phenylephrine (Efricel, Mydfrin, Neo-Synephrine)	*Tox:* tachycardia, HTN, PVCs, myocardial ischemia, agitation
Hydroxyamphetamine (Paredrine)	

Abbreviations: IOP, intraocular pressure; Tox, toxicity; Rx, treatment; Ix, interaction; N/V, nausea and vomiting; PVCs, premature ventricular contractions; CNS, central nervous system; GI, gastrointestinal; COPD, chronic obstructive pulmonary disease; CHF, congestive heart failure; HTN, hypertension

Patient: A Problem-Oriented Approach to Management; and *Goodman and Gilman*' *s The Pharmacologic Basis of Therapeutics.* It is then wise to consult two experts on the drug or disease and determine who is best able to care for the patient. The expert who is best qualified should be observed while he or she is attending to the patient, not only preoperatively and intraoperatively but also postoperatively. It is important to remember that few prospective controlled studies have shown that any preoperative technique, treatment, or management decreases perioperative risk. However, common sense and foreknowledge of potential pitfalls, as well as diligence in avoiding those pitfalls, should reduce avoidable perioperative complications.

Chapter 26 - Patient Positioning

Roy F. Cucchiara
Ronald J. Faust

INTRODUCTION: GOALS OF POSITIONING FOR THE SURGICAL PATIENT

In general, the goal of surgical positioning is to facilitate the surgeon's technical approach while balancing risk factors. Surgical techniques have been expanded by the flexibility provided by anesthesia methodology, so that new areas of the body have become accessible and new positions have been developed. All surgical positions carry some degree of position-related risk; these risks are increased in the anesthetized patient, who cannot make the clinician aware of compromised positions. The goal of providing the best surgical exposure is always balanced by the need to minimize the risk to the patient.

PHYSIOLOGIC EFFECTS OF CHANGE IN POSITION FROM VERTICAL TO HORIZONTAL IN HUMANS

Body responses to alterations in position are in response to gravity. Most of the changes are related to gravitational effects on blood and its distribution within the venous, pulmonary, and arterial systems. There are also important effects on pulmonary mechanics and perfusion, again related to gravity.

Cardiovascular System

There is evidence that changes in blood volume occur as we change from erect to supine. Some of these are demonstrable within minutes, [1] whereas others are associated with long-term bed rest. For most purposes, the redistribution of blood volume within the vascular system that is caused by position changes is more important. In the erect position, there is opportunity for considerable increase in transmural vascular pressure in the lower extremities because of the hydrostatic effects of the columns of blood. This increase is limited by increased pressure in the tissue surrounding the vessels, which is due to muscle tone and contraction required to maintain the erect position, and by venous valves. Even with this compensation, clinically there is considerable blood volume or capacity within the lower-extremity vascular bed. [2]

A complex system of reflexes in both the venous and the arterial systems maintains blood pressure during changes in position. Although these reflexes work in concert, anesthesia can blunt the response of selected limbs of the system, thereby altering the final response in either direction. The venous atrial reflexes are responses both to stretching of the atrial wall and to autonomic nervous influences. Arterial pressor reflexes are more directly related to autonomic response to baroreceptors in the aortic arch and the carotid sinus. Changes in position alone do not alter the responsiveness of these reflexes, but other factors, including drugs and age, are important in this alteration of response.

Cardiac output tends to increase immediately on assumption of the supine position. Venous blood from the lower body flows back to the heart, stretching the atrial wall, and stroke volume increases. If contractility and arterial tone remained constant, arterial pressure would rise. Baroreceptor impulses travel afferently from the aorta via the vagus nerve and from the carotid sinus via the glossopharyngeal nerve to the medulla. Increased efferent parasympathetic and decreased efferent sympathetic activity change the parasympathetic/sympathetic balance, which causes decreased heart rate, stroke volume, and contractility and thereby results in little change in blood pressure. [3]

Pulmonary System

During spontaneous ventilation in the erect position, the primary force of inspiration is the downward movement of the diaphragm. In the supine position, the diaphragm shifts upward and outward and contributes only about two-thirds of the ventilatory force. In the erect position, the abdominal contents and the diaphragm shift downward, allowing functional residual capacity and total lung capacity to increase. When supine, the abdominal contents move cephalad, stretching the posterior portion of the diaphragm more cephalad. The resulting diaphragmatic contraction provides greater movement of the posterior portion of the diaphragm, with increased ventilation of the dependent portions of the lung. This aids in matching ventilation to perfusion because the dependent portions of the lung are also preferentially perfused. However, total lung capacity and functional residual capacity decrease in the supine position. In the anesthetized, mechanically ventilated, supine patient, the position of the diaphragm and its subsequent function change slightly. The diaphragm shifts still more cephalad, reducing functional residual capacity even more from the awake value. Intermittent positive-pressure ventilation (IPPV) does not restore the diaphragm to the awake position. Differential ventilation occurs within the lung during IPPV, and those areas that are gravitationally lower receive proportionately more ventilation. In the supine position, ventilation is more nearly uniform throughout, with a smaller gradient anterior to posterior. [4] [5]

HORIZONTAL POSITIONS

The transition from supine to lateral to prone is a continuum, with various procedures placing the torso at all points of the circle. The usual and common supine position is generally considered to be safer than modifications. The most common serious positional injuries are peripheral nerve injuries.

Supine

The lithotomy position is most used in gynecologic and urologic surgery. The simultaneous elevation of the legs while the person is in the supine position provides the advantages of reducing torsion on the pelvis and lower back and promotes translocation of vascular volume centrally (Fig. 26-1) (Figure Not Available) . However, the areas that support the weight of the legs provide points of potential nerve and muscle injury. The goal is to suspend or support the legs so that they are flexed at the hips perpendicular to the torso and spread far enough apart to allow appropriate access to the abdomen (Fig. 26-2) (Figure Not Available) . Sometimes, less or more flexion is required (Figs. 26-3 (Figure Not Available) , 26-4 (Figure Not Available)). There are several devices to support the legs, the vertical bars being common to all of these. The support from the bar may be by built-in concave metal supports (see Figs. 26-2 (Figure Not Available) , 26-3 (Figure Not Available)) or by straps (see Fig. 26-4 (Figure Not Available) ; Fig. 26-5) (Figure Not Available) Both of these positions usually require additional padding.

There is risk of injury to the peroneal nerve if it is compressed between the head of the fibula and the bar or the support structures. Pressure over the medial tibial condyle may result in saphenous nerve injury. There is no obvious sign that such compression is occurring, and it can apparently be prevented by proper padding of the leg. Femoral nerve injury is probably due to angulation of the thigh such that the inguinal ligament is stretched tightly and compresses the femoral nerve. Obturator nerve injury is also related to greater degrees of thigh flexion, perhaps by stretching the nerve as it exits the obturator foramen. Bilateral lower compartment syndrome can occur in the lithotomy position and is perhaps related to the duration of the case, the tightening of the leg straps, the dorsiflexion of the ankle, or the surgeon leaning on the suspended leg for long periods of time. [6] [7] The pathogenesis of the compartment syndrome probably involves direct local muscle pressure as the initiating event. [8] [9]

A devastating injury in this position, which is fortunately uncommon, is hand and finger injury. As the foot of the bed is being rolled to a vertical position, care must be taken that

Figure 26-1 (Figure Not Available) (A) Flexing, then raising of the legs for the lithotomy position. (B) Holding the legs and stirrups for final positioning. *(Adapted from Goldstein [55])*

Figure 26-2 (Figure Not Available) Final lithotomy position showing leg placement. See text for potential risks. *(Adapted from Goldstein [55])*

the fingers are not caught in the gap and crushed (see Fig. 26-5) (Figure Not Available) . Compartment syndrome of the hand can occur if it is compressed between the buttocks and the operating table. [10] Extension of the arms perpendicular to the body prevents such an occurrence but introduces the possibility that the arms will be pushed too far cephalad. This stretches the brachial plexus and can result in nerve injury. The general practical rule is that the arms should be at an angle no greater than 90 degrees when extended on fixed arm boards. In the lithotomy position, pooling of the preparation solution at the buttocks and lower back can result in a chemical burn; it is wise to remove all drapes in this area after preparation so that puddles of residual solution can be removed.

Lateral

As the torso is tilted slightly laterally, usually a pad is placed under the shoulder so that the head and neck can be turned without tension. Such turning of the shoulder area alone may place torque on the lower back. It may be useful to place a pad under the hip so that it can follow the tilt of the shoulder and prevent the torque on the spine. Extreme lateral neck flexion has been reported to cause transient Horner syndrome. [11]

Thoracotomy patients are usually placed in the full lateral position. The arm is placed perpendicular to the torso, either on a pillow or on an overarm rest to support its weight (Fig. 26-6) (Figure Not Available) ; the arm is usually taped in this position. Care must be taken that the tape does not impinge on the ulnar nerve at the elbow or on the radial nerve as it wraps around the radial groove in the upper third of the humerus. For some thoracotomy procedures, a higher chest exposure is needed, and the arm is placed above the shoulder plane. Special care must be taken to avoid plexus injury in these situations (Fig. 26-7) (Figure Not Available) . Tension on the brachial plexus can be reduced by bringing the arm into a more anterior plane with the body. The lower chest is generally supported with an axillary roll. This places the weight of the chest on the rib cage and prevents the shoulder and axilla from being compressed; such compression of the axilla can lead to brachial plexus injury in the down arm. Palpation of the arterial pulse in the down arm is sometimes used as a measure of the adequacy of decompression. However, because the axillary brachial plexus can be substantially compressed well before pulses are lost, this method is probably insufficient evidence of safety. If the peripheral arm pulse is absent, substantial compression must have already occurred, and the patient and roll should be repositioned.

Lateral Oblique

The lateral oblique (sometimes called the three-quarters prone) position is used primarily for exposure of the posterior fossa in neurosurgery but may be used for other procedures on the back and upper neck. In this position, the torso is rotated from supine to lateral (Fig. 26-8) (Figure Not Available) . [12] The upper leg is brought forward and flexed slightly, and the lower leg is left straight. The head-holder pins may be placed before or after the patient is turned. An axillary roll is placed under the chest to support the weight of the body and thus prevent the down axilla from being compressed. This is done at an angle, slightly higher posteriorly and slightly more caudad anteriorly. It should be possible to get part of a hand in the space between the chest wall and the axilla. The lower shoulder is brought to the forward edge of the bed or just slightly over it (Fig. 26-9) . The patient is then rotated to three-quarters prone so that the lateral occipital skull is accessible to the surgeon or so that the patient is looking directly at the floor. The upper arm is placed downward near the side wherever it falls comfortably. The upper shoulder must not be so high that it interferes with surgical access.

Figure 26-8 (Figure Not Available) Movement of the patient from the supine to the lateral oblique position. *(From Tew and Scodary [12])*

Figure 26-9 The lateral oblique (three-quarters prone) position. The axillary roll is placed under the chest, and the lower shoulder is brought forward to the edge of the bed or just slightly over the edge.

In obese patients, especially women, it may not be possible to fit the lower arm below the torso; it may have to be placed posteriorly and parallel to the torso. This position places considerable weight on the head of the humerus and acromion, and these areas should be padded carefully without excessive bulk. Attention must be paid to the lower breast to prevent pressure on the nipple and areola. Extreme flexion of the head might compromise cervical spinal cord perfusion; quadriplegia can occur in the prone position despite this precaution. [13]

Monitoring such a patient requires special attention. The electrocardiograph (ECG) electrodes must not be placed in the dependent areas, where pressure necrosis can develop under the metal connections or wires. An arterial catheter is helpful in obtaining an accurate assessment of pressure. The incidence of Doppler-detected venous air embolism (VAE) during craniectomy in this position is about 10 percent. Consideration should be given to the use of the precordial Doppler and a central access line. However, positioning the precordial Doppler in this position is difficult and may not be effective for monitoring for VAE. Opinions vary regarding the value of an atrial catheter for air retrieval in this situation.

There are several difficulties in placing a patient in this position. Pressure on the dependent axilla and its contents and breast tissue are appropriate concerns, but there are no real guidelines for how much pressure is acceptable. The ability to place one's own hand into the axilla and feel for compression there is a good starting point, as is observation to be sure that the areola is free. Clinical experience must ultimately be the guide.

Trendelenburg

The Trendelenburg modification of the supine position places the head down, often with the knees flexed, so that the patient does not slide headward on the table. Shoulder braces may be used to restrict patient movement, but the weight of the torso can put considerable tension and stretch on the brachial plexus, with resultant injury.

The position moves the viscera cephalad and is used to improve exposure during lower abdominal surgery, to increase venous return after spinal anesthesia, or to increase central blood volume to facilitate jugular or subclavian cannulation, as well as to minimize aspiration during regurgitation by facilitating removal of material from the pharynx.

This position causes an increase in central venous pressure, intracranial and intraocular pressure, myocardial work, and pulmonary venous pressure and a decrease in pulmonary compliance and functional residual capacity. [14] [15] If longer operations are planned, we believe that endotracheal intubation is clearly indicated. There are no data demonstrating a higher incidence of unexpected neurologic events in patients placed in the steep Trendelenburg position for long operations, but there is one case report of a patient who had a cerebral hemorrhage during such a procedure and emerged with a significant neurologic deficit. [16] Clinical swelling of the face, eyelids and conjunctiva, and tongue has been observed, along with a plethoric color of venous stasis in the head and neck. Lingual and buccal nerve neuropathy can occur. [17] In patients with substantial swelling, it may be prudent to delay removal of the endotracheal tube until that situation has improved.

UNUSUAL POSITIONS

Positions for Orthopedic Surgery

Total hip arthroplasty, femoral neck fractures, and midfemur fractures for open reduction and internal fixation require different positions because of the need for surgical access and roentgenographic and fluoroscopic guidance (Figs. 26-10 (Figure Not Available) , 26-11) (Figure Not Available) Ch. 60) The lateral decubitus position is usually used for total hip arthroplasty. Patients having total hip arthroplasty often have concomitant degenerative cervical spine disease or at best some limitation of motion of the neck, which causes pain if exceeded. Careful alignment of the neck and head with the thoracic spine is usually not difficult. The down hip and leg are at risk during total hip arthroplasty in the lateral decubitus position. Rhabdomyolysis, much like that in a crush injury (five of the six patients reported were obese), [18] arterial insufficiency resulting in below-the-knee amputation, massive swelling of the thigh, and renal failure associated with myoglobinuria have been reported. Use of the pulse oximeter to detect excessive pressure on the femoral triangle has been suggested. [19]

The orthopedic fracture table consists of a body section to support the head and thorax, a sacral plate for the pelvis with a perineal post, and adjustable foot plates. The most important features of the table are the ability to maintain traction on the extremity and to obtain surgical and fluoroscopic access. Because the patients requiring this table are often in pain, anesthesia is usually induced before the patient is moved to the table. If regional anesthesia is used, the fracture side should be placed up. Once the patient has been transferred, the arm on the fracture side should be placed so that it does not interfere with surgical access to the

---

Figure 26-10 (Figure Not Available) Femoral neck fractures can be managed in the supine position on the fracture table. *(Adapted from Day [15])*

fracture; placing it across the chest directly or on an overarm board is effective.

Complications from this position include brachial plexus injury, lower-extremity compartment syndrome, and pudendal nerve injury related to the post. [20] [21]

Position for Shoulder Surgery

The use of the "beach chair," "barber's chair," or semirecumbent position is increasing in popularity in parallel with surgical procedures on the shoulder. The key element of the position is that it provides both anterior and posterior access to the shoulder, with the upper extremity freely mobile. Extreme rotation of the head away from the operative side can result in stretching of the brachial plexus during surgical manipulation. Figure 26-12 shows one method of securing the endotracheal tube and head to prevent movement and accidental extubation. [22] Although the head is not elevated as much as is required for neurosurgical procedures, the surgical field is clearly higher than the heart. An impressive complication of shoulder arthroscopy is rapid, progressive, and complete airway obstruction, caused by extravasation of the fluid used during visualization out of the capsule and into the tissues of the neck. [23]

Figure 26-11 (Figure Not Available) For midfemoral fractures, the patient is placed on the fracture table in the lateral position, with the legs spaced and positioned to allow roentgenography at an angle in several planes. *(Adapted from Day [15])*

Figure 26-12 Lateral view of upright shoulder position. The endotracheal tube and head are secured to prevent movement and accidental extubation.

SITTING POSITION

The sitting position is said to offer some surgical advantages (Table 26-1) . Surgeons might weigh these advantages differently, but most would agree that ease of surgical exposure, amount of blood pooling in the operative field, and operative position of the surgeon are different among the sitting, lateral, supine, and prone positions. Some anesthesiologists believe that access to the endotracheal tube, reduction of facial swelling, and ability to observe facial nerve function are notable advantages of the sitting position in anesthetic management. One workable

TABLE 26-1 -- Practical Reasons for Selective Use of Sitting Position

Better surgical exposure
Less tissue retraction and damage
Less bleeding
Less cranial nerve damage
More complete resection of the lesion
Ready access to airway, chest, extremities
Modern monitoring gives early warning of venous air embolism
Serious problems due to venous air embolism are uncommon

arrangement of equipment and operating table for procedures using the sitting position (and performed by a right-handed surgeon) is shown in Figure 26-13 . The two most common procedures performed in the sitting position are cervical laminectomy and posterior fossa exploration. Hazards to the patient undergoing posterior fossa craniectomy in the sitting position include VAE, hypotension, vital sign changes resulting from brain-stem manipulation, specific cranial nerve stimulation, airway obstruction, and position-related brain-stem ischemia. These are not unique to the sitting position and may occur in other positions as well. Management should be directed at the prevention, early detection, and treatment of these problems.

There is much concern about the use of the sitting position, and some even suggest that it constitutes malpractice for today's surgery. These intimidating statements may have some basis in fact but in general do not consider the large body of information about the safety of the sitting position.

Safety

Several large published series show a remarkably similar and favorable safety record for operations using the sitting

Figure 26-13 Arrangement for surgery in the sitting position. The scrub nurse is to the right of the surgeon to place instruments into the surgeon's right hand. The entire left side of the patient is available for the anesthesiologist's care.

position. [24] [25] [26] [27] The sitting position is being used less, and more posterior fossa procedures are being performed in horizontal positions. The sitting position is becoming a conscious selection rather than an automatic response for any posterior fossa lesion. There are risks and benefits for each position, and these must be weighed in the overall care of the patient.

A study by Black et al [24] put the problem into perspective, and its results are consistent with those of other studies. These authors retrospectively reviewed 579 posterior fossa craniectomies (333 sitting and 246 horizontal) performed concurrently from 1981 through 1984. It is the only study in the literature comparing the sitting and horizontal positions; no prospective randomized comparative study has been performed to date. Intraoperatively, the incidence of hypotension did not differ between the two groups either from induction of anesthesia to incision or from incision to closure. About 20 percent of the patients in each group became hypotensive during each of these periods; all responded to vasopressors and/or fluids. The incidence of VAE in patients monitored by Doppler ultrasound was significantly greater in the sitting position (45%) than in the horizontal position (12%).

Another important difference between the two groups was the need for blood transfusion, confirming the traditional surgical impression that upright patients bleed less. More than 2 units of blood were required in 13 percent of the patients in the horizontal position and in only 3 percent of those in the sitting position. Average blood volume transfused was also lower for the patients in the sitting position.

After surgery, no differences were found in cardiac or respiratory complications. The perioperative myocardial infarction rate was less than 1 percent overall and was not different in the two groups. Respiratory complications were found in 2.5 percent of patients and did not differ between groups or in comparison with other studies. [26] Thus, the data do not support the general selection of either the sitting or the horizontal position based on outcome. There are certain risks and advantages to each, and selection of position should be made with these in mind as they relate to the specific patient.

There are some conditions that seem prudent to consider as relative contraindications to the sitting position (Table 26-2) . However, there are few objective data to support our approach. If a shunt tube is in place from the cerebral ventricular system to the right atrium, air may enter the end of the shunt as cerebrospinal fluid drains out and may be pulled into the heart. The noncollapsible tubing acts as a noncollapsible vein and allows air to pass unimpeded into the heart. This is not a potential problem with a ventriculoperitoneal shunt, because the air would have no venous access. We recommend that a patient with a ventriculoatrial

TABLE 26-2 -- Relative Contraindications to Operative Sitting Position

Ventriculoatrial shunt in place and open
Cerebral ischemia upright awake
Left atrial pressure < right atrial pressure
Platypnea-orthodeoxia
Preoperative demonstration of patent foramen ovale or right-to-left shunt

? Cardiac instability ? Age extremes	Chest compression and resuscitation not really better in prone or lateral position

shunt in place have the shunt tied off before the patient undergoes an intracranial procedure in the sitting position. Some patients experience cerebral ischemia whenever they assume the upright position. Their cardiovascular and cerebrovascular systems may both be implicated in this situation. These patients may present for an extracranial-intracranial bypass for the posterior cerebral circulation; some surgeons believe that the sitting position gives the best exposure for this procedure. We cannot be sure that cerebral circulation will be maintained in the sitting position, because we must not only place the patient upright but must also provide an anesthetic. It seems a reasonable balance of risks and benefits to place such a patient in the horizontal position.

There has been a suggestion that if the left atrial pressure, as measured by pulmonary artery occlusion pressure, is less than the right atrial pressure in the sitting position, the patient should be placed horizontally because of an increased risk of paradoxical embolism. [28] This is based on two important assumptions: first, the left atrial pressure will be greater than the right atrial pressure in the horizontal position; second, the atrial pressure gradient and its direction constitute a prognostic indicator of whether VAE will become paradoxical air embolism (PAE). Some work suggests that these assumptions may not be applicable. In a pig model with an iatrogenic atrial septal defect, the atrial pressure gradient before air embolism was unrelated to the occurrence of PAE. [29] Thus, we believe that decisions regarding the use of the sitting position based on estimates of preoperative atrial pressure gradients are not well founded. Some patients demonstrate a potential right-to-left shunt before surgery. Platypnea-orthodeoxia is an unusual cardiovascular illness in which the atrial gradients apparently reverse when the upright position is assumed [30] ; patients with this condition are well oxygenated in the supine position but become desaturated in the upright position because of unsaturated blood passing from right to left at the atrial level. Other patients demonstrate a patent foramen ovale before surgery during a cardiac work-up, and still others may have a known right-to-left shunt. These patients might be at greater risk for PAE should VAE occur, and therefore it seems prudent to give these findings appropriate consideration before using the sitting position for such patients.

Some suggest that the sitting position should be avoided in patients with cardiac instability or at extremes of age because of a possible need to resuscitate intraoperatively. We believe that it is no easier to provide chest compression in the prone or lateral position than in the sitting position; all are equally undesirable. The rare need to resuscitate probably does not justify giving up whatever surgical advantage is thought to be gained by the use of the sitting position. Thus, in our opinion, these last considerations are not relative contraindications.

There are several details that should be considered when a patient is placed into a sitting or semirecumbent position (Fig. 26-14) (Figure Not Available) . Attention to detail in these matters probably only rarely prevents complications, but some of the complications can be major and are long remembered. Strict attention should be paid to the flexion of the head on the neck. We usually position the awake patient for up to 1 minute to see how much flexion can be tolerated, and that degree of flexion is not exceeded after the patient has been anesthetized. In general, we try to place two fingers between the chin and the sternum when positioning is complete as a possible way to

Figure 26-14 (Figure Not Available) The patient is in a semisitting position with the knees flexed slightly. The headrest support is fastened to the upper part of the table so that the head can be lowered without changing the relationship of the pinion head holder to the torso. The arms must be supported (not shown) so that the weight of the arm does not stretch the brachial plexus. The buttock area is padded. *(Adapted from Martin [60])*

prevent spinal cord ischemia with postoperative quadriparesis or quadriplegia. We have accepted one fingerbreadth, but only in selected circumstances. Although there is no study to show that this approach is effective, we have had no cases of quadriplegia attributable to cervical flexion in our practice.

In the sitting position, the arms tend to hang by the side. When muscle relaxants are used, the downward force caused by the weight of the arms is sufficient to stretch the brachial plexus and cause unilateral arm paralysis or weakness. This is not a theoretical consideration in our practice. This situation can be prevented by the placement of blankets under the elbow and forearm to support the weight of the arm so that there is no downward stretch on the arm, and the arm is actually pushed up slightly, giving the appearance of a slight shoulder shrug.

The hips are often flexed for two reasons: (1) this position tends to place the buttocks at an angle to support the weight of the body, and (2) it is thought to aid venous return. The legs must not be outstretched, however, because this places considerable tension on the sciatic nerve and can result in postoperative weakness. Bending the legs at the knees removes this tension, and placing an artificial fat pad under the buttocks to include the sciatic notch of the pelvis may reduce the chances of pressure ischemia of the nerve. Venous return may be aided and thromboembolism may be prevented by the use of elastic leg wrapping or alternating inflatable leg wraps (e.g., sequential TEDS).

Monitoring

The data from many studies indicate that the sitting position seems relatively safe, provided that adequate monitoring is used (Chs. 28 to 38).

Central Nervous System

Central nervous system monitoring techniques for patients in the sitting position are directed not only at minimizing the hazards of the position but also at providing positive information to the surgeon, particularly during posterior fossa exploration. The same central nervous system monitoring is required for any infratentorial procedure, regardless of surgical position. The response of the vital signs to brain-stem manipulation and the response of the cranial nerves to stimulation can provide pathophysiologic data that the surgeon can use in real time during dissection (Table 26-3) .

The ECG is an effective monitor of brain-stem compression. Spontaneous respiration has been advocated as a means of detecting transgression of the respiratory centers during posterior fossa exploration. However, a large series has indicated that monitoring the ECG provides adequate warning of brain-stem compromise during light anesthesia while mechanical ventilation is used to maintain reduced arterial carbon dioxide tension levels. [31] Brain-stem auditory evoked responses and somatosensory evoked potentials can provide an electrophysiologic monitor for early detection of brain-stem compromise. Stimulation of the seventh cranial nerve results in a facial twitch that is visible in the seated patient. Electromyography over the distribution of this nerve can aid in the detection of stimulation of the facial nerve if

TABLE 26-3 -- Cranial Nerve Stimulation During Posterior Fossa Surgery

CLASSIC ACTIVITY DESCRIPTION -- PHYSICAL SIGNS	ELECTRONIC TECHNIQUE
V. Motor: jaw jerk	EMG

Gasp, irregular respirations	Respirator "trigger"

EMG, electromyography; ECG, electrocardiography; BAER, brain-stem auditory evoked responses; SEP, sensory evoked potentials

the face is not accessible to palpation or visual assessment. This is especially true in the prone patient because it is not appropriate to have the anesthesiologist under drapes with a flashlight looking for facial twitch. The observation period can be protracted and can result in failure to properly monitor other parameters of anesthesia response because of unavoidable diversion of field of view and attention.

Cerebral Perfusion Pressure

Blood pressure and pulse rate are measured to monitor several interrelated systems and factors. Some operations performed in the sitting position might result in sudden and extreme changes in pulse rate and blood pressure either because of the surgery or because of VAE. Intra-arterial blood pressure measurements yield instantaneous information, particularly with regard to cerebral perfusion pressure. They can be easily obtained when the strain gauge is zeroed to the base of the skull, which can be accomplished by use of the routine zero at the heart level with the patient supine and by placement of the strain gauge at the level of the external auditory meatus once the patient is placed in the sitting position.

Venous Air Embolism

Let us examine the most troublesome complications of the sitting position as well as those that are common but not very troublesome. The most feared complication of surgery in the sitting position is VAE with subsequent PAE to the brain. This complication not only places the patient at risk from the air itself but also can cause a surgeon who lacks confidence in the ability of the anesthesia team to take care of the problem to become distracted and concerned; this takes the focus away from the job at hand, namely performing the surgery. Thus, we believe that open communication between the anesthesiologist and the surgeon about air before and during the surgery improves the level of awareness and the confidence that the situation can be managed appropriately. That is not to say that disasters cannot happen even with the best of management; however, early detection of such problems usually prevents their progression to disastrous consequences. We also believe that it is an oversimplification to place all patients in the horizontal position because of the risk of air without regard for the increased surgical risk of compromised exposure in certain patients.

Monitoring for VAE can be approached from several aspects. Monitors include a precordial Doppler device, a right-sided heart catheter, a capnograph or mass spectrometer, an esophageal stethoscope, a transcutaneous oxygen monitor, and a transesophageal echocardiogram. The most sensitive of these methods are transesophageal echocardiography and Doppler ultrasound, followed by expired nitrogen fraction, end-tidal carbon dioxide, transcutaneous oxygen, right-sided heart catheterization, and, least sensitive, esophageal stethoscope measurements. None of these monitoring methods is totally reliable; we believe that it is generally necessary to use at least three of them to ensure that VAE can be detected (Fig. 26-15) (Figure Not Available) .

The risk of VAE is not eliminated by placing the patient horizontal, but it is reduced. A 12 percent incidence of Doppler-detected air occurs in supine infratentorial craniectomy cases. [24] Once VAE has occurred, about 20 percent of patients will have hypotension, regardless of their position. Except in the unusual situation of massive VAE, these episodes can be expected to respond promptly to vasopressor therapy.

The precordial Doppler device is advocated as the basic monitor for reducing complications caused by VAE. It is reasonably priced, relatively easy to use, noninvasive, and sensitive; its position over the right side of the heart can be verified by rapid injection of agitated saline into the central venous circulation, and its sounds can be heard by both surgeon and anesthesiologist. Its sensitivity has led some to criticize its use because it may indicate "insignificant air" before hemodynamic consequences ensue. Protagonists argue that such sensitivity is precisely the early warning needed to identify the occurrence of VAE and to stop its entry surgically to prevent further secondary complications.

The use of the right-sided heart catheter has evolved and has been improved to an extent such that air can frequently be aspirated when it is detected by Doppler monitoring. But what are the real functions of the right-sided heart catheter? [32] Rapid injection of agitated saline through the catheter can help to confirm that the Doppler probe is properly

Figure 26-15 (Figure Not Available) Changes in detection parameters for venous air embolism with increasing air volume. Data are aggregated from human and animal studies under a wide variety of circumstances. *(Modified from Cucchiara et al [61])*

placed over the right side of the heart. The aspiration of air confirms or establishes the diagnosis of VAE. The role of the catheter in the treatment of VAE is more anecdotal and less solidly founded. The aspiration of air from the right atrium during VAE is occasionally life saving; this is limited to the rare situation of massive VAE. Whether routine aspiration of smaller or medium quantities of air from the heart can prevent PAE or cardiopulmonary complications is not known. Right atrial multiorifice catheters allow a larger amount of air to be aspirated than single-orifice catheters. Proper placement of the right atrial catheter high in the right atrium can increase its effectiveness because this is where the air tends to localize (Fig. 26-16) (Figure Not Available) . [33]

The right-sided heart catheter may be positioned by ECG control, roentgenography, or pressure recordings. It is likely that the ECG trace from a multiorifice catheter comes from the proximal hole, usually 2 cm from the tip. [34] [35] Thus, the tracing sought is slightly different with these catheters. The standard concept of a progressively more negative P wave as the catheter is advanced still applies, but the proximal orifice should be placed in the superior vena cava, allowing the

Figure 26-16 (Figure Not Available) The air tends to localize at the atrial superior vena caval (SVC) junction, moving through the tricuspid valve or into upright portions of the atrium. The multiorifice catheter placement most likely to aspirate air is shown. The ECG tracing from the catheter in this position is described in Fig. 30-17 (Figure Not Available) . The conceptualization of localization of air embolism in the upright heart is based on a human cardiac model and human echocardiographic findings. *(From Cucchiara et al [61])*

Figure 26-17 (Figure Not Available) The intracardiac ECG for each position is shown. With a single-orifice catheter, tracing 4 indicates mid-right atrial position. Since the ECG trace originates from the proximal orifice of a multiorifice catheter and since placement as shown in Fig. 30-15 (Figure Not Available) is desirable, tracing 2 should be sought. *(From Cucchiara et al [37])*

portion of the catheter that has the holes to float at the superior vena cava/high right atrial level. The P wave should be large and negative, with no positive component (Fig. 26-17) (Figure Not Available) . This indicates that the proximal orifice is not in the atrium. In practice, one can usually obtain an increasingly negative P wave that finally develops a small positive deflection and then withdraw slightly to an all-negative P wave. Care must be taken when the arm is returned to the side because the catheter will likely migrate a little more centrally and may need to be withdrawn slightly. [36] Placement of the right atrial catheter through an arm vein by ECG control can be performed in 5 minutes or less in 53 percent of patients and in 15 minutes or less in 92 percent of patients. The overall success rate in several studies was greater than 90 percent. [37]

The use of a pulmonary artery catheter for the aspiration of a VAE has generally been unsatisfactory because of the small lumen size and slow speed of blood return. However, other information can be obtained from the pulmonary artery catheter. The entry of air into the pulmonary circulation causes pulmonary artery pressures to rise. One can use this information to evaluate when the VAE has cleared the pulmonary circulation. If pulmonary artery pressure rises during the VAE and the Doppler recording clears, a return of pulmonary artery pressure to previous levels suggests that the air obstructing the pulmonary circulation has been moved more distally and has probably been excreted through the lungs. [38]

Capnography and mass spectrometry demonstrate a decrease in end-tidal carbon dioxide during VAE with intermediate sensitivity. One can expect to see changes in end-tidal carbon dioxide after Doppler changes occur but before hemodynamic changes occur. When enough air has been entrained to cause hemodynamic changes, the end-tidal carbon dioxide usually decreases within a few breaths after the Doppler change. Sensitive mass spectrometry can show increases in expired nitrogen fraction as the VAE is excreted through the lung. Transcutaneous oxygen tension monitoring is also intermediate in sensitivity but has more practical and technical problems, making its use in the operating room somewhat less popular. [39]

Figure 26-18 (Figure Not Available) Paradoxical air as noted by transesophageal echocardiography. (A) Normal; (B) air in right atrium; (C) air in left atrium, right atrium nearly opacified; (D) more air in left and right atrium. *(From Cucchiara et al [40])*

Transesophageal echocardiography is still a research tool but holds considerable promise in the diagnosis of VAE. It is very sensitive and allows visualization of air in the cardiac chambers themselves, thus providing the unique opportunity to identify the occurrence of air in the left side of the heart [40] (Fig. 26-18) (Figure Not Available) . Transcranial Doppler monitoring may identify air in the arteries of the brain. The only other clinical way to identify PAE during surgery in the sitting position is for the surgeon to visualize air in the small arteries of the brain or spinal cord. This implies that it is already late because the air is already in the vessels to the brain in amounts large enough to be readily seen and is likely to cause focal cerebral ischemia.

PERIPHERAL NERVE INJURY

Mechanism of Peripheral Nerve Injuries

In position-related nerve injuries, there are two basic forces that impair nerve function and, if severe or prolonged, impair axonal structure. Nerves that course superficially for long distances between two points of fixation are particularly vulnerable to stretch injury. Neural structures that are adjacent to or pass over bony surfaces in a small area are subject to compression between internal and ex-ternal structures, with resultant injury. The final result is likely the same--nerve ischemia resulting from reduction of blood flow through the intraneural vasa nervorum. The combination of stretch and ischemia makes the nerve more vulnerable to injury. [41] Compression injury usually occurs at a point along the nerve course; the smaller the contact point, the greater the focus of the force in compressing the nerve. Awake patients usually move when pain and paresthesia associated with nerve ischemia occur. Ischemia that persists for over 30 minutes can result in nerve palsy. [41]

Intraoperative diagnosis of nerve impairment during general anesthesia is usually clinical. The distal pulse should be checked where nerves and blood vessels pass together. Pulse oximetry and capillary refill are measures of impaired blood flow. If there is sufficient external pressure on the axilla, for example, to decrease these parameters from prepositioning values, there is certainly enough pressure to reduce blood flow to the nerve through the small vessels supplying the adjacent nerves. Conversely, intact perfusion by these clinical measures does not guarantee normal nerve perfusion and function. Somatosensory evoked potentials from medial nerve stimulation can be lost despite preservation of peripheral pulse, capillary refill, and pulse oximetry saturation and plethysmography. [42]

There are three types of nerve injury based on structure and function. Neurapraxic injury occurs with a loss of function (or occurrence of dysfunction) in the nerve without demonstrable anatomic injury. This is the type of injury related to positioning that is most likely to occur during anesthesia. Recovery is complete within 6 weeks, and no long-term treatment is indicated or needed. Axonotmesis occurs with anatomic disruption of the axon but preservation of the nerve sheath and connective tissue. The axon degenerates distal to the lesion and regenerates at a rate of about 1 mm/day. Function gradually returns, but in longer

nerves, such as those of the upper extremity, this may take a year. Surgery is not usually indicated, but physical therapy is helpful to prevent degeneration of the joints and muscles and to reintroduce those structures to load bearing when they are reinnervated. Neurotmesis results in axon, sheath, and connective tissue disruption. This leads to degeneration of the axon distal to the injury, but regeneration usually does not occur. Neurosurgical, rehabilitation, and pain services intervention may be helpful in these types of injuries. [43]

Ulnar Nerve Injury During Anesthesia

Although the true frequency of nerve injuries during anesthesia and surgery is not known, some pieces of information help to place the problem in perspective. A 1990 analysis of the American Society of Anesthesiologists Closed Claims Project database showed that 15 percent of the claims were for nerve injuries. Three distributions accounted for 73 percent of those cases: ulnar (34%), brachial plexus (23%), and lumbosacral nerve root (16%). The mechanism of ulnar nerve injury during anesthesia is unclear. In most cases, the injury seems to have occurred despite all the precautions of padding and careful placement of the elbow to protect the nerve. Some have questioned whether the injury is even preventable. [44]

The so-called cubital tunnel external compression syndrome has been advanced as a possible mechanism for postoperative ulnar nerve injury. [44] The ulnar nerve passes through the cubital tunnel of the elbow as it courses to the forearm. The anatomic boundaries of the cubital tunnel are the floor (the medial ligament of the elbow) and the roof (the arcuate ligament, which extends from the medial epicondyle of the humerus to the medial aspect of the olecranon process of the ulna). The nerve lies superficially in the tunnel and thus is vulnerable to injury. Perhaps when the arm is fixed at the patient's side or to an abducted arm board with the forearm pronated, the cubital tunnel is placed in contact with the surface of the cushion, and the nerve is externally compressed within the tunnel. Supination of the forearm places the olecranon process of the ulna in contact with the flat surface and might reduce its vulnerability. Importantly, flexion of the elbow to more than 90 degrees tenses the arcuate ligament and reduces the volume of the tunnel containing the ulnar nerve, possibly compressing it. Although this is a theoretical consideration, there is no evidence that altering the position of the arms in the supine patient during anesthesia and surgery decreases the likelihood of ulnar nerve injury. Ulnar nerve injury is more common in men (5:1, male/female ratio), which suggests some anatomic predisposition of the tunnel [45] or hypermobility of the nerve. [46] Preexisting medical diseases, such as diabetes and vitamin deficiency, and chronic subclinical compression of the ulnar nerve at this level have also been implicated as possible causes of this postoperative complication. Warner et al [47] retrospectively reviewed the records of 1,129,692 consecutive procedures on patients undergoing diagnostic or noncardiac surgical procedures at the Mayo Clinic over a 35-year period. Persistent (>3 months) ulnar neuropathies occurred at a rate of 1:2,729 patients. Nine percent were bilateral, and most were not noted until at least 24 hours after the procedure.

A particularly high incidence of postoperative ulnar nerve palsy has been noted in patients having cardiac surgical sternal retraction (60%). [48] [49] [50] Intraoperative somatosensory evoked potentials have been shown to identify those patients in whom persistent peripheral nerve deficits have occurred. [51] The mechanism is again unclear, but wide retraction of the sternum and first rib fractures may play a role. Placement of the arms at the side or abducted 90 degrees on padded arm boards did not eliminate the problem of ulnar nerve injury. There is a separate clinical entity of chronic compression of the ulnar nerve by focal constriction under the aponeurosis connecting the heads of the flexor carpi ulnaris muscle (Fig. 26-19) . [52] [53] Perhaps the effects of the blood pressure cuff, decreased neural vascular flow during cardiac bypass, and external pressure of positioning and/or central line placement produce additive effects on a more vulnerable nerve. [44] Evidence supports the conclusion that ulnar nerve palsy is not always a preventable complication despite the best efforts at careful positioning and padding.

EYE INJURY

The frequency of eye injury during anesthesia and surgery is low. If the pressure on the eye exceeds venous pressure, the veins may collapse, arterial inflow may continue, and arterial hemorrhage may occur. If pressure on the eye exceeds arterial pressure, arterial inflow may be dramatically reduced, resulting in ischemia of the retina. The use of the horseshoe headrest (Fig. 26-20) (Figure Not Available) carries the risk of such pressure injury to the eye because the head may shift during the procedure, even if the head is properly positioned at the beginning of the case. Corneal abrasion during neurosurgical procedures has been shown to be largely preventable by the application of eye tape but has not been shown to be influenced by the use of eye ointment. In patients undergoing lumbar laminectomy, the abrasions usually occur in the down eye. [54]

Figure 26-19 Anatomic compression of the ulnar nerve.

Figure 26-20 (Figure Not Available) The head can slip while in the horseshoe headrest, and pressure may develop in the eye owing to the weight of the head. *(Adapted from Reid and Grundy [62])*

Chapter 27 - Malignant Hyperthermia

Gerald A. Gronert
Joseph F. Antognini
Isaac N. Pessah

INTRODUCTION

Malignant hyperthermia (MH) identifies a clinical syndrome classically observed during general anesthesia--rapidly increasing temperature (as great as 1°C/5 min) and high mortality rate. This results from acute uncontrolled increases in skeletal muscle metabolism that may proceed to severe rhabdomyolysis. The early mortality rate reached 70 percent, but with earlier diagnosis and the advent of dantrolene, it has dropped to less than 5 percent. Wilson et al's [1] group apparently first used the term malignant hyperthermia in print in 1966. A Danish survey [2] indicates an incidence of fulminant MH of one in 250,000 anesthetics. However, when only the potent anesthetics and succinylcholine (SCh) are considered, fulminant MH occurred in one in 62,000 anesthetics. A suspicion of MH occurred in one of 16,000 anesthetics overall, and in one of 4,200 anesthetics involving potent volatile agents in combination with SCh.

A layman's organization provides public education and communication among affected families (Malignant Hyperthermia Association of the United States [MHAUS], 32 S. Main St., PO Box 1069, Sherburne, New York 13460-1069) and a 24-hour 7-day telephone service for emergency consultation (MH Hotline: 1-800-MH-HYPER). The routine telephone number of MHAUS for information purposes is 800-98MHAUS; fax: 800-440-9990; e-mail: mhaus@ norwich.net; website: www.mhaus.org. The professional subsidiary of MHAUS, the North American MH Registry, collates findings from biopsy centers in Canada and the United States and provides access to specific patient data, via either the hotline or its Director, Dr. Greg Allen, Department of Anesthesiology, Pennsylvania State University, Hershey, Pennsylvania, 17033-0850, telephone 717-531-5437.

This review focuses on new developments: the concept that disorders of the ion channels that control skeletal muscle may be grouped as channelopathies, that is, disorders of sodium, potassium, chloride, and calcium, and that their various mutations are associated with specific neuromuscular disorders. Of the three forms of the ryanodine receptor (Ry), Ry_1 , Ry_2 , and Ry_3 , only mutations in Ry_1 have been linked to MH. The genetics of MH and its related abnormal function of Ry_1 are now investigated at the level of molecular biology, with the porcine model providing intricate detail. Equivalent parallels in humans are limited by scarcer material for scientific study and difficulty in identifying underlying sources of abnormal responses, complicated by the fact that phenotypes vary within a genotype. Dantrolene remains the key in therapy, but its precise mechanism of action continues to be elusive. Standardization of MH testing with two protocols, the European and the North American, has resulted in sufficiently large databases to confirm acceptable sensitivity and specificity. However, minor differences in these protocols create problems in interpretation

among test center results, and it is time to focus standardization into one international protocol, admittedly a challenge in cooperation. Fulminant MH is now seldom seen because of greater awareness and consistent use of more sophis-ticated monitoring, especially of expired carbon dioxide. Diagnostic challenges are now provided by intraanesthetic changes that mimic MH, especially in its earlier manifestations.

HISTORY

Between 1915 and 1925, one family experienced three anesthetic MH deaths featuring rigidity and hyperthermia and was puzzled for decades regarding their cause. Susceptibility was eventually confirmed in three descendants. [3] In 1929, Ombredanne [4] described anesthesia-induced postoperative hyperthermia and pallor in children with significant mortality (Ombredanne's syndrome) but did not detect familial relationships. Critical worldwide insight into MH began in 1960, when Denborough and Lovell [5] described a 21-year-old Australian with an open leg fracture who was more anxious about anesthesia than about surgery because 10 of his relatives had died during or after anesthesia. Lovell initially anesthetized him with the then-new agent halothane, halted it when signs of MH appeared, and subsequently used a spinal anesthetic. Further evaluations of affected families came from Locher in Wausau, Wisconsin, in conjunction with Britt in Toronto, Canada. Direct skeletal muscle involvement rather than central loss of temperature control was established by recognition of increased muscle metabolism or muscle rigidity early in the syndrome, low-threshold contracture responses by Kalow et al, [6] and elevated values for creatine kinase (CK).

The pig, when inbred for muscle development (e.g., Landrace, Pietrain, and Poland China), provides an excellent animal model. The ubiquitous single-point mutation of porcine MH is likely due to the random occurrence of the altered Ry_1 allele, followed by deliberate inbreeding for desirable traits. International sharing of breeding stock probably spread the mutation worldwide. The experimental model evolved from earlier reports describing unsuitable pork [7] ; the stresses of the abattoir resulted in accelerated metabolism and rapid deterioration of the muscle, resulting in pale soft exudative pork. [8] Its incidence increased with breeding patterns designed to produce rapid growth rate, superior muscling, and hybrid vigor, although the drawback is a link with stress susceptibility. This increased incidence led to the term porcine stress syndrome. [9] Any stresses, such as separation, shipping, weaning, fighting, coitus, or preparation for slaughter, could lead to increased metabolism, acidosis, rigidity, fever, and death.

In 1966, Hall et al [10] reported on MH induced by halothane and SCh in stress-susceptible swine. The human and porcine forms are virtually identical, in comparisons of the clinical and laboratory changes of anesthesia-induced MH. [11] In 1975, Harrison [12] described the efficacy of dantrolene in preventing and treating porcine MH, which was confirmed in humans by a multihospital evaluation of dantrolene used to treat unanticipated episodes that occurred during anesthesia. [13]

There is now little doubt that MH in swine is a manifestation of a generalized susceptibility to stress. The sympathetic nervous system undoubtedly exaggerates skeletal muscle responses during stress, but its role in MH appears to be secondary (see Sympathetic Nervous System). Stress-induced awake triggering is common in MH swine but uncommon in MH-susceptible humans (see Awake Triggering).

Malignant hyperthermia presents several paradoxes. Anesthetics are inconsistent in their ability to trigger MH and are therefore frequently ineffective in triggering episodes in affected humans [14] ; this may be related to delay of the response by various depressants and nondepolarizing muscle relaxants. [15] Conversely, "safe" anesthetics, which are more aptly described as those less likely to trigger MH, can still be associated with apparent MH episodes. [16] Generally, susceptible individuals appear normal in regard to structure and function until they are stressed, thereby complicating detection of the condition. Detection requires either an anesthetic challenge or an invasive destructive muscle biopsy with contracture responses to caffeine or halothane. Testing in the pig is possible solely by genetic tracing of the single-point mutation in Ry_1 , but this test is weakened in humans by heterogeneity.

PATHOPHYSIOLOGY, MOLECULAR BIOLOGY, GENETICS, DANTROLENE

Malignant hyperthermia is a myopathy, usually subclinical, that features an acute loss of control of intracellular calcium (Ca^{2+}). Normally, the wave of depolarization from end plate to transverse tubule (T tubule) is transferred to the sarcoplasmic reticulum (SR), resulting in release of Ca^{2+}. The dihydropyridine receptor (DHPR), which is located in the wall of the transverse tubule, functionally couples the T tubule membrane to the SR membrane. A physical link between DHPR and Ry_1 is thought to transmit a signal across the triadic junction to promote the release of Ca^{2+} necessary to activate the contractile apparatus. The free ionized unbound intracellular Ca^{2+} concentration within the muscle cell increases from the relaxed level of 10^{-7} M to about 5×10^{-5} M. This increase in Ca^{2+} removes the troponin inhibition from the contractile proteins, resulting in muscle contraction. The intracellular Ca^{2+} pumps rapidly transfer Ca^{2+} back into the SR, and relaxation occurs when the concentration is restored to less than mechanical threshold. Both contraction and relaxation require adenosine triphosphate (ATP) (i.e., both are energy-related processes that consume ATP) (Fig. 27-1) (Figure Not Available) .

The clinical and laboratory data in swine and humans indicate decreased control of intracellular Ca^{2+}, resulting in a release of free unbound ionized Ca^{2+} from storage sites that normally maintain muscle relaxation. Aerobic and anaerobic metabolism increases to provide more ATP to drive the Ca^{2+} pumps that maintain Ca^{2+} homeostasis across the sarcolemma into extracellular fluid and into the SR and mitochondria. Virtually all of these reactions are exothermic, that is, they produce heat. Rigidity occurs when unbound myofibrillar Ca^{2+} approaches the contractile threshold.

Figure 27-1 (Figure Not Available) The key ion channels involved in neuromuscular transmission and excitation contraction coupling. Nerve impulses arriving at the nerve terminal activate voltage-gated Ca^{2+} channels (1). The resulting increase in cytoplasmic Ca^{2+} is essential in exocytosis of acetylcholine. Binding of acetylcholine to postsynaptic nicotinic cholinergic receptors activates an integral nonselective cation channel, which depolarizes the sarcolemmal membrane (2). Depolarizing the sarcolemma to threshold activates voltage-gated Na^{+} channels (3), which propagate action potential impulses deep into the muscle via the transverse tubule system. Within the transverse tubule system, L-type voltage-gated Ca^{2+} channels sense membrane depolarization and undergo a conformational change (4). A physical link between the $alpha_1$-subunit and the ryanodine receptor is thought to transfer the signal to sarcoplasmic reticulum to induce the release of stored Ca^{2+} (5). *(Modified from Alberts et al [144])*

Dantrolene is therapeutic because it reduces Ca^{2+} release from the SR without altering Ca^{2+} reuptake.

A more comprehensive description follows; several excellent reviews have been published. [17] [18] [19] [20] [21]

Molecular Events in Excitation-Contraction Coupling

Understanding the mechanisms underlying MH requires brief review of the process of excitation-contraction (EC) coupling, the process by which skeletal muscle transforms a chemical signal in the form of a neurotransmitter at the surface of the fiber into muscle contraction. Figure 27-1 (Figure Not Available) depicts a neuromuscular junction in which an efferent motoneuron synapses with muscle fibers to form a motor endplate. Membrane depolarization at the nerve terminal activates voltage-dependent Ca^{2+} channels on the presynaptic membrane. Rise of cytosolic Ca^{2+} within the nerve terminals initiates a process of vesicle migration and fusion that leads to exocytosis of acetylcholine (ACh) stored within the synaptic vesicles. Simultaneous release of thousands of quanta of ACh results in excitatory postsynaptic potentials. ACh binds to nicotinic ACh receptors, which are nonselective cation channels, and activates inward current (primarily carried by the sodium ion [Na^{+}]), thereby depolarizing the muscle cells. When excitatory postsynaptic potentials sum to threshold, action potentials are propagated from the sarcolemma to the T tubule. Acetylcholinesterase present in the synaptic cleft catalyzes rapid breakdown of ACh; rapid removal of ACh from the synaptic cleft enables the motor unit to be ready for another stimulus within a few milliseconds.

Within the T tubule of skeletal muscle, L-type voltage-gated Ca^{2+} channels, that is, DHPR, are clustered in tetrads and are in close proximity to the terminal cisternae, or junctional SR (Fig. 27-2) (Figure Not Available) . The $alpha_1$-subunit of DHPR functions as a voltage sensor within the T tubule membrane. Membrane depolarization induces a discrete movement of charge within the S4 segment of the DHPR $alpha_1$-subunit. A mechanical signal, thought to be in the form of a conformational transition, is transmitted to the cytoplasmic loop between repeats II and III of the $alpha_1$-subunit. Some evidence suggests a direct physical coupling between the II-III loop of DHPR $alpha_1$ and an as-yet unidentified region within the large hydrophilic cytoplasmic domain of Ry_1. Such a link could transmit a signal across the narrow gap of the triadic junction and could lead to SR Ca^{2+} channel activation. These results are consistent with the nature of skeletal muscle EC coupling, which is independent of extracellular Ca^{2+}. However, after the initial signal, which activates Ca^{2+} release from SR, Ca^{2+}-induced Ca^{2+} release appears to play a role in regulating the temporal and quantitative characteristics of Ry_1 activation. Cytosolic Ca^{2+} is rapidly removed through active transport by sarcoplasmic endoplasmic reticulum Ca^{2+} adenosine triphosphatase ATPase pumps located on junctional and longitudinal SR. Calsequestrin inside the lumen of SR binds to Ca^{2+} and further enhances Ca^{2+} loading within SR. Cytosolic Ca^{2+} is typically brought back to basal nanomolar concentration within 30 ms of muscle contraction. The rapid removal of cytosolic Ca^{2+} is essential for normal muscle relaxation and requires rapid termination of Ca^{2+} efflux from SR. Aberrant termination of Ry_1 activity has emerged as a key underlying mechanism in the etiology of MH susceptibility.

Structure of Ryanodine Receptor

The toxic plant alkaloid ryanodine was first purified and characterized from the powdered stemwood and roots of *Ryania speciosa* Vahl by Rogers and coworkers in 1948. The

---

Figure 27-2 (Figure Not Available) Schematic representation of the triad junction of skeletal muscle showing the junctional foot protein (ryanodine receptor) and its associated proteins. See text for details. *(Modified from Pessah et al [145])*

alkaloid produces profound rigidity in skeletal muscle. Isolation of 9,21-dehydroryanodine from *Ryania* has facilitated the synthesis of radiolabeled ryanodine ([^{3}H]ryanodine) and has permitted direct studies aimed at understanding the mechanism of this muscle poison. The availability of [^{3}H]ryanodine led to identification of a Ry receptor, which in fact is synonymous with the junctional foot protein and possesses Ca^{2+} release channel activity. Ry receptors bind [^{3}H]ryanodine with selectivity and the high-affinity binding interaction is sensitive to the conformational state of the channel (see Fig. 27-2 (Figure Not Available) Fig. 27-3 (Figure Not Available)). High-affinity and low-affinity ryanodine binding sites appear to be located within a 76-kd tryptic fragment from the C-terminus of Ry_1 of rabbit skeletal muscle. The hydrophobic segments within residues 3985-4362 are thought to form the M1-M4 transmembrane domains, enabling Ry_1 to span the SR membrane four times.

However, based on the criteria of MacLennan for structure elucidation of the SR Ca^{2+} -ATPase, Zorzato and coworkers have proposed the presence of an additional eight transmembrane domains. The M1-M4 domains of Ry_1 have high sequence homology to the analogous domains of inositol trisphosphate receptors, suggesting a possible role in forming the SR/ER Ca^{2+} channel pore.

Skeletal (Ry_1), cardiac (Ry_2), and "brain" (Ry_3) isoforms are encoded by three genes located on human chromosomes 19q13.1, 1q42.1-q43, and 15q14-q15, respectively. Based on sedimentation analysis and channel reconstitution studies in bilayer lipid membranes, each functional Ry consists of four identical subunits. Complementary DNA sequence analysis reveals that each Ry protomer is composed of 5032-5037, 4968-4976, and 4872 amino residues with calculated molecular weights of 564-565, 565, and 552 kd for Ry_1, Ry_2, and Ry_3 isoforms, respectively. Typically, a sequence homology of 66 to 70 percent is observed between any two conspecific isoforms. Ry receptors are also highly conserved in the same tissue among different species (>95% sequence homology of Ry_1 found in mammalian skeletal muscle of human, pig, and rabbit). The tetrameric organization of the Ry_1 from skeletal muscle has been corroborated by electron microscopy of cryosections of purified Ry_1 protein. Threedimensional reconstruction of Ry_1 cryosections have revealed the quatrefoil appearance of each homooligomer with four radial channels on the cytoplasmic face, which may converge into a single common transmembrane pore on the luminal face. Direct coupling of alpha $_1$ -subunit of DHPR and Ry_1 has been suggested to be involved in the initial steps of EC coupling in skeletal muscle. In addition, channel gating of Ry_1 has been shown to be modulated by several accessory proteins.

Calmodulin interacts directly with Ry_1 of skeletal muscle with a stoichiometry of two to three calmodulin molecules per subunit. The calmodulin sites with greatest affinity have been localized to the foot region of Ry_1 (see Fig. 27-3 (Figure Not Available)). Through a mechanism independent of kinase activity, calmodulin enhances channel activity at low cytoplasmic Ca^{2+}, whereas it inhibits channel activity at optimal Ca^{2+} (10-100 muM).

Calsequestrin, the major Ca^{2+} binding protein within SR lumen, links indirectly to a luminal domain of Ry_1. The conformational change in Ry_1 also conveys information to the SR lumen through calsequestrin and may be essential in regulating the Ca^{2+} release process. Functional interactions between Ry_1 and calsequestrin have been suggested to play an important role in regulating excitability of the Ca^{2+} channel in response to different filling states of SR.

Triadin, a 95-kd highly basic glycoprotein, was initially suggested to couple Ry_1 and the alpha$_1$ -subunit of DHPR; however, amino acid analysis of triadin indicates but a single pass

---

Figure 27-3 (Figure Not Available) Image reconstruction using cryoelectron microscopy of skeletal muscle ryanodine receptors showing the positions of FKBP12 (FK506 binding protein 12kDa) and calmodulin (CaM). See text for details. *(Modified from Wagenknecht et al [146])*

through the SR membrane, which thus contradicts its hypothesized role in coupling. The extremely high density of basic residues in the luminal terminus of triadin may be critical in interacting with the acidic moiety of Ry_1. The linkage between Ry_1 and triadin is also thought to provide an anchorage site for calsequestrin within the SR lumen.

FKBP12, the major T-cell immunophilin, tightly associates with Ry_1 in skeletal muscle with a stoichiometry of four per channel oligomer. The site on Ry_1 that recognizes FKBP12 is distinct from that which binds calmodulin (see Fig. 27-3) (Figure Not Available) . Binding of FKBP12 appears to stabilize both the closed conformation of the Ca^{2+} channel complex and its full conductance transitions. The immunosuppressant FK506 promotes dissociation of FKBP12 from Ry_1 by competing with a common binding site essential for proteinprotein interaction of the heterocomplex. The resulting FKBP12-deficient channel conducts current with multiple subconductance states. In the presence of channel activators like Ca^{2+} and caffeine, activity of the FKBP12-deficient channel is further enhanced by increasing the mean open time and open probability. Association of FKBP12 to Ry_1 may promote cooperativity among subunits. Dissociation of FKBP12 with FK506 increases maximal binding capacity of [^{3} H]ryanodine with lowered binding affinity, suggesting loss of negative allosteric interaction between high-affinity and low-affinity [^{3} H]ryanodine binding sites. Furthermore, the association of FKBP12 to Ry_1 complex may be involved in promoting cooperativity between neighboring channels. The "coupled gating" behavior of multiple channels has been reported in measurements with multiple channels reconstituted in membrane lipid bilayer by use of recombinant Ry_1 (coexpressed with FKBP12), as well as native SR. Introduction of FK506 dissociates FKBP12 from the recombinant Ry_1 complex and eliminates the coupled gating behavior of multiple channels. The cooperativity between neighboring Ry_1 channels may contribute significantly to the robust release of Ca^{2+} from SR during EC coupling.

Two novel proteins, 60 kd and 90 kd, whose function is unknown, are also found to be associated with the Ry_1 complex; one possesses kinase activity, and the other is the substrate of this kinase. Finally, another 150/160-kd protein is found to be associated with Ry_1. Phosphorylation of the 150/160-kd protein by casein II kinase inhibits Ry_1 channel activity.

The Ry_1 Mutation in Malignant Hyperthermia

Fujii et al first reported MH susceptibility in swine as an autosomal dominant trait that cosegregates with a mutation (Arg615Cys) within the Ry_1 locus on chromosome 6. A homologous mutation occurs within the Ry_1 receptor

---

(Arg614Cys) in humans at q13.1 on chromosome 19, although segregation of this mutation with MH syndrome occurs in less than 5 percent of susceptible individuals. At least 15 additional mutations within the Ry_1 locus have been associated with human MH susceptibility, [22] including Arg163Cys, Gly248Arg, Gly341Arg, Ile403Met, Tyr522Ser, Arg552Trp, Gly2433Arg, and Arg2434His. Association of chromosome 19-linked mutations with MH has been demonstrated in fewer than 50 percent of the families examined. Many of these MH studies are based on *in vitro* contracture tests; the threshold chosen to define a positive diagnosis for MH susceptibility greatly influences the outcome of linkage studies. [22] [23]

Mutations that do not cosegregate on chromosome 19 may be associated with MH. These include region q11.2-24 on chromosome 17 coding for the alpha-subunit of the sodium channel and for the beta- and gamma-subunits of the L-type Ca^{2+} channel; a mutation on chromosome 7 near the gene encoding the alpha$_2$ /delta-subunit of the L-type Ca^{2+} channel; region q31-32 of chromosome 1 coding for the alpha $_1$ -subunit of DHPR. Monnier et al [24] showed a high logarithm of the odds score (LOD = 4.38) between an Arg1086His mutation within the CACNL1A3 gene encoding the alpha $_1$ -subunit of the human skeletal muscle, DHPR-sensitive, L-type, voltagedependent Ca^{2+} channel and susceptibility to MH in a large French family. The mutation is localized in a different part of the alpha $_1$ -subunit than that in previously reported mutations found in patients with hyperkalemic periodic paralysis. If these results are confirmed as MH associated, then human MH is a genetically heterogeneous disorder in which one of several abnormalities occurring in proteins involved in the regulation of EC coupling could render a person susceptible, that is, an MH episode may be the result of abnormalities leading to a final common path.

Functional Changes in Ry_1 Associated with Malignant Hyperthermia Mutations

Altered SR Ca^{2+} channel gating kinetics are thought to underlie the uncontrolled skeletal muscle metabolism associated with administration of halogenated anesthetics or depolarizing agents. The sustained elevation of Ca^{2+} level in the sarcoplasm results in abusive stimulation of both aerobic and glycolytic metabolism, which accounts for a combined acidosis, rigidity, altered permeability, and hyperkalemia. Although studies using Ca^{2+} -selective microelectrodes have indicated that MH-affected muscle has a higher level of resting Ca^{2+}, this has not been confirmed by ratiometric fluorescent Ca^{2+} dyes. Study of the chronologic relationship of the biochemical and clinical development of porcine MH demonstrates that the increase in $[Ca^{2+}]_i$ precedes the increase in expired carbon dioxide and the classic first

sign, tachycardia. [25]

The porcine model has been extensively studied to determine the biochemical and functional changes in SR Ca^{2+} transport and Ry_1 function underlying the MH syndrome. The validity of the single-point porcine Ry_1 mutation for studying the cause of MH has been affirmed by use of the fluorescence calcium indicator indo-1 to determine the concentration of Ca^{2+} in myoblastic cells transfected with either wild-type or mutated Ry_1 complementary DNA. The cells expressing the porcine Ry_1 mutation showed higher sensitivity to caffeine. Further, clinical doses of halothane resulted in a rapid increase of $[Ca^{2+}]_i$ in cells expressing the mutated Ry_1, whereas no changes in $[Ca^{2+}]_i$ were observed in cells expressing the wild-type receptor. These results provide definitive evidence that a single amino acid mutation, namely Arg615Cys, in Ry_1 is causative of porcine MH.

Although active SR Ca^{2+} accumulation appears to be normal in MH-affected pig muscle, significant abnormalities in the Ca^{2+} release process have been documented in several types of *in vitro* bioassays. In skinned muscle fiber preparations, the rate and the extent of Ca^{2+} release from SR were higher in fibers with MH abnormalities than in normal fibers. These results in skinned fibers correlate well with those obtained from isolated SR membrane preparations enriched in Ry_1 protein. Although initial studies revealed a difference in the Ca^{2+} threshold for activation for SR Ca^{2+} release, later studies using rapid quench methods found no apparent difference in the sensitivity of SR Ca^{2+} release with respect to Ca^{2+}. O'Brien and Li [26] developed a microassay that reveals functional differences in Ca^{2+} transport in SR membranes isolated from normal pigs and those with MH susceptibility. They found that SR from swine with MH susceptibility had normal maximal Ca^{2+}-ATPase pumping but that the activity of Ry_1 after addition of a bolus of Ca^{2+} was 50 percent greater in heterozygotes and 100 percent greater in homozygotes for the MH mutation. Hypersensitivity to receptor agonists, such as caffeine, and an associated hyposensitivity to inhibition with Mg^{2+} were also demonstrated. There has been some controversy about whether changes exist in the sensitivity of MH-affected muscles to inhibition by Mg^{2+} compared with normal fibers. [16] Owen et al [27] demonstrated that fibers from pigs heterozygous or homozygous for the Ry_1 MH allele needed only a smaller reduction in free $[Mg^{2+}]$ to induce Ca^{2+} release from SR. Dantrolene counteracted the effect of reduced Mg^{2+} inhibition in MH-affected muscle. Thus, the abnormal responsiveness of MH-affected muscle to various stimuli may and perhaps in large part result from the reduced ability of myoplasmic Mg^{2+} to inhibit Ca^{2+} release from SR.

Reconstitution of channels isolated from MH-susceptible pigs studied in bilayer lipid membranes has revealed significantly reduced sensitivity to inactivating concentrations of Ca^{2+}, whereas the sensitivity of channels to activating Ca^{2+} remains unchanged. [28] Interestingly, Ca^{2+} channels from pigs with MH susceptibility exhibit a significantly higher open probability compared with wild-type channels across a broad range of Ca^{2+} (7muM-10mM) on the cytoplasmic face when measured at pH 6.8. Whether Ca^{2+} channels reconstituted in bilayer lipid membranes from pigs with MH susceptibility exhibit an altered response to inhibition by Mg^{2+} remains controversial. In porcine MH, Mg^{2+} inhibition of Ry_1 channels was not altered, whereas Laver et al [28] found a threefold lower potency for Mg^{2+} inhibition of MHaffected Ca^{2+} channels. The underlying cause of these different experimental results is unclear, but the concentration of monovalent ions used in measuring channel activity may have influenced the inhibitory potency of Mg^{2+}. Channels isolated from pigs heterozygous for the MH mutation suggest that the heterozygous porcine Ca^{2+} release channel population contains heterotetramers with properties distinct

from those of either MH homozygote or normal channels. The data also imply that the Ca^{2+} release channel population in humans with MH syndrome who are heterozygous for a dominant mutation in this protein also contains heterotetrameric channels. In contrast to Ca^{2+} uptake and release studies with isolated SR, single-channel measurements have failed to reveal an altered sensitivity of channels to activation by caffeine.

Radioligand-receptor binding studies with nM [^{3}H]ryanodine have been utilized to determine whether differences exist between SR isolated from normal humans and pigs and those with MH susceptibility. [^{3}H]Ryanodine binding assays represent a sensitive means of assessing functional anomalies regulating the channel pore by use of a simple tube assay. This is possible because [^{3}H]ryanodine binds to a conformationally sensitive site within or near the channel pore. Mickelson et al first demonstrated that the binding of [^{3}H]ryanodine to MH homozygotic porcine heavy SR exhibits an altered Ca^{2+} dependence at the low-affinity (inhibitory) Ca^{2+} site as well as a lower affinity for ryanodine when compared with normal porcine SR. However, the maximum capacity of SR to bind [^{3}H]ryanodine was the same in both tissues, indicating an altered structure and/or function of the receptor rather than a change in expression associated with the disease. Studies performed with Ry_1 isolated from human biopsies revealed a higher affinity for [^{3}H]ryanodine and a higher sensitivity to activation by caffeine with MH syndrome preparations. Surprisingly, it was the activation, not the inactivation, of the binding of [^{3}H]ryanodine by Ca^{2+} that was abnormal in human MH SR.

Dantrolene

Dantrolene is the drug of choice for preventing and reversing the symptoms of MH. Dantrolene sodium is a hydantoin derivative (1-[[[5-(4-nitrophenyl)-2-furanyl]methylene]imino]-2,4-imidazolidinedione) that relaxes but does not totally paralyze skeletal muscle. These properties of dantrolene have been closely correlated with its ability to reduce Ca^{2+} efflux from SR *in vitro.* Using mechanically skinned skeletal muscle fibers from pigs of different Ry_1 genotypes, Owen and coworkers [27] showed that for fibers from pigs homozygous for normal Ry_1, the free Mg^{2+} concentration had to be lowered from the normal resting level of 1 mM to approximately 0.1 mM to induce Ca^{2+} release and a force response. Fibers from pigs heterozygous or homozygous for the MH Ry_1 needed only a smaller reduction in free Mg^{2+} to induce Ca^{2+} release (reduction to 0.1-0.2 and 0.2 mM, respectively). Dantrolene (20 muM) counteracted the effect of this reduced Mg^{2+} inhibition in MH affected muscle. Caffeine contractures induced after K^+ conditioning of skeletal muscles from pigs and mice were found to render muscles refractory to brief electrical stimulation, but there was still an enhancement of contracture tension elicited by subsequent direct caffeine stimulation of SR calcium release. This enhanced sensitivity to caffeine was inhibited by dantrolene (20 muM) and its water-soluble analogue azumolene (150 muM).

Preparations of skeletal SR membrane vesicles have been utilized to examine the ability of dantrolene to alter Ca^{2+} fluxes. Dantrolene (10-90 muM) was shown to inhibit SR Ca^{2+} release, especially when assayed in the presence of caffeine and adenine nucleotide. Later, depolarizationinduced Ca^{2+} release measured from triadic vesicles by use of a stopped-flow apparatus and fura-2 was shown to be inhibited by dantrolene. [29] However, the exact mechanism by which dantrolene induces muscle relaxation is unclear, and some results have been conflicting. For example, halothane-activated Ry_1 from frog skeletal muscle was unaffected by as much as 100 muM of dantrolene, whereas single-channel studies with porcine and human Ry_1 revealed a biphasic action of dantrolene; channel activation at low (0.5-2 nM) concentrations and channel inhibition at a higher (5 muM) concentration. Species differences may in part account for this difference in response.

Radioligand receptor-binding experiments performed with [^{3}H]ryanodine have shown that under certain assay conditions, muM dantrolene or its water-soluble derivative azumolene could inhibit the binding of ryanodine to its conformationally sensitive site. In this respect, doxorubicin-stimulated binding was much more inhibited by dantrolene than by either caffeine or Ca^{2+}-stimulated binding. These results are in agreement with Ca^{2+} transport studies with skeletal SR, in which azumolene was shown to block doxorubicin-induced Ca^{2+} release. However, a later investigation found little pharmacologic overlap between the modulation of [^{3}H]ryanodine and [^{3}H]dantrolene binding sites in porcine skeletal muscle. For example, the binding of [^{3}H]dantrolene was insensitive to ryanodine and Ca^{2+} and adenine nucleotides. Experiments performed with [^{3}H]dantrolene have revealed that specific binding sites for the drug colocalize to junctional SR membranes with [^{3}H]ryanodine-binding sites. [^{3}H]Dantrolene-binding sites were not detected in either T tubule membranes or sarcolemmal membranes. There is still controversy as to whether dantrolene binds directly to the Ry_1 protein or to an accessory protein. Using differential solubilization techniques, Palnitkar and Parness separated specific binding sites for [^{3}H]ryanodine and [^{3}H]dantrolene, suggesting a distinct effector protein for the latter.

Potential Factors in Malignant Hyperthermia Other Than Ry_1 Abnormalities

Other cellular processes affect MH episodes; this impact may be due to their own inherited abnormalities, especially in heterogeneic humans, or to secondary changes prompted by the altered Ry_1. These other processes include DHPR, inositol trisphosphate, lipase and fatty acids, catechol-amines, oxidation-reduction activity, altered ionic reactivity, and the mechanical threshold of muscle.

/das/book/view/29494766/875/286.html

SPECIFIC ORGAN/TISSUE ABNORMALITIES

Skeletal Muscle

Affected human muscle frequently has no histologic defect or else has protean nonspecific pathology so variable that none can be directly attributed to MH. These include

central cores, internal nuclei, target fibers, supercontracted fibrils, and marked variation in fiber diameter. A histologic study found various myopathic and neurologic abnormalities in 58 of 75 patients suspected of having MH; 20 of these 58 patients were MH susceptible. [30]

Metabolism, Enzymatic Considerations, and Heat Production

Affected muscle has greater responses to potent volatile anesthetics, classically halothane, and the depolarizing muscle relaxants, such as SCh, than does normal muscle, whether pig [11] or human. [31] Aerobic metabolism (oxygen consumption, V_{O_2}) and glycolytic metabolism increase dramatically. There is an approximate threefold increase in V_{O_2} and a 15- to 20 fold increase in blood lactate level, with related acid-base imbalances. The earliest changes appear as an increase in muscle intracellular Ca^{2+} concentration [25] and in the venous effluent from skeletal muscle, as decreases in pH or partial pressure of oxygen (Po_2), or as increases in partial pressure of carbon dioxide (Pco_2), lactate, potassium, or temperature. [31] These changes occur before the increases in heart rate, temperature, and circulating catecholamine levels. The most sensitive early sign during anesthesia is an increase in expired carbon dioxide (during constant ventilation), but it can be misleading (see Diagnosis). Heat production during acute MH derives from aerobic metabolism, glycolysis, neutralization of hydrogen ions, and hydrolysis of high-energy phosphate compounds involved in ion transport and contraction-relaxation. [32] Precise calculations of the expended energy are difficult because of unsteady metabolic and circulatory states, variable and uncontrolled heat loss, and production of heat by neutralization of acid.

Contractures

The muscle rigidity that occurs during MH episodes is a contracture rather than a contraction. A contracture is similar to a muscle cramp; it is nonpropagated and prolonged and can be irreversible. A contraction is due to a propagated wave of depolarization that is brief and reversible. Contractures are used in tissue baths in the laboratory to study various aspects of MH. Unfortunately, satisfactory samples of tissue are difficult to obtain; an intact muscle fiber undamaged from tendon to tendon is preferred. Most contracture studies use cut muscle excised from quadriceps; these specimens function satisfactorily in a bath but progressively deteriorate as a result of injury currents from the cut ends. A further modification is the skinned fiber, in which the sarcolemma and portions of the T tubules are either stripped away mechanically or "eaten away" chemically. The tissue bath now becomes the intracellular environment, and laboratory manipulations directly affect function of intracellular organelles. Responses of all these preparations are qualitatively similar; the cut muscle preparation develops much less tension.

Although tension can vary as a result of amounts of Ca^{2+} available to the fibrils, in general, they are exposed to contracture-producing drugs acting via the SR, either directly or indirectly. These drugs include caffeine, [6] halothane [6] [33] or other potent volatile anesthetics, potassium, ryanodine, [34] and 4-chloro-m-cresol. [35] Standardized protocols use either the European or the North American guidelines (see Evaluation of Susceptibility). Whatever the method or drug used, MH syndrome bundles produce low threshold responses.

Intrafibrillar Proteins

The lack of consistent correlation of fiber-type or fiber proteins with abnormal function underscores the difficulties in analyzing this disorder--stress is necessary to detect the abnormality. The altered Ry_1 is expressed in both fast and slow fibers.

Calcium

The SR is the intracellular organelle primarily responsible for control of intracellular Ca^{2+} transients, and mitochondria serve a secondary reserve function in binding Ca^{2+}. When intracellular Ca^{2+} levels increase beyond the capabilities of the SR, the mitochondria begin to bind it. The mitochondrion provides the greatest supply of ATP via aerobic metabolism; only secondarily does it bind and store Ca^{2+}. There is evidence of muscle mitochondrial binding and accumulation of Ca^{2+} during acute MH. [36] In these studies, pigs were evaluated by biopsy before and during MH and after treatment with dantrolene, and mitochondrial functions analyzed elegantly.

Mitochondrial deficiencies do not explain the diminished aerobic responses in MH. V_{O_2} consistently increases about threefold during MH, in contrast to the 10-fold increase possible during severe exercise. In view of the serious acid-base imbalances and depletion of muscle energy stores, this increase seems paradoxically low. Perhaps V_{O_2} and hence ATP production by mitochondria are limited during MH by several factors, including ATP translocation, mitochondrial Ca^{2+} binding, intracellular acid-base, and electrolyte aberrations.

Ca^{2+} antagonists generally affect smooth or cardiac muscle more than skeletal muscle and have contradictory effects in MH: they can block contractures in affected human muscle *in vitro* and are associated with hyperkalemia and potentially increased mortality *in vivo* when used in conjunction with dantrolene. [37] [38] [39] They do not prevent or effectively treat MH in susceptible pigs. [40] [41] Furthermore, in addition to the risk of hyperkalemia with Ca^{2+} antagonists and dantrolene, there is the added hazard that the hyperkalemia could trigger MH in susceptible skeletal muscle. [42]

Electrophysiologic Measurements

The Ca^{2+} control abnormalities of MH are reflected in altered electrophysiology. Multiple pulse stimulation of porcine muscle (six pulses with 5-ms spacing) demonstrated an increase in tension and an increased rate of rise of tension in susceptible pigs; this difference was accentuated after

dantrolene was given, as the susceptible pig muscle recovered much more effectively from the effects of dantrolene than did that of the normal animals. [43] This again suggests abnormally increased Ca^{2+} transients via intracellular organelles. Similar studies in humans disclosed parallel significant differences, but not striking enough

to use in MH testing. [44] During slaughter, affected swine are found to have a lower (and rapidly declining) resting membrane potential than that of normal swine. [45] [46] This may contribute to the rapid decline of muscle pH and energy stores as this is prevented or attenuated by curarization and ventilation to maintain oxygenation. [45] Halothane lowers mechanical threshold in both susceptible and normal muscle, predis-posing susceptible muscle toward the development of a contracture. [47]

Channelopathies

One of the considerations regarding MH and disorders of EC coupling in general is the existence of channelopathies, disorders of the voltage-gated ion channels that control fluxes of ions across membranes. [48] These channels are ion-conducting proteins with a membrane spanning pore, gates, and voltage sensors, equipping them for passage of sodium, calcium, and chloride ions. Chloride channels provide 75 to 80 percent of membrane conductance at rest, thus contributing to the fast repolarization phase of the action potential. These channels are present in the surface and inner membranes of all excitable and most nonexcitable cells. There are naturally occurring mutations that alter their function, with specific pathologic consequences. Abnormalities relating to skeletal muscle pathology include the sodium channel (hyperkalemic periodic paralysis, paramyotonia congenita, and some others, known collectively as potassium-aggravated myotonias), potassium channel (myo-kymias, e.g., episodic ataxia), calcium channel (e.g., DPH receptor (hypokalemic periodic paralysis, muscular dysgenic mouse), and the chloride channel (myotonia congenita in humans, mice, and goats). Channel abnormalities of other tissues are not a part of this chapter, nor are considerations of ligand-gated channels, such as those involving the ACh receptor. The Ry_1 is not a voltage-gated channel per se.

Implications of Findings in Skeletal Muscle

The single-point mutation of Ry_1 in all susceptible pig breeds strongly suggests that this is the major cause of porcine MH [49] and that other abnormalities are secondary or occurring in parallel. Inositol trisphosphate is a major physiologic second messenger mobilizing Ca^{2+} from endoplasmic reticulum, but it does not seem likely to be involved in MH, because it lacks the surface membrane interactions possessed by the Ry_1 for SR. [21] Because human MH does not correlate as strongly genetically with the Ry_1 abnormality, it may be that other inherited abnormalities are important factors. Altered lipase, fatty acids, and triglycerides could then play a more important role. [50] Free-radical peroxidation likely occurs during porcine MH as an adaptive response to sustained stress that contributes to abnormal calcium homeostasis and fatty acid metabolism. [51] Volatile anesthetics and SCh represent a stress for skeletal muscle because they perturb membranes and disturb Ca^{2+} homeostasis. In general, normal muscle can withstand and compensate for these stresses. However, in susceptible muscle, the membrane perturbation induced by halothane or the depolarization induced by SCh may cause an earlier Ca^{2+} release that itself strikingly stimulates greater Ca^{2+} release. Coupled with the lower mechanical contractile threshold, an early MH response may result. Although MH-susceptible muscle may briefly tolerate these stresses, a cascading cycle of increasing metabolism, temperature, and acidosis eventually results. Skeletal muscle represents a "sleeping giant" in regard to metabolism, and, once aroused, it dominates whole body responses. Furthermore, the resting concentration of intracellular Ca^{2+} may be increased in susceptible subjects, apparently without an associated stimulation of metabolism. Thus, MH affected muscle may always be closer to "loss of control" than normal muscle. Normal muscle can respond abnormally with extreme prolonged effort, such as the overstraining disease or capture myopathy of wild animals after prolonged chase. [52]

Heart

Myocardial function is severely altered in human and porcine MH. Initially, tachycardia and arrhythmias occur and are followed by hypotension, decreased cardiac output, and eventual cardiac arrest. The controversy is whether the heart is primarily abnormal, as a consequence of dysfunction directly related to MH, as in skeletal muscle, or whether the heart is affected secondarily by the hyperthermia, acidosis, hyperkalemia, and increased membrane permeability.

Porcine data suggest a secondary involvement: increased myocardial oxygen consumption during MH is related to beta-agonist stimulation of sympathetic activation without the lactate production or potassium efflux that would be suggestive of a primary MH response. [53] Porcine MH myocardium does not respond abnormally to exaggerated concentrations of calcium, digoxin, potassium, or carbon dioxide. [42] Much work has been done on cardiac responses during MH. Overall, it appears to be affected primarily by the tremendous potentially ischemic demands placed on it by exaggerated whole-body metabolism. [54] The Ry defect is expressed in fast and slow skeletal muscle fibers but not in porcine cardiac muscle. [55]

Human myocardial abnormalities were inferred by the higher incidence of sudden death in members of susceptible families and by the occurrence of nonspecific cardiomyopathies and abnormal thallium scans in some affected patients. [31] One might expect that pigs, with their recognized greater frequency of awake MH episodes and MH homogeneity, would provide evidence for primary myocardial abnormalities, if they indeed exist.

Central Nervous System

Central nervous system involvement during fulminant human MH appears to be secondary to increased temperature,

acidosis, hyperkalemia, and hypoxia. With the involved ionic and fluid shifts, changes in plasma osmolality may be factors that in part induce cerebral edema. The extreme picture of coma, areflexia, unresponsiveness, and fixed, dilated pupils suggests acute cerebral edema and intracranial hypertension. Recovery is variable and is related to the duration and severity of the MH episode. Severe fever itself, to 42.5°C, may result in a virtually flat electroencephalogram and coma, but recovery is still possible. [56]

An MH episode is not likely related to the central nervous system, because a limb tourniquet prevented rigidity in the isolated limb when whole-body rigidity existed dur-ing acute episodes. [57] Cerebral oxygen consumption and lactate production are not increased in swine during MH. [58] Kochs et al [59] observed early profound electroencephalographic depression during porcine MH and improvement with dantrolene, and these investigators suggested primary brain involvement. Hofer et al [60] contradicted this opinion by correlating alteration of electroencephalographic and cerebral metabolites with beginning whole-body MH episodes.

Sympathetic Nervous System

Activation of the sympathetic nervous system during MH occurs early. In addition, "fight, fright, or flight" can initiate an MH episode in susceptible swine without anesthetic agents. [9] This is rarely observed in humans (see Awake Triggering). During MH, circulating levels of epinephrine and norepinephrine increase markedly (e.g., from less than 1 ng/mL to 30 ng/mL). Sympathetic responses appear secondary in porcine MH, although the physiologic effects of sympathetic excitation would be expected to magnify the changes of an MH episode. For example, metabolic responses precede altered sympathetic activity [31] ; the MH response is unaltered despite acute sympathetic denervation (total spinal anesthesia) [61] ; infusion of norepinephrine to blood levels greater than those associated with MH does not trigger MH [62] [63] and norepinephrine does not potentiate halothane-induced porcine MH, although triggering is delayed when blood flow to muscle is reduced. [63] beta-Agonist effects result in pronounced myocardial stimulation. [53] alpha- Agonists and beta-agonists do not result in increased metabolism in susceptible porcine muscle. [62] [64]

Sympathetic antagonists may protect from or ameliorate episodes of MH by lowering body temperature and modifying acid-base changes. [65] This protection has been found to be variable and, when demonstrated, has been attributed to an effect on sympathetic-induced MH. It seems more likely that alpha-antagonists merely increase heat loss and potentially increase muscle perfusion. beta-Antagonists attenuate metabolism and fever during MH, yet do not improve survival. [65] In large doses, they completely block the myocardial stimulation that occurs during porcine MH, but this stimulation of metabolism is secondary to beta-agonist effects without evidence of active myocardial MH. [53] Thus, although Wingard's theory resulted in a variety of investigations and counterinvestigations over the ensuing years, there is still no direct evidence that the sympathetic nervous system initiates or plays an important primary role in MH. [31]

Miscellaneous

Disseminated intravascular coagulation frequently occurs during MH, with varying severity. Although a number of causes have been proposed, the most likely appear to be release of tissue thromboplastin during fever, acidosis, hypoxia, hypoperfusion, and gross alterations in membrane permeability of various body tissues. [31] Porcine MH erythrocytes show greater fragility [66] and peroxidation. [67] These findings directly support MH alteration of porcine tissue other than skeletal muscle.

Liver from normal swine transplanted into MHsusceptible swine remains normal, whereas liver from swine with homozygous MH transplanted into normal swine

functions as normal. [68] Pulmonary changes during MH appear to be secondary to systemic manifestations. These include tachypnea, hyperventilation, V/Q abnormalities, increased blood and expired carbon dioxide, decreased blood Po_2, and ultimately pulmonary edema. The increase in whole-body carbon dioxide stores during MH is better reflected by measurements of expired carbon dioxide or mixed venous carbon dioxide than arterial measurements. Renal function during active MH is altered indirectly (i.e., oliguria and anuria secondary to shock, ischemia, cardiac failure, myoglobinuria, and myoglobinemia).

CLINICAL SYNDROME

The onset of MH can be acute and rapid, particularly during induction of anesthesia with an inhaled anesthetic or with the use of SCh. On rare occasions, the onset can be delayed for some hours and may not become overt until the patient is in the recovery room. Regardless of the time of onset, once initiated, the course of MH can be extraordinarily rapid. When clinical signs, such as increased expired carbon dioxide, muscle rigidity, tachycardia, and fever, suggest the presence of MH, the association is not strong unless more than one abnormal sign is noted. When there is but a single suggestive adverse sign, the diagnosis is usually not MH.

The volatile anesthetics and SCh cause affected subjects to undergo a striking increase in metabolism, both aerobic and anaerobic, resulting in intense production of heat, carbon dioxide, and lactate and an associated respiratory and metabolic acidosis. [11] [31] These reactions markedly alter whole-body acid-base balance and temperature because of the large proportion of skeletal muscle to body weight (40-50%) and are magnified as temperature increases. Whole-body rigidity occurs in almost all pigs and in most humans. Temperature may exceed 43°C (109.4°F), Pa CO_2 may exceed 100 mm Hg, and pHa may be less than 7.00. Associated with this is increased permeability of muscle with increased serum levels of potassium, ionized calcium, CK (although MH-related changes do not differ overall from CK changes observed during surgery [69]), myoglobin, and serum sodium. [31] Later, serum potassium and calcium levels decrease; muscle edema may occur. Sympathetic hyperactivity occurs early as a sign of increased metabolism (tachycardia, sweating, hypertension). With metabolic exhaustion, cellular permeability in general may increase, with whole-body

edema, including acute cerebral edema. As MH progresses, disseminated intravascular coagulation and cardiac or renal failure may develop. MH is a disorder of increased metabolism--it need not involve increased temperature, for example, if heat loss is greater than production, or if cardiac output plummets early.

The clinical MH syndrome can occur as a "final common path" in situations that may not involve susceptibility to MH. This is somewhat analogous to observing Raynaud's phenomenon in the absence of Raynaud syndrome. Examples (Table 27-1) include exaggerated heat stroke, the neuroleptic malignant syndrome (NMS), thyroid storm, [70] diabetic coma, [71] alcohol therapy for limb arteriovenous malformation, [72] free blood in cerebrospinal fluid, [73] [74] hypokalemic periodic paralysis, [75] and various myopathies involving constantly and precariously altered permeability of cellular membranes and intracellular organelles, such as Duchenne's muscular dystrophy. [76]

Trismus-Masseter Spasm

Trismus-masseter spasm is defined as jaw muscle rigidity in association with limb muscle flaccidity after administration of SCh. Trismus occurs as a unique property of jaw muscle in normal people.

Masseter and lateral pterygoid muscles contain slow tonic fibers that can respond to depolarizers with a contracture. [77] [78] This is manifested clinically on exposure to SCh as an increase in jaw muscle tone, which was well defined by van der Spek et al. [79] When this increase in jaw muscle tone becomes exaggerated, prolonged, and tight--the so-called jaws of steel--the risk of MH increases greatly. Thus, there

Figure 27-4 Succinylcholine usually increases jaw muscle tone slightly. In some patients, this increase is moderate, and, in very few, extreme, i.e., "jaws of steel." As much as 50% of this latter group may be MH susceptible. See text for details.

is a spectrum of normal responses: a tight jaw that blends into a rigid jaw and then to a very rigid jaw (Fig. 27-4) . Somewhere in the area of the curve is the boundary for the MH population--the difficulty is in defining it. Trismus may still occur after pretreatment with a defasciculating dose of a nondepolarizing relaxant. If there is rigidity of other muscles in addition to trismus, the association with MH is absolute; anesthesia should be halted as soon as possible and treatment of MH begun. The following considerations involve trismus without rigidity in other muscles.

When trismus occurs, should administration of the anesthetic be halted? Should the patient be given dantrolene? Once trismus occurs, proper monitoring should include end-expired carbon dioxide, examination for cola-colored urine, and arterial or venous blood sampling for CK acid-base status, and electrolyte levels, particularly potassium. The initial degree of tightness of the jaw and its duration should dictate the response of the anesthesiologist. With jaws of steel, the procedure should be halted, especially if the condition persists for more than several minutes. If the jaw is slightly resistant to opening, the anesthesiologist should continue anesthesia while observing the patient. If the jaw is modestly tight and distinctly a problem, then there are two choices: (1) halt the procedure, and (2) continue with nontriggering agents. Any suggestion of MH should prompt MH therapy, including the use of dantrolene. The patient with a fever may have an exaggerated response to SCh's effect in increasing jaw muscle tension. Patients who experience trismus should undergo testing for MH susceptibility to help further our understanding of MH and to provide the means whereby we can determine the relationship of masseter spasm to MH. Trisumus that occurs after use of nondepolarizing muscle relaxants is not apparently related to MH or to hyperkalemia. [80]

Sudden Unexpected Pediatric Cardiac Arrest

MH rarely begins as an abrupt cardiac arrest after the use of SCh during the induction of anesthesia. In the absence of upregulation of nicotinic skeletal muscle ACh receptors, [81]

such a response appears to be due to an occult myopathy that responds to SCh with abrupt massive rhabdomyolysis and an associated acute rapid massive hyperkalemia. [82] [83] Many of these patients are subsequently found to have a myopathy, usually Duchenne. For these reasons, there should be definite indications for using SCh in young children. Case reports available to the MH hotline suggest that this response occurs on five to six occasions in the United States per year, or perhaps in one in every 1 million pediatric anesthesias. It is a devastating response to the caregivers and the family because a previously healthy child can scarcely be resuscitated because of the difficulties during cardiopulmonary resuscitation in redistributing potassium from levels greater than 10 mEq/L to the normal range. With these young patients, heroic efforts in care, including cardiopulmonary bypass, may be successful. [84] These cases may respond acutely to the use of dantrolene because of its effect in stabilizing muscle membrane permeability, and to calcium because it aids in counteracting hyperkalemia by reestablishing the ionic membrane balance in the heart. Because of potential cerebral ischemia, glucose should be administered with caution. A regional survey [85] of 280 British anesthetists (180 responded) noted that 84 percent use SCh routinely and that there were 13 cardiac arrests (with two additional cases of hyperkalemia without accompanying arrest). They concluded that "life-threatening reactions were rare." We wonder how they define "life-threatening reactions."

Rhabdomyolysis

Rhabdomyolysis (see preceding section) may occur during an MH episode or trismus, but milder forms of rhabdomyolysis occur more often than realized. In a study of 11 normal children, those given SCh had a serum myoglobin level of 1,187 ± 615 ng/mL, in contrast to 30 ± 9 ng/mL in those not given SCh. [86] Myoglobinuria with rhabdomyolysis can occur in various muscle disorders and without exposure to SCh. Because of the virtual identity of myoglobin and hemoglobin, myoglobinuria can be misdiagnosed as hemolysis if massive fluid shifts occur during an MH episode. Any unusual anesthetic incident--muscle response, arrhythmia, trismus, fever--should prompt examination of urine color and plasma electrolytes, especially potassium.

TRIGGERING OF MALIGNANT HYPERTHERMIA

Acute episodes depend on three variables: (1) a genetic (perhaps rarely acquired) predisposition, (2) the absence of inhibiting factors, and (3) the presence of a sufficiently potent anesthetic or nonanesthetic trigger.

Anesthetic Triggering

Anesthetic drugs that trigger MH include halothane, enflurane, isoflurane, desflurane, and sevoflurane, as well as SCh. The onset may be explosive if SCh is used. [31] Inbred susceptible swine are identified predictably during an inhalation induction with a potent volatile anesthetic; they develop pronounced hindlimb rigidity within 5 minutes. [31] Prior exercise even an hour before induction of anesthesia increases the severity and hastens the onset of these attacks in swine. [31] Mild hypothermia, depressants such as barbiturates and tranquilizers, and nondepolarizing relaxants delay the onset of MH. [15] [87] [88]

Susceptible humans respond less predictably than swine to these triggers. Many affected humans have previously tolerated potent triggers without visible difficulty. [14] This unpredictability might in part be related to the delaying effects described earlier, as well as to the brevity of short-duration anesthetics. Some patients have experienced MH episodes during anesthesia that did not involve recognized triggering agents [16] ; fortunately, all have responded appropriately to dantrolene. Obviously, the mechanism of anesthetic triggering in humans is unsolved.

Succinylcholine has several variant responses that can occur singly or in combination: (1) a muscle contracture, also noted in muscle that is myotonic or denervated [81] ; (2) a change in muscle membrane permeability without contracture, resulting in the release of CK and myoglobin from muscle (even in normal patients, SCh releases CK and myoglobin from muscle in small amounts; this is exaggerated in the presence of halothane and attenuated by curare, [31] and myoglobin release can be fairly marked even in the absence of obviously discolored urine [86]); and (3) an increase in metabolism, as in MH, usually associated with both muscle contracture and increased membrane permeability. [31]

Nitrous oxide has been proposed as a weak trigger of human MH. [31] This is most unlikely because it has been used repeatedly as the basic anesthetic in MH-susceptible humans and swine without triggering MH. Hyperbaric nitrous oxide does not produce MH in susceptible swine, even in concentrations causing apnea. [89]

Nondepolarizing muscle relaxants block the effects of SCh in triggering MH. They attenuate the effects of the volatile anesthetics. [15] [87] *d*-Tubocurarine has been incriminated as an MH trigger because it produced fever in two susceptible children. [31] *d*-Tubocurarine has been associated with greater lactate production in susceptible pigs exposed to environmental stress, [31] but it has not been shown to be a trigger of MH in susceptible swine; it does produce a contracture in denervated muscle, suggesting that it may have a mild depolarizing action that is not apparent under usual conditions. [90] Reversal of a nondepolarizing neuromuscular blockade has been performed without untoward events in humans with MH susceptibility.

Episodes of MH have been reported during various operative procedures, with general or regional anesthesia, and in extremes of ages. Although rare, prolonged and recurrent MH can still occur despite the absence of triggering agents. [16] Prior fever or SCh-induced trismus should not be ignored, even if the patient survived without obvious mishap. [91] The youngest probable case of MH involved an episode of SCh-related muscle rigidity occurring in utero just before birth. [92] Presumably, the fetus inherited susceptibility from his father that was triggered by anesthetic agents given to his mother.

Volatile agents reportedly stimulate MH Ca^{2+} release in site-specific channel gating actions that occur at lower concentrations than in normal muscle, and perhaps even at subclinical

---

concentrations (see Pathophysiology). It was previously believed that amide local anesthetics, such as lidocaine, could trigger MH. However, the evidence for this effect is weak. Animal data demonstrating Ca^{2+} release from the SR by amide anesthetics involve millimolar concentrations, which can only be achieved clinically by doses of about 2 g. [31] MH is not triggered in the most susceptible species, inbred swine, even if enormous doses of lidocaine are administered intravenously. It is ironic that Kalow et al [6] first commented about the possible efficacy of intravenous local anesthetics in treating MH, when one of the two cases the investigators were referring to involved treatment with intravenous lidocaine. Finally, amide anesthetics are now routinely used without untoward events for nerve block anesthesia in susceptible patients undergoing muscle biopsy.

It has been suggested that long-term propofol infusions in pediatric intensive care may induce MH-type reactions. [93] However, propofol has been demonstrated as safe in patients with MH syndrome, [94] and its effects on membranes of MH-affected skeletal muscle are stabilizing and opposite to those of volatile triggers. [95]

Awake Triggering

Malignant hyperthermia episodes can be triggered with environmental stress in swine (see History). Specific factors include exercise, heat stress, anoxia, apprehension, and excitement. [31] That these responses may be related to muscle movement or to increased temperature is suggested by the following findings: (1) susceptible swine *in vitro* or *in vivo* react with abnormally increased oxygen consumption and lactate production to carbachol or heat (41 to 42°C) but not to alpha-sympathetic and/or beta-sympathetic agonists, [64] [96] and (2) abnormal responses can be blocked or delayed by nondepolarizing relaxants. [15] [31] [45] [87]

Several findings suggest that human MH unrelated to anesthesia may occur. Anxiety reactions may precipitate an apparent MH response. [97] Susceptible families may have an increased incidence of unexplained sudden deaths and may tend to have a nonspecific cardiomyopathy. [31] We cite four case reports as examples of unusual events relating heat stroke, sudden and unexpected death, unusual stress and fatigue, or myalgias to possible awake MH episodes. [98] [99] [100] [101] Two of these involved environmental exposure to highly volatile vapors, and two were related to exercise. Although it is difficult to be certain how many of these types of cases represent human MH episodes in the absence of the anesthetic environment, some of these situations undoubtedly reflect that. The incidence of awake episodes in humans is undoubtedly low, and the less than 100 percent specificity in MH testing will result in some false-positive diagnoses (see Evaluation of Susceptibility). In general, susceptible patients should be advised that it is safe to live their everyday lives. Finally, proposed mechanisms explaining porcine awake MH may not be applicable to human awake MH.

/das/book/view/29494766/875/289.html

DIAGNOSIS

Malignant hyperthermia is a disorder of increased metabolism, the early signs of which may be subtle or masked. Its onset may be delayed until the patient is emerging from the anesthetic. Fulminant MH is now rarely seen because of greater awareness and sophistication in monitoring, and the more subtle onsets must be distinguished from other disorders with similar signs (see Table 27-1) . Some rare families manifest repeated hyperthermia during or after anesthesia, despite pretreatment with dantrolene and other various precautions. [102] These episodes do not feature clinical or laboratory evidence of MH and appear to be familial fever. Postoperative fever in the absence of other signs of MH is unlikely to represent MH.

When the diagnosis is obvious, that is, fulminant MH or SCh-induced rigidity with rapid metabolic changes, there is marked hypermetabolism and heat production, and there may be little time left for specific therapy to prevent death or irreversible sequelae. One could make the diagnosis directly with measurements of increased expired carbon dioxide during constant ventilation. However, other causes must first be ruled out, such as increased temperature with increased V_{O_2}/V_{CO_2} and unchanged controlled ventilation, and a stuck valve with increased inspired carbon dioxide (see Table 27-1 for an exhaustive list). Further, if end-tidal carbon dioxide increases and ventilation is then increased to maintain normal end-tidal values, diagnosis of MH may be delayed. [103] CK values aid in MH diagnosis if they acutely increase to greater than 10,000 U/L, but changes in CK during MH, especially if dantrolene is involved, overlap with changes observed in patients undergoing ordinary surgical procedures, particularly if the surgery is major. [69] A clinical grading scale aids in establishing the likelihood of MH in specific problem cases. It is based on weighted scores for muscle tone, muscle breakdown, acid-base parameters, temperature, tachycardia or other arrhythmias, and response to dantrolene. This scale is hampered if clinical laboratory evaluation has been minimal. [104]

In general, MH would not be expected to occur in any patient given barbiturate/nitrous oxide/opiate/tranquilizer/ nondepolarizing relaxant anesthesia, although there are rare exceptions. [16] When volatile anesthetics or SCh is used, MH should be suspected if there is undue tachycardia, tachypnea, arrhythmias, mottling of the skin, cyanosis, increased temperature, muscle rigidity, sweating, or unstable blood pressure. If any of the preceding abnormalities occurs, signs of increased metabolism, acidosis, or hyperkalemia must be sought. Analysis of arterial blood gases demonstrates metabolic acidosis and may show respiratory acidosis if the patient is unable to increase ventilation as metabolism increases. Central venous oxygen and carbon dioxide levels change more markedly than do those in arterial blood; therefore, end-expired carbon dioxide or central venous carbon dioxide levels are a more accurate reflection of whole-body carbon dioxide stores. Venous carbon dioxide, unless the blood drains an area of increased metabolic activity, should have P_{CO_2} levels only about 5 mm Hg greater than that of expected or measured Pa_{CO_2}. Suggested limits for venous blood include 55 mm Hg for P_{CO_2} and 35 mm Hg for P_{O_2}, assuming that Pa_{O_2} is greater than 100 mm Hg. If Pa_{CO_2} is greater than 60 mm Hg and base deficit is 5 to 7 mEq/L or more, the diagnosis is established (again assuming that other factors have been ruled out). In small children, particularly those who have had no oral food or fluid for a prolonged period, base deficit may be 5 mEq/L because of their smaller energy stores.

ASSOCIATION WITH OTHER DISORDERS

The King-Denborough syndrome, characterized by short stature, musculoskeletal abnormalities, and mental retardation, is associated with susceptibility to MH, as is central core disease (CCD). CCD was present in the family of Denborough's original patient, [5] as was discovered during later evaluations. Phenotypic expression of the Ry_1 mutation is variable; CCD appears to result when more deleterious mutant effects impose greater channel alterations. [105] This may be in part because although MH and CCD can share a locus, CCD must also have an additional locus. [106] Duchenne dystrophy is an X-linked myopathy; the associated deterioration of muscle membranes can result in a clinical MH episode on exposure to membrane perturbors such as MH triggers, despite normal contracture testing results. [76] Patients with Duchenne dystrophy can respond to anesthesia with sudden acute difficult-to-resuscitate cardiac arrest or sudden acute rhabdomyolysis, even without the use of SCh. [76] [82] Patients with occult myopathies of any type, and not necessarily related to MH or to the use of SCh, may experience these potentially and rapidly disastrous anesthetic events [82] (see Sudden Unexpected Pediatric Cardiac Arrest).

Neuroleptic malignant syndrome is caused by central effects of long-term administration of psychoactive drugs (e.g., butyrophenones, phenothiazines, monoamine oxidase inhibitors, lithium, or a combination of these drugs). These result in a slow-onset MH with varied symptoms. There are three key elements of pathophysiology: (1) the patient usually experiences an impairment of motor function with generalized rigidity, akinesis, and/or extrapyramidal disturbances; (2) deterioration in mental status occurs, with coma, stupor, and/or delirium; and (3) hyperpyrexia develops, with deterioration and lability of other "vegetative" functions, resulting in diaphoresis, dehydration, fluctuations in blood pressure and heart rate, and tachypnea. The picture may be similar to that of acute MH, but the onset generally requires several days to several weeks. Treatment involves discontinuation of the drugs and symptomatic control of temperature, acid-base balance, intravenous fluid balance, and muscle tone. Recovery is slow because the drug effects dissipate slowly. Dantrolene aids in therapy of NMS because it lowers muscle heat production and therefore body temperature, and in addition, it eases rigidity without the need for tracheal intubation. NMS and MH are different. [107] NMS responds favorably to electroshock therapy, and MH triggers are safe. Some NMS patients have positive MH muscle biopsy results, and some results are normal.

The relationship of isolated CK elevations and MH susceptibility in otherwise normal asymptomatic individuals remains unclear. In a study of 49 patients, 36 of whom were male, with CK level greater than twice normal on three occasions during a 3-month period, the Mayo group found 19 males and five females with MH susceptibility on contracture testing. This finding may represent another point on the MH spectrum, confirming heterogeneity, or it could include some false-positive results. [108] Some of these patients had received triggers uneventfully.

Other disorders are less convincing in their possible association with MH: crib death, or the sudden infant death syndrome; Smith-Lemli-Opitz syndrome [109] ; Charcot-Marie-Tooth syndrome [110] ; and heat stroke. Exertional heat stroke likely occurs more easily in MH-susceptible individuals. SCh induces contractures in myotonic muscle, which could be confused with MH. Myotonic goats develop brief rigidity after SCh administration but, even with the concomitant use of halothane, show no evidence of MH. In myotonia, there appears to be rigidity in the absence of serious metabolic abnormalities; infrequent positive biopsy results appear to relate to non-MH factors.

TREATMENT

Discontinuation of the trigger may be adequate treatment for acute MH if the onset is slow or if there was a brief administration of the trigger. However, if MH is fulminant (i.e., Pa CO_2 greater than 60 mm Hg and increasing, mixed venous P CO_2 greater than 90 mm Hg and increasing, base deficit greater than 5 mEq/L and falling, and temperature increasing 1°C/15 min), then adequate therapy is urgently needed for survival. In some patients, cardiac output falls rapidly, and there are minor metabolic and acid-base changes because of minimal tissue perfusion. This can result in rapid demise.

Dantrolene is the specific therapeutic drug, but it must be given while adequate muscle perfusion is present. [13] [31] It is also important to use symptomatic therapy to control body temperature, acid-base balance, and renal function. Adjunctive drugs are seldom necessary if proper treatment is begun soon enough. Dantrolene rapidly halts the increases in metabolism and secondarily results in a return to normal levels of catecholamines and potassium. [12] [13] The homeostatic mechanisms of the body then rapidly restore arterial blood pressure, heart rate, and sympathetic hyperactivity back toward normal.

For clinical use, dantrolene is packaged in 20-mg bottles with sodium hydroxide with pH 9 to 10 (otherwise it will not dissolve) and mannitol (for isotonicity). Dantrolene must be dissolved in sterile water rather than solutions such as 5 percent dextrose in water or bicarbonate because the extra molecules in solution lead to a salting-out effect with greater difficulty in dissolving dantrolene. If it does not dissolve immediately, producing a clear yellow to yellow-orange color, it should be heated under tap water or autoclaved for a few minutes. In a dire emergency, it should be administered through a blood filter without concern for crystals. In a fulminant episode in a large adult, as many as 10 bottles may be required to provide the therapeutic dose of 2 mg/kg. This requires the full-time efforts of three or four people. Preoccupation with facets of therapy other than dantrolene can accomplish control of symptomatic factors but can lead to the patient's death as a result of uncontrolled metabolic mayhem within the cells, leading to cell destruction. Dantrolene administration is the key therapy.

Dantrolene cardiac effects are complex and include interactions with calcium antagonists (see Calcium). Intravenous dantrolene, 2 mg/kg, provides therapeutic blood levels with a half-life of at least 10 hours in children and adults. [111] [112] Dantrolene in high doses does not paralyze because the effect plateaus. Peak effects include moderate muscle weakness with adequate strength for deep breathing and coughing. Weakness is accentuated in myopathic patients. The

therapeutic dose may be repeated every 5 minutes for a total dose of 10 mg/kg. Aside from cholestasis during long-term (more than 3 weeks) therapy for spasticity, dantrolene has no serious side effects.

Acute therapy for MH can be summarized as follows:

1. Discontinue all anesthetic agents and hyperventilate with 100 percent oxygen. Normal ventilation is that required to remove metabolic carbon dioxide. Therefore, with increased aerobic metabolism, normal ventilation, by definition, must increase. However, carbon dioxide production is also increased because of neutralization of fixed acid by bicarbonate. Therefore, hyperventilation is needed to remove this additional carbon dioxide.
2. Repeat dantrolene, 2 mg/kg, every 5 minutes to a total dose of 10 mg/kg, if needed.
3. Administer bicarbonate, approximately 2 to 4 mEq/kg. Continued efflux of lactate from skeletal muscle may result in recurrent acidosis [113] because lactate, being ionized, slowly crosses the muscle cell membrane to extracellular fluid.
4. Control fever by whatever means are available, including use of iced fluids, surface cooling, cooling of body cavities with sterile iced fluids, and heat exchanger with a pump oxygenator. [84] One should not become so preoccupied with cooling techniques and other busy work that he or she neglects the prime factor in therapy: intravenous administration of dantrolene. Cooling should be halted at 38 to 39°C to prevent inadvertent hypothermia.
5. Monitor urinary output to prevent shock to kidneys or acute tubular necrosis, as well as to examine for myoglobinuria.
6. Further therapy is guided by blood gases, electrolytes, temperature, arrhythmia, muscle tone, and urinary output.
7. Some clinicians recommend steroids.
8. Perform blood studies (electrolytes, CK, liver profile, blood urea nitrogen, lactate, glucose), coagulation studies (prothrombin time, fibrinogen, activited partial thromboplastin time, fibrinolytic split products, platelet count), and serum hemoglobin and myoglobin and urine hemoglobin and myoglobin studies.

Repetition of the drugs or laboratory studies depends on the clinical course. Dantrolene should probably be repeated at least every 10 to 15 hours (because this is its half-life) for several doses. [111] [112] If there are no signs of recurrence, dantrolene administration may be discontinued.

Treatment of the hyperkalemia should be performed slowly. Plasma K^+ level must be serially monitored because it may be an important factor in treatment (e.g., persistently elevated K^+ level may prevent defibrillation). The most effective way to lower serum potassium is reversal of MH by effective doses of dantrolene. Calcium administration is indicated only for related arrhythmias or for poor cardiac function. However, when indicated, calcium and cardiac glycosides may be used because their administration to the susceptible pig does not trigger MH. [42] They can be life saving during persistent hyperkalemia. [82] Arrhythmias may be treated with either procainamide or lidocaine.

Permanent neurologic sequelae, coma or paralysis, may occur in advanced cases, probably secondary to inadequate cerebral oxygenation and perfusion for the increased metabolism and, because of the fever, acidosis and potassium release. Even satisfactory care during anesthesia may not prevent neurologic complications. Measurements of intracranial pressure may help in the evaluation of cerebral edema.

Disseminated intravascular coagulation or consumptive coagulopathy may be caused by hemolysis, release of tissue thromboplastins, overt tissue damage, or shock. The best treatment is adequate therapy for MH to prevent stagnation of peripheral blood flow and to lower temperature.

Among the ineffective therapeutic adjuncts are calcium antagonists, drugs such as nimodipine, verapamil, nifedi-pine, and diltiazem, and sympathetic antagonists, such as propranolol. Calcium antagonists do not increase porcine survival. [40] [41] Further, they may interact with dantrolene to produce hyperkalemia; this can result in retriggering of MH [42] or in profound myocardial depression. [37] [38] [39] Magnesium reduces the increase in intracellular calcium during porcine MH but does not prevent the increase in metabolism. Although it may play a role in MH mechanisms (see Pathophysiology, Molecular Biology, Genetics, Dantrolene), [27] [28] its therapeutic value appears to be minimal.

Early diagnosis and treatment of MH are essential. The complications that may arise are all difficult to treat and may lead to serious and permanent sequelae. Finally, retriggering may occur even with dantrolene therapy, as the initial dose of the drug is redistributed, metabolized, or excreted.

ANESTHESIA FOR SUSCEPTIBLE PATIENTS

Anesthesia should consist of nitrous oxide, barbiturates, etomidate, propofol, opiates, tranquilizers, and/or nondepolarizing muscle relaxants (Table 27-2) . Potent volatile agents, such as halothane, enflurane, sevoflurane, desflurane, and isoflurane, and the depolarizing muscle relaxants, such as SCh, must be avoided, even in the presence of dantrolene. Some human patients have experienced a hypermetabolic state despite these precautions; however, these patients have always responded favorably to intravenous

TABLE 27-2 -- Drugs in Patients Susceptible to Malignant Hyperthermia

UNSAFE	SAFE
Volatile anesthetics [31]	Amide anesthetics
Desflurane	Barbiturates [15] [31]
Enflurane	Calcium [42]
Halothane	Dantrolene [12] [13]
Isoflurane	Digitalis drugs [42]
Sevoflurane [110]	Epinephrine [64]
	Ester anesthetics
Cyclopropane [91]	Etomidate
Ether [3]	Ketamine [31]
Relaxants	Nitrous oxide [31] [89]
Succinylcholine [10] [82] [83]	Nondepolarizing relaxants [87] (except curare, a weak depolarizer [90])
Cautious use:	Norepinephrine [62] [63] [64]
Dantrolene in combination with calcium antagonist [37] [38] [39] [40] [41]	Opiates [31]
	Propofol [94] [95]
	Tranquilizers in general (except chlorpromazine)

dantrolene. [16] The consensus is that in most instances, preoperative dantrolene is not needed in susceptible patients because the use of nontriggering agents is almost always associated with uneventful anesthesia. If used, the dose is 1 to 2 mg/kg given intravenously just before induction. This approach avoids the side effects of lengthy pretreatment. If used in obstetrics, it is best given after the cord is clamped, to avoid the problems of a floppy child because cord blood levels may approach 65 percent of maternal levels. [114] Dantrolene has been used in a heart transplant patient without evident problems. [115]

Regional anesthesia is safe and may be preferred for certain procedures in susceptible patients. Amide anesthetics had been considered dangerous in susceptible patients because they induce or worsen contractures *in vitro* as a result of their effect in increasing calcium efflux from the SR. However, these effects require millimolar concentrations of these drugs, far greater than the plasma values achieved in clinical use. Because of these theoretical considerations, procaine was proposed as a therapeutic drug for MH, and lidocaine was condemned as dangerous. Eventually, porcine and human studies demonstrated the lack of danger of amide anesthetics, and, at present, ester or amide anesthetics may be used safely. Further, intravenous lidocaine was used as long ago as 1970 to treat acute MH without apparent harm and with apparent good results. [6]

It is no longer necessary to clean the anesthetic machine by flushing with oxygen and/or air for many hours. Removal or sealing of the vaporizers, change of soda lime, perhaps replacement of the fresh gas outlet hose, and use of a disposable circle with a flow of 10 L/min for 5 minutes suffice. [116] Use of an expired gas analyzer aids in demonstrating that volatile vapors have been removed from the anesthetic system.

One should discuss the anesthetic care with the patient with the confidence that all will be done to avoid difficulties with MH, and should any problems occur, the appropriate drugs, knowledge, and skills are immediately at hand. Some physicians are overly cautious in handling patients with MH to the point that medical precautions and apprehension are magnified to an exaggerated degree. Many of these patients have undergone certain procedures, such as dental analgesia and obstetric anesthesia, without problems before the diagnosis of susceptibility was made. With such a confident approach, the patient enters the therapeutic environment in a relaxed and comfortable state of mind. Anxiety and stress are minimal, and the patient is reassured by confidence in the doctor's ability to monitor appropriately and to provide proper treatment for any difficulties. Outpatient procedures are feasible in patients with MH in most environments; the time of discharge depends on the usual outpatient criteria.

STRESS-RELATED DISORDERS IN OTHER SPECIES

Several species, such as dogs, cats, and horses, have MH episodes with anesthesia. [31] The pig is well known to have stressed awake MH as well as anesthetic-related MH. Continuing study of the capture myopathy of wild animals, more recently in feral deer, suggests that this is "overstraining" during the chase of normal animals rather than a genetic disorder similar to MH. [117] Broiler chickens, which are inbred to grow faster and develop heftier breast muscles, have a greater incidence of sudden cardiovascular-related death than do ordinary chickens. [118] A strain of laboratory rats has an increased incidence of sudden death during acute respiratory alkalosis. [119] This does not appear to be related to the cardiac potassium shifts observed with rapid reversal of severe hypercarbia. [120]

EVALUATION OF SUSCEPTIBILITY

Evaluation includes a history and physical examination for the detection of subclinical abnormality. A genealogy going back two generations with specific information about anesthetic exposure and agents estimates the likelihood of adequate exposure to triggering agents.

Measurements of blood CK values provide a basic screening tool. CK values, when determined in a resting, fasting state without recent trauma, reflect muscle membrane stability. When CK level is elevated in a close relative of a person with known MH susceptibility, then this relative may be considered to have MH susceptibility without further testing. If the CK level is normal on several occasions, there is no predictive value, and a muscle biopsy with contracture studies is necessary.

Muscle biopsy contracture studies, performed at some 30 centers around the world, use exposures to halothane, caffeine, halothane plus caffeine, ryanodine, [34] [121] or 4-chloro-m-cresol. [35] Contracture responses are sometimes positive in patients with myopathies that bear no direct relationship to MH; one cannot be certain in these cases that the positive biopsy result indicates susceptibility. Patients must not be given dantrolene before the biopsy, because this could mask the response of abnormal muscle to contracture producing drugs. Other drugs might alter contracture responses. For example, Ca^{2+} antagonists *in vitro* decrease halothane contractures, and propranolol *in vitro* decreases caffeine contractures in MH-susceptible humans. However, it is not known whether these drugs are washed out in the muscle bath, with little effect on the results. Contracture testing also evaluates susceptibility in other species, such as pigs and dogs. Nelson [122] observed abnormal animal contracture responses in association with altered Ry_1 but recognized that association does not confirm causality. Cosgrove et al [123] examined contractures in Greyhounds in conjunction with a triggering anesthetic challenge and were unable to confirm that anesthetic-related problems were MH.

For the student of anesthesia, it is only important to remember that susceptible individuals have a lower threshold to the contracture-producing drugs than do normal individuals. However, the muscle specimen must be viable (i.e., must twitch when stimulated electrically) because the contracture threshold may vary if the fiber is degenerating or deteriorating. Bath kinetics are stable with experienced laboratories, and variations in temperature have less effect than anticipated on contracture thresholds. [124]

Once a patient is diagnosed with MH susceptibility, professional advice should include the following: precautions are necessary as regards general anesthesia, and for little else; triggers include all potent volatile agents and SCh;

awake episodes are uncommon, and, if not experienced before the diagnosis is established, are not a worry; military personnel may have restrictions because of the necessary avoidance of combat trauma and the possible mandatory use of triggers, and soldiers with MH susceptibility may be less desirable because some believe that they may fatigue sooner with harsh military conditioning because of their subclinical myopathy. [125] [126]

The predictive value (percentage of positive results that are true positives) or efficiency (percentage of all results that are true, whether positive or negative) of contracture testing in determining susceptibility cannot be estimated. False-positive results resulting from cautious interpretation or decreased specificity are masked because the patient will never be exposed to triggering agents. Both the European and the North American contracture protocols have yielded sufficient multicenter data to confirm acceptable test results. [127] [128] For separation of control patients and those with MH susceptibility based on clinical information that is entirely separate from contracture testing results, both groups used the clinical grading scale [104] to establish the strong likelihood of MH during a specific clinical episode. They used patients with a very low risk of MH susceptibility as controls. The European data include 202 low-risk control patients and 105 patients suspected of having MH, [127] and the North American include 120 low-risk controls and 32 patients suspected of having MH. [128] Both have 97 to 99 percent sensitivity (frequency of positive results in the patients with clinically established MH) and acceptable (78-94%) specificity (frequency of negative results in low-risk controls). Threshold values attempt to provide 100 percent sensitivity so as not to miss any patients with MH susceptibility; this restriction limits specificity.

Thus, the protocols of the North American MH Registry and European MH Group provide uniform contracture testing and acceptable specificity and sensitivity within their own geographic areas. However, minor differences in protocol lead to major difficulties in interpretation of results. [127] The North American protocol uses incremental caffeine concentrations of 0.5, 1, 2, 4, 8, and 32 mM, and halothane 3 percent as a bolus application. The European protocol uses additional steps in its increments, caffeine 0.5, 1, 1.5, 2, 3, 4, and 32 mM, and halothane 0.5, 1, 2, and sometimes 3 percent. Greater fractionation of caffeine and halothane increments in the European protocol results in lower diagnostic thresholds, that is, 0.2 g for both drugs. The lesser fractionation of increments in the North American protocol leads to greater thresholds, 0.3 g for caffeine, and a relatively large gray area for halothane, about 0.5 to 0.8 g. [128] Some investigators urge the use of the combination of halothane and caffeine in testing and believe that some false-negative diagnoses will otherwise occur. [129]

It is now time to standardize the two protocols into a single worldwide test. This would ease interpretation and aid other countries that plan to begin MH testing in selection of a protocol. At present, European test centers, and likely Canadian centers, are performing many more biopsies than American centers because of limitations in care with modern American medicine. Thus, genetic data collection is becoming more comprehensive in these other countries. Uniformity would benefit all and would aid in collating results. Delay in achieving uniformity will slow growth in worldwide recognition of the various mutations in humans with heterogeneic MH susceptibility and will complicate efforts in determining various aspects of human MH. People generally resist efforts at standardization, and delays can restrict development in a field. As an example, about 46 years ago, the pediatric anesthesiologist M. Digby Leigh had the foresight to attempt to establish standard monitoring of expired carbon dioxide; his efforts "... were rebuffed by incredulous scoffers," [130] thus delaying the routine use of one of our more valued standard monitors by about 2 decades.

What is needed in MH testing is an accurate noninvasive or nondestructive measure of susceptibility. Nuclear magnetic resonance probably has the greatest promise. [131] [132] The difficulty is to standardize a stress, such as forearm ischemia, that will differentiate susceptible tissue from normal. As with so many tests, a major problem is establishing conditions whereby no overlap exists between the ranges of normal and susceptible responses. Although ultrasound was recommended as possibly promising, a careful study of skeletal muscle ultrasound was unsuccessful in humans with MH susceptibility. [133] Adnet et al [134] examined masseter muscle in a skinned fiber *in vitro* preparation in attempts to explain its propensity for contracture (see Trismus-Masseter Spasm). They observed greater sensitivity to Ca^{2+} and caffeine than that noted in quadriceps muscle. However, their findings were contradicted in a contracture study of masseter biopsy specimens taken during major craniofacial cancer surgery. [135] Responses of masseter muscle contractures examined in intact cut muscle bundles were similar to those of quadriceps contractures. The response of masseter muscle remains an incompletely explained phenomenon that is fascinating but unlikely to add to innovative probes for MH testing.

/das/book/view/29494766/875/295.html

FINAL COMMENTS

Malignant hyperthermia is a subclinical myopathy that is unmasked on exposure to the potent vaporous anesthetics or SCh; skeletal muscle acutely and unexpectedly increases its oxygen consumption and lactate production, resulting in greater heat production, respiratory and metabolic acidosis, muscle rigidity, sympathetic stimulation, and increased cellular permeability. MH is caused by a loss of control of Ca^{2+} concentration within the muscle fiber, and it can involve a generalized alteration in cellular or subcellular membrane permeability. This is an EC coupling defect resulting from an alteration in Ry_1. It is a homozygous single-point mutation of Ry_1 in swine and a heterozygous disorder in humans, in whom there might also be a modification of Ry_1 function by interacting structures, membranes, or enzymes; that is, MH may occur as a final common path phenomenon. The study of channelopathies is an aid in defining this area. Diagnosis is made on the basis of extraordinary temperature and acid-base and muscle aberrations. Specific treatment is the action of dantrolene on muscle Ca^{2+} movements; symptomatic treatment is by reversal of acid-base and temperature changes. Evaluation of affected families is guided by measurements of circulating CK and by analysis of druginduced contractures in muscle biopsy specimens. Either general or regional anesthesia is safe for patients susceptible to MH, provided that if a general technique is chosen, care

is taken to specially prepare the anesthesia machine and to avoid all potent volatile anesthetics and SCh.

Research in MH has yielded new insights into the physiology of metabolism and into the molecular biology of genetic muscle disorders. Remaining challenges include identification of the genes responsible for human MH, elucidation of the mechanism that links exposure to the subsequent loss of Ca^{2+} control, development of noninvasive nondestructive testing for susceptibility, and determination of the mode of action of dantrolene.

Chapter 28 - Fundamental Principles of Monitoring Instrumentation

James F. Szocik
Steven J. Barker
Kevin K. Tremper

INTRODUCTION

Patient monitoring has been a key aspect of anesthesiology since its beginnings as a medical specialty. As anesthesiology has grown more sophisticated and complex, so have the monitors and the data they produce. The anesthesiologist's senses of sight, hearing, and touch, at first expanded with the stethoscope, sphygmomanometer, and electrocardiograph, are now supplemented by the pulse oximeter, expired gas analyzer, evoked potential monitor, and transesophageal echocardiograph, to name a few. The complexity of some of these devices can be intimidating, and we are tempted to regard them as incomprehensible "black boxes" that provide us with clinical data. However, to do so would be to shirk an important part of our clinical responsibility. We must be able not only to understand and interpret the data from our monitors but also to anticipate and recognize errors associated with their use. We cannot accomplish this without understanding how these devices work.

The purpose of this chapter is to provide an understanding of the scientific principles underlying the design and function of our most commonly used monitors. An introduction defining some concepts of basic physics is followed by more detailed descriptions of the principles. The text and figures explain these principles predominantly in a qualitative manner. For those desiring a more quantitative explanation, the relevant equations are provided in the appendices to this chapter.

BASIC PRINCIPLES

Nature of Physics and Measurement

What is monitoring? The verb *monitor* (derived from the Latin *monere,* "to warn") means to check systematically or to keep watch over. In the context of anesthesiology, monitoring means using both our senses and electronic devices to

repeatedly or continuously measure important variables in the anesthetized patient.

Physics is the science of matter and energy and of the interactions between the two, that is, it is the study of everything in the physical universe. Physics encompasses everything from the motions and inner workings of the atom to those of galaxies. Physics is quantitative, and mathematics is the language of physics. In fact, Isaac Newton invented "the calculus" as a tool for expressing and studying the laws of physics. Our monitors are also quantitative. Before we can discuss and understand the complexity of modern anesthetic monitors, we must quantitatively define that which we are attempting to measure.

We measure and monitor mass and energy: how much of a substance is present and in what energy state. Much of what we desire to monitor is outside of the range of the human physical senses. Therefore, we must measure in this insensible realm using devices that enhance or extend our senses. Just as the senses have limitations and can be "fooled" under certain circumstances (Fig. 28-1) , our physiologic monitors are limited by their design and can also be fooled under some conditions. The intelligent user of these devices must understand their basic design assumptions in order to predict when they are likely to produce erroneous data.

As we make measurements of mass, space, time, and other physical variables, we often encounter confusion between the terms *units* and *dimensions.* A dimension describes

Figure 28-1 Optical illusions. We perceive the circles to be different sizes because we infer the size by relative dimension. The closeness of the smaller circles makes the inner circle appear smaller, and vice versa. The lines appear to be different sizes because we use straight-line perspective to estimate size and distance. This illusion reportedly does not work in cultures where straight lines are not used. Therefore, our internal perceptions lead us to err in estimating size and length. In the same way, the internal programming of our monitors can lead us to misinterpret results.

the measure by which a physical variable is expressed quantitatively. For example, length (l) is the dimension used to describe distance, height, or width. Units are specific ways of measuring a given dimension: meters, feet, furlongs, and light-years are all units of length. In basic mechanics, all dimensions can be expressed in terms of the three *fundamental dimensions* of mass (m), length (l), and time (t). In problems of energy transport, a additional dimension of temperature or heat content must be added. In electricity and magnetism, the dimension of charge is also required.

As stated earlier, *units* are specific ways of measuring a particular dimension. Although there are many units of mass, length, and time, the scientific community has standardized to the *Systeme International d' Unites,* or SI units: length in meters, mass in kilograms, time in seconds. To understand how all quantities in basic mechanics can be expressed in terms of mass (m), length (l), and time (t), we must introduce one (and *only* one) equation: Newton's second law of motion, the basis of all classical physics:

Stated in English, force equals mass times acceleration. Force and acceleration are *vectors;* that is, they have both a magnitude and a direction. Mass is a *scalar;* it has only a magnitude. From this simple equation, we can see that the dimensions of force must be the dimensions of mass times those of acceleration. Acceleration is the rate of change of velocity, and velocity is the rate of change of distance. Thus, velocity has dimensions of length divided by time, l/t, and acceleration has dimensions of l/t/t, or l/t^2 The SI units of acceleration are meters per second per second, or m/s^2 . Because the SI unit of mass is the kilogram, Equation 1 tells us that the unit of *force* must be $kg\text{-}m/s^2$ (kilogram-meters per second squared). This unit is called the *newton,* after Sir Isaac, so that one newton equals one $kg\text{-}m/s^2$.

Other dimensions and units can be derived in the same way. For example, kinetic energy is proportional to mass times velocity squared (Mv^2), so its dimensions are $M(L/t)^2$, and its SI unit is the $kg\text{-}m^2/s^2$. Because "kilogram-meter squared per second squared" is quite a mouthful, we define this unit of energy as the *joule.* The term *power* refers to the time derivative of energy, that is, the change in energy per unit time. The unit of power is thus the joule per second, which we call the *watt.* One watt equals one joule per second. Throughout physics, there are many other "practical units," which can always be related to SI units. For example, we are all familiar with *horsepower* as a unit of the power of an engine. One horsepower equals 746 watts.

Measurement is the determination of a physical quantity (e.g., mass, length, time, energy, and any of their derivatives). Measuring depends on a physical interaction. If a mass or energy does not interact with anything, it cannot be perceived to exist. As we have stated, physics uses the second, meter, and kilogram to measure time, space, and matter. How do we define the size of these standard units? Historically, the second was defined as a fraction (1/60 of 1/60 of 1/24) of a day. However, because of tidal forces on the earth, the days are becoming longer, and the second is now defined as the interval required for 9,192,631,770 vibrations of the cesium-133 atom measured via atomic beam clock. The meter

was originally one ten-millionth of the distance from the North Pole to the Equator. In 1960, the meter was redefined to be 1,650,763.73 wavelengths of orange-red light from a krypton-86 lamp. Today, the meter is defined as the distance light travels in a vacuum during a time of 1/299,792,458 second because time can be measured with better accuracy and precision than the wavelengths of the krypton lamp. The gram was originally defined as the weight of that volume of pure water at 4°C, which occupies a cube that is onehundredth of a meter on all sides. Today, the kilogram is defined as a unit of mass based on a physical standard (a platinum-iridium cylinder).

Temperature is related to the energy per unit mass of a substance in the form of motions on an atomic level. When an object of higher temperature is brought in contact with one of lower temperature, thermal energy, or *heat,* spontaneously passes from the "hot" to the "cold" object until the two reach equilibrium at a temperature between the two original temperatures. In gases, temperature is a quantitative measure of the kinetic energy of molecular motion per unit mass. In 1742, Celsius proposed a temperature scale of *degrees* using the freezing point of water as 0°C and the boiling point of water at one atmospheric pressure as 100°C. A temperature of absolute zero is defined as the point at which the molecules in a substance are in their lowest possible energy state. This condition occurs at -273.15°C or, in SI units, 0° *Kelvin* (K).

Physical measurements can be either continuous or discrete. That is, we can measure a distance of 3.1416 m, but we cannot measure out 3.1416 eggs. We consider most numerically defined quantities to be continuous. However, when we measure very tiny quantities (wavelengths of light, energies of photons, masses of atoms), we find that our measurements are not continuous; they change in small jumps, or *quanta.* Continuous measurement is thus an illusion, but a practical one for most purposes.

Accuracy

All measurements have errors. Error is usually determined by the comparison of a measurement to a "gold standard" of that measure. Unfortunately, all measurements, even the so-called gold standards, are subject to errors with respect to reproducibility. From a clinician's perspective, we can depend on a physiologic measurement only if it is accurate to the degree required for clinical decision making. For example, there are several ways to measure systemic blood pressure. We can listen to Korotkoff sounds by use of a sphygmomanometer cuff and stethoscope; we can rely on an oscillometric automated noninvasive blood pressure device, or if we need continuous measurement, we may place an arterial cannula. [1] Unfortunately, each of these techniques provides a slightly different arterial blood pressure value, and each has different sources of error. Our choice of method may be determined by accuracy or by our needs for the frequency of the data and the ease of retrieving these data. An automatic oscillometric device is usually chosen over manual auscultatory measurements for ease of acquisition and reproducibility. Two people taking auscultatory blood pressure may hear the Korotkoff sounds at slightly different points and record different blood pressures. The required accuracy of a clinical monitor is determined by the smallest change in the measured variable that could affect a clinical decision. The requirements for "absolute accuracy" (is the measured value correct?) may be different from the requirements for "relative accuracy" (does the measured value follow trends?).

For example, a pulse oximeter estimates arterial hemoglobin oxygen saturation by measuring light absorbance. The pulse oximeter saturation estimate, Sp_{O_2}, is compared with the hemoglobin saturation determined from the analysis

Figure 28-2 Accuracy and precision. The bias plot is a way to compare two different methods of measuring the same variable. Examples are plotted above on the right for saturation values, blood analysis versus pulse oximetry. It is a plot of the difference between the two measurements being compared versus the average of those two measurements. If one method constantly measures slightly higher than the other by a consistent value, it has a positive bias. If it has only slight variation around that bias, it is said to have very low random error (or precision, which equals the standard deviation of the differences) (A). (B) The values are randomly scattered, such that the average difference is near zero, but the precision value is very large. This large random error makes the device unusable because calibration will not improve this random error. Figure 28-2 (C) This is the optimal device, that is a bias near zero and a very small precision (standard deviation of the differences). No amount of calibrating or "sighting in" could cause Figure 28-2 (B) to become more accurate because the error is randomly scattered.

of an arterial blood sample by a laboratory co-oximeter, Sa_{O_2}. There are errors associated with arterial blood sampling and *in vitro* analysis of the sample by the co-oximeter. Nevertheless, the co-oximeter is considered to be the gold standard in this comparison of methods.

The pulse oximeter's saturation value can be compared with that of the co-oximeter by the determination of *bias* and *precision* (Fig. 28-2). The bias is the average difference between simultaneous values from the two methods, or the systematic error. If a pulse oximeter reads an average of 5 percent higher than the co-oximeter analysis, it has a bias of 5 percent, and we can adjust for that systematic error by recalibrating the device. The precision is the standard deviation of the differences between the two measurements, and it quantifies the random error, or "scatter." A higher value of the precision indicates a larger random error. (This statistic may be more appropriately called the "imprecision.") If the random error is too large, the device may not be clinically useful. We can adjust for systematic error (bias) by recalibration, but there is no way to adjust for random error. [2]

Signal Processing

Some physiologic values are constant over time; others vary. When a measured value changes over time, it constitutes a signal. Many physiologic processes generate signals that cannot be perceived by our senses or are too small to measure directly. We must process and amplify these signals, a situation that introduces new problems. The first step in processing is to convert the raw physiologic variable (pressure, temperature, velocity, etc.) into another form of energy, usually electrical. This conversion is accomplished by a *transducer* (Fig. 28-3) (Figure Not Available) For example, a pressure transducer converts pressure (force/area) into an electrical signal, which can then be amplified and processed. The processed output is usually transmitted to a display device.

When an analog signal (e.g., voltage versus time) is amplified, both the background noise and the desired signal are amplified (Fig. 28-4) Various techniques can be used to enhance the signal-to-noise ratio. For example, most pulse oximeters assume that a patient's pulse rate is between 30 and 300 beats per minute. Therefore, the instrument filters out any pulsations that occur at frequencies below 30 or above 300 (see the section on alternating current, capacitors, and impedance). In some cases, a desired signal can be repeated and summated, and the accompanying random noise becomes a smaller fraction of the signal. Evoked potentials are an excellent example of this process. The evoked response signal for a single stimulus is actually much smaller than the random noise, but this signal is nearly identical after each stimulus. Therefore, by summing the potentials after many stimuli, we reinforce the evoked response signal but not the noise (Fig. 28-5)

Finally, the waveform of any periodic signal can be represented by a summation of sinusoidal waves, called a "Fourier series" [3] (Fig. 28-6) . The component sine waves can be described by their frequency and amplitude (or power, which is proportional to the square of amplitude). Thus, a waveform originally expressed as amplitude versus time is *transformed* into a plot of power versus frequency (Fig. 28-7) . The resulting plot, called the "power spectrum," is a common form for displaying and interpreting some types of waveform data, for example, the electroencephalogram (Ch. 35)

When we monitor a patient, we measure physical quantities in a physiologic setting, and these measurements are

Figure 28-3 (Figure Not Available) Transducer. A transducer changes a signal from one form of energy to another. A common transducer in anesthesia changes mechanical energy, e.g., an arterial pulse, into electrical energy. Microphones and speakers are also examples of transducers. *(Modified from Tremper and Barker [20])*

Figure 28-4 Digital and analogue signal processing. The analogue signal shows distortion and loss of fidelity as it is reduced and then amplified. The digital signal shows no such loss. To create the analogue example, a copying machine was used to shrink the text and then enlarge it. For the digital signal, the font size was reduced, the text copied, and the process reversed.

subject to error and uncertainty. Our task as anesthesiologists is to understand both the physiologic and the physical limitations of these measurements, judge the potential for error, and make clinical decisions in the face of these uncertainties.

Figure 28-5 Somatosensory evoked potentials. A background signal can be separated from random noise by repeatedly adding the signals. The noise (random) is equally likely to be positive or negative; hence, adding positive and negative yields zero with multiple summations.

PRESSURE MEASUREMENT

Principles of Pressure (Mass, Force, and Energy)

Many of our monitors are based on fundamental principles of the mechanics of solids and fluids, usually a derivation from F = ma. We discuss a few of these principles in this section, providing common examples of each one.

Many of our monitors measure force, which is related to mass and acceleration as described by Equation 1, Newton's second law. The force may be generated by gravity, a beating heart, a compressed gas, or a contracting muscle. When we weigh a patient, we are determining the force exerted by gravity at the earth's surface on the patient's mass (m). This gravitational force (F_g) is related to mass by the formula

where g, the gravitational constant for acceleration, equals 9.8 N/kg (Fig. 28-8) . Many anesthetic monitors measure pressure, which is force divided by the area of the surface on which that force is exerted. Pressure thus has dimensions of force/area, and its SI unit is the newton/(meter)^2, which is called the *pascal.* Because the pascal is a very small unit of pressure, we usually choose to use *kilopascals,* which equal 1,000 pascals.

As noted earlier, kinetic energy is proportional to mass times velocity squared and is measured in kg-m^2/s^2 or joules.

Figure 28-6 Fourier series. This pseudoarterial waveform was generated by adding the three sine waves with the following characteristics, y = 50 sinx, y = 25 sin2x, y = 12 sin4x.

If a force (F) acts on a mass (m) over a distance (d), we define *work* as the product of the force and distance: W = Fd. It can be shown from Equation 1 (using a little calculus; see Appendix 1 at the end of this chapter) that the work performed on a mass equals the change in its kinetic energy:

Work has dimensions of force times distance, and SI units of newton-meters. Because work and energy change are equivalent, one newton-meter must equal 1 kg-m^2/s^2 = 1 joule (J). This equivalence of units can be verified by Equation 1.

The relationship of work and energy leads to the concept of *potential energy.* If we lift mass (m) by a height (z) above the floor and let it fall, the force of gravity (F_g = mg)

Figure 28-7 Spectral arrays. A compressed spectral array can display the frequency on the x axis and power on the y axis. A number of these can be aligned with time as a third axis, giving an indication of changes in power over time.

acts on the mass through the distance (z), thus doing work, given by:

At the end of its fall, the mass has a kinetic energy equal to the work performed, mgz (Equation 3). Therefore, we say that when the mass is raised to the height (z) above the floor, we have given it a potential energy equal to mgz. A 1-kg mass lifted 1 meter off the floor has a potential energy of 9.8 J. This potential energy can be converted into kinetic energy of motion simply by letting the mass fall. Potential energy can be stored in many other forms besides height (called "gravitational potential"), for example, a compressed spring, gas at high pressure in a tank, or the electrical potential of a battery (Fig. 28-9) .

Energy is related to matter in one additional way through Einstein's famous equation: E = mc^2 . That is to say, matter and energy are the same "stuff." In the absolute sense, usually reserved for thermonuclear weapons, atomic reactors, and the sun, matter can be converted into energy, and vice versa. If a 1-kg mass were completely converted to energy via E = mc^2 , it would yield 8.987 × 10^{16} J (Table 28-1) (Table Not Available) .

We have already defined power as the rate of change of energy per unit time. With the additional relationship between work and energy (Equation 3), it is clear that power is also the "rate of work," or amount of work performed per unit time. Thus, the unit of power (1 watt = 1 J/s) can also be expressed as the newton-meter/s.

Static Pressure Measurement (Manometer)

We have defined pressure as the force acting on a surface per unit area. A *fluid* is defined as matter that continuously deforms (changes shape) as long as any stress

(surface force) is applied to it. Fluids are subdivided into liquids, which are relatively incompressible, and gases, which are compressible.

Figure 28-8 Balance. A scale is in balance when the forces are equal and in opposite directions. The force of gravity on the unknown mass of fruit is balanced by the known standard masses on the opposite side of the balance. $F_1 = F_2$, hence $m_1 a_g = m_2 a_g$; because $a_g = a_g$, m1 = m2. (a_g = acceleration due to gravity).

Pressure exists and can be measured everywhere within a fluid, even where it is not in contact with a rigid surface. Although the SI unit of pressure is the pascal (or newton per meter squared), in medicine, we more commonly use units such as millimeters of mercury (mm Hg) and centimeters of water (cm $H_2 O$). How does a unit of length become a unit of pressure? This is the principle of the liquid manometer, the oldest method of pressure measurement. The manometer *balances* the pressure to be measured against the pressure exerted by a vertical column of liquid of known density, for example, mercury and water. The density of a fluid is its mass per unit volume,

Figure 28-9 Potential energy and kinetic energy. Potential energy is stored energy that can be released or converted into kinetic energy, the energy of motion. Energy can be stored as gravitational, chemical, electrical, and other forms of potential energy.

TABLE 28-1 -- Comparison of Energy Levels of Common and Uncommon Events

(Not Available)

(Modified from Hecht. [19] *)*

---

which has SI units of kilograms per cubic meter (kg/m^3) or commonly, grams per milliliter. The pressure exerted by a liquid column of height (z) and density (rho) is simply rhogz (see Appendix 2 at the end of this chapter for derivation). If the manometer liquid is mercury, which has a density of 13,600 kg/m^3 , then the manometer pressure in pascals is

Because these large numbers are rather awkward, we express p in kilopascals (kPa) and z in millimeters of mercury (mm Hg):

A useful reference for the various pressure units in use today is the pressure of the earth's atmosphere at sea level, called "one atmosphere" or 1 atm:

= 760 millimeters of mercury (mm Hg)

= 14.7 pounds/square inch (psi)

= 988 cm $H_2 O$

For slowly changing pressures, a water or mercury manometer is simple and dependable (Fig. 28-10) . The manometer cannot respond quickly to rapid changes in pressure because of its inertia; that is, the mass of the liquid column resists rapid changes in height. If a fluid-filled catheter is connected to a patient, the height of the fluid in the manometer determines the mean pressure at the tip of the catheter. If the pressure measured is the central venous pressure, we can use these data to infer right ventricular preload. Because this manometer is in direct continuity with the patient's circulation, the manometer fluid must be compatible with blood, that is, it must be iso-osmolar, as well as nontoxic.

Figure 28-10 Manometer. A water manometer uses a balance of forces. In this case, the downward pressure of the fluid, as determined by its density and height, balances the upward pressure of the central venous system, caused by hydrostatic and elastic recoil forces.

Dynamic Pressure Measurement (Transducer)

The accurate measurement of a rapidly changing pressure, such as arterial blood pressure, is more difficult and complex. There are many characteristics of the pressure versus time waveform that we might wish to determine. The systolic, diastolic, and mean arterial pressures are given by the maximum, minimum, and average pressure values during the cardiac cycle (Fig. 28-11) . In addition, we can measure the maximum upward slope of the waveform during systole, which is related to the speed of ventricular ejection. An abnormally rapid downslope after aortic valve closure (indicated by the dicrotic notch) suggests possible aortic insufficiency. Thus, the details of the pressure-time waveform as well as its maxima and minima are potentially important to the clinician.

The modern pressure transducer is a device that changes either electrical resistance or capacitance in response to changes in pressure on a solid-state device. The variable transducer resistance is placed in an electrical circuit involving three known resistances (Wheatstone bridge; see Appendix 3 at the end of this chapter), which converts the resistance change into an electrical voltage. The moving part of the transducer itself is very small and has little mass. However, it is not clinically or commercially practical to place the transducer in contact with the arterial blood, so we use a liquid-filled tube to connect the intra-arterial catheter to the pressure transducer. This system of a fluctuating driving pressure (i.e., the arterial pressure being measured), a liquid-filled tube, and a pressure transducer is mechanically equivalent to the mass-spring harmonic oscillator shown in Figure 28-12 . The mass (m) represents the mass of the fluid in the tubing. The spring represents the elasticity of the tubing. The damper, shown schematically as a piston moving in oil, represents the friction generated by the fluid moving to and fro in the tubing.

A more commonly encountered harmonic oscillator is that of a car driving down a bumpy dirt road (see Fig. 28-12) .

Figure 28-11 Arterial waveform. Systolic pressure is defined as the instantaneous maximal pressure; diastolic, the instantaneous minimum pressure; and mean, the average pressure over a cycle. DP/dT refers to the upstroke of the arterial pressure, i.e., the rate of pressure generation. The mean pressure is estimated as the diastolic plus 1/3 the pulse pressure (systolic-diastolic) when only the

systolic and diastolic are known.

In this case, the oscillating driving pressure is provided by the bumps in the road, which force the car wheel to oscillate up and down. The car springs are analogous to the compliance of the arterial pressure tubing, and the car's shock absorbers, which oppose motion of the wheel in either direction are analogous to the friction of the fluid moving back and forth in the fluid-filled tube. Depending on the frequency of the bumps (i.e., driving pressure frequency) the system can either suppress the bumpy road or may initiate dramatically increased oscillations. The frequency of the driving force that causes maximal amplification of the signal is called the natural resonant frequency (Fig. 28-13) (Figure Not Available) . The degree of amplification is directly related to the mass and is inversely related to the amount of friction present; for large amounts of friction, there is attenuation rather than amplification (see Appendix 4 at the end of this chapter).

To visualize this intuitively, hang a weight on the end of a rubber band, holding the upper end of the band in your hand. If you move your hand up and down slowly, the weight follows your hand movements almost exactly. As you increase the frequency of your hand oscillations, the weight begins to "lag" behind your hand, and the amplitude of the weight movement begins to increase. As you approach the natural frequency of this simple system, you will observe the phenomenon of "resonance" when the amplitude of the weight motion becomes very large. If you try different rubber bands and weights, you will find that stiffer bands or smaller weights yield higher natural frequencies. The same is true of our fluid-couple pressure transducer system. A stiffer (i.e., less compliant) tubing or a shorter length of tubing (less mass) produces higher natural frequencies in this system, that is, it requires a much higher pulse rate before amplification.

To minimize the potential of an amplification of the real arterial pressure, the system should have very noncompliant (i.e., stiff) tubing and the total mass of liquid in the system

Figure 28-12 Damping and resonance. Pressure measured in an invasive arterial catheter can actually overshoot or amplify the real blood pressure. This phenomenon is referred to as the dynamic frequency response of the fluid-filled arterial line and transducer system. This phenomenon has a physical model, which can generate an equation to predict the output pressure response, depending on the frequency of the input pressure and several physical parameters of the system. In the physical model on the right, the driving pressure (the arterial blood pressure) acts on a mass (the fluid within the arterial pressure tubing), pushing it up and down against a spring, which stores energy (the compliant pressure tubing), and a dash pot, which opposes motion in either direction (the resistance of the fluid as it moves to and fro within the pressure tubing). Depending on the input frequency, the output may go through an amplification as it reaches a specific frequency, known as the resonant frequency of the system. On the left side of the figure, there is a common phenomenon noted when a car drives along a bumpy dirt road. In this situation, the driving force is the bumps in the road, which act on the tire. The car spring is equivalent to the compliance to the pressure tubing, and the shock absorber corresponds to the resistance of fluid moving back and forth in the arterial line. The mass of the fluid is analogous to the mass of the front of the car. You may have experienced the phenomenon in which you reach a certain speed as you are driving along a bumpy road when the front of the car starts to oscillate with increasing amplitude. If you speed up or slow down, this phenomenon disappears. The car bounces highest when you have reached the resonant frequency of this harmonic oscillator. See Appendix 4 for detailed mathematical description of this process.

Figure 28-13 (Figure Not Available) Amplitude and frequency. As the frequency increases, the amplification can increase to a maximum, and then the signal becomes attenuated. *(Adapted from Sykes et al [5])*

should also be minimized. This can be accomplished by having small-diameter tubing and as short a length as possible. In most clinical systems, the natural resonant frequency is 10 to 15 Hz, which is much higher than the primary frequency of the arterial wave form (the heart rate, 60-120 beats/min or 1-2 Hz). Unfortunately, the arterial waveform is not a sine wave but is the more complex shape shown in Figure 28-6 and is made up of a summation of sine waves, a Fourier series. The higher-frequency components of the arterial waveform (higher harmonics) are the ones that are closer to the natural frequency and are therefore amplified. This is why we see a "whip" in the waveform where the peak systolic pressure and the initial upstroke are amplified significantly above the true systolic pressure, even if the heart rate itself is not in the range of the resonant frequency. In theory, the mean arterial pressure should be the same because this amplification of systolic pressure also produces a reduction in diastolic pressure (Appendix 4)

Signal-Processed Pressure Measurement (Noninvasive Blood Pressure Monitor)

Systolic pressure can be estimated by noting the return to flow pulse after occlusion of the artery by a cuff. The return to flow can be detected by (1) simple palpation of the radial artery, (2) recording with a Doppler device over the radial artery, or (3) use of a pulse oximeter. Most anesthesiologists are familiar with the loss of pulse oximeter signal when the noninvasive blood pressure monitor is cycling.

Automated noninvasive blood pressure monitoring devices used in most operating rooms employ a more sophisticated application of this principle. These devices monitor the oscillating signal generated in the cuff by the arterial pressure changes. The cuff first inflates to above systolic pressure, at which point the signal and oscillations are abolished. Then the cuff slowly deflates in a stepwise fashion. The pressure at which the signal first appears is interpreted as the systolic pressure. The signal increases in amplitude as the cuff pressure decreases. When the signal is at maximal amplitude, this is interpreted as mean arterial pressure. As

Figure 28-14 (Figure Not Available) Noninvasive blood pressure measurement. Using the signal from the arterial pulse, oscillometric blood pressure measurements are obtained by determining the point at which the signal is first detected, its maximal amplitude, and the signal decay rate. [4] *(Adapted from Ehrenwerth and Eisenkraft [21])*

the cuff pressure decreases further, the oscillations drop off rapidly. Diastolic pressure is mathematically inferred from the systolic and mean values (Fig. 28-14) (Figure Not Available) . [4] Errors can be introduced in the same manner as for manual ausculation of Korotkoff sounds: too small or too large a cuff requires a higher or a lower pressure to occlude the arterial flow, and stiff atherosclerotic arteries are resistant to compression. External compression by a patient's motion or a surgeon's leaning on the noninvasive blood pressure monitoring cuff can cause oscillations in the cuff pressure that are not related to the arterial pressure and may result in erroneous reading, most commonly a high diastolic pressure.

FLOW MEASUREMENT

Principles of Flow

Pressure in fluids can be thought of as a form of potential energy, as described earlier. Kinetic energy in fluids is expressed in terms of *flow,* the bulk movement of fluid with a given direction and speed. We must carefully distinguish between fluid *flow* and fluid *velocity,* which are often confused. Flow (Q) refers to the volume of fluid passing a particular location per unit of time; its SI units are meter cubed per second, but it is more commonly measured in milliliters per second or liters per minute. Fluid velocity (U) is simply the speed of the fluid at a particular point in space, measured in meters per second. By analogy, imagine a multilane freeway: the speed (velocity) of individual cars may vary depending on the lane; the flow is the number of cars passing a point per minute. The potential energy of pressure can be converted into the kinetic energy of flow: for example, the hydrostatic pressure generated by gravity acting on a vertical column of liquid can be transformed into flow by opening a valve at the bottom of the column. Pressure and flow can also change independently. With the human circulatory system used as an example, a healthy young trauma patient can have relatively high blood pressure but low blood flow (hypovolemic shock) with high systemic resistance. On the

TABLE 28-2 -- Comparison of Hydronamic and Electrical Energy Commonly Encountered

WATER	ELECTRICITY	ENERGY
Squirt gun	Static electric spark	High pressure, low flow, low energy
Garden hose	House current	Moderate pressure, moderate flow, moderate energy
	Car battery	Low pressure, moderate flow, moderate energy
River flood		Low pressure, huge flow, huge energy
Fire hose	High-tension wires	High pressure, high flow
	Lightning	High pressure, high flow

other hand, a septic patient can have very low blood pressure accompanied by high blood flow (high-output septic shock). The total mechanical energy of a moving fluid is the sum of the kinetic (flow) energy and the potential (pressure) energy (Table 28-2) .

A pressure gradient exerts a force on the fluid, tending to accelerate the fluid in the direction of *decreasing* pressure. Pressure gradient is only one of the forces that commonly act on fluids; other forces include gravity (discussed earlier) and viscous force or friction. If these other forces are negligible and if the fluid is incompressible (i.e., a liquid with constant density), then the equation of motion (F = ma) can be integrated to yield

where P is pressure, rho is fluid density, U is the magnitude of the fluid velocity, and P_o is a constant called the *stagnation pressure* (see Appendix 5 at the end of this chapter). This form of the *Bernoulli equation* tells us that as velocity increases in a frictionless flow, pressure decreases, and vice versa. This concept resolves the common misconception that pressure always decreases in the direction of flow. For example, in the flow inside a tube (a pipe or a large vein) of gradually increasing diameter, the fluid velocity (U) decreases in the downstream direction as the diameter and cross-sectional area of the tube increase. As U decreases, Equation 5 tells us that p actually increases in the direction of flow. This example again shows the relationship of potential and kinetic energy in fluids: as the kinetic energy of this tube flow decreases (U^2 falls) in the flow direction, the potential energy increases (p rises) by equal amount. The total energy remains constant because we have assumed no friction.

Flow can be determined from knowing the average velocity of the across the tube. In laminar flow, Figure 28-15 A, the velocity profile is distributed such that the highest velocity is in the center and the fluid at the edges is virtually stationary. In turbulent flow, the velocity profile is "flattened" (Fig. 28-15 B) Some monitors measure flow directly, but most measure flow indirectly, by either pressure or velocity measurements.

The Bernoulli equation applies to a specific subset of flow parameters as listed earlier. Many flows important to anesthesiologists do not follow the Bernoulli equation. Most commonly, the flow that we desire to measure is not laminar but is turbulent. The transition from laminar to turbulent flow depends on the type of fluid and the shape of flow. The fluid factors are summarized in the Reynold's number:

where rho is the density of the fluid, U is the mean flow velocity, D is the diameter of tube, and mu is the viscosity of fluid. Thus, as the average speed of flow increases, the flow becomes more turbulent. In straight tubes, the change from laminar to turbulent flows occurs at Re >2100 (Appendix 5). Many flowmeters require laminar flow for their measured values (pressure or velocity) to be accurately transformed into a flow measurement (e.g., Pitot tube; see later section).

Mass/Volume Flowmeters (Urometer, Volumeter, Dilutional Measurements)

We can actually measure the mass or volume of fluid flowing per unit time by catching fluid in a container and either weighing it or measuring its volume. The common urometer for measuring urine volume is an example. The volumeter used in North American Drager anesthesia machines also

Figure 28-15 Laminar and turbulent flow. In a smooth-walled tube at low flow rates, i.e., small pressure gradients, the flow rate is laminar, i.e., flow moves smoothly in concentric circles, with the

centermost area having the greatest flow velocity and the area nearest the wall of the tube being virtually stationary. As flow rate (and pressure gradient) increases, the flow transitions from laminar to turbulent. Instead of a neatly ordered flow, the velocities are more randomly distributed, energy is dissipated as heat, and the energy needed for a given flow rate increases. Many factors govern this transition, including size of the tube, viscosity of the fluid, flow rate and pressure gradient. These are combined in the determination of the Reynold's number (Appendix 5).

Figure 28-16 (Figure Not Available) Volumeter. Flow can be described as volume over time. This design of flowmeter allows gas to pass in only little aliquots, each of which turns a counter to measure the amount flowing past. When divided by time, this results in a flow measurement. *(Adapted from Ehrenwerth and Eisenkraft [21])*

measures aliquots of volume, integrated over time to measure tidal and minute volumes (Fig. 28-16) (Figure Not Available) . [5]

Both volume and mass flow can be measured by dilutional techniques. If some measurable indicator (a bolus of dye, a thermal pulse) is injected into a flow and its concentration is measured downstream, then the volume flow (Q) can be calculated by integration. The most common medical application is the determination of cardiac output by the pulmonary artery thermodilution method (see Appendix 6 at the end of this chapter). Errors associated with these methods involve using the wrong injectate volume (too small a volume, resulting in too large a flow) or an error in temperature measurement (see the section on temperature).

Velocity/Flow Measurements (Venturi, Pitot, Doppler)

A Venturi tube is a very gradual contraction and expansion in a tube, in contrast to the sudden contraction of an orifice flowmeter (Fig. 28-17) . Because the contraction is smooth and gradual, the Bernoulli equation (Equation 5) applies to this geometry. If we measure the pressure difference between the widest and the narrowest parts of the Venturi tube, we can solve the Bernoulli equation for the velocity (Appendix 5) The Venturi tube derives fluid velocity (U) from the pressure difference, not volume flow (Q). In laminar flow, fluid velocity is proportional to flow. The Venturi tube is used in many industrial applications and is also used on some aircraft to measure speed.

A Pitot tube is a cylindrical tube whose open end is pointed directly into the flow, that is, "upstream" (Fig. 28-18) (Figure Not Available) . The pressure measured in the pitot tube is the *stagnation pressure,* given earlier by Equation 5. If we also measure the static pressure (p) (the p_1 side port in the figure) and we know the fluid density rho, then we can easily solve Equation 5 for the fluid velocity (U). Note again that the Pitot tube derives velocity (U), not volume flow (Q). The Pitot tube is simple and reliable and is almost universally used on aircraft to measure their speed. In anesthesia, the Pitot tube is used in Datex Ultima monitors. In order to measure gas flow in two directions, the Datex monitor incorporates two pitot tubes, one facing in each direction. Additionally, the monitor samples gas composition to correct for the density and the viscosity of the gas mixture.

Balance-of-Pressure Flowmeters (Bourdon Tube, Thorpe Tube)

If flow in a tube passes through a sudden restriction, such as an orifice, the volume flow (Q) is proportional to the area of the orifice and the square root of the pressure drop through the orifice. (The Bernoulli Equation 5 does not apply to this flow geometry.) This is the principle of all orifice flowmeters, including the floating bobbin rotameter of an anesthesia machine, described later (Appendix 5).

The most common flowmeter seen by anesthesiologists is the rotameter on the anesthesia machine (Fig. 28-19) . This is a variable-orifice flowmeter that uses a balance of forces to determine pressure change. When the flowmeter valve is opened, the flow of gases through the annular orifice between the bobbin and the tapered glass tube provides a force to raise the bobbin. As the bobbin rises, the area of the annular gap between the bobbin and the tube increases as a result of the taper of the tube. As the area of this gap (orifice) increases, the pressure change across the bobbin decreases because the pressure change across an orifice is inversely

Figure 28-17 Venturi tube. By measuring the pressure difference between two points in a laminar flow, the average flow velocity can be determined because the mass flow must be the same (Appendix 5).

Figure 28-18 (Figure Not Available) Pitot tube. As flows increase, wall pressure decreases as a result of the Bernoulli principle. The Pitot tube measures the difference in pressure from the middle of the flow to the wall and converts this to a flow measurement (Appendix 5). *(Adapted from Ehrenwerth and Eisenkraft [21])*

proportional to the square of the orifice area. The bobbin ceases its upward motion at an equilibrium point when the downward force of gravity is balanced by the upward pressure forces. Thus, the height of the bobbin in the tube is proportional to the gas flow. Although this flowmeter is simple in principle, its application becomes more complex when the flow in the tube changes from laminar to turbulent as velocity and diameter increase. For mathematical derivations, see Appendix 5.

Another flowmeter (Bourdon tube, Fig. 28-20 (Figure Not Available)) keeps the orifice constant and allows the pressure to vary. As flow (Q) increases, the gradient of P1 to P2 increases, causing the flattened metal tube to uncoil and move the pointer.

Vane Spirometer Flowmeters (Wright Spirometer)

Vanes or propellers placed in a confined flow turn at a rate proportional to the volume flow if there is no friction in the propeller bearings. Various vane spirometers (Fig. 28-21) (Figure Not Available) (e.g., Wright spirometer) work by this principle. These tend to be less accurate at both very high and low flow rates because of frictional forces.

Figure 28-19 Thorpe tube flowmeter. At low flows, density of gas predominates, and the flows balance when the gravitational attraction equals the pressure gradient across the equivalent orifice. At higher flows, viscosity takes over, and the balance is the same, except for the formula determining pressure (Appendix 5).

Figure 28-20 (Figure Not Available) Bourdon tube flowmeter. Unlike the Thorpe tube, which has a constant pressure but a variable orifice, the Bourdon tube has a constant orifice but a variable pressure. The tube uncoils under the high back pressure. This drawback makes it unsuitable for use in low-pressure respiratory systems. However, it receives much use in portable oxygen tanks. Of note, if the orifice is increased in radius, the flowmeter will underread actual flow. If dirty (i.e., decreased radius), the flow will be overestimated. *(From Mushin and Jones [22])*

Summary of Flow Measurement

There are problems associated with every method of measuring flow. Because not all gases are pure, with a known, constant density, flowmeters based on the Bernoulli equation 5 are subject to errors. Furthermore, any device inserted into a fluid flow can disturb the flow by its presence. For example, a rotating vane spirometer may reduce the gas flow at high flow rates because of friction. Several methods of flow or fluid velocity measurement are dependent on a pressure measurement (Pitot tube, Venturi tube, orifice flowmeter); hence, the flow measurement is no more accurate than the pressure measurement.

Figure 28-21 (Figure Not Available) Vane spirometer. Moving gases contain kinetic energy. This can be sampled by a rotating "windmill" in the gas stream. [4] *(Adapted from Ehrenwerth and Eisenkraft [21])*

MEASUREMENT UTILIZING SOUND

Principles of Sound

Sound waves are small fluctuations in pressure, density, and velocity that can propagate through matter of any form: solid, liquid, or gas. Unlike electromagnetic waves, such as light (see the section on light), sound cannot propagate through a vacuum. Sound is called a *longitudinal wave* because the motion of the particles occurs in the same direction as wave propagation. In contrast, waves on the surface of the ocean are *transverse waves* because the motion of the particles is mainly perpendicular to the direction of wave propagation (Fig. 28-22) .

In 1842, Christian Johann Doppler first described the apparent change in pitch of a sound that occurred when either the source of the sound or the listener was moving. [6] This Doppler effect now has several applications in patient monitoring, including precordial and esophageal Doppler ultrasound monitoring of local blood velocities or cardiac output.

When a sound source is moving toward the listener, the apparent pitch increases, and vice versa. The amount of frequency shift depends on whether the listener or the sound source is moving (Fig. 28-23 (Figure Not Available) ; see Appendix 7 at the end of this chapter). Because changes in the frequency of sine waves can be measured precisely, the Doppler principle provides a very accurate method of measuring the velocities of moving sound reflectors. At the high frequencies often used (
5 MHz), objects as small as red corpuscles can scatter enough sound for detection.

Sound has been used for many years in medical diagnosis and monitoring. It can be used as a diagnostic method in two ways: passive and active. In a passive examination, the sounds generated by the patient are studied. The basic examination of this type uses the stethoscope. In an "active" examination, acoustic energy is transmitted into the patient, and the resulting interaction of this energy with the patient is analyzed for information. Both types of examination employ the same physics principles.

Passive Sound Examination (Stethoscope)

Vibrations, such as those caused by the closing and opening of heart valves or air traveling through the respiratory passages, travel through the body as sound waves. Sound is generally conducted better and more rapidly in liquids than in gases. Thus, bronchial breath sounds are heard better when the bronchi are surrounded by lung consolidation. When sound waves reach a sudden change in density, some of the energy is reflected.

Some simple facts about sound waves can facilitate an understanding of the reflection and scattering process in the body. First, all sound waves can be represented as a summation of sinusoidal waves of various frequencies and amplitudes. This process of Fourier or power spectral analysis has been discussed earlier in this chapter. A note from a musical instrument thus consists of a sine wave at the "fundamental frequency" plus many "harmonics." The fundamental is the frequency that describes the pitch of the tone: middle C is standardized at 256 Hz, for example. Harmonics are sine waves at frequencies that are multiples of the fundamental frequency.

Fortunately for our ears, all of these many frequencies propagate at the same speed, the speed of sound (called "a"). For ideal gases, the speed of sound is proportional to the square root of temperature. The speed of sound in room temperature air is 344 m/s, or 1,129 ft/s, or 770 miles/hr (mph). At an altitude of 13,000 m (40,000 ft), where the standard temperature is -57°C, the speed of sound is only 295 m/s, or 661 mph. The speed of sound is much higher in liquids than in gases. For example, the speed of sound through water at 15°C is 1,450 m/s. This value approximates the speed of sound through most of the solid parts of the body. In solids, the speed of sound varies greatly, ranging from 54 m/s in rubber to 6,000 m/s in granite. Reflection of sound occurs at interfaces where the product of the tissue density and the speed of sound (rho × a) changes suddenly. Larger changes in this "acoustic impedance" result in

Figure 28-22 Transverse and longitudinal waves. In transverse waves (e.g., ocean waves), the particles move perpendicular to the motion of the wave. In longitudinal waves (e.g., sound waves), the particles move back and forth in the direction of the wave. The actual matter in either wave does not move much. The energy transfers without mass transfer.

Figure 28-23 (Figure Not Available) Doppler effect. (A) When a listener is moving toward a stationary sound source, the frequency increases because the listener transverses more waves per unit time than a stationary listener. (B) When a sound source is moving toward a stationary listener, the wave fronts "stack up," causing an apparent increased frequency. *(Modified from Tremper and Barker [20])*

greater reflection and less transmission. In the human body, the largest changes in acoustic impedance occur at gas-tissue boundaries: the lungs and the gastrointestinal tract. Reflection of sound thus makes it difficult to auscultate heart tones through an air-filled, emphysematous chest. For the same reason, a transthoracic echocardiograph provides less detail than the transesophageal technique; in the former case, the lungs are in the way.

First attempts to gather information about the inside of the patient using sound involved placing one's ear directly to the patient. Although this procedure had many limitations, it led to the development of the modern stethoscope, which is based on the physical principles of sound transmission. The stethoscope uses a large diaphragm to transmit and concentrate the sound energy. The bell acts as both an amplifier and a low-pass filter to transmit low-frequency dia-stolic rumbles. The physics of stethoscopy were described in depth by Rappaport and Sprague. [7]

Active Sound Examination (Percussion, Echo, Doppler)

The earliest "active" acoustic diagnostic technique was percussion of the chest wall. A skilled clinician can use this method to detect consolidation of the lungs, pleural effusion, and a few other chest pathologies. Although based on transmission and reflection of sound, percussion is purely qualitative and is unable to accurately localize pathologic changes. Modern ultrasound improves on percussion by using shorter-wavelength sound waves and quantitative detection of their reflections (echoes). The resolution of an examination is limited by the wavelength of the sound used (Fig. 28-24) . Using ultrasound at frequencies in the MHz (10^6 cycles/s) range allows resolution of much smaller objects. The wavelength of 1.0-MHz sound waves in solid tissue is about 1.5 mm, whereas the wavelength of a

256-Hz tone (middle C) in tissue is 5.7 m.

By use of esophageal transducers, echocardiography has become a popular intraoperative monitoring technique. [8] [9] Sound waves in the 2- to 10-MHz range are transmitted toward the heart in short bursts or pulses. After each pulse, the transducer passively listens to the reflected echoes from various tissues. The ability to place the transducer in the esophagus is advantageous because sound does not then have to pass through air spaces or bone on its way to and from the heart. The speed of sound through the heart and surrounding soft tissues is a nearly constant 1540 m/s. Thus, the elapsed time between transmission of the pulse and receipt of the echo provides the distance to the reflecting structure. The sound beam from the transducer is projected in a narrow "searchlight" pattern, so that the exact direction of reflecting structures is also known.

Doppler effect is used in echocardiography to determine the presence and the degree of valvular regurgitation by converting the Doppler shift of sound waves reflecting from the erythrocytes into a color display (Appendix 7; Ch. 31).

MEASUREMENT UTILIZING ELECTRICITY

Principles of Electricity

Most of our monitors and other anesthesiology apparatus involve basic principles of electricity and magnetism. Nearly all of our transducers use some form of electrical energy as their output, and the subsequent data processing and display are entirely electrical. We review some of the principles in this section, using examples from medical equipment.

Static Electricity.

Electricity is a manifestation of a property called *charge* that is inherent in matter. The charge can be negative, positive, or neutral. Static electricity involves charges at rest: like charges repel one another, whereas opposite charges attract. What we usually mean by the word "electricity" involves the flow of charges, or the electrical *current.* Current flows in one direction in "direct-current" (DC) electronic devices and alternates back and forth in "alternating-current" (AC) devices.

The SI unit of charge is the *coulomb,* and the smallest quantum of charge is the charge of an electron, which is equal but opposite to the charge of a proton. An *electrostatic* force is exerted between two charged objects and is directly proportional to the product of the two charges and inversely proportional to the square of the distance between them

This force is attractive when the charges are of opposite sign, repulsive when they are of the same sign. In a Nobel Prize-winning experiment, Robert Millikan determined the charge of an electron by suspending charged oil drops between two horizontal charged plates such that the electrostatic force balanced the gravitational force and the drops were held in mid-air (Fig. 28-25) Approximately 20 years

Figure 28-24 Wave size and resolution. Wave reflection depends on the relative size of waves and objects. For small objects, small waves are needed for good reflection and resolution. (A) The object size is small relative to the wave size, causing the waves to be scattered, resulting in poor spatial resolution. (B) The object size is large relative to the wavelength, leading to a clear reflection and better resolution. This principle applies to light waves also. Hence, electron microscopes can resolve smaller objects than light microscopes because the wavelengths emitted are smaller.

later, his son, Glen Allen Millikan, developed one of the earliest infrared ear oximeters, the forerunner of the pulse oximeter (see the section on Pulse Oximeter).

Direct Current.

Just as mechanical energy may be stored as potential energy, electrical energy can be stored as a *potential difference.* A common analogy is to compare electrical potential difference to water pressure (Fig. 28-26; Table 2) . The potential difference (V) between points A and B is defined as the work required to move a unit charge from A to B (see the discussion of the relationship of work and energy, earlier in this chapter). The SI unit of potential difference is the *volt;* hence, the term voltage is often used for potential difference. Charges can move easily through *conductors;* they do not move well through *insulators,* also called *dielectrics.* If there is a potential (V) between A and B and these two points are connected by a conductor, then charges will flow between them, producing a current (I).

Figure 28-25 Electric force. The quantity of charge on an electron was determined by balancing the electric force on an oil drop against the gravitational force on the same drop. $F_1 = kq_1 q_2 / r^2 = F_2 = m_1 a_g$.

Figure 28-26 Water and electricity. The pressure drop over the water wheel (A to B) is analogous to the voltage drop over the resistance (A to B) (e.g., light bulb). The amount of flow (Q) is analogous to the current (I). Both falling water and electrical potential can do work.

The SI unit of current is the coulomb per second, called the *ampere.* If A and B are separated by an insulator, no current will flow until the potential difference becomes so great that a breakdown of the insulator occurs. For example, if A and B are separated by dry air, no current will flow until the potential difference reaches 3,000 volts/mm. At this potential gradient, air suddenly becomes a conductor, and a current flows in the form of a visible (and audible) spark. To generate a spark between two electrodes 1 cm apart, one must create a potential difference of 30,000 volts. Lightning is a larger manifestation of the same phenomenon.

A battery is a chemical cell that produces a constant potential difference between two electrodes, which is called *electromotive force* (EMF). The battery can provide a continuous source of electrons, or current, to flow through any conducting circuit connected between its electrodes. Flow of electricity is opposed by *resistance,* analogous to resistance in water pipes. In most materials, the resistance (R) is related to the voltage (V) and current flow (I), in the following way:

This relationship is called Ohm's law, and materials that follow this behavior are called ohmic materials. This is analogous to hemodynamic flow, in which the pressure drop (mean arterial pressure - central venous pressure) equals cardiac output times systemic vascular resistance.

The power (i.e., rate of work, see discussion earlier in this chapter) required to drive an electric current is the product of voltage and current: P = VI. Combining this formula with Ohm's law (V = IR), we have $P = I^2 R = V^2/R$. Thus, if we double the current through a fixed resistance (R), we use four times the original power. This power loss in resistors is dissipated as heat, which is the reason why nearly all electrical devices become warm during use.

A *capacitor* is a device that stores charge (Q) in direct proportion to the potential difference (V) between its two electrodes: Q = CV. The proportionality constant (C) is called *capacitance,* which is measured in SI units of *farads.* When a capacitor is connected to a battery, current flows until the capacitor is charged to the point that the potential across the capacitor equals the EMF of the battery: V = Q/C = EMF (Fig. 28-27) . When we push the "charge" button of a defibrillator, this kind of circuit is activated to charge a capacitor to the desired level. As shown in (Fig. 28-27) B, time is required to charge a capacitor. For a large capacitor, more time is required. Hence, it takes longer to charge a defibrillator to 200 joules than to 50 joules.

Alternating Current.

In an AC circuit, the current and the voltage fluctuate rapidly (Fig. 28-28) . There are many important differences between AC and DC. The voltage in common AC house power fluctuates sinusoidally at a frequency of 60 Hz (50 Hz in Europe). We characterize the amplitude of such a fluctuating voltage by calculating its root mean square (RMS), that is, the square root of the time average of V^2 . Thus, for AC house power, V_{RMS} = 115 volts (230 V in Europe). Current in an AC system is also constantly changing and is also measured as an RMS value.

In AC circuits, there are three forms of *impedance:* resistance (R), capacitance (C) and the *inductance* (L). An inductor is a circuit element whose impedance increases with the frequency (f) of the current fluctuations (R = 2pifL). Conversely, the impedance of a capacitor decreases with increasing frequency (R = ½ pifC). Inductors thus tend to block high frequencies, whereas capacitors tend to block low frequencies (Fig. 28-29) (Figure Not Available) . This is used in stereo systems to direct the signal to either the woofer (low-frequency) speaker or the tweeter (high-frequency) speaker. In medical instruments, inductance and capacitance circuits can be used to "filter" the signal, for example, decreasing the amount of 60-Hz interference from AC wiring.

Passive Electrical Examination (Electrocardiograph, Electroencephalograph)

Electrocardiograph.

Now that some of the basics of electricity have been described, we can discuss the electrocardiograph (ECG) and the electroencephalograph (EEG), where the sources of EMF are the heart and the brain.

Figure 28-27 Resistance and capacitance in a direct-current circuit. (A), Under direct current, the resistance impedes flow, developing a voltage drop across the resistance. The capacitor allows current to flow until the charge builds on the capacitor (B). Under direct current, the voltage is constant over time, and the current flow decreases as the charge on the capacitor increases. This type of circuit is used to charge a defibrillator.

Electrical potentials on biologic surfaces are too small to observe directly and must be amplified and processed before display. ECG potentials on the skin are in the 1-mV range, and EEG potentials are near 0.1 mV.

Figure 28-30 (Figure Not Available) illustrates why electrical potentials on biologic surfaces are so small. The heart generates an electrical signal as a result of the synchronous depolarization and repolarization of multiple cells. The electrical potentials generated by the heart are measured by two skin electrodes, A and B. As the figure shows, there are multiple effective resistances and capacitances in the tissues between the EMF source and the measuring electrodes. These impedances lower the magnitude of the voltage signal at the skin. The "shunt" resistors R_3 , R_4 , and R_5 combined with the "series" resistors R_1 , R_2 , and R_3 form what is called a *voltage divider network.* Lower values of shunt resistance or higher values of series resistance result in smaller voltages at the skin. The skin capacitance (C_s) also acts to attenuate the low-frequency components, distorting the waveform. The skin resistance,

Figure 28-28 Resistance and capacitance in an alternating-current (AC) circuit. In an AC circuit (A), unlike a direct-current circuit, the capacitor does not block current flow. The capacitor and resistance act to shift the phase of the AC current. Current changes lag voltage changes.

which may be a megaohm (10^6 ohms) for dry skin, can be reduced to a few hundred ohms by conductive gels.

If a DC voltage is applied between two body-surface electrodes, current flows through the tissues between them. Although the electrical current in metals consists entirely of electron flow, in tissues, both positive and negative ions migrate. Negative ions tend to accumulate at the positive electrode (the anode), and positive ions accumulate at the negative electrode (the cathode). This collection of anions and cations near each electrode creates its own EMF, and this force opposes the EMF that set up the original current. The current therefore decreases, so that the effective impedance between the electrodes increases. This phenomenon, called *polarization of electrodes,* has two harmful effects. First, the increased impedance from polarization can attenuate the ECG signal for several seconds after defibrillation or direct-current cardioversion. Such attenuation could be misinterpreted as a lack of electrical activity, resulting in inappropriate administration of a second shock. The second consequence of prolonged application of DC voltage is accumulation

Figure 28-29 (Figure Not Available) Woofer and tweeter. Stereo speakers use resistors to act as an impedance to high-frequency components of sound, allowing only the bass frequencies to pass on to the woofer speaker. Capacitors are used as a high-pass filter to allow only the high frequencies to get to the tweeter. 60-Hz interference from electrical appliances can be decreased by a similar process. *(From Hecht [16])*

of a local concentration of toxic ions near electrode sites, a condition that can cause burns or tissue necrosis. A partial solution to the problem is use of a nonpolarizable electrode, such as a silver and silver chloride combination. This electrode can act as a source of, or "sink," for both anions and cations, thereby minimizing accumulation of ions. Most disposable ECG electrodes now use such materials. Even these electrodes, however, are nonpolarizable for only a limited time, and application of prolonged DC voltages between any tissue electrodes must be avoided.

Electroencephalograph.

Similar problems complicate measurements of the EEG, but in this case, the signal is only 1/10 the amplitude: 100 muV, as compared with 1 mV for the ECG. The spontaneous surface EEG provides eight or more channels of amplitude (surface voltage) versus time data, which is of limited use for monitoring in the operating room. For rapid interpretation and diagnosis, the amplitude versus time data are usually transformed into plots of amplitude versus frequency. This process of power spectral analysis has been discussed in the section on signal processing. The EEG power spectrum facilitates rapid diagnosis of

Figure 28-30 (Figure Not Available) Why the ECG is so small. Multiple resistances and capacitances in the body decrease the potential and distort the waveform before the EMF reaches the surface. *(From Tremper and Barker [20])*

hemisphere asymmetries and changes in frequency content that accompany either deep anesthesia or cerebral hypoxia. The "bispectral density" is a newer method of analyzing the EEG that determines levels of correlation between various frequency components in the power spectrum. This type of analysis may provide improved determination of depth of anesthesia in some settings.

Active Electrical Examination (Somatosensory Evoked Potentials)

A muscle twitch is elicited by generating a 0.2- to 0.3-ms pulse of current in order to depolarize a motor nerve. This motor nerve then conducts the impulse to the muscle, where a twitch is generated. We can understand the "in-use" failings of this device by following the path of the signal. Clearly, we must start with an adequate power source (no power = no twitch). Aside from intrinsic mechanical failure, if the coupling of the electrodes to the patient is poor, that is, if the electrodes are dry and/or good skin contact is not made, the circuit has a high resistance, and very little current will flow (see earlier discussion and Equation 8), resulting in a diminished twitch. In summary, the simplest way to be certain that this monitor is functioning properly is to perform both a positive (see the desired response, i.e., thumb twitch, before the chosen drug is given) control and a negative control (see the twitch disappear in response to administered drug) (Ch. 36) .

Evoked potential (evoked response) monitors can determine the status of multiple parts of the sensory nervous system by measuring the central nervous system response to a discrete sensory stimulus. The stimulus can be auditory, optical, or peripheral sensory. The amplitude of the evoked response measured at the skin can be very small: 5 muV, in the case of some cortical potentials. This very small signal is in a "sea" of spontaneous EEG (100-muV amplitude) signals. We therefore resort to a signal-enhancement technique called "ensemble averaging." Rather than trying to measure the response to a single stimulus, we average the responses from hundreds (or thousands) of stimuli. Because the evoked responses occur consistently at the same time after the stimulus, this averaging process reinforces the signal from the evoked response, and the random "noise" cancels itself. In this way, we commonly measure signals whose amplitude is perhaps 1/20 the amplitude of the background noise (see Fig. 28-5) .

MEASUREMENT UTILIZING LIGHT

Principles of Light

What we commonly refer to as light is electromagnetic radiation in the visible range. Every substance having a temperature above absolute zero emits electromagnetic radiation. This radiation is characterized by a frequency and wavelength that are related by the speed of light: fre quency = speed of light ÷ wave length. (C = speed of light = 3×10^8 m/s or 186,400 miles/s or 7.5 times around the earth's circumference in 1 second.) High energies are associated with high frequencies and short wavelengths, such as those of gamma rays and x-rays. As wavelength increases to the micron range, ultraviolet radiation proceeds to visible light, and at larger wavelengths, infrared is then followed by microwaves and radio waves with wavelengths in the kilometer range.

There are some important differences between electromagnetic waves and sound waves. The particles in motion in sound waves are in the same direction as the propagation (longitudinal waves), where the electromagnetic waves are perpendicular to the direction of propagation (transverse waves). Sound waves can only propagate through matter, whereas electromagnetic waves propagate through a vacuum without attenuation. The speed of light is about 1 million times faster than the speed of sound in air. If an observer is moving relative to a sound source, he or she can measure a speed of sound that depends on the observer's own motion, but the speed of light is the same to any observer and any frame of reference. This statement is a basic premise of Einstein's special theory of relativity. At the high-frequency end of the electromagnetic spectrum, there are two forms of ionizing radiation: x-rays and gamma rays. These high-frequency waves are capable of knocking electrons out of their orbits and thereby can cause cell injury and cell death or ontogenesis. Gamma rays are commonly emitted by decaying radioactive nuclei.

Visible and infrared light demonstrate several properties common to all electromagnetic radiation. Light represents a form of energy that when passing through matter, may be reflected, transmitted, or absorbed. Although light itself cannot be stored, it can be converted into some other form of energy, such as electricity, chemical energy, and heat. In addition, light can be generated from other forms of energy, including heat (incandescent), electrical (gas discharge), and chemical (photoluminescent) energies.

Light as a Multifunctional Tool: Beer-Lambert Law

When light passes through matter, it is transmitted, absorbed, or reflected. The relative absorption or reflection of light is used in several monitoring devices to estimate the concentrations of dissolved substances, for example, carbon dioxide respiratory gas and hemoglobin dissolved in plasma. The field of absorption spectrophotometry is based on the Beer-Lambert law. This law states that if a known intensity of light illuminates a chamber of known dimensions, the concentration of the dissolved substance can be determined if the incident and transmitted light intensity are measured.

Solved for C,

where C is the concentration of the dissolved substance, d is the path length of the light a, and alpha is an absorption constant for the substance C at the wavelength used. I_i and I_t are the

incident and transient light intensity, respectively. The unknown concentration (C) is inversely proportional to the path length (d) of light and is directly proportional to the log of the ratio of light incident to transmitted light intensity (Fig. 28-31) (Figure Not Available) . Red and infrared light are generally used because the constituents of interest to anesthesiologists (anesthetic agents, CO_2 , Hb) absorb light in that range. It is also fortunate that red and infrared light can penetrate tissue and therefore may be used to measure the concentration of hemoglobin species in living tissue (see the section on pulse oximeters). Infrared light is absorbed by small molecules only if they have bonds and are asymmetric. Therefore, nitrogen, oxygen, and helium cannot be measured by infrared light. Another limitation of infrared light is that it is absorbed by ordinary glass; therefore, the measurement chambers for these devices must be made of sapphire, which is permeable to red and infrared light.

Light Monitors (Capnometer, Agent Analyzer)

Capnographs and agent analyzers both utilize the Beer law by analyzing the constituents of the respiratory gas stream. The physical design of most capnometers is divided into two categories: mainstream and sidestream. In mainstream capnometers, the light-absorption chamber is placed directly in the airway, and the light source shines throughout the chamber, measuring CO_2 during inspiration and expiration directly. The advantages of this technique are very fast response time and no problems with clogging of the sampling of tubes, which is a disadvantage of sidestream capnometers. Disadvantages include the necessity of having a potentially heavy, expensive infrared measurement device placed directly in the endotracheal tube and that devices are not available that can measure both anesthetic agents and CO_2 . The most commonly used devices in the operating

Figure 28-31 (Figure Not Available) Cuvette. Light entering the cuvette is reflected and absorbed. The concentration of substances absorbing and reflecting light can be determined by measuring the amount of light entering and exiting the system. *(Modified from Tremper and Barker [23])*

room are sidestream capnometers, which use a small capillary sampling tube attached to the airway, aspirating a sample at 200 to 300 mL/min into the measurement chamber, which is within the monitor. The advantages of this method are just the opposite of the disadvantages of the mainstream capnometers, that is, the sampling tube is lightweight, and the device can be used to measure carbon dioxide and anesthetic agents. The disadvantages relate mostly to the delayed response time and the potential clogging of the aspiration tubing. [10]

Agent analyzers and capnography function via the same physical principles, using different wavelengths of light (Fig. 28-32) (Figure Not Available) . The mixture of

gases can interfere with each other, so compensations are built into current devices.

Pulse Oximeters

Oximeters are devices that use light-absorbance measurements to determine the concentrations of various species of hemoglobin. One of the first *in vivo* oximeters was a noninvasive monitor employed in aviation research during World War II. This device transilluminated tissue (the earlobe) with light of two wavelengths. One wavelength was sensitive to changes in oxyhemoglobin, and the other was not. In effect, the earlobe acted as a test tube containing the suspended hemoglobin. For a review of the development of pulse oximetry, the reader is referred to Severinghaus and Astrup. [11]

Before specific engineering problems are discussed, we need to define what we wish to measure. Adult blood usually contains four species of hemoglobin: oxyhemoglobin (Hb o_2), reduced hemoglobin (Hb), methemoglobin (metHb), and carboxyhemoglobin (COHb) Each of these hemoglobin species has a different light absorption profile. Figure 28-33 (Figure Not Available) illustrates the different absorption constants for each hemoglobin over a range of light from red to infrared. Except in

Figure 28-32 (Figure Not Available) Absorption spectra. Absorption spectra of some gases and materials important to anesthesia. Note that the absorption is not constant over wavelengths. Therefore it is important to choose the proper wavelength to measure. Also, when multiple substances are present, it is still possible to measure their concentrations, provided enough wavelengths are available. (The solution becomes one of multiple equations with multiple unknowns.) *(From Gravenstein et al [10])*

Figure 28-33 (Figure Not Available) Hemoglobin extinction curves. Pulse oximetry uses the wavelengths of 660 and 940 nm because these are available in solid state emitters (not all wavelengths are able to be emitted from diodes). Unfortunately, HbCO and HbO_2 absorb equally at 660 nm. Therefore HbCO and HbO_2 both read as Sa o_2 to a conventional pulse oximeter. Also, Hbmet and Hb reduced share absorption at 660 nm and interfere with correct Sa o_2 measurement. *(Courtesy of Susan Manson, Biox/Ohmeda, Boulder, Colorado, 1986.)*

pathologic conditions, metHb and COHb occur in low concentrations. Fractional hemoglobin saturation (O_2 Hb%) is defined as the ratio of oxyhemoglobin to total hemoglobin:

Measuring this quantity requires four wavelengths of light, producing four simultaneous Beer-Lambert law equations to solve for the four hemoglobin species. Because metHb and COHb do not contribute to oxygen transport, *functional saturation* is defined as the ratio of oxyhemoglobin to oxyhemoglobin plus reduced hemoglobin:

Although functional saturation depends explicitly on only HbO_2 and Hb, four light wavelengths are still required to measure it in the presence of significant concentrations of COHb and metHb. [12] [13] If the concentrations of metHb and COHb are both zero, then O_2 Hb% and Sa o_2 become identical.

The pulse oximeter performs substantial signal processing of the optically transduced physiologic data. Although the principle governing pulse oximetry is straightforward, the application of this principle to produce a clinically useful device involves significant engineering problems. [12] [14] The remainder of this section describes the physical and physiologic problems of pulse oximeter design and the engineering solutions to these problems. The discussion is divided into (1) basic design, and (2) management of signal artifacts.

Basic Design of Pulse Oximeters.

Noninvasive in vivooximeters measure red and infrared light transmitted through, and reflected by, a tissue bed. Accurate estimation of Sa o_2 by this method entails several technical problems. First, there are many light absorbers in the transmitted light path other than arterial hemoglobin (e.g., skin, soft tissue, and venous and capillary blood). The pulse oximeter accounts for the effects of absorption of light by tissue and venous blood by assuming that only arterial blood pulsates. Figure 28-34 (Figure Not Available) illustrates schematically the series of absorbers in a typical sample of living tissue. At the top of the figure is the AC component, which represents absorption of light by the pulsating arterial blood. The DC (baseline) component represents absorption of light by the tissue bed, including venous, capillary, and nonpulsatile arterial blood. The pulsatile expansion of the arteriolar bed increases the light path length (Equations 10 and 11), thereby increasing absorbency. Pulse oximeters use only two wavelengths of light: 660 nm (red light) and 940 nm (near-infrared light). The pulse oximeter first determines the AC component of absorbance at each wavelength and then divides this value by the corresponding

Figure 28-34 (Figure Not Available) Pulse oximetry signals. A primary difficulty with pulse oximetry is that the pulsatile signal is small compared with the total absorbance of the ear or finger being examined. Pulsatile flow is needed to determine the Sa o_2 . *(Adapted from Ohmeda Pulse Oximeter model 3700 Service Manual)*

DC component to obtain a "pulse-added" absorbance, which is independent of the incident light intensity. The oximeter then calculates the ratio R of the two pulse-added absorbances (one for each wavelength): [12]

Finally, the value of R is related to the displayed saturation estimate SpO_2 by a "look-up table" programmed into the oximeter's software. The tables used in all commercial pulse oximeters are based on experimental studies in healthy human volunteers. Although each manufacturer's exact calibration curve is proprietary, these curves are very similar. For instance, when the ratio of red to infrared pulse-added absorbance is 1.0, the displayed SpO_2 is approximately 85 percent. This fact has clinical implications, which are discussed below.

Signal Artifact Management.

Probably the most difficult engineering problem in pulse oximetry is the identification of the fluctuating absorbance pattern of the arterial blood in a sea of electromagnetic and other artifacts. Artifacts have three major sources: ambient light, low perfusion (weak pulse, low AC-to-DC signal ratio), and motion (high AC-to-DC signal ratio). All of these sources of artifacts produce a low signal-to-noise ratio.

The photodiodes used in the sensor to detect light cannot differentiate one wavelength of light from another. Therefore, the detector does not know whether received light originates from the red light-emitting diode (LED), the infrared LED, or the room lights. This problem is solved in most pulse oximeters by alternating the red and infrared LED sources. The red LED is turned on first, and the photodiode detector produces a current resulting from the red LED plus the room lights. Next, the red LED is turned off, and the infrared LED is turned on. The photodiode signal then represents the infrared LED plus the room lights. Finally, both LEDs are turned off, and the photodiode generates a signal from the room lights alone. This sequence is repeated hundreds of times per second. In this way, the oximeter attempts to eliminate light interference even in a quickly changing background of room light. [12] Some sources of fluctuating light can cause problems despite this clever design.

Artifact from ambient light can be minimized simply by covering the sensor with an opaque shield.

Another engineering problem is that of low AC-to-DC signal ratio, or low perfusion. When a small pulsatile absorbance signal is detected, the pulse oximeter amplifies the signal and estimates saturation from the ratio of the amplified absorbances. In this way, the pulse oximeter can estimate saturation values of Sp o_2 for a wide range of patients who generate different amplitudes for pulsatile absorbance. Unfortunately, as with a radio receiver, when a weak signal is amplified, the background noise, or "static," is also amplified. At the highest amplifications (which can be up to a million times), some pulse oximeters may analyze this noise signal and generate an Sp o_2 value from it. Because the noise is usually equal in the red and the infrared signals, the ratio of the two is often near unity (1.0), which yields a displayed saturation of approximately 85 percent. This problem could be demonstrated in early pulse oximeters by placing a piece of paper in the sensor between the photodiode and the LED. Many early models amplified the background noise while searching for a pulse until they eventually displayed a pulse and saturation value derived from the noise. To prevent this type of artifact, manufacturers have now incorporated minimum values for signal-to-noise ratio, below which the device displays no value for Sp o_2 . Some oximeters also display a low-signal-strength error message; many also display a plethysmographic wave for visual identification of noise.

Patient motion (high AC-to-DC signal ratio) may be the most difficult artifact to eliminate. Engineers have tried several approaches to this problem, beginning with increasing the signal-averaging time. If the device averages its measurements over a longer time period, the effect of an intermittent artifact is usually less. However, this longer averaging period also slows the response time to any acute change in Sa o_2 . Most pulse oximeters now allow the user to select one of several time-averaging modes. In addition, the designer can use sophisticated algorithms to identify and reject spurious signals.

One innovation aimed at reducing motion artifact is based on the premise that motion causes pulsations of the venous blood within the tissue bed. Conventional pulse oximetry cannot distinguish these venous pulsations from those of the arterial blood; hence, large errors or loss of signal can result. In the new signal processing algorithm developed by Masimo, the oximeter actually computes a venous "noise reference signal," which is common to both light wavelengths. The noise reference is then subtracted from the total signal, leaving a "true" arterial signal. Tests in human volunteers as well as preliminary clinical studies indicate that this new technology represents an improvement in pulse oximeter performance in low signal-to-noise ratio situations. [15] [16]

Over the past decade, other *in vivo* oximeters have been developed to measure light reflected by living tissue, in an attempt to determine tissue hemoglobin saturation in specific organs. Using reflected rather than transmitted light adds complexity because the path length of the light through the tissue may be tortuous, making calibration difficult. Nevertheless, a signal reflected from living tissue may produce useful information regarding the average saturation of the hemoglobin within the tissue illuminated by the reflectance oximeter. [17] For example, a cerebral oximeter may be able to measure mean brain hemoglobin saturation, reflecting the intracerebral balance between venous and arterial blood as well as the oxygenation of both.

Raman Scattering

As stated earlier, light of a specific energy can be absorbed by, or emitted from, a substance, depending on its allowable levels of vibrational, rotational, and electronic energy. Another absorption and reemission phenomenon of light scattering occurs in a very small percentage of interactions. In this process, called Raman scattering, light in the visible and ultraviolet range is absorbed by molecules of a substance, thereby producing unstable vibrational or rotational energy states. Because these excited states are unstable, some of the absorbed energy is immediately re-emitted, allowing the molecule to relax into a stable state. This Raman scattering signal occurs very infrequently; therefore, most photons pass through the gas sample without taking part in this particular absorption-re-emission phenomenon.

If the intensity of the transmitted light is sufficiently great, the Raman-scattered signal can be measured and used to identify the molecules within the gas sample. Because the signal is scattered light, it is emitted in all directions relative to the incident beam. [10] [18] The Raman light is of low intensity, so it is best to measure it at right angles to the high-intensity exciting beam.

An advantage of Raman scattering over gas analysis based on absorption of infrared light is that a spectrum of Raman scattering lines can be used to identify all types of molecules in the gas phase (e.g., O_2 and N_2). Because it involves only vibrational and rotational energy states, Raman scattering cannot be used to identify single atoms. As discussed earlier, infrared absorption can be used to analyze molecules having a dipole moment and, therefore, cannot be used to identify oxygen or nitrogen. A disadvantage of Raman scattering as a clinical tool is the requirement for a very high-intensity laser light source to produce the small Raman-scattered signal. [10] [18]

TEMPERATURE MEASUREMENT

Principles of Temperature

Moving matter contains energy. Even stationary objects are moving at the atomic level. This kinetic energy of the molecules and atoms is described as temperature. When all atomic motion ceases, the substance is said to be at absolute zero. This provides a reference point for all temperature measurements. Heat has been defined as a form of internal kinetic energy that flows between two contacting bodies at different temperatures. When all atomic motion ceases, the substance is said to be at absolute zero. This provides a reference point for all temperature measurements.

The amount of heat required to raise the temperature of 1 g of a given substance by 1°C is called the *specific heat* of that substance. The calorie, a common heat unit, is the amount of heat required to raise the temperature of 1 g of water from 14.5 to 15.5°C. One calorie is equal to 4.184 joules. When we refer to calories in terms of the calories in the food we eat or the calories we expend exercising, we are actually referring to kilocalories, or thousands of calories. The total amount of heat energy in an object thus depends on its specific heat, its temperature, and its mass. For example, although a cup of 60°C coffee is much "hotter" than a 30°C swimming pool, the coffee contains much less total thermal energy than the pool. The same is true for potential energy stored as pressure potential or electrical potential. A small container at high pressure may have less potential energy than a larger container at a lower pressure.

Temperature Monitors (Thermometer, Thermistor, Thermocouple)

There are three general techniques for measuring temperature: those based on expansion of a material as the temperature of the material increases, those based on changes in electrical properties with temperature, and those based on optical properties of a material. As heat is added to most substances (gases, liquids, or solids), the motion of the molecules increases, causing the volume of the material to expand at constant pressure. Depending on the material, this expansion can be calibrated linearly to changes in temperature. Liquids are most commonly used, specifically, mercury, because its effective range extends from its freezing point of -39°C to approximately 250°C. Mercury thermometers have two general disadvantages. They require 2 to 3 minutes for complete thermal equilibration (mercury has a high specific heat). Also, they are enclosed in a glass tube, which may break and injure the patient. Thermometers based on the expansion of gas (the Borden tube) or metal (the bimetallic strip) are frequently used as thermostats because they respond slowly to transient changes in temperature.

Electrical techniques for measuring temperature can be subdivided into three categories: resistance thermometers, thermistors, and thermocouples. Resistance thermometers operate on the principle that the electrical resistance of metals increases with temperature. These devices most frequently use a platinum wire as the temperature-sensitive resistor; a battery; and a galvanometer to measure current, which can be calibrated to temperature. The platinum wire is incorporated into a Wheatstone bridge circuit, which accurately measures very small changes in resistance (Fig. 28-35) .

Compared with a platinum thermometer, a thermistor is a semiconductor that displays the opposite behavior with regard to electrical resistance. Specifically, as the thermistor is heated, its resistance decreases. Thermistors, being solid- state devices, can be manufactured as extremely small devices and therefore have a fast response to change in temperature (i.e., little heat is needed to increase their temperature). Most of the temperature probes used in anesthesia, from the ones at the end of Swan-Ganz catheters to esophageal probes, are thermistors.

Figure 28-35 Wheatstone bridge. A Wheatstone bridge is an electronic circuit designed so that an unknown resistance can be calculated by knowing two sets of variables: (1) the voltage drop across the bridge and (2) the other resistances in the circuit (Appendix 3).

Appendix *1*-Distance Versus Time Under Constant Acceleration: Equivalence of Potential and Kinetic Energy

Velocity **v** is the rate at which distance is changing, i.e., it is the time derivative of distance:

v = d **x**/dt (1)

v is written in boldface type to indicate that it is a vector: it has both magnitude and direction. Distance **x** is a vector pointing from the origin to the present location of the particle or object; this is called the "position vector." Time (t) is a scalar: it has magnitude but no direction and is therefore written in plain type.

Acceleration **a** is the time rate of change of velocity. Thus, it is the time derivative of the velocity vector, or the second derivative of distance with respect to time.

a = d **v**/dt = (d/dt)(d **x**/dt) = d^2 **x**/dt^2 (2)

If an object starts with zero velocity (**v** = 0) at time zero (t = 0), and then accelerates with constant acceleration (**a**), then its velocity at time t will be simply **v** = **a**t. To calculate the distance traveled by the object at between time t = 0 and time t, we must divide the time interval 0 to t into a series of very small intervals, each of time length dt. The distance traveled during the interval dt is simply the velocity at that time multiplied by the time interval:

d **x** = **v**dt = (**a**t)dt (3)

In the second step, we have substituted the constant acceleration relation **v** = **a**t from above. Now to compute the total distance traveled, we must sum the distance from all of the small dt time intervals that occur between 0 and t.

x = Sigma(**a**t)dt (4)

If we allow the length of the time interval dt to approach zero, the summation process becomes the *integral* with respect to time, from time zero to time t.

x =
vdt =
(**a**t)dt = (½) **a**t^2 (5)

Thus, an object starting from rest at t = 0 and moving with constant acceleration (**a**) will move a distance (½) **a**t^2 in time t. If this is a falling object (in a vacuum, where there is no air resistance) then a = g = 9.8 m/s^2 , and the distance formula becomes:

x = (½)gt^2 = (4.9)t^2 (6)

In the first second the object falls 4.9 ms; at the end of 2 seconds, it has fallen 19.6 meters; after 3 seconds, 44.1 meters, and so on.

The kinetic energy (KE) of a moving object is

KE = (½)mv^2 (7)

where m is the mass of the object and v is the magnitude of its velocity (also called *speed*). Note that v used in this sense is in plain type, not boldface. Consider again the falling object that started at position x = 0 at time t = 0 and falls a distance h:

Because velocity v = at = gt, we have by substitution from Equation 8:

The kinetic energy is given by

KE = (½)mv^2 = (½)m(2gh) = mgh(10)

Now let us consider the *work* required to lift the fallen object back to its original height of h. Recall that work is defined as the force exerted times the distance over which the force acts: W = Fd. The force of gravity acting on our object is F_g = mg, so the work required to lift it the distance (h) back to x = 0 is

W = Fd = (mg)d = mgh(11)

Thus, the work required to restore the object equals the kinetic energy possessed by the object at the bottom of its fall, KE = W = mgh. When we lift the object from x = h back to x = 0, we have increased its *potential energy* (PE) by an amount (mgh). This potential energy can be converted to kinetic energy by allowing the object to fall the distance h. This type of potential energy, called *gravitational potential,* has a value that clearly depends on where we locate the origin of our coordinates, x = 0. However, it is the *changes* in potential energy, not its absolute value, that the potential energy/kinetic energy balance:

DeltaKE = -DeltaPE(12)

The change in kinetic energy is equal to, and of opposite sign of, the change in potential energy.

Appendix *2*-Physics of Hydrostatic Pressure

The liquid manometer is a simple and reliable means of monitoring pressures that do not change rapidly. It simply uses the weight of a measured vertical column of liquid to balance the pressure exerted against the bottom of the column. We have defined weight as the force exerted by gravity on a mass (m): ($F_g = mg$). To determine the weight of a column of liquid of known dimensions (the manometer in Fig. 28-10) , we must first know the density (mass per unit volume) of the liquid. Density has dimensions of M/L^3 , and the SI units are kilograms per cubic meter (kg/m^3). Because liquids are almost incompressible, their density is little influenced by pressure (but is affected by temperature). The density of water at room temperature is 997.8 kg/m^3 , or 1.0 g/cm^3 .

The pressure (p) exerted by the bottom of the vertical column of liquid in the manometer (see Fig. 28-10) is determined as follows. If the cross-sectional area of the liquid cylinder is A and the height of the cylinder is z, then its volume is V = Az. If the liquid has a density of rho, then the mass of the column is

m = rhoV = rhoAz (1)

and its weight is

W = mg = rhoAzg (2)

The liquid column exerts a force equal to its weight on its base, whose surface area is A, thus creating the following pressure on the surface:

p = force/area = rhoAzg/A = rhogz (3)

The pressure exerted by the manometer is therefore independent of its cross-sectional area (A); it depends on only the density of the working fluid and the vertical height of the column. If we know the liquid density, then measurement of the column height (z) allows us the calculate the pressure (p). For example, if the working fluid is mercury (e.g., sphygmomanometers), the density is 13,680 kg/m^3 (13.68 g/cm^3 , or 13.68 times the density of water). The relationship of pressure to height of the column is then

p = rhogz = (13,600 kg/m^3)(9.8 N/kg)(z) p [N/m^2] = 133,300(z) (4)

The unit of pressure newton/$meter^2$ is called the pascal (Pa). Because a pascal is a small unit of pressure, we usually use kilopascals (10^3 pascals) or kPa. If we express p in kPa and z in millimeters of mercury (rather than meters), Equation 4 becomes

p [kPa] = 0.1333 (z) [millimeters] (5)

Appendix *3*-Wheatstone Bridge

The Wheatstone bridge is a network of four resistors connected as shown in Figure 28-35 , with a battery or direct-current voltage source (electromotive force) connected between A and C, and a voltmeter (V) connected between B and D. The bridge is said to be "balanced" when the voltmeter reads zero potential difference between points B and D. From Ohm's law (V = IR), it is easy to show that balance occurs when $R_x = R_s \times (R_2 / R_1)$. If Rs is an adjustable standard resistor and R_1 and R_2 are fixed known resistors, then the balanced bridge provides a very precise means of determining R_x, the unknown resistance. This principle has many applications in biomedical engineering, including strain-gauge pressure transducer measurements. In this case, the transducer itself is the unknown resistance R_x.

Appendix *4*-Amplification Artifact of a Fluid Tube/Transducer Pressure Wave

The amplification artifact of a fluid/transducer pressure waveform can be calculated if a few properties of the system are known. The most relevant part of this solution is the response amplitude, which is plotted against the driving frequency (f) in Figure 28-13 (Figure Not Available) . This figure shows some important properties of fluid-coupled transducers and other harmonic oscillators. One of these is the existence of a resonant frequency, f_0, which is defined as follows:

Remember, m is the mass of the system and k is the elasticity, or spring constant.

As we increase the amount of damping (i.e., friction; c is the friction constant), we observe a decrease in the peak amplitude at resonance, and the frequency at which the peak occurs decreases slightly, the damping coefficient (z), is defined as follows:

Even though the arterial pressure waveform is not actually sinusoidal, Figure 28-13 (Figure Not Available) shows the most important characteristics of the pressure transducer response. Any combination of catheter, tubing, and transducer can be characterized by two quantities: a resonant frequency (f_0) and a damping coefficient (z). Gardner measured these quantities for many transducer and tubing systems; most systems have resonant frequencies of 10 to 20 cycles/s, or hertz (Hz), and damping coefficients of 0.2 to 0.3. For clinical systems, the maximum amplification factor (the ratio of transducer output to input waveform amplitude) at resonance is near 2.5.

If the resonant frequency is 10 Hz (600 cycles/min), one might conclude that amplification plays little role in the clinical range of pulse rates, which are five to 10 times smaller. However, the arterial pressure waveform is not a sine wave. It can be represented as a summation of sine waves (a Fourier series) of frequencies up to many times the pulse rate. It is these higher harmonic frequencies that are amplified most and that yield the spiked appearance of the poorly processed arterial waveform. Depending on the shape of the actual arterial pressure wave, this distortion can introduce a 20 to 40 percent "overshoot" error in systolic blood pressure readings. Even worse, this error is dependent on pulse rate, so that an error determined for a particular patient at the beginning of an anesthetic may not remain constant.

From this discussion, we can easily predict how to optimize the performance of a pressure transducer system. First, the resonant frequency (f_0) should be as high as possible. Therefore, the value for k in Equation 1 should be large (i.e., the spring should be "stiff"), and the value for m should be small. That is, the cannula and pressure tubing should be as stiff and inelastic as possible. To minimize the mass of the moving fluid, the tubing should be short in length and small in diameter. Judging from plots of amplitude versus frequency/resonant frequency at different damping coefficients, the optimal damping coefficient would be 0.4 to 0.5. One should also carefully eliminate air bubbles from the system because these add elasticity and friction, thereby lowering the resonant frequency. In a clinical system, one can determine the approximate f_0 and z of a transducer system if graphic output is available. If the high-pressure flush is turned on and then quickly off at a high chart speed (50 mm/s), the tracing oscillates through several cycles at a frequency near f_0. The damping coefficient can be found by determining the ratio of amplitudes of successive peaks on the tracing.

This is a practical example of how fundamental principles of mechanics can be used to predict and optimize the performance of monitoring systems. These concepts of mechanics will recur in later sections of this chapter.

Appendix 5-Flowmeters, Bernoulli's Principle, Laminar and Turbulent Flow

The equations governing the motion of fluids are expressions of Newton's second law, F = ma. Forces associated with fluids fall into three major categories: (1) gravity, (2) pressure, and (3) friction. In the example using manometers, the gravitational force per unit volume of fluid is simply rg, acting in the vertical direction. Pressure forces are actually the result of differences in pressure from one point to another and are expressed mathematically as the negative of the pressure gradient. (The pressure gradient is a vector in the direction of maximum rate of pressure increase, having magnitude equal to the pressure derivative in that direction.) Friction is proportional to viscosity, the physical property of a fluid that relates shear stress to rate of strain.

$P_0 = p + (½)rhoU^2 + rhogz$(1)

Equation 1 shows the relationship between velocity and pressure of a fluid in a flow that meets the conditions described. For flows in tubes, the manometer technique provides an easy method of measuring mean pressure. Therefore, the simplest flowmeters apply a combination of these two principles to a tube of changing cross-sectional diameter. For example, the Venturi flowmeter shown in Figure 28-17 consists of a tube of varying cross-sectional area that has two ports for measurement of pressure. The Bernoulli equation for points 1 and 2 in the figure becomes

Here, the gravity terms have canceled out because the tube is horizontal, but these terms are usually negligible for gas flows in any direction.

The volume of the fluid flow (Q), (also called flux) at both locations must be the same because no fluid is entering or leaving through the tube walls. The dimensions and SI units for the volume of fluid flow are L^3/T and m^3/s, respectively. This volume is determined at each cross-section of the tube by multiplying the average velocity (U) by the cross-sectional area (A):

$Q = U_1 A_1 = U_2 A_2$ (3)

Assuming that A_1, A_2, P_1, and P_2 are known, we now have two equations for the two unknowns U_1 and U_2. Solving these for the velocity U_1 produces

To find the volume of the flow (Q), we merely multiply this result by A_1. Note that velocity is proportional to the square root of the pressure drop or that the pressure change varies as velocity squared. For a given U_1, magnitude of flow velocity, the pressure drop varies as the square of the ratio of the areas, or the fourth power of the ratio of the diameters. If we choose A_2 greater than A_1, Equation 4 implies that P_2 is greater than P_1. In this case, the pressure increases in the direction of flow, a change that initially seems contrary to intuition.

The bobbin flowmeters (also called variable-orifice flowmeters) in anesthesia machines use a similar principle. These devices consist of a slightly tapered vertical tube and a bobbin or ball that fits inside the tube (Fig. 28-19) . The cross-sectional area of the ring-shaped gap between the bobbin and the tube wall is proportional to the height of the bobbin. Because changes in the cross-sectional area of flow are abrupt rather than gradual (as in Figure 17), the Bernoulli equation does not accurately describe this type of flow. The flow above the bobbin (i.e., downstream) is highly turbulent, and turbulence is a condition that dissipates kinetic energy into heat. However, introduction of an empirical constant C_d enables one to use the same formulation as in Equation 4:

and

$P_1 - P_2 = (½\ rhoQ^2)/(C_d^2 A^2)$(6)

where C_d is a dimensionless constant called the discharge coefficient. This constant varies with the shape of the orifice and with the value for another dimensionless parameter, the Reynolds number (Re). The Reynolds number, the overall ratio of inertial forces to viscous forces in a particular flow, is determined as follows:

Re = rhoUL/mu(7)

where U is mean flow velocity, L is a characteristic length for the flow (in our flowmeter, L is the diameter of the tube), and mu is the viscosity of the fluid. The dimension for viscosity is M/LT. The value for the Reynolds number is important to any fluid flow because it determines some of the most important characteristics of the flow. For example, the transition from laminar, or "smooth," flow to turbulent flow is determined by the shape of the flow and the Reynolds number. Flow in a long, straight, smooth-walled tube becomes turbulent at an Re value of approximately 2,100. On the other hand, flow through an abrupt orifice, such as that of the flowmeter in Figure 28-19 , becomes turbulent at a Reynolds number of less than 100

Returning now to the function of the flowmeter, one can see that as gas flows upward through the tapered tube, the bobbin begins to rise. As the bobbin rises, the cross-sectional area of the orifice A increases because of the taper of the tube; therefore, the drop in pressure ($P_1 - P_2$) decreases. The bobbin reaches an equilibrium position for a given volume of flow (Q) when the pressure lifting the bobbin is exactly equal to the weight of the bobbin. In this type of flowmeter, the pressure difference is fixed by the bobbin weight, and the area of the orifice varies with the volume of the flow, hence the name variable-orifice flowmeter. Equations 5 and 6 show that calibration of these flowmeters depends on both the density and the viscosity of the gas: density (rho) appears explicitly, and viscosity (mu) appears in the dependence of C_d on the Reynolds number. If we use the wrong gas in a particular flowmeter, equations 5 and 6 and the viscosity and density of the new gas

enable us to predict the change in calibration.

Appendix *6*-Thermal Dilution Cardiac Output

A commonly used method of measuring blood flow is dilutional calculations, i.e., dye or thermal dilution. These methods are simply mass or energy balances that determine the volume of fluid that has diluted by giving a volume of dye or given thermal energy. If you have a bucket of water at room temperature (25°C) and you want to determine the volume of water within the bucket, you could add a known volume of water and a known temperature. If 100 mL of water at 35°C is added to the bucket and the final temperature is 27°C, then the unknown volume can be calculated by balancing the heat energy associated with the dilutional process. This assumes that no heat is lost to the environment. This dilutional process can be used to measure blood flow by completing this same heat balance measured over time. Thermodilution cardiac output measurements can have significant error as a result of the many assumptions associated with the technique, i.e., rapid injection of the thermodilution injectate; accurate temperature and volume of the injected fluid; constant known heat capacity of blood, which in reality is a function of hematocrit value; little heat loss to the lung; and so on.

Thermistor probes are most commonly used in clinical monitoring of patient temperature because they are inexpensive, small, and flexible. For these reasons, the thermistor probe is also used to measure cardiac output determined by the thermodilution technique. Computation of cardiac output performed in this manner is, in effect, a heat balance for the right side of the heart. (A heat balance is a method of accounting for all heat in a process or change involving transfer of heat.) The technique consists of quick injection of a known volume of a sterile solution (usually 10 mL of 5% dextrose in water) into the right side of the heart while a sensor notes the temperature of the blood in the pulmonary artery. It is assumed that the cold injected solution equilibrates thermally with the blood as it perfuses the pulmonary artery but that the solution does not acquire heat from other tissues. The following equation is the solution of this heat balance:

where CO is cardiac output (liters per minute); rhoi and rhob are the densities of the injectate and blood, respectively; C_i and C_b are the heat capacities of the injectate and the blood, respectively; V_i is the volume of the injectate; T_b and T_i are the temperature of the blood and the injectate, respectively; Cr is a computational constant that corrects for the rising temperature of the injectate; and is the area under the thermo-dilution curve. Because the injectate warms as it is injected through the catheter before mixing with the blood, the correction factor Cr is applied to the equation.

Appendix 7-Ultrasound

The simplest sound wave to represent mathematically is a sinusoidal wave propagating in one dimension:

$$p = p_0 \sin [(2\pi/\lambda)(x - at)] \quad (1)$$

where p is the pressure fluctuation, λ is the wavelength (distance between waves), x is the coordinate in the direction of propagation, and a is the speed of propagation, or the speed of sound.

The amplitude of a sound wave is measured by the root mean square value of the pressure fluctuations. This value is called the sound pressure level (SPL). Because the range of SPL values is often very wide, a logarithmic scale is used:

$$SPL = 20 \log (p^*/P_0) \quad (2)$$

where p^* is the root mean square pressure fluctuation and P_0 is a reference pressure, chosen as the lowest sound pressure detectable by the human ear. This pressure representing the threshold of hearing is 2×10^{-8} kPa at a sound frequency of 2 kHz (2,000 cycles/s). The units in this SPL scale are called decibels. Thus, a sound pressure of 2×10^{-8} kPa corresponds to an SPL of zero decibels (0 dB), the lowest audible sound level [$(p^*/P_0 = 1; \log (1) = 0)$]. Quiet conversation has an SPL of approximately 40 to 50 dB, or a pressure of 10 to 300 times that of the threshold of hearing.

When sound waves encounter a sudden change in the properties of the conducting medium, some of the sound is transmitted through the new medium, and some of it is reflected, or "scattered," in many directions. Although the mathematics of this process are complex, one conclusion is readily apparent: the greater the mismatch in density and compressibility between the two media, the more sound is reflected. The quantity that best determines the degree of reflection at an interface between two media is the ratio (R) of the products of density (ρ) and the speed of sound (a) through the two media:

$$R = (\rho_1 a_1)/(\rho_2 a_2) \quad (3)$$

We can easily see that the greatest acoustic mismatch in the body occurs between the solid tissues and the lungs. Both the density and the speed of sound are much lower in the air-filled lungs than in solid tissues. Therefore, ultrasonography cannot "look" through the lungs to tissues or organs on the other side. The second greatest mismatch occurs between soft tissues and bone, the latter having a much higher rhoa than the former. In 1842, Christian Johann Doppler first described the apparent change in pitch of a sound that occurred when either the source of the sound or the listener was moving. This Doppler effect now has several applications in patient monitoring, including precordial and esophageal Doppler ultrasound devices that measure local blood velocities or cardiac output. If a sound source radiating a frequency (f) is stationary and the listener is moving (Fig. 28-23 (Figure Not Available) A) , the wavelength of the waves can be determined by the equation

$$\lambda = a/f \quad (4)$$

because the time between wavefronts is $1/f$, and the waves are moving at the speed of sound (a). If the listener moves toward the source at speed V_0, his velocity relative to the moving wavefronts is $(a + V_0)$. The number of wavefronts the listener encounters per unit time is therefore

$$f = \text{velocity/distance between waves} = (a + V_0)/\lambda \quad (5)$$

Because the sound frequency for a stationary listener is $f = a/\lambda$ (Equation 4), the frequency f heard by the moving listener becomes

$$f = (a + V_0)/\lambda = f + (V_0/\lambda) = f + (V_0 f/a) = f[1 + (V_0/a)] \quad (6)$$

The apparent frequency of the listener is thus increased by the factor $[1 + (V_0/a)]$. A listener moving toward the source at half the speed of sound hears a frequency 1.5 times that of a stationary listener.

Now consider a stationary listener and a source moving at speed V_0, as shown in Figure 28-23 (Figure Not Available) B. The wavefronts are no longer concentric circles; they are more closely spaced in the direction that the source is moving. If the frequency of the sound emitted at the source is f, then during each vibration, the source moves a distance V_0/f. The wavelength in the direction of motion is thus shortened by V_0/f, becoming $\lambda = (a - V_0)/f$. The waves themselves are traveling at speed a, so that the frequency heard by the stationary listener is

$$f = a/\lambda = af/(a - V_0) = f[1/(1 - V_0/a)] \quad (7)$$

Now, if the source is moving at half the speed of sound toward the listener, the apparent frequency doubles. Compare this with the preceding situation, in which the listener is moving and the apparent frequency increases by only 50 percent. Doppler ultrasound systems combine the two situations shown in Figure 28-23 (Figure Not Available) . The initial acoustic source is a stationary transducer, and the sound from this device is scattered from a moving target (e.g., red blood cells). The scattered sound then returns to a stationary listener: the receiving transducer. In effect, the target is a moving listener hearing a stationary source; the target then reradiates the sound as a moving source toward a stationary listener. The

frequency heard by the receiving transducer is obtained by combining equations 6 and 7:

In this example, we have assumed that the target is moving toward the ultrasound transducers at speed V. If the target is moving at half the speed of sound, the observed frequency is increased by a factor of 3! Because changes in the frequency of sine waves can be measured precisely, the Doppler principle provides a very accurate method of measuring the velocities of moving sound reflectors. At the high frequencies often used (
5 MHz), objects as small as red corpuscles can scatter enough sound for detection.

Chapter 29 - Monitoring Depth of Anesthesia

Donald R. Stanski

INTRODUCTION

The conceptual approaches to defining depth of anesthesia are extremely varied, ranging from in-depth scientific discussions of the minimum alveolar concentration of anesthetic necessary to eliminate movement in 50 percent of subjects (MAC) [1] to clinical, anecdotal descriptions of "light," "moderate," or "deep" anesthesia. [2] The range of these approaches indicates the complexity of conceptualizing depth of anesthesia.

The chapter is divided into three general sections. The first discusses two related topics: the evolving definitions of depth of anesthesia and the problem of recall (memory) and awareness. The many attempts to define "depth of anesthesia" make one realize that our knowledge of the specific attributes of the drugs used in clinical practice has to be incorporated into our understanding of this phrase. Currently, the diverse nature of anesthetic drugs makes it difficult to define depth of anesthesia in a unifying manner. Although modern techniques and drugs have increased the intraoperative and postoperative safety of anesthesia care, the unfortunate consequence of this otherwise advantageous effect is the occasional occurrence of intraoperative recall and awareness during surgery.

The second section of this chapter involves basic pharmacologic concepts relevant to the scientific investigation of depth of anesthesia. This brief review prepares the reader for the third section, which discusses specific drugs and clinical situations in two subsections. The first subsection discusses clinical measures of anesthetic depth that derive directly from the patient. Each discussion begins with a review of the scientific approaches available for individual drugs and culminates in the more subjective clinical approaches used in anesthetic practice. The second subsection discusses several electrophysiologic approaches to assessing depth of anesthesia. This represents the application of technology to the issue of quantitation of anesthetic drug effect and depth of anesthesia.

DEPTH OF ANESTHESIA: INTRAOPERATIVE MEMORY AND AWARENESS

The word *anesthesia* was first used by the Greek philosopher Dioscorides in the first century of the current era to describe the narcotic effect of the plant *Mandragora.* The word reappeared in the 1771 *Encyclopaedia Britannica,* where it was defined as a "privation of the senses." [3] After the introduction of ether anesthesia by Morton in 1846, Oliver Wendell Holmes used the word to describe the new phenomenon that made surgical procedures possible.

Defining Depth of Anesthesia

Plomley [4] was the first, in 1847, to define depth of anesthesia. He described three stages: intoxication, excitement (both conscious and unconscious), and the deeper levels of narcosis. In that same year, John Snow [5] described "five degrees of narcotism" for ether anesthesia. The first three stages encompassed induction of anesthesia, and the last two represented surgical anesthesia. Eleven years later, Snow [6] turned his attention to chloroform. Snow's excellent characterizations of ether and chloroform anesthesia described the following signs: conjunctival reflex; regular, deep, automatic breathing; movement of the eyeballs; and

inhibition of the intercostal muscles. Many of these clinical signs were later "rediscovered." [7] Because oxygen was not readily available until the early 1900s, Snow and his successors tried to minimize the use of deep anesthesia to decrease morbidity and mortality.

The early 1900s saw the introduction of premedication with sedatives or opioids. In addition, anesthetics with more rapid onset, such as nitrous oxide and ethylene, became available. Therefore, the anesthetic excitement phase could be traversed more rapidly with the use of preanesthetic medication and rapid-onset inhaled anesthetics.

In 1937, Guedel [8] published his classic description of the clinical signs of ether anesthesia. He used clear physical signs involving somatic muscle tone, respiratory patterns, and ocular signs (Fig. 29-1) (Figure Not Available) to define four stages. In the first stage, analgesia, characterized by slow, regular breathing with the diaphragm and intercostal muscles and the presence of the lid reflex, the subject experiences complete amnesia, analgesia, and sedation. In the second stage (delirium), the subject experiences excitement, unconsciousness, and a dream state with uninhibited activity. Ventilation is irregular and unpredictable. Reflex dilatation of the pupils occurs, the lid reflex is intact, and the risk of clinically important reflex activity (e.g., vomiting, laryngospasm, or arrhythmias) increases. The third stage (surgical anesthesia) consists of four progressive planes. Plane 1 is characterized by slight somatic relaxation, regular periodic breathing, and active ocular muscles. During plane 2, breathing changes, inhalation becomes briefer than exhalation, and a slight pause separates inhalation and exhalation. The eyes become immobile. In plane 3, the abdominal muscles are completely relaxed, and diaphragmatic breathing is very prominent. The eyelid reflex is absent. In plane 4, the intercostal muscles are completely paralyzed, and paradoxic rib cage movement occurs. Breathing is irregular, and pupils are dilated. In Guedel's fourth stage (respiratory paralysis), muscles become flaccid, and eyes widely dilate. Cardiovascular and respiratory arrest occurs, as does cardiovascular collapse.

In 1954, Artusio [9] expanded Guedel's description of ether analgesia (stage 1) into three planes. In plane 1, the patient has no amnesia or analgesia. In plane 2, the patient has total amnesia and partial analgesia. In plane 3, the patient has complete analgesia and amnesia, but is comfortable and responsive to verbal stimulation; there is little depression of reflexes. Artusio observed that once patients were anesthetized past stage II (delirium) to the deeper anesthesia of stage III, they could be brought back and forth between stage III and plane 3 of stage II without ever exhibiting stage II. The clinical signs of depth of anesthesia defined by Guedel and others had significant practical utility for the administration of ether, cyclopropane, and chloroform anesthesia.

Beginning in 1942, small doses of the muscle relaxant *d*-tubocurarine were used with the deep levels of ether anesthesia that produced plane 2 or 3 of Guedel's stage III. Respiration was assisted when necessary. Over time, the dose of *d*-tubocurarine began to increase as fully controlled ventilation became commonplace. Anesthesiologists soon realized that they could combine controlled ventilation and large doses of muscle relaxants with low concentrations of inhaled anesthetics to reduce the risk of toxicity (cardiovascular and respiratory depression) and to increase the speed of emergence from anesthesia. However, the use of muscle relaxants eliminated two valuable types of clinical signs of depth of anesthesia: the rate and volume of respiration and the degree of muscle relaxation induced by the anesthetic. [10] Seven of the nine components of Guedel's classification system involved skeletal muscle activity. When muscle relaxants are used with ether anesthesia, only pupil size and lacrimation are left as clinical signs. These signs are inadequate to judge anesthetic depth clinically. [11] A 1945 editorial in the *Lancet* discussed the clinical problems that muscle relaxants would

Figure 29-1 (Figure Not Available) Guedel's classic text described the stages and planes of ether anesthesia (A) and then related them to clinical signs or relevant reflexes (B). *(From Guedel [6])*

create, [12] and descriptions of patient awareness during surgery later began to appear in the literature. [13]

In 1957, Woodbridge [14] examined the diverse use of anesthetic drugs at that time. He defined anesthesia as having four components: (1) sensory blockade of afferent nerve impulses; (2) motor blockade of efferent impulses; (3) reflex blockade of the respiratory, cardiovascular, or gastrointestinal tract; and (4) mental block, sleep, or unconsciousness. Different drugs could be used to achieve each effect. However, Woodbridge made no effort to define methods of assessing each of these components.

In a 1986 letter to the editor, Pinsker [15] described his conceptualization of "anesthesia" as a broad, descriptive term, comparable to the idea of "sickness," in that the source is not one mechanism, but rather, several components. Anesthesia has three components: paralysis, unconsciousness, and attenuation of the stress response. Any drug or combination of drugs that reversibly provides these three conditions could be used in anesthesia. Paralysis or the absence of movement or skeletal muscle tone in the operative field could be achieved by neural blockade or nondepolarizing muscle relaxants. Attenuation of the stress response could be defined only poorly because of limited knowledge regarding the nature of stress. By contrast, heart rate and blood pressure are clinically measurable components of stress. Unconsciousness, which consists of amnesia and hypnosis, is also a parameter that could not be well defined. No universal end point serves as the basis for the rational administration of drugs to achieve unconsciousness. At present, an absence of recall is the only objective criterion for unconsciousness (hypnosis or amnesia).

In a 1987 editorial, Prys-Roberts [16] made a meaningful contribution to the concept of depth of anesthesia by redefining which elements are truly relevant to anesthesia. He began by observing that depth of anesthesia is difficult to define because anesthetists have approached the issue in terms of the drugs available to them rather than the patient's needs during surgery. Prys-Roberts believed that the noxious stimulation of surgery induces a variety of reflex responses that may be independently modified to the benefit of the patient. One important premise is that pain is the conscious perception of noxious stimuli. Thus, he defined anesthesia as

the state in which, as a result of drug-induced unconsciousness, the patient neither perceives nor recalls noxious stimuli. The loss of consciousness is considered a threshold or all-or-none (quantal) phenomenon. By this definition, there can be no degrees of anesthesia or any variable depth of anesthesia. Prys-Roberts defined anesthesia in terms of the drugs producing unconsciousness and modification of noxious stimuli, classifying them by pharmacologic properties of the drugs and not by their ability to produce components of the state of anesthesia.

Prys-Roberts focused his concepts on the body's response to noxious stimuli, which he defined as factors causing potential or actual cell damage--mechanical, chemical, thermal, or induced by radiation. Figure 29-2 (Figure Not Available) shows the somatic and autonomic responses to noxious stimuli. In this scheme, one reads from left to right and from top to bottom to see the order in which reflex responses are suppressed by anesthetic drugs. For example, somatic responses include both sensory and motor activity. Sensory input obtained through the central nervous system (CNS) can originate from somatic or visceral tissue. The subject must be conscious to perceive pain. Low concentrations of inhaled or intravenously administered anesthetics can eliminate recall of pain, but they allow a motor response. The motor response to noxious stimuli is typically an all-or-none reflex withdrawal of the stimulated part. Eger et al [17] used this movement response as a clinical end point in developing the concept of MAC; MAC was used to quantitate the potency of inhaled anesthetics. The concentrations of anesthetics required to eliminate somatic motor response are higher than those necessary to induce unconsciousness and to eliminate perception of pain.

The response of the respiratory system is part of the autonomic response described by Prys-Roberts. The motor response to noxious stimuli can involve an increase in tidal volume or the frequency of breathing. This ventilatory response may occur even if there is no somatic motor response to surgical stimulation. A higher concentration is required to suppress the breathing response than is required to suppress the somatic response to noxious stimuli.

Prys-Roberts divided autonomic responses into three categories. The hemodynamic response consists of autonomic responses to noxious stimuli, namely, increased sympatho-adrenal activity that elevates arterial blood pressure and

Figure 29-2 (Figure Not Available) Depth of anesthesia can be defined by the suppression of clinically relevant responses to noxious stimul, as proposed by Prys-Roberts. *(Modified from Prys-Roberts [16])*

heart rate. The sudomotor response consists of sweating. Release of hormones is an extremely difficult response to eliminate completely.

Prys-Roberts considered pain relief, muscle relaxation, and suppression of autonomic activity as discrete pharmacologic events. These events may be engendered by specific drugs. Some drugs can produce all these end points; others can achieve only one or two. The only feature common to most anesthetics is the suppression of sensory perception and the production of unconsciousness. Prys-Roberts considered the inclusion of muscle relaxation in the definition of the anesthetic state illogical and confusing. Although muscle relaxation is necessary for laryngoscopy and surgical access, it is neither a component of anesthesia nor an alternative to adequate anesthesia.

Kissin, [18] in a 1993 editorial, expanded, refined, and further contributed to the definition of anesthesia. He began by indicating that a wide spectrum of pharmacologic actions via different drugs can be used to create the general anesthetic state. These pharmacologic actions include analgesia, anxiolysis, amnesia, unconsciousness, and suppression of somatic motor, cardiovascular, and hormonal responses to the stimulation of surgery. Kissin stated that the spectrum of effects that constitutes the state of general anesthesia should not be regarded as several components of anesthesia resulting from one anesthetic action, but rather, it represents separate pharmacologic actions, even if the anesthesia is produced by one drug. Kissin then reviewed a series of investigative studies and concepts that supported his hypothesis:

1. Several groups of drugs (benzodiazepines, opiates, alpha $_2$ -agonists) that induce anesthesia by acting on specific receptors can have their anesthetic effects reversed by administration of a specific receptor antagonist.
2. There is growing understanding that the molecular mechanisms of general anesthesia are more specific than was suggested by the previous unitary hypothesis of anesthesia.
3. The rank order of effects for two important goals of anesthesia (hypnotic effect and blockade of somatic motor response to noxious stimuli) can be different for different classes of anesthetics. Opiates induce blockade of movement response to noxious stimulation before hypnosis occurs. For intravenous anesthetics, the opposite occurs.
4. When studies of anesthetic interactions are undertaken, the type of interaction (synergism, antagonism, summation) for one component of anesthesia may differ from that of another component.
5. Classic theories of anesthesia, based on the unitary nonspecific mechanisms of anesthetic action, suggest that one anesthetic may be replaceable freely by another, and anesthetic effects of anesthetic combinations should be additive. Many combinations of anesthetic drugs prove to be supra-additive for the hypnotic effects, a finding that suggests that the mechanisms of hypnotic actions of different components of a combination are different.

If one understands general anesthesia as a spectrum of separate pharmacologic actions that vary according to the goals of anesthesia, certain conclusions can be made regarding the measurement of anesthetic potency and depth of anesthesia. Kissin stated that "Diversity of pharmacological actions that in combination provide anesthesia make[s] it almost impossible to determine the potency of different actions with one measure." [18] The accuracy of this statement will become apparent in the remainder of this chapter.

The definitions of anesthesia depth have evolved with the drugs used in clinical practice. With ether, the clinical signs described by Guedel [8] were clinically relevant, and depth of anesthesia was well defined. The use of potent inhaled anesthetics, opioids, and intravenous anesthetics in modern clinical practice has precluded simple unifying definitions of anesthetic depth. In this author's view, the editorials of Prys-Roberts [16] and Kissin, [18] which emphasize the type of noxious stimuli and the specific class of drug that eliminates that response, represent concepts most appropriate for current clinical practice.

Memory and Awareness

Before the introduction of anesthesia in 1846, surgical operations were uncommon. Robertson [19] unearthed two descriptions of the torture suffered by victims of surgical operations performed before the introduction of anesthesia. In spite of the introduction of surgical anesthesia, however, the vivid descriptions of pain during surgery have not been eliminated completely. Reports of awareness, recall, and memory under anesthesia still occur in clinical practice.

Vickers [20] described two degrees of inadequate depth of anesthesia. The first degree involves the recall or retention of memory of an event that occurred while under anesthesia. Conscious or explicit memory refers to intentional or conscious recollection of prior experiences as assessed by tests of recall or recognition. The second degree of inadequate anesthesia involves the responsiveness to auditory input, also called "wakefulness." Wakefulness has been described as the responding of a patient to a verbal command during or after surgery without recall of the stimuli. Unconscious or implicit memory refers to changes in performance or behavior that are produced by prior experiences on tests that do not require any intentional or conscious recollection of those experiences. [21]

Recall, Conscious or Explicit Memory

In some clinical situations, the risk of intraoperative recall is high. Bogetz and Katz [22] examined the incidence of recall in 51 patients having surgical procedures after major trauma. Thirty-seven patients with stable hemodynamic status were able to receive drugs for induction and maintenance of anesthesia. In this group, 4 had intraoperative recall. Two of the 4 patients considered this awareness their worst hospital experience. Fourteen of the 51 subjects were so severely injured and hemodynamically unstable that no anesthetic was administered for at least 20 minutes of surgery. Six of 14 of these patients (43%) recalled events from their surgery. Two of the latter subjects considered this intraoperative awareness the worst aspect of their hospital experience. Bogetz and Katz could not identify factors predicting which patients would have recall.

Intraoperative recall has been well described in patients given general anesthesia for cesarean section. [23] A prospective

study of 150 obstetric patients reported a 2 percent incidence of intraoperative recall, a 17 percent incidence of unpleasant dreams, and 7 percent incidence of recall of pain. [24] Anesthetic technique was not consistent in this study. Major literature reviews of awareness in anesthesia for the general surgical population have cited a 0.2 to 2 percent incidence of intraoperative recall. [25] [26] [27] Wilson et al [28] reported a 1 percent incidence of awareness, a 2 percent incidence of dreaming, and an 8 percent incidence of hallucinations in 490 adult patients. No correlation existed between the incidence of mental aberrations and anesthetic agent, sex, or length or type of surgery. Liu et al [27] reported a 0.2 percent incidence of recall of events and 0.9 percent of dreaming in a cohort of 1,000 patients evaluated over a 4-month period. Hutchinson's [29] prospective study of 656 patients reported only 6 patients who had recall or intraoperative dreams. All 6 had been given nitrous oxide, oxygen, and muscle relaxants. No recall occurred in patients given potent inhaled anesthetics. However, the use of potent inhaled anesthetics does not guarantee lack of recall. [30] [31]

Intraoperative awareness or recall has occurred with high-dose opioid anesthesia. In one case report, the patient had intraoperative awareness and hypertensive crises after fentanyl (96 mug/kg) and diazepam (0.28 mg/kg) following morphine and scopolamine preanesthetic medication. [32] Previous case reports using high-dose opioid anesthesia had not documented a significant hemodynamic response associated with intraoperative awareness. [33] [34] Two clinical signs possibly predicting the occurrence of recall are movement and autonomic response. The use of muscle relaxants can eliminate the movement response, leaving only autonomic activity as a measure of intraoperative awareness. To circumvent the problem of complete muscle paralysis, Tunstall [35] [36] proposed using the isolated forearm technique to allow the possibility of movement during and after administration of muscle relaxants. This procedure involves application of a tourniquet to an extremity before the administration of muscle relaxants. Because the muscles do not receive the relaxant, the extremity is not paralyzed and can be monitored for movement.

This technique has been used to study the relationship of purposeful muscle movement to intraoperative recall. Schultetus et al [37] used the isolated arm technique to compare the incidence of movement and recall in patients given ketamine, thiopental, or a combination of the 2 induction drugs for cesarean section. For 11 of 24 subjects given thiopental (2 mg/kg) or the combination of ketamine (0.5 mg/kg) and thiopental (2 mg/kg), movement occurred in the isolated arm. Four of the 24 patients had dreams, whereas 3 of the 24 had intraoperative recall. In 12 subjects given only ketamine (1 mg/kg), 1 had a movement response, and none had recall.

Russell [38] [39] showed that the incidence of movement with the isolated arm technique can vary markedly with the choice of anesthetic. The incidence of intraoperative movement was 44 percent after nitrous oxide and fentanyl anesthesia, but it was only 7 percent after a continuous infusion of etomidate with fentanyl. The high incidence of wakefulness (as judged by movement) in the nitrous oxide/fentanyl group caused the investigators to terminate the study. Although the incidence of purposeful movement in the isolated arm was high, the incidence of actual intraoperative recall was low (only one subject).

Other investigators have not been able to correlate other clinical signs of light anesthesia or postoperative recall to the isolated arm movement response. [40] [41] [42] Moreover, the effects of ischemia from prolonged inflation of the tourniquet at pressures higher than arterial blood pressure on this methodology are unknown. Abouleish and Taylor [43] could not correlate movement, size of pupils, or changes in blood pressure with awareness or dreams in patients given morphine (0.2 mg/kg) and diazepam (0.1 mg/kg) after cesarean section. The foregoing studies suggest that the occurrence of purposeful movement in an isolated extremity is not a good predictor of intraoperative recall.

Detection of Auditory Input, Unconscious or Implicit Memory

Although the patient may not overtly recall a stimulus or an event, auditory input can register in the brain during apparently adequate surgical anesthesia. Auditory and verbal input must be "meaningful"; however, for input to "register," frequently hypnosis or other cues may be needed to elicit recall.

Levinson [44] performed the classic study of detection of meaningful auditory input under anesthesia. Ten volunteers undergoing dental surgery were given thiopental followed by nitrous oxide and diethyl ether. Monitoring the electroencephalogram (EEG) for an irregular slow-wave high-voltage pattern allowed the anesthetist to maintain a similar depth of anesthesia in all patients. This EEG pattern was considered equivalent to moderate to deep ether anesthesia. During surgery, the anesthetist provided verbal stimulation for the patient in the form of intraoperative crisis, verbally stating that cyanosis was present and then treated appropriately. All ten patients had no spontaneous recall of the simulated intraoperative crisis. Under hypnosis, however, four patients could remember the frightening words in exact detail. An additional four remembered someone speaking to them. All eight became anxious and either emerged spontaneously from their hypnotic trance or refused to continue exploring the event. One subject had activation of the EEG pattern when the intraoperative crisis occurred, but no recall of the event.

Blacher [45] described his efforts to duplicate Levinson's experiment using noxious, threatening verbal stimuli and hypnosis for subsequent recall. He reported similar findings, but he did not complete the project, considering it too inhumane. Benign verbal stimuli did not produce significant evidence of auditory recall. He postulated that a noxious or crisis event was required. Bennett et al [46] randomly assigned 33 subjects to receive either no intraoperative verbal stimuli or a personalized but nonthreatening instruction to pull on their ear during a postoperative interview. Anesthesia was maintained with nitrous oxide, halothane, or enflurane. All subjects given the intraoperative suggestion did not recall the event. The incidence of pulling of the ear during the postoperative interview was significantly higher for patients given the intraoperative message than for those not given the message. This and other studies [47] [48] suggest that unconscious memory may occur during general anesthesia, as shown by the effect of intraoperative suggestion on postoperative

---

behavior. Other studies with similar methodology, however, demonstrate no unconscious memory. [49] [50] [51]

In a volunteer study examining subanesthetic concentrations of nitrous oxide and isoflurane on memory and responsiveness, Dwyer and colleagues [52] demonstrated that memory was decreased by increasing concentrations of each anesthetic. Both conscious and unconscious memories of the information presented during anesthetic administration were prevented by 0.45 MAC isoflurane, but they were not completely prevented by 0.6 MAC nitrous oxide. Although this volunteer study had significant methodologic rigor, it did not address the impact that surgical stimulation could have on anesthetic concentrations required to prevent conscious and unconscious memory. The stimuli in this study involved only verbal and visual input, stimuli less intense than surgical manipulation.

Little information exists regarding the postoperative consequences of intraoperative recall. Blacher [53] described a traumatic postcardiac surgery neurosis involving anxiety and irritability, repeated nightmares, preoccupation with death, and a reluctance to discuss these symptoms. He attributed this postoperative state to patients' being awake and paralyzed during open heart surgery. These patients responded favorably to assurances that their postoperative difficulties may have been caused by awareness during surgery. Ghoneim and Block [54] reviewed the consequences of intraoperative or explicit recall. The two most frequent complaints were ability to hear events during surgery and the sensation of weakness/paralysis, with some patients experiencing pain. Patients particularly recall conversations that are of a negative nature concerning themselves or their medical condition. The most frequent reported postoperative effects were sleep disturbances, dreams, nightmares, flashbacks, and daytime anxiety. For many patients, the experience of awareness may not leave prolonged aftereffects; some, however, can develop a post-traumatic stress disorder, marked by repetitive nightmares, anxiety, irritability, a preoccupation with death, and a concern with sanity. It is unclear why some patients develop a post-traumatic distress syndrome and others do not.

Although extensive literature exists regarding intraoperative recall and wakefulness, much of it is anecdotal. As a result, our understanding of the factors relevant to patient recall or wakefulness is limited. There are several reasons for this situation. The incidence of intraoperative recall is low (0.2-2%). Therefore, extremely large numbers of patients would have to be studied to identify the factors that predispose a patient to recall. Most investigators cannot or will not have the large group sizes needed for rigorous research on recall. In addition, the ethical implications of this research are significant. Ethically, one cannot subject patients to an anesthetic regimen that imposes a moderate or high risk of intraoperative recall. Finally, the measurement tools tend to be subjective. Frequently, one relies on the patient's verbal interpretation of the occurrence of intraoperative recall. The clinical implications of complex psychometric testing such as that performed by Eich et al [50] are unknown. Bonke et al [55] summarized in a textbook the multiple presentations of a symposium held in 1995 that was dedicated to memory and awareness in anesthesia. This symposium clearly demonstrated the need for postoperative recognition and appropriate management of any episode of intraoperative awareness and conscious recall in a surgical patient. Although the area of unconscious memory during anesthesia has attracted a great deal of attention and investigation, it remains unproven in clinical relevance.

Veselis and colleagues [56] used the best current clinical pharmacology methodology to characterize the pharmacodynamics of anesthetic drugs used during sedation when the patient is still awake and cooperative, but amnestic. The authors evaluated the effects of midazolam, propofol, thiopental, and fentanyl on volunteer

participants' memory of words and pictures at equi-sedative plasma concentrations. Controlling for sedation was essential in this research, because sedation itself can produce amnesia resulting from inattention to the stimuli presented for later recall. Equi-sedative concentrations were as follows: midazolam, 64.5 ng/mL; propofol, 0.7 mug/mL; thiopental, 2.9 mug/mL; and fentanyl, 0.9 ng/mL. The plasma concentrations of drugs that result in 50 percent of maximal effect (Cp_{50}) for loss of memory to words were midazolam (56 ng/mL), propofol (0.62 mug/mL), thiopental (4.5 mug/mL), and fentanyl (3.2 ng/mL). Large effects on memory were produced only by propofol and midazolam. Thiopental had mild memory effects, whereas fentanyl had none. These findings have relevance to examine the choice of drug for sedation, but they cannot be translated into an anesthetic situation with general anesthesia, surgical stimulation, and prevention of intraoperative recall. Although certain drugs used in anesthesia have very specific effects in combating recall (e.g., scopolamine, benzodiazepines), we still do not know whether routine use of these drugs will guarantee lack of intraoperative recall. [57]

PHARMACOLOGIC PRINCIPLES OF MEASURING DEPTH OF ANESTHESIA

Before discussing the clinical and electrophysiologic methods of measuring depth of anesthesia, one must understand the pharmacologic concepts governing the relationship among the dose of an anesthetic agent, its concentration in the blood biophase, and the pharmacologic response it produces. [58] Figure 29-3 depicts a situation in which a dose of drug is given to obtain a desired anesthetic response. Pharmacokinetic and pharmacodynamic concepts govern the relationship between drug dose and response. The body's interaction with the drug, through distribution and elimination processes, governs the concentration that is ultimately available at the site of action or biophase. Figure 29-3 shows that the dose-response relationship is the interaction between its pharmacokinetic and pharmacodynamic components. To quantitate a change in anesthetic dose requirement, one must be able to distinguish these components. Depth of anesthesia is a pharmacodynamic measurement.

Measurement of the pharmacologic effect of an anesthetic drug, which is the essence of measurement of depth of anesthesia, depends primarily on three factors: (1) the equilibration of the concentrations of the drug in plasma with the concentration at the drug's site of action, and with the measured drug effect; (2) the appropriate characterization of the relationship between drug concentration and drug effect; and (3) the influence of noxious stimuli. To understand

Figure 29-3 Pharmacokinetic and pharmacodynamic components of the dose-response relationship.

these issues, one must address the following questions: (1) When assessing depth of anesthesia, what methods of drug administration are important, and what site does one use to measure the concentration of the drug? (2) How does one model the relationship between concentration of drug and depth of anesthesia? (3) What pharmacokinetic and pharmacodynamic characteristics must be considered when measuring depth of anesthesia?

Equilibration of Drug Concentration and Effect

The ideal body site for measurement of a drug concentration consists of the biologic fluids immediately surrounding the site of drug action (i.e., the receptor or CNS membrane). Because such measurement is impossible in an intact organism, one must sample at sites that are less than ideal. One is left with the measurement of drug concentration in blood or plasma for intravenously administered drugs or inspired end-tidal gas concentrations for inhaled anesthetics. The most important principle in sampling for measurement of plasma or end-tidal concentrations of a drug is to obtain a representative sample of blood that is in equilibrium with the biologic fluids at the site of action or biophase. Because slow administration of a drug allows time for equilibration with the effect site, the direct measurement of drug concentrations in plasma can be related to the drug concentrations at the site of effect.

In the case of rapid intravenous administration of drugs, the disequilibrium between the concentration of the drug in plasma and the concentration at the effect site means that a plasma sample cannot be used directly to determine the relationship between concentration and response. However, once this lag has been recognized, it is possible to use mathematic modeling concepts to estimate its magnitude. [59] [60] Specifically, a first-order rate constant, K_{ec}, can be estimated from plasma concentration and effect data. This rate constant can be used to estimate the half-time of equilibration between drug concentrations in blood and at the site of effect, half-life ($t_{½}$) K_{ec}. The $t_{½}$ K_{ec} is governed by physiologic and physicochemical properties, such as the perfusion of blood at the site of action, the diffusion of blood at the site of action, the solubility of the drug at the site of action, and the time required to initiate and translate drug receptor interactions into measurable pharmacologic effect. Jacobs and Reves [61] reviewed the application of effect-site equilibration times to anesthetic drugs, specifically thiopental, and concluded that this concept is an inescapable determinant of both the temporal characteristics of acute drug effects and the appropriateness of experimental designs used to study drug effects.

The choice of arterial versus venous sites for blood sampling also can become a relevant issue when obtaining representative samples of plasma. Venous blood samples can reflect local tissue uptake of drug (i.e., muscle and skin uptake if sampled in an extremity) and are therefore less than ideal. Sampling of biologic fluids from the site of action of anesthetic drugs is not physically possible under most circumstances. Arterial blood sampling reflects the concentration of drug being delivered to all tissues and thus may be the most representative sampling site. Appropriate modeling must be undertaken to eliminate disequilibrium between arterial concentration and effect.

A similar concept also applies to potent inhaled anesthetics. Eger and Bahlman [62] showed that the concentration and partial pressure of anesthetic in arterial blood, in the alveoli, and in the brain are approximately equal after 15 minutes of administration of an anesthetic inhaled at a constant expired concentration. The easy measurement of the alveolar concentration of anesthetic in expired gas provides a convenient way of assessing the concentrations of potent inhaled anesthetics for subsequent evaluation of depth of anesthesia. The alveolar concentration of anesthetic in expired gas is in equilibration with the concentration in arterial blood, which has equilibrated with the concentration of the drug in the brain.

Characterizing the Relationship Between Drug Concentration and Effect

The ideal measurement of drug effect has several basic characteristics. A stable baseline effect that has minimal variability must occur. In addition, as the drug concentration increases, the effect should increase in a continuous fashion that is measurable with high resolution. Finally, the effect should reach some maximal plateau, after which an increase in drug concentration does not further increase effect.

Figure 29-4 (A) Sigmoidal relationship between plasma concentration of a drug (Cp) and drug effect has the following characteristics: E_{max}, the maximal drug effect; Cp_{50}, the plasma concentration of the drug that produces 50 percent of maximal effect; and the slope of the curve (or rate of change). (B) Two concentration-response curves for two anesthetics having different maximal effects.

Figure 29-4 A shows the concentration-effect relationship one expects to see under these ideal conditions. This sigmoid curve has four characteristics that can be quantitated. The baseline effect and maximal effect are the extremes of drug response. The midpoint between baseline and maximal effect is commonly referred to as the Cp_{50} . This parameter indicates the potency of the drug and the sensitivity of the individual to that drug. Finally, one can also measure the slope, or rate of change, of the curve. Although generation of the drug concentration versus effect curve is a powerful tool in assessing depth of anesthesia, it is important to understand some of the limitations of this methodology. Figure 29-4 B provides such curves for two drugs having different maximal effects. If the maximal effects differ, then the Cp_{50} values cannot be used to compare drug potency or individual sensitivity to the drugs. [63]

Many drug effects do not increase in a continuous fashion. Frequently, drug effect is an all-or-none ("quantal") response (i.e., the organism responded in some way or not at all). Therefore, when the response is quantal, only the presence or absence of a defined drug effect can be noted. However, one can construct concentration versus response curves using quantal data. Although data would include only the two extremes of "response" or "no response," it is possible to use mathematic techniques such as logistic regression, probit, or logit analysis to construct the probability of no response. [64] Figure 29-5 provides an example of the curve that results when drug concentration is plotted against the percentage probability of no drug response. The Cp_{50} now represents the midpoint of the probability curve or the concentration that has a 50 percent probability of producing no response. The drug concentrations that result in both responses and no responses define the Cp_{50} . If the drug concentrations causing both response and no response are large, then the variability of the estimated value for Cp_{50} will increase. The slope of the curve can also change. When examining drug concentration versus quantal response data, it is important to examine the raw data used to generate the fitted function, as well as the variability associated with the estimated Cp_{50} . Quantal response data are more limiting than continuous data regarding interpretation of data. A quantal response represents only a single point in a theoretic

Figure 29-5 By means of logistic regression, one can use response/no-response data ("quantal" data) to construct the probability of no response. The solid dot represents the Cp_{50} value, that is, the plasma concentration of a drug producing a 50 percent probability of no response.

continuous relationship between drug concentration and effect. [64]

Study Design, Choice and Application of Stimuli

To measure depth of anesthesia, one must apply some appropriate form of stimulus to the CNS and then observe the clinical response. This is the essence of Prys-Roberts's definition of depth of anesthesia. [16] The stimulus should have several characteristics: (1) it should be measurable and reproducible; (2) if it cannot be measured accurately, it should be supramaximal, so that variations in the degree of stimulation do not change the nature of the response; and (3) the time between initiation of stimulation and the occurrence of peak response must be known reasonably well. Ideally, the response to stimulation should occur rapidly. Given the usually finite period of time between the initiation of the stimulation and the occurrence of the clinical response, it is critically

important for the concentration of anesthetic drug to be relatively stable during this time. If the concentrations fluctuate markedly, meaningful information cannot be gathered.

Good methodology in the assessment of depth of anesthesia attempts to achieve pharmacokinetic equilibrium in which drug concentrations in plasma do not change rapidly. This condition is desired because drug concentrations would then be relatively constant. This state of affairs "freezes" the pharmacokinetic component. The appropriate stimulus can then be applied, and a finite period of time may be allowed to measure other drug responses. The ideal situation would allow the effective separation of pharmacokinetic and pharmacodynamic components of the doseresponse relationship.

SPECIFIC DRUGS AND CLINICAL SITUATIONS

This section describes the scientific approaches used for potent inhalational anesthetics, opioids, and intravenously administered hypnotics used to induce anesthesia. Following the scientific approaches, a discussion of more subjective approaches relevant to the clinical practice of anesthesia is presented.

Clinical Measures of Depth of Anesthesia

The clinical measures of depth of anesthesia to be discussed derive directly from the patient. The measures of anesthetic effect represent normal physiologic responses that can be quantitated and are used in clinical practice. Electrophysiologic techniques are discussed in a later section.

Inhaled Anesthetics

Movement Response and the MAC Concept

The purposeful movement of a body part in response to noxious perioperative stimuli is one of the most useful clinical signs of depth of anesthesia. Using this movement to quantitate depth of anesthesia induced by potent inhaled anesthetics, Eger and Merkel and their colleagues [17] [65] defined MAC as the minimum alveolar concentration of inhaled anesthetic required to prevent 50 percent of subjects from responding to a painful stimulus with "gross purposeful movement." Readers are referred to the excellent review articles that document the development of the MAC concept and its many applications in anesthesia. [66] [67] The MAC concept has four basic components: (1) an all-or-none (quantal) movement response must occur after applications of supramaximal noxious stimulus; (2) end-tidal concentrations of anesthetic in the alveoli, considered an equilibrated sample site, are used as an indication of the concentration of anesthetic in the brain; (3) appropriate mathematic quantitation of the relationship between the alveolar concentration of anesthetic and the quantal response is used to estimate MAC; and (4) MAC can be quantitated for altered physiologic and pharmacologic states.

For determination of MAC in humans, the standard noxious stimulus has been the initial surgical skin incision. [17] Skin incision represents a reproducible form of supramaximal surgical stimulation. There has been no systematic examination of other perioperative surgical stimuli (e.g., peritoneal traction) representing more profound surgical manipulation than skin incision or endotracheal intubation. For determination of MAC in animals, the standard stimulus has been application of a surgical clamp to the base of the tail. After examining other noxious stimuli in dogs, Eger et al [17] concluded that tail clamping represented the most noxious stimulation that was clinically reproducible and not excessively traumatic. Response to stimulation must entail a positive, gross, purposeful muscular movement, usually of the head or extremities. Twisting or jerking of the head is considered a movement response, but twitching or grimacing is not. Coughing, rigidity, swallowing, and chewing are not considered positive movement responses, nor is movement of an incised extremity.

The MAC concept has been expanded by evaluating other clinical end points or stimuli. Stoelting et al [68] determined the MAC of anesthetic that would allow opening of the eyes on verbal command during emergence from anesthesia ("MAC awake"). This stimulation is less intense than surgical skin incision, and response occurs at lower concentrations of anesthetic than movement to skin incision. Yakaitis et al [69] determined the MAC of anesthetic that would inhibit movement and coughing during endotracheal intubation ("MAC intubation"). This event is significantly more stimulating than skin incision; therefore, elimination of the subsequent response requires higher concentrations of anesthetic than does elimination of the movement response. Finally, Roizen et al [70] investigated the MAC of anesthetic necessary to prevent adrenergic response to skin incision ("MAC BAR"), as measured by the concentration of catecholamine in venous blood. When one examines the values for (1) MAC awake, (2) MAC skin incision, (3) MAC intubation, and (4) MAC BAR, one sees a family of concentrationresponse curves, the separation of which depends on the noxious stimuli used to elicit the response.

Zbinden and colleagues [71] undertook a comprehensive examination of the effects of different noxious stimuli on the purposeful movement response with isoflurane. Twenty-six healthy surgical patients were administered isoflurane only with adequate inspired/end-tidal equilibration. Multiple noxious stimuli were applied at varying end-tidal isoflurane concentrations. From the resulting data, the authors were able to define a family of concentration versus response curves for different noxious stimuli, as displayed in Figure 29-6 (Figure Not Available) . The end-tidal isoflurane concentrations that resulted in a 50 percent probability of no movement response for different stimuli were as follows: verbal responsiveness, 0.37 percent; trapezius muscle squeeze, 0.84 percent; 50-Hz electrical tetanus, 1.03 percent; laryngoscopy, 1.0 percent; skin incision, 1.16 percent; and laryngoscopy with intubation, 1.76 percent. This study demonstrates how varying stimuli require different isoflurane concentrations to prevent

a clinical response and can be used to define isoflurane anesthetic depth.

A second component of the MAC concept involves the use of the alveolar concentration of an anesthetic as an indication of drug concentration. Because the concentration of gas is defined as a percentage of one atmosphere, it is independent of barometric pressure and elevation. Additionally, partial pressures of inhaled anesthetics at equilibrium should be similar in all body parts, such as alveolus, blood, and brain. Thus, the measured end-tidal concentration of anesthetic (representative of the alveolar concentration) is in direct proportion to the underlying concentration in the brain. Because cerebral blood perfusion is large, it is possible to achieve an equilibration among end-tidal, alveolar, arterial, and brain anesthetic partial pressures within 15 minutes of exposure to a constant end-tidal anesthetic concentration.

Eger and Bahlman [62] quantitated the difference between arterial concentrations of halothane and the end-tidal expired concentrations of halothane. If the difference between the inspired and end-tidal anesthetic concentrations was less than 10 percent, the difference between the end-tidal and arterial concentrations would be minimal. In the early literature on MAC, the end-tidal concentration of anesthetic was frequently called the "anesthetic dose," and the MAC relationship was referred to as a "dose-response curve." However, Waud and Waud [63] pointed out that this terminology was incorrect, because the MAC concept really describes a concentration versus response relationship. These investigators also believed that a major contribution of the MAC concept was to turn attention from the inspired concentration of an anesthetic to the equilibrated alveolar concentration of the anesthetic, a more accurate and precise reflection of the concentration of the drug in the brain.

A third component of the MAC concept involves the use of appropriate mathematic approaches to quantitate the relationship between dose and response. The original MAC concept of Eger and colleagues [17] used a "bracketing approach" in humans and animals. In an individual patient, a fixed end-tidal concentration of anesthetic was achieved, and the response to a single skin incision was observed. Depending on the patient's response or lack of response, the next patient received a higher or

lower concentration. A single measurement was obtained per patient. Patients were studied over a range of end-tidal concentrations. They were placed in groups of four; the subject having the lowest end-tidal (alveolar) concentration of anesthetic was the first to be studied. For each group, the percentage of patients moving in response to stimulation was plotted against the average end-tidal concentration for that group. A visual line of "best fit" through these points yielded the concentration at which 50 percent of patients would respond (i.e., the MAC). Figure 29-7 (Figure Not Available) is an example of this analysis, using the concentration versus response data gathered for halothane alone, for halothane with morphine premedication, and for halothane with 70 percent nitrous oxide. Both morphine premedication and 70 percent nitrous oxide decreased the MAC value for halothane. [72]

In animal studies, it was possible to manipulate the end-tidal concentration of anesthetic and to apply the tail-clamp stimuli on multiple occasions. A MAC value can be obtained for each animal by sequentially increasing or decreasing the end-tidal concentrations to bracket the value between movement and no movement. de Jong and Eger [73] extended the analysis of MAC data by using more appropriate mathematic/statistical techniques to quantitate the relationship between alveolar anesthetic concentration and response/no response data. A nonlinear logistic regression analysis was used to estimate the probability of no movement at any given end-tidal concentration. [64] The logistic regression analysis produced values for MAC comparable to those produced by the bracketing technique. Logistic regression allowed estimation of the variance associated with the estimate of MAC. It was also possible to extrapolate the

Figure 29-7 (Figure Not Available) Minimal alveolar concentration (MAC) necessary to prevent movement in 50 percent of subjects subjected to a noxious stimulus (MAC) was determined for three combinations of halothane: (1) with oxygen only; (2) with oxygen and a morphine premedication (0.15 mg/kg IM), and (3) with 70 percent nitrous oxide (N_2O). The anesthetic requirement for halothane is greatly decreased by nitrous oxide, and less so by premedication with nitrous oxide. *(Modified from Saidman and Eger [72])*

probability of movement from 50 percent to any given probability within the curve. Thus evolved the concept of end-tidal concentration of anesthetic that inhibited response in 95 percent of patients. Waud and Waud [63] argued that MAC defines only one point on a hypothetic curve that plots the concentration of anesthetic against one index of depth of anesthesia. Because there are no other experimentally defined points on this curve, one cannot be certain that such curves are indeed parallel for different anesthetics or stimuli. This lack of certainty theoretically limits one's ability to infer that multiples or fractions of MAC represent equal levels of CNS depression for different anesthetics. To address this issue properly and to define the complete curve for anesthetic concentration versus response adequately, one would need a continuous measure of anesthetic effect. In the absence of such a clinical measure, indirect reasoning must be applied to the question of the soundness of adding MAC multiples or of combining MAC values for different anesthetics. Investigators have examined the relationship between MAC skin incision and a more noxious stimulus, MAC intubation [69] or a less noxious stimulus, MAC awake. [68] When different inhaled anesthetics are compared, the ratio of MAC skin incision to MAC intubation or MAC awake is relatively constant. When the possible relationship between synergism and antagonism of four different potent inhaled anesthetics was examined relative to nitrous oxide, no evidence of a relationship could be demonstrated. [74] Thus, there is only indirect evidence that MAC values can be added.

A fourth feature of MAC is that it has served as a sensitive tool to determine the interaction of other anesthetics and CNS drugs with the inhaled anesthetics. Other drugs used in anesthesia decrease anesthetic requirement, as measured by a reduction in MAC. In addition, numerous altered physiologic states (e.g., aging) change the requirements for inhaled anesthetics. Several review articles have described the many studies applying the MAC concept to the clinical practice and science of anesthesia. [66] [67] Table 29-1 summarizes the results of these studies regarding the factors that affect the MAC.

TABLE 29-1 -- Factors That Affect Minimum Alveolar Concentration

EFFECT ON MAC	FACTORS (STUDY SUBJECTS)
Decrease	Hypothermia (animals)
	Severe hypotension (animals)
	Age (humans)
	Narcotics, ketamine (humans, animals)
	Benzodiazepines, barbiturates (humans, animals)

	Acute administration of dextroamphetamine (animals)
No effect	Duration of anesthesia (humans, animals)
	Sex (humans, animals)
	Metabolic acid-base status (animals)
	Hypercarbia and hypocarbia (humans, animals)
	Isovolemic anemia (animals)
	Hypertension (animals)

MAC, minimum alveolar concentration of an anesthetic required to abolish movement in 50 percent of patients, in response to a noxious stimulus

Data from Quasha et al [66] and Cullen [67]

Much of the previous research on MAC assumed that the lack of movement response from inhaled anesthetics was due to the anesthetic effects on the central, cortical brain tissues. Rampil et al [75] suggested that the spinal cord may represent a major site of action for inhaled anesthetics. Their studies demonstrated that the MAC of isoflurane in rodents was identical in value for intact animals to that of rodents who have been decorticate or decerebrate, a finding suggesting that the main ability of inhaled anesthetics in

preventing purposeful movement occurs at the spinal cord level. [75] [76] Antognini and Schwartz [77] also drew the same conclusions from experiments whereby they determined MAC in the goat by having the animal's brain isolated from the remainder of the body using a complex cardiopulmonary bypass procedure. These investigators demonstrated that the MAC value for the goat was approximately twice as large when the brain only was exposed to isoflurane relative to when both the brain and spinal cord were exposed to the anesthetic. These series of studies strongly suggest that the response to purposeful movement is achieved by the inhaled anesthetic at both cortical and subcortical anatomic levels.

Other Clinical Responses

The movement response to noxious stimuli is not commonly used in clinical practice. The extensive use of muscle relaxants makes interpretation of movement both difficult and imprecise in most clinical circumstances. In certain clinical situations, movement of the patient would interfere with the surgical procedure. Therefore, other signs have been investigated as possible clinical measures of depth of anesthesia: the rate and volume of ventilation in spontaneously breathing subjects, eye movement, the diameter and reactivity of pupils to light, heart rate, arterial blood pressure, and autonomic signs such as sweating.

It has not been possible to use these clinical signs to generate uniform measures of depth of anesthesia for inhaled anesthetics. Although some clinical signs do correlate with depth of anesthesia for certain inhaled anesthetics, the same cannot be said for other inhaled anesthetics. In a study of clinical signs and inhaled anesthetics, Cullen et al [78] examined the relationship between alveolar concentration of inhaled anesthetics and clinical signs of depth of anesthesia in both volunteers and surgical patients. Clinical signs were found to change in usefulness over time. For example, during the first hour of halothane anesthesia, decreasing mean arterial blood pressure was the only useful clinical sign of depth of anesthesia; that is, increasing concentrations of halothane caused a progressive decrease in arterial blood pressure, whereas heart rate remained constant. Moreover, the pupils were constricted and nonreactive, and there was no eye movement or tearing. However, after 5 hours of halothane anesthesia, further increases in concentration no longer caused a decrease in arterial blood pressure. This previously useful sign of depth of anesthesia had been eliminated. For cyclopropane, diethyl ether, and fluroxene, only pupillary dilation and reduced pupillary activity correlated with changes in the concentration of anesthetic. Mean arterial blood pressure did not change as the concentration of anesthetic increased.

Cullen and coworkers [78] also found that skin incision modified most clinical signs of drug effect. For example, during anesthesia with halothane and oxygen, heart rate, respiratory tidal volume, and pupil diameter increased after skin incision. Systolic and diastolic blood pressures and respiratory rate did not change. After 12 minutes of surgical incision and manipulation (and unchanged concentrations of halothane), heart rate, tidal volume, and pupil diameter decreased to preincision levels. The clinical response during isoflurane/oxygen anesthesia was different. After skin incision, systolic and diastolic blood pressures and heart rate increased. The pupils dilated in some subjects. No patient moved in response to incision. In general, the increases in blood pressure and heart rate persisted throughout the first hour of surgery, even though higher concentrations of isoflurane were being given.

Zbinden and colleagues [79] systematically examined the interaction of isoflurane concentrations with the hemodynamic response to different noxious stimuli. In 26 healthy surgical patients receiving different equilibrated end-tidal concentrations of isoflurane, the following noxious stimuli were applied, several of them on multiple occasions: trapezius muscle squeeze, 50-Hz electrical tetanus, laryngoscopy, laryngoscopy with intubation, and skin incision. With the continuous recording of intra-arterial hemodynamics, acute increases of heart rate and systolic blood pressure were recorded and were related to the isoflurane concentration and presence or absence of purposeful movement. Table 29-2 (Table Not Available) presents the absolute increase of systolic blood pressure and heart rate at the isoflurane end-tidal concentration that had a 50 percent probability of no purposeful movement for that specific stimulus. Different noxious stimuli result in different degrees of hemodynamic response. There is a relative rank order of the degree of hemodynamic response, with laryngoscopy and intubation being the most intense stimuli. Multiple regression analysis demonstrated that the type of stimulation had the highest influence on the blood pressure increase, with the isoflurane concentration the least important. Figure 29-8 (Figure Not Available) presents the baseline systolic blood pressure and subsequent increase in systolic

TABLE 29-2 -- Hemodynamic Response to Defined Noxious Stimuli Under Isoflurane Anesthesia

pressure at a measured isoflurane concentration for the subjects receiving a skin incision. The shaded areas represent the linear regression relationship of isoflurane concentration versus prestimulus and poststimulus systolic blood pressure. Increasing isoflurane concentration did not prevent the increase of systolic blood pressure, even at very high end-tidal concentrations. Rather, increasing isoflurane concentration only decreased the prestimulation systolic pressure such that the noxious stimuli returned systolic pressure closer to the normal, awake values. Similar results were found with the other noxious stimuli on both heart rate and systolic blood pressure response, with the degree of hemodynamic response determined by the nature of the noxious stimuli.

The clinical implications of these data relative to judging anesthetic depth from hemodynamic response for inhalational anesthetics are significant. When used as a sole agent, even at high concentrations, isoflurane is unable to suppress hemodynamic responses to noxious stimuli. Rather, the hemodynamic control seen with high isoflurane concentrations occurs from a decrease of the prestimulation hemodynamic baseline. Thus, although hemodynamic responses are the most commonly used clinical measures to judge inhalational anesthetic depth of anesthesia, the scientific basis for this certainly is not obvious. In clinical practice, additional anesthetic drugs are commonly used with inhalational anesthetics. Daniel et al [80] examined how fentanyl (0-3 mug/kg) and 60 percent nitrous oxide alter the heart rate, mean arterial blood pressure, and catecholamine response (components of MAC BAR) during desflurane and isoflurane anesthesia. Fentanyl, 1.5 mug/kg, reduced MAC BAR for desflurane from 1.3 to 0.4 MAC and for isoflurane from 1.3 to 0.55 MAC. Increasing the fentanyl dose to 3 mug/kg did not cause further change of the MAC BAR values for both inhalational anesthetics. This study suggests that the addition of analgesic components, such as nitrous oxide and fentanyl, can prevent the sympathetic stimulation and hemodynamic responses seen with noxious surgical stimuli when inhalational anesthetics are used.

Eger's [81] review of the subjective interpretation of clinical signs of depth of anesthesia found increasing pupil diameter to be of limited value during halothane, enflurane, isoflurane, or methoxyflurane anesthesia. Premedication with opioids eliminates the usefulness of this clinical end point. Pupillary response to light is rapid and brisk with small amounts of the inhaled anesthetic; however, the response becomes sluggish, and the pupils do not respond at deeper levels. Eye movements may suggest a light level of anesthesia. Eyelash and corneal reflexes disappear once a surgical level of anesthesia has been achieved and normally do not return at useful surgical depths of anesthesia.

Decreasing arterial blood pressure is the most commonly used sign of increasing depth of anesthesia for halothane or enflurane anesthesia. However, many factors modify the balance between the increase in autonomic cardiovascular activity caused by surgical stimulation and the depression in cardiovascular function caused by potent inhaled anesthetics. These factors include blood volume, cardiac contractility, sympathetic tone, age, and acid-base status. Surgical stimulation also increases blood pressure to a variable degree. Change in blood pressure is also not a useful clinical sign for inhaled anesthetics that cause sympathetic stimulation, such as cyclopropane, diethyl ether, and fluroxene. Pulse rate is a relatively poor sign, because it can be influenced by many factors. Pulse rate is modulated by baroreceptor

function, which is sensitive to arterial pressure and its changes. Some anesthetics, such as enflurane and isoflurane, can actually increase pulse rate independent of the surgical stimulation or changes in blood pressure. Such an increase could lead to incorrect decisions regarding dosage.

All inhaled anesthetics depress ventilation and can ultimately cause apnea. This clinical sign is useful only during spontaneous ventilation. Inhaled anesthetics decrease tidal volume in a dose-related fashion, whereas respiratory rate increases in an amount that may sustain minute ventilation (but not necessarily alveolar minute ventilation) at normal levels. Surgical stimulation modifies respiratory depression, frequently returning alveolar minute ventilation to normal values. At light levels of anesthesia with inhaled anesthetics, adverse respiratory events such as breath-holding, coughing, and laryngospasm may occur. These respiratory events are very sensitive to the nature and degree of noxious stimulation. Normally, deeper levels of anesthesia eliminate these reflex responses.

For potent inhaled anesthetics, the MAC concept has provided clinical anesthesia with an abundant body of knowledge regarding factors that affect depth of

anesthesia and the requirement for anesthetic agents. It is unfortunate, however, that the movement response is not used extensively in clinical practice. The many clinical measures that have poor or unpredictable utility when evaluated scientifically (blood pressure or pulse) have become the mainstay of clinical assessment of depth of anesthesia in routine clinical practice. [78]

Opioids

Opioid analgesics are used extensively for premedication, as a supplement to regional and general anesthesia, as the primary anesthetic agent, and as an analgesic for postoperative pain (Ch. 10) . The narcosis produced by these drugs through specific receptor systems within the CNS decreases autonomic, endocrine, and somatic responses to noxious stimulation. However, efficient use of opioids that maximizes benefit and limits toxicity can be challenging. The difficulty arises when one attempts to monitor opioid drug effects rapidly and carefully during their intraoperative application.

Opioids as Complete Anesthetics

In 1947, Neff et al [82] used meperidine as an intravenous supplement to nitrous oxide/oxygen anesthesia in what is now known as a "balanced anesthesia" technique. The later use of opioids as complete anesthetics coincided with the development of cardiac surgery and intensive care during the early 1960s. Providing anesthesia for patients with severe valvular or congenital heart disease without causing cardiovascular collapse was problematic prior to the use of the opiates. These early cardiac surgery patients were extremely ill and had little or no circulatory reserve. During the late 1960s, Lowenstein et al [83] noted the hemodynamic stability of patients undergoing mechanical ventilation who were given frequently large doses of intravenous morphine to suppress respiration in the intensive care units. This observation encouraged Lowenstein and coworkers to become the first to administer morphine (0.5-3.0 mg/kg) as a complete anesthetic. The resulting cardiovascular stability in acutely ill patients with acquired valvular heart disease was impressive. As cardiac surgery advanced in methodology, patients with ischemic heart disease began to undergo surgical anesthesia. Unfortunately, morphine anesthesia was less satisfactory for these patients, who developed hypertension, tachycardia, and awareness during surgery, in contrast to those patients with valvular heart disease. [83]

In 1978, Stanley and Webster [84] introduced the concept of high-dose fentanyl for cardiac anesthesia. This technique minimized the undesirable effects of morphine on induction (hypotension) and provided better hemodynamic stability in patients with good ventricular function and ischemic heart disease. As clinical experience with fentanyl increased, however, investigators found that even increasingly large doses of fentanyl could not always produce a complete anesthetic state in all subjects. [85] This discovery raised the important issue of whether opioids are complete anesthetics.

Human and animal studies show that opioids are not complete anesthetics. Wynands et al [86] used moderate to large doses of fentanyl (50-150 mug/mL) and measured plasma concentrations at defined surgical stimuli (intubation, skin incision, sternotomy, aortic root dissection) in patients with good ventricular function who were undergoing coronary surgery. Figure 29-9 (Figure Not Available) shows the relationship among drug concentrations, stimulation, and hemodynamic response. In approximately 20 percent of patients, extremely high plasma concentrations of fentanyl (15 ng/mL) did not eliminate hemodynamic responses, defined as a 20 percent increase in systolic blood pressure. These results have been confirmed by Hynynen and colleagues [87] and Philbin et al. [88]

The investigations conducted by Murphy and Hug [89] in measuring depth of opioid anesthesia in animals (dogs) also address the issue of whether opioids are complete anesthetics. These investigators examined the ability of fentanyl to decrease enflurane MAC. They first anesthetized the dog with enflurane and determined MAC. Several infusions of fentanyl at progressively higher rates were used to obtain a constant steady-state plasma concentration of fentanyl in each animal. After each increase in infusion rate, enflurane MAC was determined again. Measurement of opioid concentrations in blood samples ensured that several different steady-state plasma concentrations of fentanyl were obtained in each animal. Murphy and Hug found that even high plasma concentrations of fentanyl (20 ng/mL) did not decrease enflurane MAC beyond 60 to 70 percent of its initial value (Fig. 29-10) (Figure Not Available) . That is, there was a ceiling to the enflurane-sparing effect. Morphine, sufentanil, and alfentanil also decrease enflurane MAC and have a similar ceiling effect in dogs. [90] [91] [92]

Stimulation by tail clamping in dogs anesthetized with sufentanil and enflurane produces nearly equivalent increases in heart rate and blood pressure, whether the animals move or not. [90] This observation suggests that hemodynamic and somatic signs are not equally good indicators of depth of anesthesia. When the agonist-antagonist analgesics butorphanol and nalbuphine were examined using this model, enflurane MAC could only be decreased by 11 and 8 percent, respectively. [92] Therefore, the agonist-antagonist analgesics have markedly lower maximal anesthetic effects

Figure 29-9 (Figure Not Available) Plasma concentration of fentanyl at the time of certain clinical stimuli, along with the presence or absence of hypertension. During sternotomy and aortic dissection, even high plasma concentrations of fentanyl (>15 ng/mL) do not always prevent hypertension. *(Modified from Wynands et al [86])*

Figure 29-10 (Figure Not Available) Percentage reduction in enflurane minimum alveolar concentration (MAC) as a function of the logarithm of the plasma concentrations of fentanyl. than the pure opioid agonists. Even massive doses of fentanyl (3,000 mug/kg with no use of supplemental analgesics) produce a very temporary and transient anesthetic state, as judged by absence of response to tail clamping. [93]

Ardnt et al [94] [95] attempted to develop a trained, unanesthetized, spontaneously breathing dog model to examine the relationship between plasma concentration of fentanyl or alfentanil and clinical signs of depth of anesthesia. They measured hemodynamic and movement responses at low opioid doses that resulted in moderate ventilatory depression. Interpretation of their data is confounded by their use of increasingly large intravenous administered bolus doses of each opioid. Thus, all plasma concentrations of opioids were measured in a non-steady-state environment, and an unknown degree of disequilibrium existed between drug concentration and clinical responses. However, their data appear to confirm the observation of Hug and colleagues that the plasma concentration of fentanyl and alfentanil at which maximal anesthetic effects occur in dogs are very similar to those for humans. McEwan and colleagues [96] undertook similar studies in humans, thus characterizing the decrease of isoflurane MAC with varying constant fentanyl plasma concentrations achieved with a computer-driven infusion pump. Movement response to initial skin incision was examined relative to end-tidal isoflurane concentrations. McEwan and coworkers [96] found very similar results in humans to those observed by Hug's group in dogs (see earlier). Isoflurane MAC decreased 39 percent at a steady-state fentanyl plasma concentration of 1 ng/mL and 63 percent at a fentanyl plasma concentration of 3 ng/mL. Increasing fentanyl plasma concentrations to more than 3 ng/mL produced a minimal further reduction of isoflurane MAC. The maximal MAC reduction was 82 percent at a steady-state fentanyl plasma concentration of 10.6 ng/mL. Similar MAC reduction results have been obtained with other inhaled

anesthetics (desflurane, sevoflurane) and other opiates (alfentamil, sufentanil, remifentanil). [97] [98]

As mentioned earlier, different investigations show that high-dose opioid anesthesia does not induce complete anesthesia. It has not been possible to identify why or which 30 to 40 percent of patients undergoing coronary artery bypass will have a hemodynamic response to noxious stimuli during even high plasma concentrations of fentanyl. Therefore, it has not been possible to use autonomic responses to noxious stimuli as reliable and predictable measures of depth of anesthesia. If a patient shows clinical signs of responsiveness, the administration of additional opioid may or may not result in hemodynamic control. If it does not, the extra opioid will certainly prolong postoperative respiratory depression and may delay emergence from anesthesia. Thus, no consistent and reliable clinical signs exist that can be used to quantitate depth of anesthesia induced by opioids. Current clinical practice supplements high-dose opioids with amnestic drugs (benzodiazepines) or low concentrations of potent inhaled anesthetics. Profound hypertensive or tachycardic responses are treated with vasodilating and cardiovascular depressant drugs. Empirically, additional opioid may be given, and, if no response occurs, vasodilating drugs are administered.

Whereas opioids are used alone for cardiovascular procedures, these drugs are usually accompanied by nitrous oxide for surgical procedures involving no postoperative mechanical ventilation. By itself, 70 percent nitrous oxide provides approximately 0.7 MAC anesthesia. Nitrous oxide also interacts profoundly with opioids, markedly decreasing the amount of opioid necessary to provide surgical anesthesia. When alfentanil is used with oxygen, plasma concentrations of approximately 1,500 to 2,000 ng/mL are needed to suppress hemodynamic response in most patients. [99] The addition of 70 percent nitrous oxide decreases this

plasma concentration to approximately 300 ng/mL. [100] A similar degree of potentiation occurs with fentanyl.

Clinical Signs of Inadequate Anesthesia and Plasma Concentration of Opioids

Ausems and colleagues [100] used pharmacodynamic modeling concepts to relate clinical signs of inadequate opioid anesthesia to plasma concentrations of the drug. In their study paradigm, patients were premedicated with a benzodiazepine, anesthesia was induced with alfentanil (150 mug/kg), and the trachea was intubated with the aid of succinylcholine. Anesthesia was maintained with 70 percent nitrous oxide and a variable-rate infusion of alfentanil. The infusion was titrated to the following clinical end points: (1) increased systemic arterial blood pressure greater than 15 mm Hg higher than the patient's normal value; (2) heart rate exceeding 90 beats/min in the absence of hypovolemia; (3) somatic responses, such as body movements (minimal muscle paralysis allowed physical movement), swallowing, coughing, grimacing, or opening of the eyes; and (4) autonomic signs of inadequate anesthesia (e.g., lacrimation, flushing, or sweating). If any clinical signs occurred, the infusion rate was increased 25 to 50 mug/kg/h, and a small bolus dose (7 mug/kg) was given. Good hemodynamic control was possible in all subjects. If no clinical signs occurred, however, the infusion rate was decreased at regular 15-minute intervals.

Table 29-3 shows the incidence of response to intraoperative noxious stimuli in 37 patients; 3 different types of surgical procedures are represented. Although hypertension was the most common clinical response, the other 3 clinical measures occurred a significant number of times. The authors could not predict which patients would have somatic responses, tachycardia, or hypertension. Measurement of plasma concentrations made it possible to describe the concentration versus response relationship for different perioperative stimuli. Figure 29-11 (Figure Not Available) A shows the relationship between the plasma concentration of alfentanil and response/no response for 3 clinical end points: intubation,

TABLE 29-3 -- Response of 37 Patients to Noxious Intraoperative Stimulation During Anesthesia With Alfentanil and Nitrous Oxide [a]

	SURGICAL PROCEDURE		
	BREAST	***LOWER ABDOMINAL***	***UPPER ABDOMINAL***

Data from Ausems et al [100]

[a] Data are presented as the median number of response episodes per patient. Numbers in parentheses represent the range of number of episodes among the patients in each group. Hypertension is an increase in systemic arterial systolic blood pressure of more than 15 mm Hg above the patient's normal value; tachycardia is a heart rate higher than 90 beats/min in the absence of hypovolemia.

Figure 29-11 (Figure Not Available) (A) Relationship between the plasma concentration of alfentanil and response/no response at three specific events of short duration. The quantal data are characterized with logistic regression in the lower panel. -, ±SE for the Cp_{50}, which is the plasma concentration of alfentanil producing a 50 percent probability of no response. (B) Plasma concentration of alfentanil versus the probability of no response for each of 34 patients during the intra-abdominal phase of lower abdominal surgery. Dots represent the Cp_{50} values, and the heavy dark line represents the average response of the 34 patients. *(A from Ausems et al [100] ; B from Ausems et al [101])*

skin incision, and skin closure. Regarding elimination of response to noxious stimulation, intubation required significantly higher plasma concentrations of alfentanil than skin incision, and skin closure required significantly lower concentrations than skin incision.

Use of logistic regression made it possible to define Cp_{50} values for these clinical events (Table 29-4) . The plasma concentrations of alfentanil were varied in the individual subject during surgery to obtain multiple response/no response data points, after which a curve plotting plasma concentration against response was constructed for each subject [101] (Fig. 29-11 (Figure Not Available) B). Especially noteworthy are the steep slope of the individual curves and the moderate pharmacodynamic variability among individuals. Table 29-3 demonstrates that upper abdominal surgery required significantly higher plasma concentrations of alfentanil than lower abdominal or breast surgery. The foregoing pharmacodynamic modeling concept has been used to examine the alfentanil dose requirement, pharmacokinetics, and pharmacodynamics in heavy alcohol consumption. Lemmens et al [102] showed that moderate consumers of alcohol (20-40 g/d) have an increased requirement for alfentanil because of decreased CNS sensitivity to alfentanil. The Cp_{50} of alfentanil in patients with alcohol consumption was 522 ± 104 ng/mL compared with 208 ± 26 ng/mL in a control group. This finding suggests that there may be a cross-tolerance between opiates and ethanol. Lemmens et al [103] also defined the role of plasma protein binding in determining the clinical effects of alfentanil anesthesia. By examining the alfentanil plasma concentration versus clinical response relationship both total bound and free, and the degree of alfentanil plasma protein binding, they determined there was a significant negative correlation ($r = .67$) between Cp_{50} (total drug) and the free fraction of alfentanil. These data suggest that 45 percent of the variability in alfentanil CNS response, as estimated by the Cp_{50} , could be explained by variability in the plasma protein binding of alfentanil.

Remifentanil is a newer opioid, related to the fentanyl family of short-acting, 4-aniliopiperidine derivatives; however, it is unique in having ester linkages that are susceptible to hydrolysis by nonspecific blood and tissue esterases, resulting in very rapid metabolism. Egan and colleagues [104] described the comparative clinical pharmacology of remifentanil to alfentanil. Both opioids have a similar, small volume of distribution, because of limited tissue solubility; however, remifentanil has a significantly higher metabolic clearance, 2.9 L/min versus 0.36 L/min for alfentanil. Remifenanil has

TABLE 29-4 -- Cp_{50} Values for Perioperative Events and Intraoperative Manipulation Associated With Three Types of Surgical Procedures During Alfentanil Anesthesia

EVENT	CP_{50} (ng/mL)
Single events	
Intubation	475 ± 28 [a]
Skin incision	279 ± 20
Skin closure	150 ± 23
Spontaneous ventilation	233 ± 13
Intraoperative manipulation	
Breast surgery ($n = 12$)	270 ± 63 [b]
Lower abdominal ($n = 14$)	309 ± 44
Upper abdominal ($n = 11$)	412 ± 135

Cp_{50} , the plasma concentration of a drug producing a 50 percent chance of suppressing response to a certain stimulus

Data from Ausems et al [101]

[b] Values are presented as mean ± SD

a similar rate of blood-brain equilibration, with a $t_{½}$ K_{e0} value of 1.6 minutes versus 0.96 minute for alfentanil. Remifentanil, however, is significantly more potent than alfentanil, with an EEG Cp_{50} value of 19.9 ng/mL versus 375.9 ng/mL for alfentanil. Minto and colleagues [105] [106] quantitated the population pharmacokinetics and dynamics of this opioid, using simulation techniques to develop dosing guidelines. Drover and colleagues [107] applied the opioid anesthetic depth concepts developed by Ausems et al [100] to define therapeutic plasma concentrations of remifentanil in surgical patients.

The rapid blood-brain equilibration of alfentanil and remifentanil means that a given plasma concentration has a close relation to the CNS concentration, hence to drug effect. [108] Drugs having a slower rate of blood-brain equilibration (e.g., fentanyl, sufentanil, morphine) would be less amenable to the type of pharmacodynamic analysis of the plasma concentration versus clinical effect relationship used by Ausems and coworkers. [100] Glass and colleagues [109] applied the fundamental concepts proposed by Ausems et al to fentanyl, using a computer-driven infusion pump to obtain constant fentanyl plasma concentrations from induction of anesthesia to skin incision. Because of the long equilibration delay between plasma and the effect site in the CNS ($t_{½}$ K_{e0} of 6.4 minutes), a significant period of time was allowed between establishing the constant plasma concentration and application of the noxious stimuli. Only fentanyl and 70 percent nitrous oxide were used, no premedication or induction sedative was given, and fentanyl plasma concentrations were also measured. Following skin incision, patients were observed for purposeful somatic movement. The fentanyl plasma concentration that had a 50 percent probability of no movement (Cp_{50}), with 70 percent nitrous oxide, was 3.26 ng/mL.

The approach to opioid administration presented by Ausems and colleagues [100] provides useful insight into the clinical assessment of depth of anesthesia. Overdosage with opioids cannot be judged intraoperatively. Only at the end of anesthesia, when spontaneous ventilation should occur, does one know whether administration of opioids has been excessive. To prevent overdosage, Ausems and coworkers [100] proposed using a viable rate of infusion in which one titrates plasma concentrations to clinical effect to find the lowest possible effective rate of opioid administration. To achieve this end point, one must look for clinical signs of inadequate anesthesia. Once the infusion rate just causing inadequate anesthesia has been determined, one increases the rate slightly, thus providing adequate anesthesia. The steep slope of the concentration versus response curve for alfentanil (see Fig. 29-11) (Figure Not Available) demonstrates that a small increase in the plasma concentration of the drug rapidly converts inadequate anesthesia (100% probability of response to stimuli) to adequate anesthesia. Because of the moderate variability in the pharmacokinetics of alfentanil, this process of titrating dose (infusion rate) against clinical effect and pharmacodynamics is necessary for each patient. This concept is most applicable to alfentanil, which has rapid blood-brain equilibration, [108] and it is ideal with remifentanil, which has extremely rapid pharmacokinetics along with rapid blood-brain equilibration. [104] Intermittent intravenous bolus administration of opioids is not as efficient as variable-rate infusion when titrating plasma concentrations of opioids to clinical effects. [101]

Intravenously Administered (Nonopioid) Anesthetics

Traditionally, these intravenous anesthetics were used only for induction of anesthesia as a single intravenous bolus. Only with the clinical introduction of propofol have these agents been infused for maintenance of anesthesia, in which assessment of depth of anesthesia becomes more relevant.

Assessing Depth During Induction of Anesthesia

Induction of anesthesia consists of a rapid intravenous bolus injection of a hypnotic anesthetic (i.e., thiopental, etomidate). Plasma concentrations peak within ½ to 1 minute and decline rapidly on redistribution of the drug. The rapidly changing plasma concentrations cause a corresponding fluctuation in the degree of CNS depression. Depth of anesthesia increases rapidly (causing loss of consciousness), peaks, and then decreases as plasma concentrations decline. CNS depression lags behind the plasma concentrations, manifesting as hysteresis on curves plotting effect against plasma concentration. All the concepts discussed earlier regarding non-steady-state conditions produced by rapid administration of a drug make assessment of the relationship of plasma concentration and depth of anesthesia difficult, if not impossible, during bolus intravenous administration.

Clinical end points useful in assessing depth of anesthesia during induction include loss of verbal responsiveness, loss of eyelid reflex, and loss of corneal reflex. Typical stimulation occurring during induction of anesthesia include laryngoscopy and intubation, which constitute profoundly noxious stimuli. Frequently, response to these two procedures cannot be eliminated completely with just the intravenously administered anesthetic. In one study, administration of thiopental (6 mg/kg) was followed by an average increase in systolic blood pressure of 53 mm Hg on laryngoscopy and intubation. [110] In another study, administration of thiamylal (4 mg/kg) was followed by an increase in mean arterial blood pressure from 92 mm Hg (control) to 136 mm Hg on laryngoscopy. [111] Because most intravenous anesthetics do not provide a significant analgesia, the hemodynamic response to major noxious stimuli is great, even when large doses are given. Thus, assessment of depth of anesthesia using clinically relevant noxious stimuli such as laryngoscopy and intubation requires the concurrent administration of other analgesic drugs (opioids or nitrous oxide) to provide reasonable and clinically acceptable hemodynamic control.

Most research on estimating depth of anesthesia induced by intravenous anesthetics has focused on the relationship between dose and response. For example, Brett and Fisher [112] reported that the dose of thiopental associated with a 50 percent probability of no movement in response to a firm squeeze of the trapezius muscle was 3 to 7 mg/kg for

adults and more than 7 mg/kg for infants 1 to 11 months of age. It is possible that a larger initial volume of distribution or a more rapid redistribution (both pharmacokinetic mechanisms) in infants accounts for the difference in dose requirement. It is also possible that brain sensitivity to thiopental differs for infants and adults. Dose-response studies cannot differentiate between these two very different mechanisms.

Dose-response studies can have meaningful scientific and clinical value if they are performed with multiple measures of drug effect, concomitant variables, and appropriate statistical data analysis. Avram et al [113] demonstrated this point by successfully examining the thiopental induction dose requirement using an EEG end point (3-5 s of isoelectric signal), clinical end points (dropping of a syringe), and measurement of multiple covariates (age, gender, lean body mass, cardiac output). Avram's group [113] concluded that age and either lean or total body weight are the most important predictors of thiopental dose requirement, with gender and cardiac output less important. Jacobs and Reves [61] provided editorial comment on this article and used computer simulations to confirm and extend the findings of the study by Avram et al.

Assessing Depth During Maintenance of Anesthesia

Becker [114] presented one of the first studies to quantitate the relationship between plasma concentrations of an intravenous anesthetic (in this case, thiopental) and clinical measures of depth of anesthesia. First studying patients anesthetized with 67 percent nitrous oxide and thiopental, Becker found that the corneal reflex and movement response to a firm squeeze of the trapezius muscle correlated highly with the movement response to surgical stimulation (cervical dilation or skin incision). He then related the plasma concentration of thiopental to three clinical signs (loss of eyelid reflex, loss of the corneal reflex, and absence of movement in response to squeezing the trapezius muscle) in another group of patients given thiopental/oxygen anesthesia. Anesthesia was induced with thiopental, 2 to 2.5 mg/kg, followed by an intravenous infusion of 1 to 1.5 mg/kg/min. Patients were observed for the three clinical signs. Arterial blood samples drawn at these clinical end points were analyzed for both total plasma concentration and free (or unbound) plasma concentrations of thiopental. Plasma levels of thiopental gathered under these pseudo-steady-state conditions, especially free or unbound plasma levels, are believed to be accurate predictors of brain levels of the drug and are therefore good indicators of depth of anesthesia. The eyelid reflex was lost at significantly lower levels of thiopental than corneal reflex or the movement response. Similar plasma concentrations of thiopental were needed for loss of corneal reflex and loss of movement response to squeeze of the trapezius muscle, both of which had been found to correlate highly with loss of movement in response to skin incision. Becker did not report hemodynamic responses to the corneal or trapezius stimuli. For the patients given 67 percent nitrous oxide, the plasma concentrations of thiopental necessary to achieve the same surgical end points were as much as 71 percent lower

than those in patients given only thiopental.

Hung et al [115] proposed a conceptual approach to examining intravenous anesthetic pharmacodynamics using clinical measures. A computer-driven infusion pump using a pharmacokinetics model of thiopental disposition was used to achieve rapidly and then maintain constant thiopental plasma concentrations in 26 surgical patients. A low (10-40 mug/mL) and then high (40-90 mug/mL) constant thiopental plasma concentration was achieved and then maintained for 10 minutes. After allowing 5 minutes for blood-brain equilibration, the following sequential clinical stimuli were applied to the patient at 1-minute intervals: verbal command, 50-Hz electrical tetanus, trapezius muscle squeeze, laryngoscopy, and laryngoscopy followed by intubation. Purposeful movement response was used as the measure of clinical response. Logistic regression was used to relate the measured constant thiopental plasma concentration to the presence or absence of movement and to estimate the Cp_{50} value. Figure 29-12 (Figure Not Available) displays the thiopental plasma concentration versus response/no response in the data, along with the logistic regression characterization. Prevention of movement for intubation required significantly higher thiopental concentrations (78.8 mug/mL) relative to laryngoscopy (50.7 mug/mL), trapezius muscle squeeze (39.8 mug/mL), electrical tetanus (30.3 mug/mL), and verbal responsiveness (15.6 mug/mL). These data confirm the utility of purposeful movement as a measure of depth of anesthesia for intravenous anesthetics and demonstrate that different noxious stimuli can be statistically separated with this methodology. The conceptual approach developed by Hung et al [115] can be used to examine how altered physiologic states and diseases alter intravenous anesthetic requirement.

Kazama and colleagues [116] examined the pharmacodynamics of propofol alone and then of propofol with fentanyl using the defined noxious stimuli/movement responses that Hung et al [115] used for thiopental and the hemodynamic methodology developed by Zbinden et al [79] for isoflurane. Kazama et al found propofol Cp_{50} values for the following defined stimuli: loss of verbal responsiveness, 4.4 mug/mL; electrical tetanus, 9.3 mug/mL; laryngoscopy, 9.8 mug/mL; skin incision, 10.0 mug/mL; and intubation, 17.4 mug/mL. With the addition of a steady-state fentanyl plasma concentration of 1 or 3 ng/mL, there was only a minimal decrease of the loss of verbal responsiveness Cp_{50} of 11 percent for 1 ng/mL and 17 percent for 3 ng/mL. For the other, more intense noxious stimuli (tetanus, laryngoscopy, skin incision, and intubation), a much greater decrease of propofol Cp_{50} occurred. Fentanyl, 1 ng/mL decreased the Cp_{50} values 31 to 34 percent, whereas fentanyl, 3 ng/mL, decreased the Cp_{50} values 50 to 55 percent. Further increases of fentanyl plasma concentrations did not further decrease propofol Cp_{50} values. Kazama et al found that systolic blood pressure response to propofol alone was profound, similar to what Zbinden et al described. The addition of fentanyl to propofol attenuated the systolic blood pressure increases in a dose-dependent manner. The conceptual methodology used by Kazama et al allows for characterization of anesthetic depth, using multiple, defined noxious stimuli. The combination of the hypnotic anesthetic, propofol, with the analgesic effects of fentanyl allows a clinically successful anesthetic to be given to patients with quantitative methodology.

Figure 29-12 (Figure Not Available) (A) Move/no move versus serum thiopental concentration for five different clinical stimuli. Each bar indicates the serum thiopental concentration and response for stimuli applied to an individual patient. (B) Predicted probability of no movement versus serum thiopental concentrations, obtained using logistic regression of the data indicated in A. The bars indicate the 95 percent confidence bounds of the estimate of the serum thiopental concentration producing a 50 percent probability of no movement response. I, laryngoscopy and intubation; L, laryngoscopy; S, trapezius muscle squeeze; T, tetanic nerve stimulation; V, verbal. *(From Hung et al [115])*

The quantitation of clinical depth of anesthesia for the combination of opioid and intravenous anesthetic was reported by Vuyk et al. [117] Using the pharmacodynamic methodology developed by Ausems et al, [100] the interaction of a constant plasma concentration of propofol (in place of nitrous oxide) was examined as the alfentanil was titrated to clinical responses. Propofol had a significant interaction with alfentanil, thus decreasing the total dose of alfentanil and the alfentanil plasma concentrations needed for adequate anesthesia. Table 29-5 (Table Not Available) indicates how the total dose of alfentanil needed decreased from 22.8 mg with 66 percent nitrous oxide to 10.3 mg with a steady-state propofol plasma concentration of 4 mug/mL. The mechanism of this decreased dose requirement was a marked potentiation of alfentanil, such that alfentanil plasma concentrations needed to achieve the same degree of pharmacologic effect were two to four times lower with propofol.

TABLE 29-5 -- Interaction of Propofol and Nitrous Oxide With Alfentanil in Lower Abdominal Surgery

(Not Available)

Modified from Vuyk et al [117]

In a subsequent study, Vuyk et al [118] used this same methodology, but they randomized the surgical subjects into a range of constant propofol blood concentrations. With blood propofol concentrations increasing from 2 to 10 mug/mL, the alfentanil Cp_{50} for laryngoscopy decreased from 170 to 25 ng/mL, from 280 to 23 ng/mL for intubation, from 259 to 9 ng/mL for opening of the peritoneum, and from 209 to 16 ng/mL for the intra-abdominal surgical stimulus. With plasma alfentanil concentrations increasing from 10 to 150 ng/mL, the Cp_{50} for propofol to the regaining of consciousness decreased from 3.8 to 0.8 mug/mL. This study confirms the profound, synergistic interaction of propofol with alfentanil. Vuyk and colleagues used computer simulations of their gathered data to suggest that the optimal blood propofol and plasma alfentanil concentrations that allow the most rapid recovery from intraoperative anesthesia occur at 3.5 and 85 ng/mL, respectively. An editorial [119] comment on this study provided more general guidelines for using the quantitative interaction of propofol and alfentanil to design dosing regimens for total intravenous anesthesia.

In clinical practice, intravenously administered anesthetic drugs are frequently combined with other drugs that provide additional analgesia (opiates, nitrous oxide, potent inhaled anesthetics). As indicated earlier, large intravenously administered doses of thiopental or propol are less than effective in eliminating hemodynamic response to relevant clinical stimuli such as laryngoscopy and intubation. [110] [111] [116] Fentanyl decreases the anesthetic requirement for thiopental or propolol by providing antinociceptive effects that thiopental does not provide. [116] [120] Clinically, the hemodynamic response to laryngoscopy, intubation, or skin incision is most commonly used to assess depth of anesthesia. The use of muscle relaxants to ease endotracheal intubation precludes use of the movement response. Because laryngoscopy and intubation are single events, if clinical depth is inadequate (e.g., in the event of profound hemodynamic

response), additional intravenous anesthetics, opioids, or maintenance anesthetic agents are rapidly administered. When precise hemodynamic control becomes important (as in coronary artery disease), larger doses of opioids are used instead of intravenously administered anesthetics. The scientific basis for the clinical use of intravenously administered anesthetics is rapidly developing to approach knowledge of potent inhaled anesthetics or opioids.

Electrophysiologic Approaches to Measuring Depth of Anesthesia

Spontaneous Electroencephalogram

The realization that anesthetic drugs alter the EEG dates back to the discovery that the brain produces electrical activity [121] (Ch. 35) . In 1875, Caton [122] used chloroform to convince himself that the electrical oscillations from the brain were indeed biologic in origin. During the 1920s and 1930s, when electronic amplifiers allowed the recording of these small voltages through the skull, Berger [123] measured the influence of chloroform on the EEG. In 1937, Gibbs et al [124] reported that anesthetics changed EEG activity from low-voltage fast waves to high-voltage slow waves and postulated that the EEG could be used to measure the effects of anesthesia. In 1952, Faulconer [125] demonstrated with ether that the depth of anesthesia, based on recognition of EEG patterns, correlated with the arterial concentration of ether. He also demonstrated that the presence of nitrous oxide lowered the arterial concentration of ether necessary to produce a given EEG effect.

The EEG can be considered a measure of depth of anesthesia for several reasons. It represents cortical electrical activity derived from summated excitatory and inhibitory postsynaptic activity, which are controlled and paced by subcortical thalamic nuclei. This electrical activity has direct physiologic correlates relevant to depth of anesthesia. Cerebral blood flow and cerebral metabolism are related to the degree of EEG activity. [126] Anesthetic drugs affect both cerebral physiology and EEG patterns. The EEG is a noninvasive indicator of cerebral function when the patient is unconscious and unresponsive. Although recording of the raw EEG involves accumulating a large amount of information and EEG tracing, new computer analysis techniques can summarize and distill the EEG into a condensed, descriptive format (the "processed" EEG). [127] [128] Rampil [129] reviewed the value of the processed EEG in the clinical practice of anesthesia.

Inadequate anesthesia generally causes EEG activation. Peripheral noxious stimuli reach the brain via afferent systems that pass through the ascending reticular activating systems of the brain stem. These systems regulate corticocerebral function and thus affect the underlying EEG pattern. Noxious stimuli can cause three types of changes on the electroencephalogram: (1) desynchronization with the appearance of 20- to 60-Hz fast rhythms (EEG activation); (2) the appearance of 6- to 10-Hz spindles; and (3) bursts of 1- to 3-Hz slow waves. [130] These patterns vary with individual anesthetics and with the nature of stimulation. [131] For example, during light levels of thiopental anesthesia in dogs (steady-state plasma concentrations of 15-27 mug/mL), supramaximal stimulation of the sciatic nerve caused EEG activation and increased cerebral metabolic oxygen requirement and blood flow by 15 percent. [132] During deep levels of thiopental anesthesia (37-49 mug/mL), stimulation produced no change in these variables. A distinct threshold concentration of thiopental seems to block the response to noxious stimuli during anesthesia in animals.

All anesthetics change the underlying raw EEG signal. [133] Figure 29-13 indicates the raw EEG changes that occur with administration of thiopental or fentanyl, including changes in the voltage and frequency of the signals. Techniques such as the use of fast Fourier transform and aperiodic waveform analysis are being used to extract univariate (single-value) parameters that can be related to drug concentration and clinical depth of anesthesia. [127] [128] In Figure 29-14 , aperiodic waveform analysis was used to process the signal and extract the number of waves per second for thiopental, whereas for fentanyl, the fast Fourier transform was used to derive the spectral edge, which is the frequency below which 95 percent of the EEG power is located. Using the processed EEG requires that one choose EEG parameters that can be appropriately used as measures of drug effect or depth of anesthesia.

The EEG is a valuable tool because it reflects cerebral physiology, it is a continuous and noninvasive measure, and

Figure 29-13 Increasing plasma concentrations of thiopental or fentanyl produce a characteristic progression of changes on the electroencephalogram (EEG). In stage 1, the frequency and amplitude of waveforms increase (thiopental). In stage 2, both drugs produce a decrease in frequency and an increase in amplitude. In stage 3, thiopental produces a burst-suppression pattern and, finally, an isoelectric EEG. Fentanyl has its maximal effect in stage 3, that is, large, slow delta waves.

Figure 29-14 (A and B) Relationships between (1) the plasma concentration (Cp) of thiopental or fentanyl and time and (2) the response on the processed electroencephalogram (EEG) and time. The two drugs were characterized in different ways. A periodic waveform analysis provided the number of waves per second produced by thiopental. The fast Fourier transform was used to estimate the spectral edge produced by fentanyl. Note the biphasic effect of thiopental on the EEG: the number of waves first increases and then decreases as the plasma concentration of thiopental increases. Note also the lag or hysteresis between plasma concentration and EEG effect for each drug.

it changes markedly on administration of anesthetic drugs. However, early studies concluded that the EEG was not a meaningful measure of depth of anesthesia. Galla et al [134] examined raw EEG signals for 43 patients and correlated EEG patterns with clinical signs of anesthesia. A discrepancy seemed to exist between the clinical signs and EEG patterns, especially during emergence from, and induction of, anesthesia. During induction, clinical signs indicated that the patients were more lightly anesthetized than EEG patterns suggested, whereas on emergence, clinical signs indicated greater anesthetic depth. Levy [135] examined processed EEG signals during induction and before bypass in patients undergoing cardiac surgery who were given potent inhaled anesthetics and opioids. He examined a series of univariate descriptors, including median frequency (the frequency below which 50% of the EEG power is located) and spectral edge (the frequency below which 95% of the EEG power is located). He concluded that the multimodal EEG activity observed in 64 percent of the cases precluded the use of single univariate parameters to describe the anesthetic state. Berezowskyj et al [136] had similar findings using power spectral analysis of patients given nitrous oxide, opioid, and halothane for anesthesia. Clinical assessment of depth of anesthesia did not correlate well with EEG patterns.

Two studies attempted to correlate univariate EEG parameters to the clinical end point of awakening from anesthesia. Drummond et al [137] examined five numeric descriptors derived from the processed EEG during imminent arousal (spontaneous movement, coughing, or eye opening) from isoflurane/nitrous oxide anesthesia. Drummond and colleagues determined the threshold value for each parameter that best served to predict imminent arousal. Although several parameters (median frequency, spectral edge 90% frequency, total power, and frequency band ratio) thresholds predicted imminent arousal with sensitivities of 90 percent and specificities of 82 to 90 percent, none of the EEG descriptors could serve as a completely reliable, sole predictor of imminent arousal. Long et al [138] undertook a similar analysis, using either isoflurane or fentanyl anesthesia. For isoflurane anesthesia, these investigators found that awakening was always presaged by an abrupt decrease in power in the 1- to 4-Hz frequency range (decrease of delta power). During emergence from fentanyl/nitrous oxide anesthesia, there was no obvious change in the overall EEG power spectrum; however, the same numeric EEG descriptors that were predictive of awakening from isoflurane also occurred during emergence from fentanyl. These two studies concluded that consistent trends in the EEG can be expected to occur with changing depth of anesthesia, with the available EEG descriptors providing potentially useful trend information regarding changing depth of anesthesia. However, sensitivity and specificity of the available parameters are such that none can serve as the sole indicator of anesthetic depth.

Dwyer and colleagues [139] examined the power spectrum of the EEG in surgical patients receiving 0.6 to 1.4 MAC isoflurane-only anesthesia with skin incision. A second group of volunteers received 0.15 to 0.45 MAC isoflurane with memory testing. Different time-dependent, frequency EEG parameters (e.g., spectral edge, median frequency) were examined relative to the clinical measures. The authors found that isoflurane caused some decrease of EEG activity; however, there was no difference in EEG parameters between subjects who moved and those who did not move with skin incision. In volunteers receiving lower-dose isoflurane, memory of the information presented did not correlate with values of any EEG parameter. The authors concluded that the examined EEG parameters did not predict depth of anesthesia as defined by response to surgical skin incision, response to verbal command, or development of memory.

The previously described clinical research attempting to relate EEG effects to clinical anesthetic depth has resulted in inconclusive findings. When single anesthetic drugs are examined under defined conditions, it has been possible to demonstrate scientifically valid relationships between EEG parameters and anesthetic drug concentrations and to use pharmacokinetic and pharmacodynamic modeling concepts to link the drug concentrations to the EEG drug effects. [140] Different EEG waveform data analysis approaches have

been used to define different univariate EEG parameters as measures of anesthetic drug effect. The most powerful application has been to understand further the fundamental clinical pharmacokinetics of the anesthetic drugs.

The application of the EEG to measure clinical depth of anesthesia failed previously for several reasons. There has been a lack of understanding of the effects of interactions of several concurrently administered anesthetic drugs on the EEG. There has not been a standard approach to choosing an optimal EEG parameter, and finally, a "gold standard" for the measurement and assessment of clinical depth of anesthesia has been lacking. Only recently has an integrated research effort been undertaken to develop the EEG as a measure of anesthetic depth, directed by Aspect Medical Systems, a medical device company in Natick, Massachusetts. This company has developed a medical device that quantitates the anesthetic effects on the brain, specifically the hypnotic component of anesthesia. The device presents a continuous, EEG parameter, the Bispectral Index (BIS), which ranges from an awake, no-drug-effect value of 95 to 100 to zero with no detectable EEG activity.

Bispectral EEG Monitoring

The successful development of the Aspect Bispectral (BIS) EEG monitoring system can be identified with the following concepts:

1. The use of a more advanced EEG signal processing approach that allows for incremental information compared with the traditional fast Fourier transformation methodology.
2. The concurrent collection of clinically relevant (movement, hemodynamics, drug concentrations) data in patients/volunteers with EEG data, followed by the use of advanced multivariate statistical data analysis techniques to correlate the components of the EEG bispectrum with the clinical data to create the BIS

parameter.

3. The recognition that the BIS measured the hypnotic components of the anesthetic and was less sensitive to the analgesic/opiate components of an anesthetic.
4. The development of relevant clinical outcome data to demonstrate that BIS EEG monitoring can improve the quality of an anesthetic regimen.
5. The development of optimal hardware/signal processing technology adapted to the noisy electrical environment of the operating room.

Bispectral EEG Signal Processing

Bispectral EEG signal processing has been elegantly reviewed by Ramil [141] and Sig and Chamoun. [142] To date, most EEG signal processing has involved a form of time domain analysis, which examines the EEG signal as a function of frequency. The frequency analysis involves characterizing the EEG signal into sine waves with Fourier analysis, with the sine waves being described relative to amplitude, frequency, and phase angle. The sine wave amplitude is one-half the peak-to-peak voltage, the frequency is the number of complete cycles per second, and the phase angle is the way to describe the starting point (angle) of the waveform. Fourier analysis is a mathematical technique that takes a time varying waveform and decomposes it into the sum of simple sine or cosine waves. For a short, defined period of EEG signal, the Fourier analysis generates a frequency spectrum that is a histogram of the amplitudes and phase angles as a function of frequency. Traditional power (Fourier) spectral analysis assumes that the amplitudes of the EEG are normally (gaussian) distributed, the statistical properties do not change over time (stationary), and the frequency constituents are uncorrelated (linear). In Fourier analysis, only frequency and amplitude (power) estimates are used; the phase information is ignored.

Bispectral analysis is a higher-order statistical approach, relative to Fourier analysis, that was first applied to geophysics in the early 1960s to study wave motion, atmospheric pressure changes, seismic activity, and sunspots. [142] Bispectral analysis can characterize the correlation of the phase among different frequencies of the Fourier transform (phase coupling). The meaning of EEG phase relationships is not yet clear, but one simplistic approach holds that strong phase relationships relate inversely to the number of independent EEG pacemakers in the brain. In addition, bispectral analysis can identify nonlinearities in the EEG that may be important in the EEG signal-generation process and that allow for suppression of gaussian sources of noise that can enhance the signal/noise ratio of the nongaussian EEG. [141] Bispectral analysis, along with estimation of the Fourier transform of data, can also quantitate the relationship among the underlying sinusoidal components of the EEG to calculate a phase parameter termed the bicoherence. Thus, use of the bispectrum allows for a more comprehensive description of the information available from Fourier analysis to be used in determining an EEG parameter.

Developing the Bispectral Index

The BIS is a complex, proprietary EEG parameter that has been under development since 1985 by Aspect Medical Systems. The commercially available version of this EEG parameter was approved by the U.S. Food and Drug Administration (FDA) in 1996 as a monitor of anesthetic effect on the brain and is the only FDA-approved device for this indication. Figure 29-15 (Figure Not Available) displays the conceptual process whereby Aspect took EEG and clinical data from approximately 1,500 anesthetic regimens and 5,000 hours of EEG signal gathered under a broad range of anesthetic regimens. The approach involved taking EEG data, removing artifacts, and then performing spectral calculations, both Fourier and bispectral. Additionally, clinical data such as movement or no movement to skin incision along with equilibrated anesthetic concentration data were gathered. Statistical data analysis techniques were used to identify the components of the EEG that appeared to correlate best with the clinical and pharmacologic end points. As prototype versions of the BIS were developed over several years, subsequent clinical testing was used to improve and to refine the algorithms and components of the EEG parameter. The BIS algorithm was adapted to handle burst-suppression EEG, to minimize the initial activation of the EEG seen with some anesthetic drugs, and optimally to utilize components of Fourier analysis

Figure 29-15 (Figure Not Available) Algorithm for the development of the bispectral index. A library of high-quality, artifact-free electroencephalogram (EEG) were first accumulated. Different prospective subparameters were calculated, and their correlation to clinical measures of anesthetic response and drug concentrations was tested. The EEG parameters with the best performance were used in a multivariate analysis for the creation of the final composite parameter. This process was repeated with at least three major sets of data at different times. *(Modified from Rampil [141])*

and bispectral analysis. Thus, the BIS is a complex parameter composed of a combination of time domain, frequency domain, and higher-order spectral subparameters derived from clinical data. [141]

Clinical Development and Validation of the Bispectral Index

The initial studies with early versions of the BIS algorithm demonstrated, in a retrospective manner, that the BIS could be used to predict movement in response to skin incision using isoflurane/oxygen, [143] propofol/nitrous oxide [144] or propofol/alfentanil anesthesia. [145] In the first major clinical evaluation, a large, multicenter study by Sebel et al [146] randomized 300 patients into 2 groups. One group had the BIS continuously monitored and drug dosing adjusted to create a BIS value whereby 50 percent of the subjects would respond. In the second group, while BIS was recorded, no drug dosage adjustment occurred. In the control group, the mean BIS was a mean of 66 + 19 (SD) with a 43 percent movement rate. In the BIS-adjusted group, the BIS was lower, a mean 51 ± 19 (SD) with a significantly lower movement rate of 13 percent. This study was the first suggestion that the utility of BIS depends on the anesthetic technique. When hypnotic drugs such as propofol or isoflurane are used as the primary anesthetic, changes in BIS correlate with the probability of movement response to skin incision. When opiate analgesics are used at higher doses, the correlation to patient movement becomes much less significant.

A subsequent study by Glass et al [147] was designed to examine further the relationship among BIS, measured drug concentrations, and increasing levels of sedation when the anesthetic drugs propofol, midazolam, isoflurane, and alfentanil were given to volunteers in a controlled manner. The data from this study were used to provide greater optimization of the currently available BIS algorithm. Seventy-two volunteers received a single drug at 4 or 5 defined, increasing target concentrations that ultimately created an unconscious subject. The BIS EEG, arterial drug, or end-tidal concentrations and subjective sedation score and memory were measured. The BIS score correlated significantly with measured drug concentrations and had effective correlation with the clinical measures of sedation. None of the alfentanil patients lost consciousness and had minimal change of BIS, a finding confirming that the BIS EEG is not sensitive to low concentrations of opiate analgesics. The pooled BIS values at which 50 and 95 percent of volunteers were unconscious were 67 and 50, respectively.

Liu, Singh, and White [148] demonstrated in 26 surgical subjects that the BIS index accurately tracked the degree of clinical sedation with intermediate (4-mg) to large (20-mg) doses of midazolam given during regional anesthesia. When midazolam created an unresponsive subject, the mean BIS value was 69.2 + 13.9 (SD). Katoh, Suzuki, and Ikeda [149] found similar results with low, sedating doses of sevoflurane and also with higher, anesthetic concentrations in sixty-nine surgical patients. The BIS and sevoflurane end-tidal concentrations correlated closely with the clinical sedation scores of the patients. With end-tidal sevoflurane concentration increasing from 0.2 to 1.4 percent, BIS values decreased almost linearly from a median value of 95.3 to 45.5. Sevoflurane concentrations greater than 1.4 percent produced a limited further reduction of the BIS. Figure 29-16 (Figure Not Available) indicates the relationship between BIS, spectral edge, sevoflurane end-tidal concentration, and clinical response to defined stimuli. One can see the clear activation of the spectral edge parameter at low sevoflurane concentrations, whereas this is not seen with BIS. Flaishon et al [150] examined the behavior of BIS when surgical patients were given a single, intravenous bolus of propofol, 2 mg/kg or thiopental, 4 mg/kg with concurrent muscle relaxants. The isolated arm technique was used to identify loss then return of consciousness. No patient with a BIS of less than 58 was conscious; a BIS of less than 65 signified a less than 5 percent probability of return of consciousness within 50 seconds.

Kearse et al [151] undertook a more detailed examination of memory and command performance during propofol/ nitrous oxide sedation and BIS monitoring. These investigators

Figure 29-16 (Figure Not Available) Comparison of the cumulative probability of patients remaining unconscious after the discontinuation of propofol. The light hatched area is the bispectral index (BIS)-titrated group, and dark area is standard clinical practice (SP), without BIS monitoring. *(From Gan et al [152])*

found that there was a strong association between BIS and command scores, whether the command consisted simply of a uniform voice asking a volunteer to move a hand or foot or incorporated graded, then varied, stimuli. The relationship between BIS and responsiveness scores remained consistent over time and with increases or decreases of propofol concentrations. No subject was responsive when BIS was less than 57.

Several studies examined the clinical and economic outcome benefits of BIS monitoring in routine surgery. Gan and colleagues [152] studied 302 subjects in 4 different institutions using a propofol/alfentanil/nitrous oxide anesthetic regimen. Half the subjects were randomized to a "standard practice" whereby the propofol and alfentanil were infused and were adjusted to provide a stable anesthetic with the fastest possible recovery. The remaining subjects received a "standard-practice plus BIS monitoring." BIS was recorded in the standard-practice group, but it was not displayed to the practitioner. In the BIS group, propofol infusions were adjusted to achieve a target BIS between 45 and 60 and then were increased to 60 to 75 during the final 15 minutes of the anesthetic regimen. In the standard-practice group only, propofol adjustments were made using clinical signs and judgment, without BIS information. Patients in the BIS group required significantly lower normalized propofol infusion rates (134 versus 116 mug/kg/min), were extubated significantly sooner (11.2 versus 7.3 min), had a higher percentage of patients oriented on arrival in the recovery room (43 versus 23%), and had more rapid discharge from the recovery room. Figure 29-17 (Figure Not Available) displays the cumulative probability of patients' remaining unconscious after the discontinuation of propofol in the two study groups. This study demonstrated that titrating propofol with BIS monitoring during balanced anesthesia decreased propofol use and significantly improved recovery with no difference in intraoperative conditions.

Similar findings were presented by Song and colleagues [153] using inhalational anesthetics. Sixty surgical patients were randomized to desflurane or sevoflurane with 65 percent nitrous oxide and low doses of fentanyl. Half the patients

Figure 29-17 (Figure Not Available) Scatter diagram showing the relation among bispectral index (A), 95 percent spectral edge (B), end-tidal sevoflurane concentration, and response to different defined stimuli. Open symbols denote either responders or movers, whereas filled symbols denote either nonresponders or nonmovers. *(From Kaoh et al [149].)*

were randomized to standard practice whereby the inhalational anesthetic was titrated according to clinical end points and judgment. The second group had the volatile anesthetic titrated to a BIS value of 60. During the maintenance period, the BIS values were significantly lower in the standard-treatment group (mean, 42), a finding suggesting a deeper anesthetic compared with the BIS-titrated group with a mean of 60. The volatile anesthetic usage in the BIS-titrated group was 30 to 38 percent lower compared with the control group. Similarly, the times to verbal responsiveness were 30 to 55 percent shorter in the BIS-titrated group. This study demonstrated that titrating desflurane and sevoflurane using the BIS monitor decreased the utilization of the drugs and contributed to faster emergence from anesthesia.

The role of BIS monitoring in many other aspects of anesthesia care remains to be examined with clinical research. This includes the role of BIS monitoring in special patient populations, (pediatrics, pregnancy, disease states) and other clinical situations such as sedation in the intensive care unit.

The previously described development of the BIS and its application to patient care monitoring represents the first scientifically validated and commercially supported monitor of anesthetic drug effect on the CNS that has clinical applicability and relevance. The utility of the BIS is maximal when the anesthetic is a combination of a low or moderate dose of opiate analgesic and a hypnotic drug (volatile inhalational anesthetic, intravenous anesthetic) that is titrated to the bispectral response. For the BIS to reflect the pharmacodynamics of the hypnotic drugs on the CNS maximally, lower doses of opiates are needed. High-dose opiates result in significant synergistic interaction with the hypnotic drugs, as demonstrated by Glass and colleagues, [97] [98] such that minimal amounts of hypnotic drug are required to obtain adequate anesthesia. The reduced amounts of hypnotic drug present result in less profound hypnotic EEG drug effects on the CNS and therefore a less sensitive BIS response. It appears that the synergistic interaction of opiates with volatile anesthetics or intravenous anesthetics on clinical end points (hemodynamics, movement responses), does not occur with the EEG effects of the hypnotics. Stated another way, the pharmacodynamic relationship of the BIS to hypnotic drug concentrations (decrease of BIS with increasing hypnotic drug concentrations) is unchanged as opiates are added to the anesthetic. There is not an equal synergistic interaction of the EEG and clinical end points.

The clinical use of BIS monitoring involves separating the hypnotic and analgesic components of an anesthetic regimen. The concept involves increasing the hypnotic component dosage (isoflurane, desflurane, sevoflurane, propofol, midazolam) to lower the BIS to a range of 50 to 60. This appears to be the therapeutic window associated with a high probability of unconsciousness. A small to moderate amount of analgesic drug (opiate) is also given with the hypnotic drug. The anesthesiologist then evaluates the clinical and BIS responses to the surgical procedure over time. During times of intense surgical stimulation, if the BIS increases and the patient exhibits movement and hemodynamic responses, the anesthesiologist should respond by increasing the hypnotic component to lower the BIS value to the 50 to 60 range. If the BIS is lowered, but movement and hemodynamic responses continue, incremental opiate should be added to increase the analgesic component of the anesthetic until movement and hemodynamics are controlled. If the patient has a BIS in the 50 to 60 range, but movement and hemodynamic responses occur, then the analgesic component of the anesthetic should be increased. As the end of the anesthetic regimen approaches, the hypnotic component should be decreased to allow the BIS value to begin to increase. BIS monitoring provides an important, new dimension to the ability to adjust the components of an anesthetic in a logical manner.

Other Measures of Anesthetic Depth

Two other electrophysiologic measurement techniques have been studied as potential monitors of anesthetic depth: sensory evoked potentials and esophageal motility.

Evoked Responses

Sensory or nerve stimulation produces a low-amplitude signal, or evoked response, within the CNS. This evoked response can be separated by means of special computer signal-averaging techniques, from the underlying, spontaneous EEG. The ability to evoke a response is a measure of the functional integrity of the sensory receptors and the pathways between the sensory receptor and neural generator of peaks in the evoked response waveform. The evoked responses are used primarily to monitor the functional integrity of the neural structures, to identify neural structures, and to diagnose neurophysiologic conditions. Because evoked responses are sensitive to anesthetic drugs, they have been investigated as possible measures of anesthetic drug effect and depth of anesthesia. [133] The sensory stimulation most commonly used in recording of evoked responses consists of the following: somatosensory (electrical) stimulation of peripheral nerves; auditory stimulation, in which noises (clicks) are applied to the auditory canal; visual stimulation using flashing lights; or electrical stimulation of the tooth pulp.

Recording of evoked responses involves recording of EEG epochs and time-referencing them to sensory stimuli that have been applied in a repeated fashion. Computer techniques for processing EEG signals extract the evoked potential from the underlying EEG after repetitive stimuli; the evoked potential represents 100 to 1,000 stimuli. Therefore, the evoked response represents a time versus voltage relationship that can be quantitated by measuring the poststimulus latency and interpeak amplitudes in the waveform. Evoked response methodology has been reviewed by Grundy. [154] [155]

Many investigations have been performed with evoked potentials, with special emphasis on auditory evoked potentials. [156] [157] [158] [159] [160] [161] [162] [163] Relationships between anesthetic concentrations and changes of evoked potential parameters have been demonstrated. However, no consistent systematic relationships with clinical depth of anesthesia have been demonstrated.

Contractility of the Lower Esophagus

Measuring lower esophageal contractility is a novel method of assessing depth of anesthesia. The human esophagus is composed of striated muscle in the upper quarter, smooth muscle in the lower quarter, and both types of muscle in the middle portion. The striated portion of the esophagus is innervated by the reticular formation of the brain stem. Three different types of esophageal contraction have been identified: (1) primary contractions initiated by swallowing; (2) secondary propulsive contractions that occur in response to esophageal dilatation; and (3) tertiary or spontaneous nonpropulsive contractions that occur only in the lower quarter of the esophagus. As with the evoked potentials, no consistent, systematic relationship of lower esophageal contractility has been demonstrated relative to anesthetic depth.

SUMMARY

The definitions of "anesthesia" and "depth of anesthesia" are among the most controversial, emotional, and subjective aspects of our discipline, frequently becoming philosophic exchanges instead of thoughtful scientific analysis. With the inhalational anesthetic diethyl ether and spontaneous ventilation, judging and quantitating the presence or absence and depth of anesthesia were relatively easy. With the introduction of the muscle relaxants in the 1940s and the subsequent evolution of the modern anesthetic pharmacologic armamentarium in the next 50 years, progress in defining, measuring, and understanding anesthetic depth has moved forward at a very slow pace compared with other aspects of the science of anesthesia. In the opinion of this author, the two most useful conceptual contributions to the topic of anesthetic depth have been the editorial comments by Prys-Roberts in 1987 [16] and by Kissin in 1992. [18]

Prys-Roberts [16] pointed out that "anesthesia" and "depth of anesthesia" are two different entities that are frequently confused because of the sharing of a common word. Anesthesia can be defined as the lack of response and recall to noxious stimuli. Anesthesia does not include paralysis, nor does it include analgesia when consciousness is present. He defined anesthesia in terms of the drugs that produce unconsciousness and modification of the responses to noxious stimuli, classifying them by pharmacologic properties of the drugs and not by their ability to produce components of the state of anesthesia. Kissin [18] extended these concepts by stating his view that the spectrum of effects that constitutes the state of general anesthesia should not be regarded as several components of anesthesia resulting from one anesthetic action, but rather as separate pharmacologic actions, even if produced by a single drug.

Depth of anesthesia can only be defined by examining specific noxious stimuli and defined clinical responses under specific pharmacologic conditions, that is, one versus two drugs at defined plasma concentrations. Moreover, for both hypnotic anesthetic drugs (i.e., propofol, inhalational anesthetics) and opiate analgesic anesthetics, different types of noxious stimuli require different concentrations of anesthetic agent to suppress somatic, autonomic, and hemodynamic responses. [164] Suppression of sympathetically mediated hemodynamic responses does not guarantee suppression of somatic responses and vice versa. Anesthesia using the currently available drugs involves using the combination of at least two different classes of anesthetic drugs to obtain adequate clinical anesthesia, a hypnotic anesthetic (intravenous anesthetic, inhalational anesthetic) and an analgesic opiate. Thus, to define anesthetic depth fundamentally, it is essential to understand in a quantitated manner the interaction of these two classes of anesthetic drugs. Finally, in recent years, the BIS, as developed by Aspect Medical Systems, has been established as an objective electrophysiologic measure of the hypnotic component of an anesthetic regimen. This CNS monitoring device, coupled with observation of surgical stimuli and clinical responses, can be used to adjust the amount of hypnotic versus analgesic drug in patients.

J. Gerald Reves

/das/book/view/29494766/875/322.html

INTRODUCTION: EXTENDING THE PHYSICAL EXAMINATION

Although some might consider electronic devices as the only cardiovascular monitors, the fundamental basis for circulatory monitoring remains in the eyes, hands, and ears of the anesthesiologist. Just as inspection, palpation, and auscultation are the cornerstones for standard physical examination of the cardiovascular system, these procedures remain the critical elements of perioperative cardiovascular monitoring. These procedures must be adapted and focused on the unique requirements of surgical and critically ill patients. Furthermore, their limitations must be recognized.

Many standard physical means of assessing circulation are employed throughout an operation. For many healthy patients undergoing minor procedures, these physical signs

* *See Appendix 1, Practice Guidelines for Perioperative Transesophageal Echocardiography and Practice Guidelines for Pulmonary Artery Catheterization*

may provide a considerable fraction of the total cardiovascular monitoring. When the operation becomes more complex or the patient comes to surgery with more advanced or unstable cardiovascular disease, the extent of supplemental electronic monitoring grows accordingly. However, careful physical assessment still provides the clinician with an all-important back-up system used to confirm or refute information derived from other monitoring devices. The most obvious, perhaps trivial, example is the patient whose electrocardiogram (ECG) shows asystole. Detection of a normal pulse by direct palpation directs the anesthesiologist back to correct the monitoring artifact rather than to initiate cardiopulmonary resuscitation. In a sense, the clinical examination here is an example of redundant monitoring. Heart rate is monitored continuously by the ECG, but checking the heart rate by intermittently palpating the pulse provides the most important supplemental safety monitor.

Early advances in cardiovascular assessment beyond the methods of basic physical examination were not accepted readily into medical practice. Around 1900, introduction of sphygmomanometry to measure blood pressure was criticized because it would weaken clinical acuity by blunting the senses and acute perceptions of the clinician. Even chest stethoscopy had its critics, simply on the basis that it placed the physician at greater distance from the patient. [1] Today, these concerns might appear somewhat ludicrous, given our patient care responsibilities in unusual environments, as in the use of magnetic resonance scanners, where clinicians must monitor patients from a remote site. Nonetheless, there can be little doubt that increased reliance on electronic monitoring devices has diminished our fundamental clinical skills of physical assessment.

Palpation of the pulse, its rate and character, should not be forgotten in the perioperative setting. Unique constraints in the operating room may dictate which pulses are accessible for monitoring. The anesthetist standing at the patient's head during induction of anesthesia can easily palpate the carotid artery, the superficial temporal artery anterior to the ear, or the facial artery at the mandible. When only an arm is accessible, the axillary, brachial, radial, and ulnar pulses may be examined. Even procedures necessitating that the anesthetist be positioned near the patient's feet permit palpation of femoral, popliteal, dorsalis pedis, and posterior tibial pulses. Many of these vessels also serve as suitable sites for sampling arterial blood or direct arterial cannulation for pressure monitoring (see later in chapter). Perhaps most important, one should consider the unique opportunities for pulse monitoring during surgery, rather than just the constraints of this environment. During cardiac surgery, the beating heart may be observed directly and palpation of the ascending aorta by the surgeon provides a useful estimate of central blood pressure. In fact, the surgeon's evaluation of any arterial pulse within the surgical field should be considered whenever severe hemodynamic instability develops.

Clinical evaluation of venous pressure is often technically difficult perioperatively. Factors hindering the anesthesiologist include unusual patient positions, positive pressure mechanical ventilation, and lack of access to observe the neck veins. However, early recognition of venous obstruction in an extremity or the head and neck may have important clinical consequences. Not only might this observation herald hemodynamic problems for the patient, but communicating these observations to the operating surgeon should allow timely correction of associated technical problems, such as a malpositioned venous cannula during cardiopulmonary bypass.

Given that the cardiovascular system is responsible for transport of substrates and byproducts to and from all organ systems, monitoring end-organ function reflects the adequacy of cardiovascular system performance. Inspection of mucous membranes, skin color, and skin turgor can reveal pertinent clues about hydration, oxygenation, and perfusion. Additional simple clinical techniques include empiric estimation of fluid deficits and measurement of intraoperative blood loss. Decreased urine output may indicate hypo-volemia or reduced cardiac output, and altered mental status may be a sign of inadequate cerebral perfusion. Unfortunately, preexisting end-organ dysfunction may confound interpretation of these simple physical signs and measurements. Furthermore, drugs may alter organ function directly. For example, general anesthesia makes it impossible to monitor mental status or sensory or motor function using physical examination; diuretic therapy obviates urine output monitoring as an indicator of overall systemic perfusion. As a result, simple clinical assessment of end-organ function is of limited value in many anesthetized or critically ill patients, so that additional cardiovascular monitoring techniques are required.

Stethoscopy

Although Laennec is credited with introducing the stethoscope into general medical practice in 1818, nearly a century elapsed before Harvey Cushing proposed in 1908 that the stethoscope be used as a routine continuous cardiopulmonary monitoring device during surgery. [2] Today, intraoperative monitoring with either a precordial or esophageal stethoscope has become a fundamental extension of the physical examination for all anesthetized patients. [3] [4]

Stethoscopy provides a simple and reliable means of listening to heart and breath sounds continuously throughout an operation. The most common equipment used for precordial stethoscopy consists of a heavy metal bell or accumulator attached to a length of rubber or plastic extension tubing and a custom-molded monaural plastic earpiece. Electronically amplified stethoscopes have been designed in an attempt to improve the quality and clarity of heart and breath sounds, and wireless systems, using radiotransmitted signals, allow continuous monitoring without the anesthetist being tethered to the patient by the stethoscope extension tubing. [5] [6] [7] However, stethoscopes with these electronic modifications have not supplanted the standard inexpensive mechanical device in everyday practice.

Although minimally invasive and practical only for the patient who is undergoing general endotracheal anesthesia, the esophageal stethoscope provides monitoring benefits not available with its precordial cousin. Clear breath sounds and distinct heart sounds are audible in most patients with the stethoscope tip positioned 28 to 30 cm from the incisors. [8] Core body temperature can be measured via a thermistor incorporated in the tip of the stethoscope. Specially configured stethoscopes permit recording of a transesophageal ECG, which may be useful to diagnose atrial

arrhythmias, right ventricular ischemia, or posterior left ventricular ischemia. [9] [10] The esophageal stethoscope may also be a valuable therapeutic tool for treating intraoperative sinus bradycardia or junctional rhythm. For this special application, transesophageal atrial pacing can be accomplished with a stethoscope equipped

with bipolar pacing electrodes on its outer surface. [11] [12] Use of the esophageal stethoscope is safe in most patients, but it has been associated with occasional complications including hypoxemia from unintended tracheobronchial placement or compression of the membranous posterior trachea in small infants, loss down the esophagus, detachment of the acoustic cuff, and distortion of surgical anatomy in the neck. [13] [14] [15] Placement of the esophageal stethoscope may also cause pharyngeal or esophageal trauma and interfere with nasogastric tube positioning or transesophageal echocardiography.

Despite the apparent value of the precordial or esophageal stethoscope for basic patient safety monitoring, its widespread application in clinical practice has diminished in recent years. [15] [16] This may be driven by the routine use of pulse oximetry, capnography, and other electronic safety monitors that have become ubiquitous and even required by law in some locations. As a practical matter, clinicians may not recognize the loss of heart or breath sounds as readily as might be expected, owing to reliance on the more modern electronic devices or distractions and noise pollution inherent in the operating room. [2] [13] These practice patterns appear to be borne out by the 1993 Australian Incident Monitoring Study, which noted that a stethoscope was employed in only 5 percent of the 1,256 critical incidents reported. Furthermore, it was the first monitor to detect the morbid incident--cardiac arrest--in only one instance. [16]

The current role of intraoperative stethoscopy may be summarized as follows: [2] [13] [16]

1. Use of the stethoscope as a continuous monitor has become limited to enthusiasts (mainly pediatric anesthetists) and to institutions with insufficient resources to purchase electronic monitors.
2. A stethoscope should be immediately available in all locations where anesthesia is administered. Its role in diagnosing important respiratory problems (e.g., bronchospasm) probably exceeds its value as a continuous circulatory monitor.
3. Monitors like the oximeter, capnograph, and ECG detect untoward incidents more often than the stethoscope, in part because it is difficult to concentrate continuously on listening to both heart and breath sounds.
4. The stethoscope thus remains a valuable additional safety monitor, but only as a supplement to standard disconnect alarms, pulse oximetry, capnography, and direct observation of the patient.

Heart Rate Monitoring

The simplest and least invasive form of cardiac monitoring remains the measurement of heart rate. This vital sign provides an important guide to the baseline condition of the circulation as well as the influence of anesthetics and surgical stimuli. Ability to estimate heart rate quickly using a "finger on the pulse" is a skill as important as this expression is common. However, under most circumstances in modern anesthesia practice, electronic monitoring devices are used to provide a continuous, numeric display of heart rate.

Although any monitor that senses the period of the cardiac cycle can be used to determine heart rate, the most common technique applied in the operating room is electrocardiography. Current monitors use multiple ECG leads to sense cardiac electrical activity. [17] This redundancy aids detection of the R wave and improves the accuracy of heart rate measurement. As a result, a single noisy lead, or one in which the R waves are of very low amplitude, will not prevent the monitor for calculating heart rate properly.

Electrocardiographic measurement of heart rate begins with accurate detection of the R wave and measurement of the R-R interval. The digital value displayed for heart rate is generated from an algorithm designed to count and average a certain number of beats and then display a number that is updated every 5 to 15 seconds. [18] As a result, acute but transient changes in heart rate may have little impact on the displayed digital value. For example, consider an episode of complete heart block, which interrupts slow sinus rhythm. Depending on the algorithms employed by the monitor, the digital value for heart rate may show only a slight reduction from the baseline value. In this instance, the heart rate of 49 beats/min displayed by the monitor fails to alert the clinician of the dangerous transient bradyarrhythmia (Fig. 30-1) (Figure Not Available) . Although the monitor could update the digital value for heart rate after each beat by reporting an instantaneous R-R interval, this would result in numbers flashing on the display screen, changing with each heart beat, owing to the normal physiologic beat-to-beat variability in heart rate. Instead, the displayed digital value for heart rate (and for all the direct pressure measurements as well) is derived by the monitor using a *moving average filter.* In more sophisticated monitors, this filter weights the most recent values more heavily than older values in deriving the average value for the digital display.

Occasionally, the clinician must check electrode attachment, increase ECG signal gain, or select alternate ECG leads to facilitate heart rate monitoring. Some monitors allow manual adjustment of threshold or sensitivity for R-wave detection. Despite these measures, the monitor may display inaccurate heart rates when the ECG trace is distorted by patient movement or other electrical interference. In the operating room, this frequently occurs when the electrosurgical unit is in use. Visual inspection of the ECG trace always should be used to confirm the numeric value for heart rate displayed on the monitor. Spurious values are recognized quickly, and true heart rate can be estimated by noting the R-R interval when the ECG trace reappears briefly on the monitor screen. In addition, the arterial pressure trace or the pulse oximeter plethysmograph confirms the pulse rate in these instances.

Electrical interference in the ECG trace may arise from sources other than the electrosurgical unit. Power line noise appears as a 60-Hz artifact and may be eliminated by selecting narrower bandpass ECG filters, including a 60-Hz notch filter. Fortunately, this type of power line electrical artifact rarely prevents accurate ECG measurement of heart rate. Other artifacts result from muscle twitching and fasciculations, as well as various medical devices, including litho-tripsy machines, cardiopulmonary bypass equipment, and fluid warmers. [19]

Figure 30-1 (Figure Not Available) Digital heart (HR) displays may fail to warn of dangerous bradyarrhythmias. Direct observation of the electrocardiogram (ECG) and the arterial blood pressure traces reveals complete heart block and a 4-sec period of asystole, while the digital display reports an HR of 49 beats/min. Note that the ECG filter (arrow) corrects the baseline drift so that the trace remains on the recording screen. *(From Mark JB: Atlas of Cardiovascular Monitoring. New York, Churchill Livingstone, 1998: Fig. 13-2.) (Figure Not Available)*

Paced rhythms often produce problems for ECG measurement of heart rate. When tall pacing spikes are present, the monitor may misinterpret these high amplitude signals as R waves and miscalculate heart rate. Tall T waves may produce the same artifact when the monitor mistakenly double counts these T waves along with the R waves. These problems may be lessened by decreasing ECG gain, adjusting R-wave detection sensitivity, or changing the ECG lead to one with a reduced pacing spike or T-wave amplitude.

Pulse Rate Monitoring

Although the preceding discussion has focused on methods to estimate heart rate from the ECG trace, it might be argued that monitoring pulse rate is more important than monitoring heart rate, in terms of perioperative hemodynamic assessment. By definition, the distinction centers on whether a given electrical depolarization and systolic contraction of the heart (heart rate) generates a palpable peripheral arterial pulsation (pulse rate). Pulse deficit describes the extent to which the pulse rate is less than the heart rate. This is typically seen in patients with atrial fibrillation, in which short R-R intervals compromise cardiac filling during diastole, resulting in reduced stroke volume and imperceptible arterial pulse. The most extreme example of a pulse deficit is electrical-mechanical dissociation or pulseless electrical activity, seen in patients with cardiac tamponade, extreme hypovolemia, and other conditions in which cardiac contraction does not generate a palpable peripheral pulse.

Most monitors report heart rate and pulse rate separately. The former is measured from the ECG trace, and the latter is determined by a pulse source, which is generally selectable by the user. For example, the pulse oximeter plethysmograph trace will provide a suitable pulse measurement source for most patients except those with severe arterial occlusive disease or those with marked peripheral vasoconstriction. Automatic noninvasive blood pressure devices determine the pulse rate by counting oscillations in pressure sensed by the surrounding cuff. When direct arterial pressure measurement is in place, the pressure waveform provides a reliable pulse source. As already emphasized, this is particularly useful in distinguishing artifactual ECG signals and erroneous heart rates from important real cardiac events. Beware, however, that even the arterial pressure trace may be misleading when nonsystolic arterial pulsations are detected by the monitor and counted separately. In patients treated with intraaortic balloon counterpulsation, the pressure pulse resulting from balloon inflation during diastole may be detected and produce a factitiously high pulse rate. [19] Other arterial pressure waveforms that have a bisferiens, double-peaked morphology, such as those arising in patients with aortic valve regurgitation, may produce a similar artifactually increased pulse rate measurement. In contrast, patients with pulsus alternans may have inappropriately low pulse rates measured, owing to the diminished magnitude of every other arterial pulsation. In these cases, selection of an alternative pulse source, such as the pulmonary artery pressure waveform, can provide a reliable pulse rate.

In summary, pulse rate monitoring and heart rate monitoring complement one another. Even though monitoring both pulse rate and heart rate may seem redundant in many cases, such intentional redundancy is being applied to modern computerized monitoring algorithms. One example is termed robust fusion sensor technology, which fuses heart rate and pulse rate data from multiple sources--ECG, pulse oximeter plethysmogram, and arterial pressure waveform. [20] This approach improves the accuracy of heart and pulse rate monitoring and reduces the frequency of distracting false alarms. [21] In the end, however, as with all numeric information displayed on the bedside monitor, it is the clinician's ultimate responsibility to scrutinize the analog ECG and pressure waveforms to ensure the veracity of all digital values displayed by bedside monitors.

ARTERIAL BLOOD PRESSURE MONITORING

As with heart rate, blood pressure is a fundamental cardiovascular vital sign, which reflects the force that derives perfusion of the body. In addition, blood pressure is the most important determinant of left ventricular afterload, the workload of the heart. Consequently, frequent measurement of arterial blood pressure is a critical part of monitoring anesthetized or seriously ill patients. The importance of

monitoring this vital sign is underscored by the fact that standards for basic anesthetic monitoring mandate measurement of arterial blood pressure at least every 5 minutes in all anesthetized patients. [3]

Techniques for measuring blood pressure fall into two major categories: indirect Riva-Rocci cuff devices and direct arterial cannulation and pressure transduction. These methods differ in nearly every respect, notably in terms of the physical process being monitored and in the level of invasiveness of their application. In clinical practice, blood pressures measured by different techniques often yield significantly different values. [22] So common are these inconsistencies that some investigators have declared: "Blood pressure is a function of the way it is measured." [23]

Studies comparing different blood pressure monitoring techniques usually use direct arterial pressure measurement as the reference standard against which another method is judged. However, there are many ways in which direct arterial pressure measurement can yield spurious results (see the section *Technical Aspects of Direct Blood Pressure Measurement*). In view of these considerations, Gorback's [24] comments provide a valuable guide: "It is preferable to understand the strengths and weaknesses of the various techniques and expected relative values, since they do not measure the same event." In the end, the clinician must acquire sufficient understanding of the performance characteristics of these monitors to become the arbiter of measurement discrepancies by integrating all available data.

Indirect Measurement of Arterial Blood Pressure

Manual Intermittent Techniques

Most indirect methods of blood pressure measurement rely on a Riva-Rocci sphygmomanometer. As described by Riva-Rocci in 1896, [25] this apparatus included an armencircling inflatable elastic cuff, a rubber bulb to inflate the cuff, and a mercury manometer to measure cuff pressure. [26] Riva-Rocci described the measurement of systolic arterial blood pressure by determining the pressure at which the palpated radial arterial pulse disappeared as the cuff was inflated. The scientific rigor and attention to detail of Riva-Rocci's work are chronicled in a translation celebrating his original publications. [26]

A variation of the Riva-Rocci method commonly employed today is generally termed the *return-to-flow technique.* Whereas the Riva-Rocci technique recorded the pressure during *cuff inflation* at which the pulse completely disappeared, the return-to-flow method records the pressure during *cuff deflation* at which the pulse reappears. Using this technique, systolic blood pressure can be estimated without a stethoscope using only a cuff and manometer. When the patient has a finger pulse oximeter or indwelling arterial catheter in the ipsilateral arm, the return to flow can be determined visually by the reappearance of the plethysmographic or arterial pressure waveforms.

Although return-to-flow methods provide a simple, rapid means to estimate systolic blood pressure, they do not allow measurement of diastolic blood pressure. Undoubtedly, the most widely used intermittent manual method for blood pressure determination is the auscultation of sounds originally described by Korotkoff in 1905. [27] [28] Using a Riva-Rocci sphygmomanometer and cuff, Korotkoff applied a stethoscope to the artery directly below the cuff to auscultate the sounds generated as the cuff was slowly deflated. These sounds are a complex series of audible frequencies produced by turbulent flow, instability of the arterial wall, and shock wave formation created as external occluding pressure on a major artery is reduced. [24] The pressure at which the first Korotkoff sound is auscultated is generally accepted as the systolic pressure (phase I). The sound character progressively changes (phases II and III), becomes muffled (phase IV), and finally absent (phase V). Diastolic pressure is recorded at phase IV or V. However, phase V may never occur in certain pathophysiologic states, such as aortic regurgitation. [29]

The auscultatory method for blood pressure determination is limited by excessively long or loose stethoscope tubing, which impairs sound transmission, or by poor hearing sensitivity of the observer. Aneroid manometers are subject to calibration errors and should be checked periodically. A more basic shortcoming of auscultation is the reliance on blood flow to generate Korotkoff sounds. Pathologic or iatrogenic causes for decreased peripheral blood flow, such as cardiogenic shock or high-dose vasopressor infusion, can attenuate or obliterate sound generation and result in significant underestimation of blood pressure. [30] In contrast, low compliance of the tissues underlying the cuff, as encountered in a shivering patient, will require an excessively high cuff-occluding pressure and produce "pseudohypertension." [24] Patients with severe calcific arteriosclerosis may have relatively noncompressible arteries, another circumstance wherein cuff blood pressures will yield spuriously elevated results compared with true intra-arterial blood pressure. [31]

Other common sources of error during intermittent manual blood pressure measurement include selection of an inappropriate cuff size or excessively rapid cuff deflation. Blood pressure cuff width should be 20 percent greater than arm diameter, and the cuff should be applied snugly after any residual air has been squeezed out. The pneumatic bladder inside the cuff should span at least half the circumference of the arm and be centered over the artery. Although too large a cuff generally will work well and produce little error, cuffs that are too narrow yield erroneously elevated values for blood pressure (Fig. 30-2) . [32] [33] Cuff deflation rate is another important variable that influences accurate blood pressure measurement, especially when deflation is performed manually. The decrease in cuff pressure should proceed slowly enough for the Korotkoff sounds to be auscultated and assigned properly to the current pressure in the cuff. Failure to identify the initial Korotkoff sounds will result in a falsely low measure of blood pressure. A deflation rate of 3 mm Hg/s limits this source of error, and coupling deflation rate to heart rate--2 mm Hg/beat--has been found to improve accuracy further. [34]

Automated Intermittent Techniques

Many limitations of manual intermittent blood pressure measurement have been overcome by automated noninvasive blood pressure (NIBP) devices, which are now used widely in medical care. By applying a single algorithm or

Figure 30-2 Effect of cuff size on manual blood pressure measurement. An inappropriately small blood pressure cuff yields erroneously high values for blood pressure because the pressure within the cuff is incompletely transmitted to the underlying artery. See text for greater detail.

method of data interpretation, NIBP devices provide consistent, reliable values for systolic, diastolic, and mean arterial pressure (MAP). In addition, automated NIBP devices provide alarm systems to draw attention to extreme blood pressure values and have the capacity to transfer data to an automated trending device or information system. However, the greatest advantage of automated NIBP devices compared with manual methods of blood pressure measurement is that they free the operator to perform other vital clinical duties while simultaneously ensuring frequent, repetitive blood pressure measurements.

Most automated NIBP devices are based on the technique termed oscillometry, a technique first described by von Recklinghausen in 1931. [35] In this method, variations in cuff pressure resulting from arterial pulsations during cuff deflation are sensed by the monitor and used to determine arterial blood pressure values. Peak amplitude of arterial pulsations corresponds closely to true MAP. [36] [37] (Interestingly, the reason many clinicians still refer to an automated NIBP device as a "Dinamap" is that the original clinically available monitors provided only this single, easily measured pressure value--MAP.) Values for systolic and diastolic pressure are derived using proprietary formulas that examine the rate of change of the pressure pulsations (Fig. 30-3). Systolic pressure is generally chosen as the pressure at which pulsations are increasing and are at 25 to 50 percent of maximum. Diastolic pressure is more difficult to determine but is commonly placed at the point where the pulse amplitude has declined by 80 (Figure Not Available) percent. [24]

Although oscillometry is used primarily in automated NIBP measurement, the same principles may be applied to determine blood pressure manually using a standard cuff and aneroid manometer. If the cuff is deflated slowly until the needle on the aneroid gauge begins to flicker or oscillate, this pressure value will provide a close estimate for systolic blood pressure. The primary advantage of this technique is that it can be performed quickly, using only one hand on the inflation bulb and pressure relief valve, thereby leaving the anesthesiologist's other hand free to maintain the patient's airway.

In clinical practice, oscillometric automated NIBP measurement has focused largely on pressures measured from

Figure 30-3 (Figure Not Available) Comparison of blood pressure measurements using Korotkoff sounds and oscillometry. Oscillometric systolic blood pressure is recorded at the point where cuff pressure oscillations begin to increase, mean pressure corresponds to the point of maximal oscillations, and diastolic pressure is measured where the oscillations become attenuated. Note the correspondence between these measurements and the Korotkoff sounds that determine auscultatory systolic and diastolic pressures. *(From Geddes LA: Cardiovascular Devices and Their Applications. New York; John Wiley, 1984: Fig. 34-2 . Reprinted by permission of John Wiley & Sons, Inc.)*

the upper arm. Sometimes the patient's surgical procedure or medical condition requires that the cuff be applied to the calf, ankle, or thigh. These are all acceptable alternatives, keeping in mind that an appropriate size cuff must be employed. Because the oscillometric NIBP technique provides accurate pressure measurements in pediatric patients, [38] [39] [40] several investigators have proposed using neonatal sized cuffs placed around a finger or thumb of an adult patient. [41] [42] [43] Although these alternatives may be appropriate in certain circumstances, their overall accuracy has not been widely validated and may not conform to accepted industry standards. [44]

Many other techniques have been described for automated NIBP measurement, but none have supplanted the standard oscillometric technique. One device uses the Doppler principle to determine blood flow distal to the cuff [45] and another senses motion of the arterial wall. [46] Although these have been found to record blood pressure with acceptable accuracy, they require extra efforts to place and stabilize additional sensing transducers. Supraorbital artery oscillometry has been studied as an alternative site for blood pressure measurement but appears inaccurate compared with direct radial artery pressure values, perhaps owing to the peripheral location and vasoreactive sensitivity of the supraorbital artery. [47] Photo-oscillometry to detect brachial artery movement has also been described, but awaits broader validation in clinical practice. [48]

Under controlled clinical conditions, numerous investigators have demonstrated that automated NIBP measurements closely approximate directly measured arterial pressure. [22] [32] [37] [49] However, other studies underscore the fact that marked disagreement occurs when direct and indirect pressure measurements are compared, [50] particularly when radial artery pressure is used as the direct measurement standard [23] [51] or when techniques are compared under changing clinical conditions. When direct brachial artery pressures have been compared with various indirect methods, (including manual auscultation, automated oscillometry, aneroid manometer visual onset of needle oscillations, and return to flow), the relation between the indirect and direct pressures varied between patients, within patients over time, and with changing hemodynamic conditions. [52]

As noted, some authors have emphasized the lack of exact agreement between different measurements of blood pressure. [23] [24] [48] [53] Standards for performance of automated NIBP devices have been advanced by organizations such as the American Association for the Advancement of Medical Instrumentation (AAMI) and the British Hypertension Society. AAMI standards require a monitor to record blood pressure to within 5±8 mm Hg (mean ± standard deviation) prediction error compared with the reference method. [48] However, clinical performance of an NIBP monitor should be evaluated by other criteria as well. These include the number of outlier values, duration of discrepancies, magnitude of individual errors, and performance under variable clinical conditions. [48]

Although automated blood pressure measurement techniques are considered noninvasive and relatively safe, complications have been reported. These include pain, petechiae and ecchymoses, limb edema, venous stasis and thrombophlebitis, peripheral neuropathy, and even compartment syndromes. [48] [54] [55] [56] These morbid events occur more often following prolonged periods of excessively frequent cuff inflation/deflation cycling, resulting in local trauma or impaired distal limb perfusion. Other factors that may contribute include cuff misplacement across a joint or repeated attempts to determine blood pressure in the presence of an artifact-producing condition, such as involuntary muscle tremors. [57] Caution should be exercised when using these monitors in patients with depressed consciousness, preexisting peripheral neuropathies, arterial or venous insufficiency, or irregular cardiac rhythms. [54]

Automated Continuous Techniques

In the past, continuous blood pressure monitoring required direct arterial cannulation. Advances in microprocessor and servomechanical control technology have enabled noninvasive techniques to provide a reasonable representation of the arterial pressure waveform and a nearly continuous assessment of blood pressure. The most widely investigated of these devices measures finger blood pressure using a servoplethysmomanometer, designed and first reported by Penaz in 1973. [58]

In essence, the finger blood pressure device uses an *arterial volume-clamp* method. It consists of a small cuff secured around the middle phalanx of a finger or the base of the thumb. The inflatable, flexible cuff contains an infrared photoplethysmograph. The cuff and photoplethysmograph are linked through a sophisticated servocontrolled mechanism housed within a small box that is strapped to the wrist. The plethysmograph continually measures the size (i.e., diameter) of the digital arteries using transillumination. To begin monitoring, a "locking" calibration procedure is performed by varying cuff pressure to establish the vessel size at which oscillometric pressure variation is maximal. As noted, this corresponds to MAP. An electromechanical feedback loop is then established, and external pressure applied to the cuff is varied continuously to keep the measured vessel size constant at the set-point. Thus, cuff pressure tracks arterial pressure throughout the cardiac cycle and is displayed on the monitor screen as a continuous waveform. More detailed descriptions of this technology are readily available. [59] [60] [61] [62] [63]

Over the past 15 years, continuous noninvasive finger blood pressure measurement devices have undergone numerous clinical evaluations comparing their performance with direct arterial pressure measurements. [59] [60] [61] [62] [63] Many of these investigations have demonstrated small overall mean differences between finger and intra-arterial pressure meas-urements. However, as noted earlier, small overall mean pressure differences do not necessarily indicate good meas-urement agreement. In clinical practice, the frequency of major measurement errors may be the more relevant and important issue. For example, Smith et al [63] found that finger arterial spasm precluded accurate pressure measurement in 5 percent of patients. Gibbs et al [64] studied 20 patients during anesthesia for major surgery and reported that MAP measured from a finger cuff differed from direct arterial pressure values by more than 10 mm Hg in 30 percent of patients and more than 20 mm Hg in 5 percent of patients. Other investigations in patients undergoing thoracic [65] and vascular [66] surgery similarly have shown small

average pressure differences overall but large discrepancies in a significant number of individual patients.

In addition to the questionable accuracy of finger blood pressure measurement, other factors undoubtedly have limited more widespread application of this technology. Unlike direct invasive arterial blood pressure monitoring, indirect noninvasive pressure measurement does not provide access for blood sampling, which is a frequent requirement in the setting of continuous pressure monitoring. By definition, finger blood pressure monitoring records a distal arterial pressure, which tends to be lower than brachial arterial pressure in elderly patients with atherosclerosis and to be higher than brachial pressure in young patients, because of peripheral pulse wave amplification. Using sophisticated electronic processing techniques, Bos et al [67] demonstrated that the pulse wave shape and pressure values of the finger blood pressure signal could be corrected to resemble direct brachial artery pressure waveforms within the limits of accuracy described by the AAMI. However, these sophisticated algorithms have not yet been integrated into commercially available monitors. Because the "transducer" recording blood pressure with this method is the finger, the vertical height of the finger becomes an important determinant of the pressure recorded, just as transducer height is important with direct arterial pressure measurement (see later discussion). [63] Finally, the potential for circulatory impairment of the distal finger caused by the constantly inflated cuff has been a cause for concern. Gravenstein et al [68] demonstrated mild hypoxemia in the capillary blood of the fingertip during finger blood pressure monitoring. No adverse outcomes were noted in these study patients or in others in whom finger blood pressure measurement was performed for as long as 7 hours. [63] Despite the apparent safety of these devices for short-term use, it is not surprising that these considerations have limited more widespread clinical application of continuous finger blood pressure monitoring.

Other automatic and continuous techniques have been used to measure blood pressure noninvasively. One such device reconstructs an arterial pressure waveform from *arterial wall displacement* measurements, following an oscillometric calibration. Unfortunately, changes in arterial compliance affect the clinical performance of this instrument. [69] Because arterial pulse wave velocity depends on arterial blood pressure, another device uses *pulse transit time* as recorded from dual pulse oximeter probes placed on the ear and finger following oscillometric calibration from the contralateral arm. [70] This device has also performed poorly in clinical settings, with indirectly monitored blood pressures changing in an opposite direction from the direct intraarterial pressure more than 30 percent of the time. [70] A third method used for continuous noninvasive pressure monitoring is *arterial tonometry,* a version of applanation tonometry. [71] [72] [73] In brief, a superficial artery (usually the radial) is compressed and partially flattened against the underlying bone. This flattened arterial surface serves as a "transducer" for intravascular pressures acting perpendicularly against the vessel wall. An array of piezoelectric crystals positioned on the skin overlying this flattened portion of artery senses arterial pressure changes and translates them into a continuous arterial pressure waveform. The device is calibrated at intervals by cuff oscillometry from the upper arm. Early investigations suggested that the clinical performance of this device was better than other forms of continuous noninvasive pressure monitoring. [71] [72] Unfortunately, more recent clinical studies have identified limitations of this device in pediatric patients [74] and in patients receiving vasodilating drugs. [48] Like other automated, continuous noninvasive blood pressure techniques, arterial tonometry holds promise as a means of rapidly detecting changes in blood pressure. However, in terms of absolute accuracy of blood pressure measurement, intermittent oscillometry appears to be superior to radial artery tonometry. It remains unclear whether any noninvasive technique will significantly reduce the need for direct arterial pressure monitoring or whether these methods will replace automated intermittent oscillometry as the standard noninvasive blood pressure monitoring method in anesthesia and critical care.

Direct Measurement of Arterial Blood Pressure

Arterial cannulation with continuous pressure transduction and waveform display remains the accepted standard for blood pressure monitoring. Although direct blood pressure measurement is more costly, has the potential for more complications, and requires more technical expertise to initiate and maintain compared with noninvasive monitoring, this technique is selected in many patients undergoing anesthesia. Indications for and advantages of direct arterial blood pressure measurement can be considered to fall into five major categories:

1. *Arterial blood sampling.* When frequent samples ofarterial blood are required, an arterial catheter provides reliable vascular access and obviates the need for multiplearterial punctures. New clinical devices allow continuous monitoring of arterial blood gas values using fiberoptic sensors placed directly into the artery through the vascular catheter. [75] [76] An alternative newer technology uses an automated, in-line sampling method for point of care *ex vivo* analysis of blood gases and chemistries. [77]
2. *Continuous real-time monitoring.* Direct arterial catheterization is chosen when rapid, moment-to-moment blood pressure changes are anticipated, and their immediate detection is considered to be a high priority. These changes in blood pressure might be expected when the patient has circulatory instability caused by an underlying medical condition, or when the planned operative procedure will cause large, sudden cardiovascular changes. Direct arterial monitoring is employed for many operative procedures in which major blood loss or fluid shifts are anticipated. The Australian Incident Monitoring Study of 1993 confirmed the superiority of direct arterial pressure monitoring over indirect monitoring techniques for the early detection of intraoperative hypotension. [78]
3. *Intentional pharmacologic or mechanical cardiovascular manipulation.* Direct arterial pressure monitoring is vital whenever the clinician expects to employ therapies that will cause major circulatory changes. Familiar examples include cardiac surgery with cardiopulmonary bypass, intra-aortic balloon counterpulsation, deliberate induced hypotension, major vascular surgery, and administration of vasoactive drug infusions.

4. *Failure of indirect blood pressure measurement.* The limitations of indirect blood pressure measurement are reviewed earlier in this chapter. Any cuff-based measurement techniques may prove impossible in some morbidly obese patients or those with burned extremities.
5. *Supplementary diagnostic clues.* Many diagnostic clues about the patient's condition may be derived from a critical analysis of the arterial pressure waveform. Fifty years ago, Eather et al [79] emphasized these diagnostic insights in a paper that introduced and promoted direct monitoring of "arterial pressure and pressure pulse contours" in anesthetized patients. Some of these diagnostic insights are readily apparent and commonly sought, such as identification of the arterial pressure dicrotic notch to guide proper timing for intra-aortic balloon counterpulsation. Careful analysis of the arterial pressure waveform can provide many additional subtle pathophysiologic insights. [80] Some important examples appear at the end of this section.

Percutaneous Radial Artery Cannulation

Several peripheral arteries are available for percutaneous cannulation, but radial artery pressure monitoring is most common in anesthesia and critical care. It is technically easy to perform and rarely associated with complications, owing to good collateral circulation of the hand. [81] Slogoff et al [82] described 1,700 cardiovascular surgical patients who underwent radial artery cannulation without ischemic complications, despite evidence of radial artery occlusion after decannulation in more than 25 percent of patients. Serious complications after radial artery cannulation are extremely rare in the absence of contributing factors, such as preexisting vasospastic arterial disease, previous arterial injury, protracted shock, high-dose vasopressor administration, prolonged cannulation, or infection. [83] [84] Like any procedural skill, percutaneous arterial cannulation is best learned by observing and emulating the methods of more experienced professionals. From the various elements of this collected array of techniques, the clinician should settle on a method that produces greatest overall personal success.

Before attempting radial artery cannulation, many clinicians assess the adequacy of collateral flow to the hand by performing a modified Allen test. This bedside examination, originally described by E.V. Allen in 1929, [85] provided a technique to assess arterial stenosis in the hands of patients with thromboangiitis obliterans. To perform the Allen test, the examiner compresses the radial and ulnar arteries and asks the patient to make a tight fist to exsanguinate the palm. As the ulnar occlusion is released, the color of the open palm is observed. Normally the palm will have a striking flush in several seconds; severely reduced ulnar collateral flow is present when the palm remains pale for more than 10 seconds.

Although the Allen test is meant to identify patients at high risk for ischemic complications from radial artery catheterization, the predictive value of this test has been questioned. Many reports reviewing permanent ischemic sequelae noted normal Allen tests prior to catheterization. [83] [86] [87] [88] In contrast, numerous radial cannulations performed despite abnormal Allen test results have not produced ischemic complications. [82] [89] [90] Allen tests of radial artery patency bore no relationship to distal blood flow assessment by fluorescein dye injection [91] or photoplethysmography. [92] Although it is obviously of great importance that the clinician minimize the chances of significant distal ischemia from arterial pressure monitoring, it appears that the Allen test cannot be relied on to predict this adverse outcome.

The following technique is offered as one method for consistent, successful radial artery cannulation (Fig. 30-4) . The wrist and hand are immobilized in mild dorsiflexion and secured with the wrist resting across a soft pad, folded towel, or stack of sponges. The course of the radial artery at the wrist is identified by gentle palpation. After sterile preparation of the skin, local anesthetic solution (typically 1% lidocaine) is injected intradermally and subcutaneously alongside the artery, using a 25- or 26-gauge needle. Generous local anesthetic infiltration not only ensures that the procedure is pain free, but it may also reduce vessel spasm at the time of arterial puncture. A small nick is placed in the skin at the intended puncture site with a #11 surgical blade or large hypodermic needle. This serves to prevent "burring" of the catheter tip as it passes through tough skin.

Next, the arterial catheter is checked for frictionless movement over the needle. Many catheters come encased in a plastic sleeve that should be inserted into the needle hub to serve as a reservoir for the blood that pulses out when the artery is entered. Alternatively, a 3-mL syringe with the plunger removed should be used as a blood reservoir. Although a 20-gauge Teflon catheter is the most common one used for radial artery cannulation, the size (20- or 18-gauge) and composition (Teflon or polypropylene) of the catheter seem to have little influence on the frequency of complications. [82] The catheter is advanced toward the palpated artery at a comfortable angle for the operator, generally 30 to 45 degrees. The needle tip is often perceived to be piercing the artery, but successful puncture is confirmed by identifying a "flash" of arterial blood flow into the needle hub and reservoir.

Because the needle always protrudes slightly beyond the tip of the catheter, the needle tip is the only portion of the needle-catheter assembly that is certainly within the arterial lumen when the flash of blood is first identified. To ensure that the catheter enters the vessel lumen, the clinician must lower the angle and advance the entire needle-catheter assembly a few millimeters (see Fig. 30-4) . If blood continues to flow into the needle reservoir, it is certain that the needle and catheter are both within the lumen of the radial artery, and the catheter alone can now be advanced gently its full length into the artery. Failure to recognize that the needle is the leading edge of the needle-catheter assembly is responsible for most technical failures by inexperienced operators. The novice often attempts to advance the catheter into the radial artery when only the needle tip has entered the lumen. The catheter then "fails to thread" because it has not yet entered the radial artery. One should never try to advance the catheter unless blood is flowing into the collecting reservoir, thereby confirming that the catheter tip is within the arterial lumen.

Once the catheter is fully advanced into the vessel lumen, occlusive pressure is held transiently on the proximal artery

Figure 30-4 Percutaneous radial artery cannulation. (A) The wrist is positioned and the artery identified by palpation. (B) The catheter-over-needle assembly is introduced through the skin and advanced toward the artery. (C) Entry of the needle tip into the artery is identified by the flash of arterial blood in the needle hub reservoir. (D) Needle-catheter assembly is advanced at a lower angle to assure entry of the catheter tip into the vessel. (E) If blood flow continues into the needle reservoir, the catheter is advanced gently over the needle into the artery. (F) The catheter is attached to pressure monitoring tubing while maintaining proximal occlusive pressure on the artery. See text for greater detail.

to limit blood loss, and the needle is removed. A narrow bore, low compliance pressure tubing is then fastened to the catheter, an appropriate sterile dressing is applied, and the apparatus is taped securely or sutured to the wrist.

If the needle punctures the back wall of the artery, it is not a grievous error as long as the operator recognizes this by observing that blood no longer enters the needle reservoir (Fig. 30-5) . In fact, some clinicians choose the "transfixion" technique, in which both the front and back walls of the artery are punctured intentionally, the needle is removed from the catheter, and the catheter is pulled back into the vessel lumen. Although it is unnecessary to place an additional hole in the back wall of the radial artery for successful cannulation, technique per se does not appear to influence the incidence of postcannulation arterial thrombosis. [90] [93] [94]

When blood flow into the needle reservoir ceases, it is

Figure 30-5 Salvaging arterial cannulation (I). (A) When blood flow into the needle reservoir ceases, the needle tip has exited the vessel lumen. (B) The needle tip is withdrawn several millimeters so that the catheter tip becomes the leading edge of the needle-catheter assembly and arterial blood flow reappears in the collection reservoir. (C) When arterial blood flow is reestablished, the catheter is advanced into the arterial lumen.

easy to salvage the procedure if one considers the two most likely explanations and acts accordingly. Either the needle tip alone or both the needle and catheter tips have pierced the back wall of the artery, and one can easily determine which has occurred. At this point, even though blood flow into the collection reservoir has stopped, one should not withdraw the entire needle-catheter assembly. Instead, the needle alone should be retracted several millimeters into the catheter, thereby making the catheter tip the "leading edge." If arterial blood flow reappears in the collection reservoir, the catheter tip evidently has remained in the vessel lumen, and the catheter now may be advanced fully (see Fig. 30-5) . Conversely, if retraction of the needle into the catheter fails to restore blood flow into the collection reservoir, the catheter is pulled back slowly until pulsatile blood flow reappears, and then the catheter is advanced into the artery (Fig. 30-6) . The key point is for the operator to note at all times whether the needle tip or the catheter tip is the leading edge of the assembly.

If one is unsuccessful in passing the catheter, repeated attempts can be made, but excessive punctures of the artery will increase the risk of hematoma, damage to the vessel wall, and loss of radial artery flow. If the catheter appears to be in the lumen of the artery, but there is difficulty in advancing further into the vessel, a sterile guide wire may be passed through the catheter into the artery to aid insertion (Fig. 30-7) . Some arterial cannulation kits have integrated needle-guide-wire-catheter assemblies for this purpose. When these devices are employed, the needle tip is introduced into the artery, the wire is inserted through the needle, and then the catheter is inserted over the guide wire (Fig. 30-8) . Although some authors have suggested that guide-wire-based techniques will improve arterial cannulation success rate in some patients, [95] it appears that success is more a function of operator experience and personal preference. [96]

Alternative Arterial Pressure Monitoring Sites

If the radial arteries are unsuitable for pressure monitoring, several alternative cannulation sites are available. The *ulnar artery* is cannulated using a technique much like that described for the radial artery. Even in circumstances in which previous attempts to cannulate the ipsilateral radial artery have failed, the ulnar artery may be cannulated safely. [82] However, adequacy of collateral flow from the radial artery to the hand should be established prior to this procedure with a modified Allen test in which one releases radial artery occlusion, maintains ulnar artery compression, and observes restoration of flow to the hand. Although *brachial artery* cannulation does not have the anatomic benefit of the collateral circulation present at the wrist, some investigators have confirmed the safety of this cannulation site. [97] [98] Bazaral et al [99] reported the use of more than 3,000 brachial artery catheters in patients undergoing cardiac surgery over a 3-year period, with only one patient requiring a postoperative thrombectomy and no untoward sequelae. A slightly longer catheter is preferred for the brachial site, owing to the need for the catheter to traverse the elbow joint. Other small peripheral arteries occasionally chosen for pressure monitoring include the *dorsalis pedis, posterior tibial,* and *superficial temporal arteries.* The dorsalis pedis and posterior tibial arteries form the same collateral circulation to the foot that the radial and ulnar arteries provide to the hand. However, this anatomic safety feature is more theoretical than real in older adults because of the high incidence of lower extremity vascular

Figure 30-6 Salvaging arterial cannulation (II). (A) When blood flow into the needle reservoir ceases, both the needle tip and catheter tip may have exited the vessel lumen. (B) The needle tip is withdrawn several millimeters so that the catheter tip becomes the leading edge of the needle-catheter assembly. (C) If arterial blood flow does not reappear in the collection reservoir, the entire needle catheter assembly is now withdrawn, allowing the catheter tip to reenter the vessel as the leading edge. This is confirmed by the reappearance of arterial blood flow in the collection reservoir. (D) When arterial blood flow has been reestablished, the catheter is advanced into the arterial lumen.

disease in many of these same patients who require direct arterial pressure monitoring. Consequently, successful clinical experience using these smaller peripheral arteries for pressure monitoring has been reported predominantly in children. [100]

Axillary artery monitoring provides another site for long-term pressure monitoring. Advantages include patient comfort and mobility and access to a central arterial pressure waveform. Complications appear to be infrequent. [101] [102] A wire-guided catheterization technique and a longer indwelling catheter may improve the success rate of axillary cannulation. Clinicians should be aware, however, that the risk of cerebral embolization is increased when using more centrally located catheters. The *femoral artery* is the largest artery commonly selected for pressure monitoring and appears to have a safety record comparable with that of other sites. [103] As with axillary arterial pressure monitoring, the femoral artery waveform more closely resembles aortic pressure than waveforms recorded from peripheral sites. Although the risk of distal ischemia may be reduced because of the large luminal diameter of the artery, infectious complications may occur more often with femoral than with radial artery catheters. [102] [104] Catheterization of the femoral artery is best achieved with a guide-wire technique, much like the procedure for central venous cannulation. The operator must be careful to puncture the femoral artery below the inguinal ligament, thereby limiting the risk of catastrophic complications, such as uncontained hemorrhage, into the pelvis or peritoneum. [105] [106]

Choosing the Site for Arterial Pressure Monitoring

Several factors influence the choice of site for arterial pressure monitoring, even though the radial artery of the nondominant hand is usually preferred for most applications. One important consideration is whether significant regional differences in blood pressure exist. Frank et al [107] demonstrated that 21 percent of patients undergoing peripheral vascular surgery had a blood pressure difference between the two arms that exceeded 20 mm Hg. In view of the prevalence of this problem, when the blood pressure is lower in one arm than the other, or when the pulses are weaker on one side, one should never select the side with the weaker pulse, because the blood pressure from this site will likely underestimate aortic pressure. [107] Clearly, evidence for abnormal collateral

Figure 30-7 Using a guide wire to aid arterial cannulation. (A) A catheter may not thread into a tortuous artery. (B) The needle is removed from the catheter, and a guide wire is advanced through the catheter into the artery. (C) The catheter is advanced over the guide wire into the arte-rial lumen.

flow in one hand but not the other would be another important reason to select the more normal side.

Several surgical and anatomic considerations also influence the site of arterial pressure monitoring. Regional arte-rial pressure gradients caused by atherosclerosis, arterial dissection, and embolism preclude monitoring from the affected sites, because the true central aortic pressure may be underestimated significantly. Unusual patient positions during surgery may produce regional arterial compression, and surgical retraction, particularly during cardiothoracic operations,

Figure 30-8 Arterial cannulation using an integrated needle-guide-wire-catheter assembly. (A) The artery is identified by a flash of arterial blood into the collection reservoir as the needle tip enters the vessel. (B) The guide wire is advanced through the needle into the vessel lumen. (C) The catheter is advanced over the guide wire.

can produce local vascular compression. [53] [108] The nature of the operative procedure is another important determinant of the appropriate site for arterial pressure monitoring. Operations requiring placement of a proximal thoracic aortic cross-clamp may interrupt arterial flow to the left subclavian artery and its tributaries in the left arm, as well as branches of the aorta beyond the clamp. In these cases, blood pressure monitored from the right arm best estimates aortic root pressure and carotid arterial pressure and is used to

guide anesthetic management. In addition, pressure may be monitored simultaneously from a femoral artery in an attempt to estimate perfusion pressure to vital organs distal to the aortic cross-clamp.

Various pathophysiologic disturbances will produce generalized arterial pressure gradients in the body and thus should be considered when choosing a site for arterial pressure monitoring. Large differences between peripheral and central arterial pressures may be seen in patients with shock. [30] Femoral artery systolic pressure may exceed radial artery systolic pressure by more than 50 mm Hg in septic patients receiving high-dose norepinephrine infusions, an observation that has significant therapeutic implications for the management of critically ill patients. [109] Other vasoactive drugs, anesthetics (particularly neuraxial block), and changes in patient temperature produce pressure gradients that alter the relation between central and peripheral arterial pressure measurements. [48] During hypothermia, thermoregulatory vasoconstriction causes radial arterial systolic pressure to exceed femoral artery systolic pressure. [110] Conversely, during rewarming, vasodilation reverses this gradient and causes radial artery pressure to underestimate femoral artery pressure. [110] This phenomenon is observed daily in cardiac surgical patients who are rewarmed rapidly at the termination of cardiopulmonary bypass (Fig. 30-9) . Numerous investigations have documented that the radial arterial pressure underestimates central aortic pressure in these patients, often by more than 20 mm Hg. [48] [111] [112] [113] [114] [115] [116] These pressure differences persist after bypass for several minutes in most patients, usually resolve within an hour, and should be considered when one uses the radial artery pressure to guide treatment in this setting. Its mechanism is still unresolved. [48] [117] Some investigators believe that the lower radial arterial than central arterial pressure results from vasodilation and decreased resistance in the forearm and hand vasculature during rewarming. [111] [113] [114] [115] [116] Others have demonstrated that the gradient arises because of radial artery

Figure 30-9 Arterial pressure gradients following cardiopulmonary bypass. (A) Femoral and radial artery pressure traces recorded 2 minutes after bypass (2 min postbypass), when radial artery pressure underestimates the more centrally measured femoral artery pressure and 30 minutes later (30 min postbypass), when radial and femoral arterial pressures have been equalized and radial pressure has assumed a more typical morphology. Note that dicrotic notch (arrows) is visible in the femoral pressure trace after bypass, but not initially in the radial pressure trace. (B) Femoral and radial artery pressure traces recorded before cardiopulmonary bypass (prebypass), two minutes following bypass (2 min postbypass), and 30 minutes following bypass (30 min postbypass). Note changing relationship between femoral and radial artery pressure measurements at these different times. See text for greater detail.

vasoconstriction, which begins shortly after aortic cross-clamping. [48] [118] Finally, one must recognize that even under normal circumstances, the arterial pressure waveform changes its morphology as it is transmitted through the vascular tree, resulting in a wider pulse pressure recorded from a peripheral artery than from a more central location. [119] [120] These normal physiologic differences in arterial pressure recorded from different sites should be considered whenever direct arterial pressure monitoring is performed.

Complications of Direct Arterial Pressure Monitoring

The widespread application of invasive arterial pressure monitoring in anesthesia and intensive care is related, no doubt, to the extremely good safety record of this technique. Large clinical investigations confirm the low incidence of long-term complications following radial artery cannulation, in particular, the small risk of distal ischemia, which is likely in the range of 0.1 percent or less. [81] [82] Despite suggestions in the literature that catheter size and composition influence the frequency of arterial thrombosis, it is unlikely that these factors are important determinants of clinical complications. [82]

The Australian Incident Monitoring Study provides some noteworthy recent observational data describing the incidence and types of complications of blood pressure monitoring. [78] [121] Of 2,000 untoward clinical events reported in this investigation, only 13 related to peripheral arterial cannulation, fewer than the number associated with central venous or peripheral venous cannulation (18 and 33 incidents, respectively). [121] Five of these 13 cases involved equipment faults or misassembly; in three cases, the arterial line was mistaken for an intravenous line and used for drug injection; in three cases, the arterial line was either disrupted or kinked; in one case, a fragment of guide wire was broken off inside the patient; and in only one instance did transient vasospasm follow radial artery cannulation. [121] A second report from this study, which focused entirely on blood pressure monitoring, noted that direct pressure monitoring failed or gave misleading results in ten instances, including five in which there was either incorrect calibration, incorrect interpretation of the pressure display, or unrecognized subclavian artery stenosis. [78]

Certain clinically relevant conclusions can be drawn from these data. First, it is striking that many if not most of the complications from direct arterial pressure monitoring can be attributed to equipment misuse. This serves to highlight the importance of proper operator knowledge, training, and experience in ensuring patient safety. Second, it is vital to have a system for the manual determination of blood pressure readily available at all times. The clinician should have a low threshold to measure the blood pressure manually and from a different site, particularly when the results of invasive pressure monitoring do not match the patient's general clinical appearance.

In summary, serious complications, although rare, do occur following arterial cannulation. Reports describe retained guide wires requiring surgical extraction, [122] fatal hemorrhage following difficult femoral artery cannulation, [105] and upper extremity compartment syndrome following brachial artery cannulation. [123] In almost all cases, however, there were technical problems during catheter placement or confounding medical problems, such as shock or coagulopathy. Infectious complications are increasingly rare now that disposable transducers have replaced reusable ones. Because retrograde arterial embolism is possible whenever forceful flushing of a peripheral arterial catheter is performed, [124] special care should be exercised whenever more centrally located arterial catheters are used, including those in the superficial temporal artery, axillary artery, or aorta, when monitoring from the central lumen of an intra-aortic balloon pump.

Technical Aspects of Direct Blood Pressure Measurement

Direct measurement of arterial blood pressure requires that the original pressure waveform from the cannulated artery be reproduced accurately on the bedside monitor. Not surprisingly, the displayed pressure signal is influenced by the system plumbing, including the arterial catheter, extension tubing, stopcocks, flush devices, transducer, amplifier, and recorder. Consequently, it is very important to appreciate how the monitoring system may influence the contour of the pressure waveform, as well as the displayed values for systolic and diastolic blood pressure. [55] [125] [126]

Direct pressure monitoring systems used in the operating room and intensive care units are described as *underdamped second-order dynamic systems.* [125] [127] Other authors have provided detailed technical descriptions of the underlying physical principles. [125] [128] [129] [130] Briefly, fluid-filled, catheter-transducer monitoring systems may be modeled after simple mass-spring systems. [128] Intuitively, when the mass at the end of a spring is displaced and then released, a characteristic simple harmonic motion is observed. Clinical pressure monitoring systems exhibit similar physical behavior. This behavior depends on three characteristic physical properties: elasticity, mass, and friction. These three properties determine the system operating characteristics, termed the *frequency response* or *dynamic response,* which in turn is characterized by two important system parameters, *natural frequency* (f_n, omega) and *damping coefficient* (zeta , *Z,* alpha , *D).* Natural frequency describes how rapidly the system oscillates, and the damping coefficient describes how rapidly it comes to rest. Natural frequency and damping coefficient are relatively easy to measure and dramatically influence the appearance of the recorded pressure waveform. Before describing how these parameters can be measured in clinical practice, it is useful to consider why they are important.

Frequency Content of the Arterial Pressure Waveform

The arterial blood pressure waveform is a periodic complex wave, which can be reproduced by Fourier analysis, a technique that recreates the original complex pressure wave by summing a series of simpler sine waves of various amplitudes and frequencies. [126] [131] The original pressure wave has

Figure 30-10 (Figure Not Available) Arterial blood pressure waveform produced by summation of sine waves. The fundamental wave (top) added to 63% of the second harmonic wave (middle) results in a pressure wave (bottom) that resembles an arterial blood pressure waveform (box). See text for greater detail. *(From Mark JB: Atlas of Cardiovascular Monitoring. New York, Churchill Livingstone, 1998: Fig. 9-1.)*

a characteristic periodicity termed the *fundamental frequency,* which is equal to the pulse rate. Note that the pulse rate is reported in beats per minute, whereas the fundamental frequency is reported in cycles per second or Hertz (Hz). For example, a pulse rate of 60 beats/min equals 1 beat/s or 1 cycle/s or 1 Hz.

The sine waves that sum to produce the complex wave have frequencies that are multiples or *harmonics* of the fundamental frequency. A crude arterial waveform, which displays a systolic upstroke, systolic peak, dicrotic notch, and so forth, can be reconstructed with reasonable accuracy from two sine waves, the fundamental frequency and the second harmonic (Fig. 30-10) (Figure Not Available) . If the original arterial pressure waveform contains high-frequency components such as a steep systolic upstroke or other sharp details, higher frequency sine waves (and more harmonics) are needed to provide a faithful reconstruction of the original pressure waveform. As a general rule, six to ten harmonics are required to provide adequate reproduction of most arterial pressure waveforms, [131] [132] Hence, accurate blood pressure measurement in a patient with a pulse rate of 120 beats/min (2 cycles/s or 2 Hz) requires a monitoring system dynamic response of 12 to 20 Hz. Clearly, the faster the heart rate and the steeper the systolic pressure upstroke, the greater will be the dynamic response that is required from the monitoring system. As a corollary, venous pressure waveforms, which generally do not have steep waves or high frequency components, do not require monitoring systems with such high frequency responses.

Natural Frequency and Damping Coefficient

If the monitoring system has a natural frequency that is too low, frequencies in the monitored pressure waveform will approach the natural frequency of the measurement system. As a result, the system will resonate, and pressure waveforms recorded on the monitor will be exaggerated or amplified versions of true intra-arterial pressures (Fig. 30-11) (Figure Not Available) .

Figure 30-11 (Figure Not Available) Underdamped arterial pressure waveform. Systolic pressure overshoot and additional small, nonphysiologic pressure waves (arrows) distort the waveform and make it hard to discern the dicrotic notch (boxes). Digital values displayed for direct arterial blood pressure (ART 166/56, mean 82 mm Hg) and noninvasive blood pressure (NIBP 126/63, mean 84

mm Hg) show the differences in pressure measurement that arise because of an underdamped arterial pressure waveform. *(From Mark JB: Atlas of Cardiovascular Monitoring. New York, Churchill Livingstone, 1998: Fig. 9-4.)*

This phenomenon is the familiar arterial pressure waveform that displays *overshoot, ringing,* or *resonance.* Tachycardia and steep systolic pressure upstrokes present the greatest challenge for clinical monitoring, because the higher frequency contents of these waveforms more likely approach the resonant frequency of the measurement system.

The bedside monitoring system must not only have a sufficiently high natural frequency, but it must also have an adequate damping coefficient. The *overdamped* arterial pressure waveform has a slurred upstroke, absent dicrotic notch, and loss of fine detail. Severely overdamped pressure waves display a falsely narrowed pulse pressure, although the MAP value may remain reasonably accurate (Fig. 30-12) (Figure Not Available) . In contrast, *underdamped* pressure waveforms display systolic pressure overshoot and contain additional artifacts that are produced by the measurement system but not part of the original intravascular pressure waveform (see Fig. 30-11) (Figure Not Available) . It is a mistake to attach physiologic significance to these small waves or artifacts, because they are produced by an underdamped monitoring system that continues to ring or oscillate abnormally in response to the input pressure signal.

Adequate Dynamic Response

With a basic understanding of natural frequency and damping, the way in which these two parameters interact in a monitoring system to produce the observed waveforms can be considered. Most catheter-tubing transducer systems are underdamped but have an acceptable natural frequency that exceeds 12 Hz. If the system natural frequency is lower than 7.5 Hz, the pressure waveform may be distorted, and damping adjustment cannot make the monitored waveform resemble the original waveform adequately. [55] [125] Conversely, if

Figure 30-12 (Figure Not Available) Overdamped arterial pressure waveform. The overdamped pressure waveform (A) shows a diminished pulse pressure compared to the normal waveform (B). The slow speed recording below demonstrates a 3-minute period of damped arterial pressure. Despite the damped pressure waveform, mean arterial pressure remains unchanged during this period. *(From Mark JB: Atlas of Cardiovascular Monitoring. New York, Churchill Livingstone, 1998: Fig. 9-3.)*

natural frequency can be increased sufficiently (e.g., 24 Hz), damping will have minimal effect on the monitored waveform, and faithful reproduction of intravascular pressure is achieved more easily (Figs. 30-13 (Figure Not Available) and 30-14) (Figure Not Available) . In other words, *the lower the natural frequency of the monitoring system, the more narrow will be the range of damping coefficients that can be tolerated to ensure faithful pressure wave reproduction or adequate dynamic response.* For example, if the monitoring system natural frequency is 10 Hz, the damping coefficient must be between 0.45 and 0.6 for accurate pressure waveform reproduction. In this situation, too low a damping coefficient causes the system to be underdamped, to resonate, and to produce a factitiously elevated systolic blood pressure. In contrast, too high a damping coefficient produces an overdamped system, in which systolic pressure is falsely decreased and fine detail in the pressure trace is lost.

In summary, a pressure monitoring system will have optimal dynamic response if its natural frequency is as high as possible. In theory, this is achieved best by limiting the length of tubing and using only stiff tubing that is designed for pressure monitoring. Normal intravenous extension tubing should not be used because it is too compliant and will cause the monitoring system to have too low a natural frequency and be excessively damped. Blood clots and air bubbles contained within the tubing-stopcock transducer plumbing will adversely affect the dynamic frequency response in a similar fashion. These clots and bubbles are often trapped and concealed in stopcocks and other connection points, so it is best to keep the monitoring system simple with the fewest components necessary.

Because clinical pressure monitoring systems are typically underdamped and display some degree of systolic pressure overshoot, some clinicians may attempt to increase the damping in the system by introducing a small air bubble into the monitoring tubing line. There are several problems with this approach. First, placing an air bubble in the line exposes

Figure 30-13 (Figure Not Available) Interaction between damping coefficient (D) and natural frequency (f_n) in pressure waveform recordings. (A) Underdamped pressure waveform (f_n 10 Hz, D 0.1) displays small artifactual waves and systolic pressure overshoot. (B) A small increase in D (0.2) diminishes these artifacts. (C) Critical damping (D 0.4) provides an accurate pressure waveform, even though f_n remains low. (D) Overdamping results in loss of fine detail and precludes determination of f_n or D. (E) Increased f_n (20 Hz) allows a low D (0.1) to have minimal impact on waveform morphology. Notice the similarities between waveforms (C) and (E). See text for greater detail. *(From Mark JB: Atlas of Cardiovascular Monitoring. New York, Churchill Livingstone, 1998: Fig. 9-7.) (Figure Not Available)*

the patient to the risk of arterial air embolism and the potential for retrograde flushing of the air bubble into the cerebral circulation. [124] Second, the "proper" size for the air bubble is not known. Too large a bubble will overdamp the system, distort the pressure waveform, and decrease systolic blood pressure artifactually. The third reason for avoiding air bubbles is somewhat counterintuitive but equally important. A small air bubble not only increases system damping, but it simultaneously lowers natural frequency. Consequently, resonance in the system may increase paradoxically, and systolic pressure overshoot may worsen. In this example (Fig. 30-15) (Figure Not Available) , a 0.1-mL air bubble markedly dampens the system but lowers natural frequency and causes an artifactual 25 mm Hg increase in systolic pressure.

As an alternative to placing air bubbles in the monitoring system, devices can be added to increase damping without lowering natural frequency (see Fig. 30-13) (Figure Not Available) . [125] To be more precise, these devices actually work through *impedance matching,* which eliminates wave reflections and prevents resonance in the monitoring system. The theoretical basis by which these devices work is beyond the scope of this chapter but is well described by other authors. [125] [128] [130] Although use of these devices in monitoring systems has been advocated by some, [125] others have highlighted the limitations of

Figure 30-14 (Figure Not Available) Interaction between damping coefficient and natural frequency. Depending on these two system parameters, catheter tubing- transducer systems fall into one of five different dynamic response ranges. Systems with an optimal dynamic response will record faithfully the most demanding pressure waveforms, whereas those with adequate dynamic response will record accurately most pressure waveforms seen in clinical practice. Overdamped and underdamped systems introduce artifacts characteristic of these technical limitations. Systems with a natural frequency less than 7 Hz are considered unacceptable. The rectangular cross-hatched box indicates the ranges of damping coefficients and natural frequencies commonly encountered in clinical pressure measurement systems. The point within the box shows the mean values of 30 such systems recorded by Schwid. [134] See text for greater detail. *(From Mark JB: Atlas of Cardiovascular Monitoring. New York, Churchill Livingstone, 1998: Figs. 9-6 (Figure Not Available) , 9-8 (Figure Not Available) , and 9-11.)*

these devices, including the inability to adjust or tune the monitoring system to provide the most accurate *in vivo* pressure recordings. [48] [130]

Clinical Measurement of Natural Frequency and Damping Coefficient

Although it may be preferable to limit the length of pressure monitoring tubing to optimize the system's dynamic response, this may not be possible in clinical practice. Thus, it becomes important to be able to assess the amount of distortion existing in the monitoring system in clinical use. The method used most often to evaluate the dynamic response of the monitoring system is the *fast flush test.*[125] [127] Under most conditions, this method yields results that are essentially identical to those from the standard laboratory square-wave testing. [133] The fast flush method has several practical advantages. It can be performed at the bedside without additional equipment beyond the normal monitors and recorders, and it tests the entire monitoring system, from catheter tip to transducer. [55] [125] [127]

To perform this test, the fast flush valve is opened briefly several times, and the resulting flush artifact is examined. Monitoring system natural frequency is related to the time period or distance between two successive oscillation cycles. An example is illustrated (Fig. 30-16) (Figure Not Available) , where the distance between two cycles is 1.7 mm at a recorder speed of 25 mm/s (standard ECG speed). Natural frequency is then easily calculated: 1 cycle/1.7 mm × 25 mm/s = 14.7 cycles/s or 14.7 Hz. Note that the distance between successive oscillation

Figure 30-15 (Figure Not Available) Effect of small air bubbles within arterial pressure monitoring systems. Arterial pressure waveforms are displayed, along with superimposed fast flush square-wave artifacts. (A) Original monitoring system has an adequate dynamic response (natural frequency 17 Hz, damping coefficient 0.2). (B) A small 0.1-mL air bubble added to the monitoring system produces a paradoxic increase in arterial blood pressure. Note decreased natural frequency of the system. (C) A larger 0.5-mL air bubble further degrades dynamic response and produces spurious

arterial hypotension. See text for greater detail. *(From Mark JB: Atlas of Cardiovascular Monitoring. New York, Churchill Livingstone, 1998: Fig. 9-14.)*

cycles (i.e., cycles 1 to 2, 2 to 3) should be identical, because this is a fundamental characteristic of the measurement system--its natural frequency. Furthermore, *the tighter the oscillation cycles, the higher the natural frequency will be.* To measure natural frequency most accurately, a fast recording speed should be chosen (e.g., 50 mm/s), several flush cycles should be examined, and an average value calculated.

The damping coefficient is determined from the flush artifact by measuring the amplitudes of successive oscillation cycles. The amplitude ratio so derived indicates how quickly the measuring system comes to rest. *A low amplitude ratio corresponds to a high damping coefficient, or a system that comes to rest quickly. Conversely, a high amplitude ratio corresponds to a low damping coefficient, or a system that tends to resonate.* The damping coefficient can be calculated mathematically, but it is usually determined graphically from the measured amplitude ratio. [125] [129] In this example,

Figure 30-16 (Figure Not Available) Clinical measurement of natural frequency and damping coefficient. (A) Two square-wave fast flush artifacts interrupt an arterial pressure waveform recorded on standard 1-mm grid paper at a speed of 25 mm/sec. Natural frequency is determined by measuring the period of one cycle of adjacent oscillation peaks (1.7 mm). Damping coefficient is determined by measuring the heights of adjacent oscillation peaks (17 and 24 mm). From these measurements, a natural frequency of 14.7 Hz and an amplitude ratio of 0.71 may be calculated. See text for greater detail. (B) Relation between amplitude ratio and damping coefficient. The amplitude ratio determined in the fast flush test in (A) corresponds to a damping coefficient of 0.11. See text for greater detail. *(From Mark JB: Atlas of Cardiovascular Monitoring. New York, Churchill Livingstone, 1998: Figs. 9-9 (Figure Not Available) and 9-10.) (Figure Not Available)*

the amplitudes of two successive oscillation cycles are 24 and 17 mm, respectively, giving an amplitude ratio of 17/24 or 0.71, which corresponds to a damping coefficient of 0.11 using the graphic solution shown (see Fig. 30-16) (Figure Not Available) . As in the case for measuring natural frequency, any two adjacent peaks may be used to determine the amplitude ratio, because the ratio of successive peaks should be relatively constant. Again, this is a fundamental characteristic of the measurement system--the damping coefficient.

Note that the monitoring system illustrated here has an adequate natural frequency of approximately 15 Hz but is notably underdamped, with a damping coefficient of 0.11. Consequently, this catheter-tubing-transducer system falls into the underdamped region illustrated in Figure 30-14 (Figure Not Available) , and one would expect to find systolic pressure overshoot in such a system.

Although the technical requirements for accurate blood pressure measurement are evident from the preceding considerations, it appears that these conditions are often unmet in routine clinical practice. Schwid [134] examined the frequency response of 30 radial artery catheter-transducer systems used in routine intensive care monitoring. Mean values (± standard deviation) for natural frequency (14.7 ± 3.7 Hz) and damping coefficient (0.24 ± 0.07) were worse than values typically reported for measurements made under laboratory conditions, falling instead in the underdamped response region reported by Gardner. [125] Furthermore, the range of frequency responses (10.2-25.3 Hz) and damping coefficients (0.15-0.44) measured in this setting suggests that distortion of the arterial waveform is common in clinical practice, with systolic arterial pressure overshoot resulting from a relatively underdamped system the most common problem. Figure 30-14 (Figure Not Available) shows these data from Schwid [134] in the format suggested by Gardner [125] and graphically highlights this situation.

Several practical points for direct pressure monitoring in daily clinical practice emerge from these technical considerations. First, in an attempt to optimize the dynamic response of the monitoring system, one should attempt to keep the catheter-tubing-transducer system as simple as possible, using the minimum length of tubing and number of stopcocks required for patient-care purposes. Second, one should know how the natural frequency and damping coefficient might be calculated using the fast flush method. One practical application is that this testing allows the clinician to distinguish true hypotension from an artifact that results from an overly damped system caused by a large air bubble or blood clot in the catheter or tubing (see Fig. 30-15) (Figure Not Available) . A third practical point regarding these technical considerations relates to the clinical interpretation of systolic arterial hypertension. Owing to the dynamic response limitations of most clinical pressure-monitoring systems, direct measurement of systolic arterial pressure often exceeds indirect noninvasive measurement, simply because of underdamping and resonance (see Fig. 30-11) (Figure Not Available) . [130]

Pressure Monitoring Systems

Arterial pressure monitoring systems have a number of components beginning with the intra-arterial catheter and including extension tubing, stopcocks, continuous flush device, pressure transducer, and bedside monitor with a waveform display screen. The flush device provides a continuous, slow (1-3 mL/h) infusion of saline to purge the monitoring system, which thereby prevents thrombus formation within the arterial catheter. Historically, a dilute concentration of heparin (1-2 units/mL saline) has been added to this flush solution to reduce further the incidence of thrombosis. [135] However, this practice may unnecessarily expose the patient to heparin and increase the risk of immune-mediated thrombocytopenia. [136] [137] The monitoring system also includes a spring-loaded valve that allows periodic, highpressure flushing to purge the extension line of blood after an arterial sample has been taken. The stopcocks in the system provide sites

for blood sampling and allow the transducer to be exposed to atmospheric pressure to establish a zero reference value.

Newer systems include "needle-less" sampling ports and in-line aspiration systems. These permit blood sampling without the use of sharp needles and allow the aspirated waste blood to be returned to the patient within a convenient closed system. Modifications such as these are intended to reduce the risk of needle injury and blood exposure to health-care workers, as well as to decrease waste of the patient's blood during sampling. However, these additional features may degrade the dynamic response of the monitoring system.

Transducer Setup: Zeroing, Calibrating, and Leveling

Prior to initiating patient monitoring, the pressure transducer must be zeroed, calibrated, and leveled to the appropriate position on the patient. The initial step in this process is to expose the transducer to atmospheric pressure by opening the adjacent stopcock to air, pressing the zero pressure button on the monitor, and thus establishing the zero pressure reference value. The transducer now has a reference--ambient atmospheric pressure--against which all intravascular pressures are measured. This process underscores the fact that all pressures displayed on the monitor are referenced to atmospheric pressure, outside the body. Although clinicians generally refer to "zeroing the transducer," actually the transducer is exposed to atmospheric pressure via an open stopcock affixed to the transducer. To be precise, it is this air-fluid interface at the level of the stopcock that is the zero pressure locus. This point must be aligned with a specific position on the patient to ensure the correct transducer level.

When a significant change in pressure occurs, the zero reference value should be rechecked prior to initiating therapy. [55] This can be accomplished quickly, by opening the stopcock and exposing the transducer to atmospheric pressure. The monitor should be inspected to ensure that the pressure trace overlies the zero pressure line on the display screen and the digital pressure value equals zero. Note that checking the zero value is different from establishing the zero reference, which is done at the beginning of the monitoring procedure. [138] If the stopcock is exposed to atmospheric pressure and pressure is not equal to zero, baseline drift of the transducer's electrical circuit may have occurred. This transducer drift is caused by problems with membrane dome coupling to the electronic pressure transducing elements, as well as other technical problems with the transducer, the attached electrical cable, or the monitor itself. [55] [139] [140] These technical problems appear to be uncommon now that high-quality disposable transducers are widely available. [141]

Historically, transducer calibration was the next step following the zeroing procedure. Calibration is an adjustment of system gain to ensure the proper response to a known reference pressure value. Traditionally, this has been performed using a mercury manometer as the standard. [55] Currently, however, disposable pressure transducers meet or exceed accuracy standards established by the AAMI and the American National Standards Institute. [141] Transducer calibration at the bedside thus appears to be unnecessary. By avoiding daily calibration, attendant serious risks of arterial air embolism and infection may be reduced. [141] In general, if a pressure transducer or monitoring cable is faulty, the initial zero value cannot be established, and the monitoring system must be changed. Rarely, despite successful zeroing, the recorded pressure values appear erroneous, and a malfunctioning pressure transducer, cable, or monitor must be suspected and replaced. [139] [140] [142]

The final step in transducer setup is leveling the pressure monitoring zero point to the appropriate position on the patient. In general, zeroing and leveling the

transducer are accomplished at the same time, prior to initiating patient monitoring. However, these are two distinct procedures. Zeroing exposes the transducer to ambient, atmospheric pressure via an open stopcock. Leveling assigns this zero reference point to a specific position on the patient's body.

In the supine patient, pressure transducers are leveled most often to the midchest position in the midaxillary line, [55] a site chosen because it is easy to estimate by eye and provides a reasonable approximation for the midpoint of the heart in the chest. Although precise location for the zero reference level is important for all pressure monitoring, it is critical for measurement of cardiac filling pressures. An error in arterial blood pressure measurement of 10 mm Hg is generally of minor clinical importance, but the same error in central venous pressure (CVP) or pulmonary artery wedge pressure (PAWP) may have major diagnostic implications.

Some investigators have questioned the use of the midchest position as an appropriate zero reference level. In addition, they suggest that experienced clinicians and researchers do not understand how hydrostatic pressure influences the measurement of pressure with fluid-filled catheter-transducer systems. [143] *The only factor that contributes to measured hydrostatic pressure with a fluid-filled catheter-transducer system is the level of the transducer relative to the uppermost fluid level in the chamber in which pressure is being measured.*[143] *It follows that to remove all such hydrostatic pressure influences, transducers should be leveled to the top of the fluid column in the chamber or vessel being measured.* For example, errors in measurement of left ventricular filling pressure up to 7 mm Hg occur when transducers are leveled to the midchest rather than to the top of the left ventricle. [143] Consequently, transducers used to measure pressures in the cardiac chambers or pulmonary artery are best positioned 5 cm below the left sternal border at the fourth intercostal space, to obviate the confounding influence of hydrostatic pressure. Because many critically ill or anesthetized patients have direct arterial pressure meas-ured along with other direct intravascular cardiac filling pressures, it seems prudent to use the same zero reference level for all direct pressure measurements.

In some circumstances, the clinician may choose to level the arterial pressure transducer at a different position on the body. During neurosurgical operations, performed with the patient in a seated position, the pressure transducer is often aligned with the patient's ear to approximate the level of the circle of Willis and better estimate cerebral perfusion pressure. The transducer should not need to be rezeroed by pushing the zero pressure button on the monitor, in that only the reference level has been altered. In fact, if zero is

Figure 30-17 (Figure Not Available) Effect of pressure transducer level on measurement of blood pressure. (A) In the supine patient, the same arterial blood pressure (ART) is measured at the level of the heart or the brain. (B) With the patient in the sitting position, blood pressure recorded from a transducer that remains at heart level (#1) will be unchanged, but blood pressure recorded from a transducer adjusted to the level of the brain (#2) will be lower by an amount equal to the hydrostatic pressure difference between these two transducer positions (20 cm H_2O, or approximately 15 mm Hg). See text for greater detail. *(From Mark JB: Atlas of Cardiovascular Monitoring. New York, Churchill Livingstone, 1998: Fig. 9-19.)*

rechecked, it should be unchanged, regardless of transducer location, because atmospheric pressure changes little over the few inches of height alteration being considered in this situation. Arterial blood pressure now recorded at the level of the head will be lower than that recorded at the heart, the difference being precisely equal to the hydrostatic pressure difference between the head and the heart (Fig. 30-17) (Figure Not Available) . [138]

Often, pressure transducers are attached to an intravenous (IV) pole, and patient position is altered by adjusting the height of the operating room table or intensive care bed. A sudden change in blood pressure is noted and is attributable entirely to the change in transducer level in relation to patient position. Raising the patient above the transducer will produce spuriously high pressures, whereas lowering the patient below the transducer will produce spuriously low pressures. Again, the error introduced is exactly equal to the hydrostatic pressure difference between patient and transducer. Although these leveling artifacts are generally small relative to arterial blood pressure, they are of critical importance when measuring CVP or pulmonary artery pressure (PAP). However, on occasion, a pressure transducer will fall from its normal position and come to rest near the floor. In this instance, the blood pressure may be falsely elevated by nearly 80 mm Hg. Taping pressure transducers directly to the patient can obviate these types of level artifacts. Without question, the most common major mistakes in pressure monitoring involve failure to establish zero, failure to recheck the zero value for transducer drift, and failure to relevel the transducer appropriately when changes in patient position occur. [55]

A final example may help to understand the distinction between zeroing and leveling pressure transducers. Consider the difference between invasive blood pressure and NIBP measurement in a patient in the lateral position (Fig. 30-18) (Figure Not Available) . While the patient is supine, blood pressure is 120/80 mm Hg in both arms, as measured by noninvasive cuffs and direct indwelling radial artery catheters. The patient is now placed in the right lateral decubitus position, the left arm is 20 cm above the heart, and the right arm is 20 cm below the heart. The invasive blood pressure transducers remain leveled to the heart at the midthoracic position. Blood pressure measured in the left arm by cuff will be lower, that is, 105/65 mm Hg, because the left arm is 20 cm above the level of the heart, whereas blood pressure measured in the right arm by cuff will be higher, 135/95 mm Hg. However, blood pressure measured from either the left or right radial catheters will remain unchanged, 120/80 mm Hg, given that the reference level for zero pressure remains fixed at the midchest position. Indeed, if the arterial pressure transducers were attached to the arms, the zero reference levels for the transducers would have changed as the patient assumed the lateral position, and pressures recorded from right and left radial artery catheters would equal those recorded by the ipsilateral noninvasive cuffs.

Arterial Pressure Waveforms

Direct arterial pressure monitoring in anesthetized patients began more than 50 years ago. [79] In that early era, arterial pulse waveform analysis was noted to provide useful diagnostic information, but somewhat surprisingly, modern physicians pay little attention to the morphology and detail of the arterial pressure waveform. O'Rourke and Gallagher [144] attribute this change in practice to the reliance on cuff sphygmomanometry, which provides "numbers which came to be linked in a simplistic way to cardiac strength (systolic pressure) and arteriolar tone (diastolic pressure). Pseudoscience had arrived with (these) numbers.... Even when monitored directly in operating theatres and critical care areas, anesthetists and intensivists show little interest in the waveform and base their judgments on values of systolic, diastolic and mean pressure."

Because clinicians today benefit from the widespread availability of high resolution, multicolored monitor displays,

Figure 30-18 (Figure Not Available) Effect of patient position on the relation between direct arterial blood pressure (ART) and indirect noninvasive blood pressure (NIBP) measurements. (A) In the supine patient, pressures measured from the right (R) or left (L) arms by either technique will be the same. (B) In the right lateral decubitus position, ART pressures recorded directly from the right and left radial arteries will remain unchanged so long as the respective pressure transducers remain at heart level. However, NIBP will be higher in the dependent right arm and lower in the nondependent left arm. Differences in NIBP are determined by the positions of the arms above and below the level of the heart and are equal to the hydrostatic pressure differences between the level of the heart and the respective arm. A 20-cm difference in height produces a 15-mm Hg difference in pressure. See text for greater detail. *(From Mark JB: Atlas of Cardiovascular Monitoring. New York, Churchill Livingstone, 1998: Fig. 9-22.) (Figure Not Available)*

renewed interest in waveform analysis should expand clinical monitoring capabilities. [80] Appreciation of the diagnostic clues provided by the direct arterial pressure waveform requires full understanding of normal waveform components, their relation to the cardiac cycle, and differences in waveforms recorded from different sites in the body.

The systemic arterial pressure waveform results from ejection of blood from the left ventricle into the aorta during systole, followed by peripheral arterial runoff of this stroke volume during diastole (Fig. 30-19) (Figure Not Available) . The systolic components follow the ECG R wave and consist of a steep pressure upstroke, peak, and decline and correspond to the period of left ventricular systolic ejection. The downslope of the arterial pressure waveform is interrupted by the dicrotic notch, then continues its decline during diastole following the ECG T wave, reaching its nadir at end-diastole. The dicrotic notch recorded directly from the central aorta is termed the *incisura* (from the Latin, *a cutting into*). The incisura is sharply defined and undoubtedly is related to aortic valve closure. [145] In contrast, the peripheral arterial waveform generally displays a later, smoother dicrotic notch that only approximates timing of aortic valve closure and depends more on arterial wall properties. [146] Note that the systolic upstroke of the radial artery pressure trace does not appear for 120 to 180 milliseconds after inscription of the ECG R wave (see Fig. 30-19) (Figure Not Available) . This interval reflects the sum of times required for spread of electrical depolarization through the ventricular myocardium, isovolumic left ventricular contraction, aortic valve opening, left ventricular ejection, transmission of the aortic pressure wave to the radial artery, and finally, transmission of the pressure signal from the arterial catheter to the pressure transducer.

The bedside monitor displays numeric values for the systolic peak and end-diastolic trough pressures. Measurement of mean pressure is more complicated and depends on the algorithm employed by the monitor. [147] In simplest terms, MAP is equal to the area beneath the arterial pressure curve divided by the beat period and

averaged over a series of consecutive heartbeats. Although MAP is often estimated as diastolic pressure plus one-third times the pulse pressure, this estimation can be misleading. At equivalent heart rates, narrow or thin arterial pressure waveforms spend more time at lower pressures, resulting in a low MAP, whereas wide or full arterial pressure waveforms spend more time at higher pressures, resulting in a higher MAP.

One of the most important features of the arterial pressure waveform is the phenomenon of distal pulse amplification. Pressure waveforms recorded simultaneously from different

Figure 30-19 (Figure Not Available) Normal arterial blood pressure waveform and its relation to the electrocardiographic R wave. (1) Systolic upstroke, (2) systolic peak pressure, (3) systolic decline, (4) dicrotic notch, (5) diastolic runoff, and (6) end-diastolic pressure. *(From Mark JB: Atlas of Cardiovascular Monitoring. New York, Churchill Livingstone, 1998: Fig. 8-1.)*

Figure 30-20 (Figure Not Available) Distal pulse wave amplification of the arterial pressure waveform. Compared with pressure in the aortic arch, the more peripherally recorded femoral artery pressure waveform demonstrates a wider pulse pressure (compare 1 and 2), a delayed upstroke (3), a delayed, slurred dicrotic notch (compare arrows), and a more prominent diastolic wave. See text for greater detail. *(From Mark JB: Atlas of Cardiovascular Monitoring. New York, Churchill Livingstone, 1998: Fig. 8-4.) (Figure Not Available)*

arterial sites will have different morphologies owing to the physical characteristics of the vascular tree, namely impedance and harmonic resonance (Fig. 30-20) (Figure Not Available) . [48] [109] [119] [144] [148] As the arterial pressure wave travels from the central aorta to the periphery, several characteristic changes occur. The arterial upstroke becomes steeper, the systolic peak becomes higher, the dicrotic notch appears later, the diastolic wave becomes more prominent, and the end-diastolic pressure becomes lower. Thus, compared with central aortic pressure, peripheral arterial waveforms have higher systolic pressure, lower diastolic pressure, and wider pulse pressure. Furthermore, there is a delay in the arrival of the pressure pulse at peripheral sites, so that the systolic pressure upstroke begins approximately 60 milliseconds later in the radial artery than in the aorta. Despite morphologic and temporal differences between peripheral and central arterial waveforms, the MAP in the aorta is just slightly greater than that in the radial artery. [119] [148]

Pressure wave reflection is the predominant factor that influences the shape of the arterial pressure waveform as it travels peripherally. [119] [144] [149] [150] [151] As blood flows from aorta to radial artery, mean pressure only decreases slightly, because there is little resistance to flow, but then falls markedly in the arterioles, owing to the dramatic increase in vascular resistance at this site. This high resistance to flow diminishes pressure pulsations in small downstream vessels but acts to augment upstream arterial pressure pulses owing to pressure wave reflection. [119] [152] Murgo et al [150] [151] and O'Rourke et al [119] [144] provide detailed explanations of the arterial pressure wave, along with models of the circulation that provide more complete insight into these phenomena. These studies underscore the importance of wave reflection in determining the shape of the arterial pulse recorded from all sites in the body, in health and disease. For example, elderly patients have reduced arterial distensibility, which results in early return of reflected pressure waves, an increased pulse pressure, a late systolic pressure peak, and disappearance of the diastolic pressure wave (Fig. 30-21) (Figure Not Available) . [119] [144] [152]

From these considerations, it becomes evident that the morphology of the arterial waveform and the precise values for systolic and diastolic blood pressure vary throughout the body under normal conditions in otherwise healthy individuals.

Figure 30-21 (Figure Not Available) Impact of pressure wave reflection on arterial pressure waveforms. In elderly individuals with reduced arterial distensibility, early return of reflected waves increases pulse pressure, produces a late systolic pressure peak (arrow), and attenuates the diastolic pressure wave. Myocardial oxygen balance is more tenuous in the elderly because these changes in blood pressure cause an increased myocardial oxygen demand during systole and a reduced myocardial oxygen supply during diastole. See text for greater detail.

Perhaps of even greater importance, the relation between central and peripheral arterial pressure varies with age and is altered by various physiologic changes, pathologic conditions, and pharmacologic interventions. (See the section *Choosing the Site for Arterial Pressure Monitoring* for more detail.)

Morphologic features of individual arterial pressure waveforms provide diagnostic clues to various pathologic conditions. *Aortic stenosis* produces a fixed obstruction to left ventricular ejection, resulting in a reduced stroke volume and an arterial pressure waveform that rises slowly *(pulsus tardus)* and peaks late in systole (Fig. 30-22) (Figure Not Available) . A distinct shoulder, termed the *anacrotic notch,* often distorts the pressure upstroke. [153] In addition, the dicrotic notch may not be discernible and the arterial pressure is small in amplitude *(pulsus parvus).* All of these features make the arterial pressure waveform appear overdamped, in contrast to the normal arterial pressure waveform, which has a sharp upstroke and distinct dicrotic notch.

In *aortic regurgitation,* the arterial pressure wave rises rapidly, pulse pressure increases, and diastolic pressure is low, owing to the runoff of blood into the left ventricle as well as the periphery during diastole. Because of the large stroke volume ejected from the left ventricle in this condition, the arterial pressure pulse may have two systolic peaks *(bisferiens pulse)* (see Fig. 30-22) (Figure Not Available) . These two peaks represent separate percussion and tidal waves, with the former resulting from left ventricular ejection and the latter arising from the periphery as a reflected wave. [153] The bisferiens pulse is also described in patients with mixed aortic regurgitation and stenosis and in patients with hypertrophic cardiomyopathy, although the physiologic basis is different in the latter condition. In *hypertrophic cardiomyopathy,* the arterial pressure waveform assumes a peculiar bifid shape, termed a "spike-and-dome" configuration. After an initial sharp pressure upstroke that results from rapid left ventricular ejection in early systole, arterial pressure falls rapidly as

---

Figure 30-22 (Figure Not Available) Influence of pathologic conditions on arterial pressure (ART) waveform morphology. (A) Normal ART and pulmonary artery pressure (PAP) waveform morphologies demonstrating the similar timing of these waveforms relative to the electrocardiographic R wave. (B) In aortic stenosis, the ART waveform is distorted and demonstrates a slurred upstroke and delayed systolic peak. These changes are particularly striking in comparison with the normal PAP waveform. Note the beat-to-beat respiratory variation in the PAP waveform. See text for greater detail. For (A) and (B), the ART scale is on the left and the PAP scale is on the right. (C) Aortic regurgitation produces a bisferiens pulse and a wide pulse pressure. See text for greater detail. (D) Arterial pressure waveform in hypertrophic cardiomyopathy shows a peculiar "spike-and-dome" configuration. Pressure waveform assumes a more normal morphology following surgical correction of this condition. See text for greater detail. *(From Mark JB: Atlas of Cardiovascular Monitoring. New York, Churchill Livingstone, 1998: Figs. 3-3 (Figure Not Available) , 17-21, and 17-24.)*

dynamic left ventricular outflow obstruction develops during midsystole, and a late systolic reflected wave follows, thereby creating the characteristic double-peaked waveform (see Fig. 30-22) (Figure Not Available) . [153] [154]

Observation of arterial waveform patterns over consecutive heartbeats provides an additional set of diagnostic clues. *Pulsus alternans* is recognized by the alternating beats of larger and smaller pulse pressures (Fig. 30-23) (Figure Not Available) . In general, it is considered to be a sign of severe left ventricular systolic dysfunction, often noted in patients with advanced aortic stenosis. It may be seen occasionally during general anesthesia, presumably as a consequence of the anesthetic-induced reduction in sympathetic nervous system activity in patients with underlying impairment of left ventricular contractility. [155] Pulsus alternans should be distinguished from the bigeminal pulse that arises from a bigeminal rhythm, usually ventricular bigeminy. Both abnormalities create an alternating pulse pressure in the arterial pressure waveform, but the rhythm is regular in pulsus alternans.

Pulsus paradoxus is an exaggerated inspiratory fall in systolic arterial pressure, exceeding 10 to 12 mm Hg during quiet breathing (see Fig. 30-23) (Figure Not Available) . [153] [156] [157] [158] The term may be confusing because a small inspiratory reduction in blood pressure is a normal phenomenon, and pulsus paradoxus is not truly paradoxic, but rather an exaggeration of this normal inspiratory decline in blood pressure. Pulsus paradoxus is a characteristic, almost universal finding in cardiac tamponade and occurs in many patients with pericardial constriction. It is said to occur in patients with airway obstruction, bronchospasm, dyspnea, or any condition in which there are large swings in intrathoracic pressure. [153] However, in cardiac tamponade, the pulse pressure and left ventricular stroke volume fall during inspiration, in contrast to the blood pressure changes observed in patients with forced breathing patterns and exaggerated changes in intrathoracic pressure in which pulse pressure is relatively unchanged. [156]

Pulsus paradoxus is a phenomenon described during spontaneous ventilation, not during positive-pressure mechanical ventilation in which large cyclic changes in systolic blood pressure occur in many patients. [156] [159] [160] These large arterial pressure changes during mechanical ventilation have been noted as an incidental observation on the bedside monitor for a long time, but only recently have they been shown to have clear diagnostic implications. [160] [161] [162] [163] [164] [165] [166] [167] *Systolic pressure variation* is the difference between maximal and minimal values of systolic arterial pressure recorded over the mechanical positive-pressure respiratory cycle. [164] [168] Using end-expiration as the equilibrium period for pressure measurement, the total systolic pressure variation is divided into an early inspiratory increase in pressure, Delta up, and a later decrease in pressure, Delta down (see Fig. 30-23) (Figure Not Available) . Delta up reflects the inspiratory augmentation in left

ventricular

Figure 30-23 (Figure Not Available) Beat-to-beat variability in arterial pressure waveform morphologies. (A) Pulsus alternans. (B) Pulsus paradoxus. The marked decline in systolic arterial pressure and pulse pressure during spontaneous inspiration (arrows) is characteristic of this condition. (C) Systolic pressure variation. Compared with systolic blood pressure recorded at end expiration (1) a small increase occurs during positive pressure inspiration (2, Delta up) followed by a decrease (3, Delta down). Normally, total systolic pressure variation does not exceed 10 mm Hg. In this instance, the large Delta down indicates hypovolemia even though systolic arterial pressure and heart rate are relatively normal. See text for greater detail. *(From Mark JB: Atlas of Cardiovascular Monitoring. New York, Churchill Livingstone, 1998: Figs. 18-10C , and 16-16.)*

output, and Delta down reflects the impairment in systemic venous return that becomes manifest in the arterial pressure trace shortly thereafter. Normally, mechanically ventilated patients will have Delta up and Delta down of about 5 mm Hg each and total systolic pressure variation of approximately 10 mm Hg. [160]

The greatest clinical use of systolic pressure variation has been in the early diagnosis of hypovolemia. [161] [163] [164] [168] Both in experimental animals and patients, hypovolemia causes a dramatic increase in systolic pressure variation, particularly Delta down. Some authors have suggested that the increase in systolic pressure variation and Delta down may herald hypovolemia, even in patients in whom the arterial blood pressure is maintained near normal by compensatory arterial vasoconstriction. [168] In a heterogeneous group of intensive care patients, Marik [162] demonstrated that a large systolic pressure variation (>15 mm Hg) was highly predictive of a low PAWP (<10 mm Hg). Using echocardiography to measure left ventricular cross-sectional area as a surrogate for preload, Coriat et al [161] found Delta down to be an even better predictor of left ventricular preload than wedge pressure. Other uses of systolic pressure variation focus on changes in the Delta up portion of the arterial pressure trace. Just as Delta down may reveal changes in cardiac preload, the Delta up portion of the arterial pressure trace may provide clues to the afterload dependence of the left ventricle. Preliminary evidence suggests that a marked increase in Delta up during positive-pressure inspiration occurs when the increased pleural pressure reduces transmural left ventricular pressure sufficiently that left ventricular stroke output increases in the failing, afterload-dependent left ventricle. [164] [166] [168] [169]

The arterial pressure waveform provides diagnostic clues in other more unusual physiologic states. Proper time of *intra-aortic balloon counterpulsation* mandates a detailed interpretation of the arterial waveform (Fig. 30-24) (Figure Not Available) . [170] Even during nonpulsatile cardiopulmonary bypass, the minor variations in

Figure 30-24 (Figure Not Available) Unusual arterial pressure waveforms. (A) Intraaortic balloon counterpulsation with a 1:2 balloon-assist ratio produces a characteristic change in the arterial pressure waveform. Four cardiac cycles are shown, two with balloon assistance and two without. (0) Unassisted enddiastolic pressure, (1) unassisted systolic pressure, (2) dicrotic notch, (3) assisted or augmented diastolic pressure, (4) end-diastolic or presystolic dip, (5) assisted systolic pressure. Effective afterload reduction by the intraaortic balloon is evidenced by the presystolic dip pressure (4) lower than the unassisted end-diastolic pressure (0) and the assisted systolic pressure peak (5) lower than the unassisted systolic pressure peak (1). (B) Arterial pressure waveform during cardiopulmonary bypass. Small phasic pressure variations (arrows) result from the mechanical action of the bypass roller pump. Bypass pump flow rate may be estimated by measuring these pulsations. Nineteen pulsations are recorded in a 3-sec time interval. In this case, the pump configured with 3/8-in tubing has an effective stroke volume of 27 mL. Pump flow rate may be calculated as follows: (19 pulsations/3 sec) × (1 pump revolution/two pulsations) × (27 mL/revolution) × (60 sec/min) = 5130 mL/minute. This calculated pump flow rate should equal the flow rate displayed on the pump console (i.e., 5.2 L/minute). *(From Mark JB: Atlas of Cardiovascular Monitoring. New York, Churchill Livingstone, 1998: Figs. 20-3 and 19-8.)*

blood pressure created by the arterial roller head allow calculation and confirmation of the adequacy of systemic blood flow (see Fig. 30-24) (Figure Not Available) . [171]

CARDIAC FILLING PRESSURE MONITORING

Physiologic Considerations: Diastolic Pressure-Volume Relations and Transmural Pressure

Cardiac filling pressures are monitored to estimate cardiac filling volumes, which, in turn, determine the stroke outputs of the left and right ventricles. According to the Frank-Starling principle, the force of cardiac contraction is directly proportional to end-diastolic muscle fiber length at any given level of intrinsic contractility or inotropy. [131] [135] This muscle fiber length or preload is proportional to end-diastolic chamber volume. Even though it would be ideal to monitor cardiac chamber volumes continuously in critically ill patients, this remains an elusive goal in clinical practice. Transesophageal echocardiography has brought continuous

Figure 30-25 (Figure Not Available) Ventricular diastolic pressure-volume relation. Along the flat portion of the curve, a 20-mL increase in ventricular volume causes a small increase in ventricular pressure (A to B). In contrast, the same increase in volume along the steep portion of the ventricular filling curve causes a marked increase in filling pressure (C to D). Another problem associated with the use of filling pressure as a surrogate for filling volume arises when shifts in the pressure-volume relation occur. At point C, ventricular volume is 100 mL and ventricular pressure is 8 mm Hg. An increase in filling pressure to 15 mm Hg may accompany either an increased volume (D) or decreased volume (E). The latter occurs when ventricular compliance changes and shifts the ventricular diastolic pressure-volume relation up and to the left. See text for greater detail. *(From Mark JB: Atlas of Cardiovascular Monitoring. New York, Churchill Livingstone, 1998: Fig. 15-2.)*

monitoring of left ventricular volume or cross sectional area a step closer, [172] but the accuracy of this technique applied in real time remains suboptimal. [173]

When a cardiac filling pressure is measured as a surrogate for estimating cardiac volume, one must not assume that these two variables always change in direct proportion or even in the same direction. In fact, the diastolic pressure-volume relation in cardiac muscle is not linear, but rather curvilinear, with a progressively steeper slope at higher volumes (Fig. 30-25)) (Figure Not Available) . [174] [175] [176] [177] This diastolic pressure-volume relation is one limb of a pressure-volume loop, which describes the relation between pressure and volume for the left or right ventricle during an entire cardiac cycle. When a ventricle is operating along the flat portion of its diastolic filling curve, a significant increase in filling volume or preload results in a small increase in filling pressure. In contrast, the same increase in filling volume causes a significant increase in filling pressure when the ventricle is operating on the steep portion of its curve (see Fig. 30-25) (Figure Not Available) . [178] An even more confusing situation arises when the diastolic pressure-volume relation of the ventricle changes, for example with the onset of myocardial ischemia. [176] [179] [180] [181] [182] Rather than moving along the same diastolic pressure-volume curve, the ventricle now shifts to a different, steeper curve where--somewhat paradoxically--an increase in filling pressure may accompany a decrease in filling volume (see Fig. 30-25) (Figure Not Available) . [183] [184] As a result, one cannot assume that a given measured change in cardiac filling pressure reflects a proportional change in ventricular preload, and on occasion, diastolic pressure and volume can change in opposite directions. [177] [183] [184] [185] [186] [187]

The relation between ventricular volume and filling pressure depends on the portion of the pressure-volume curve over which the patient's heart is operating and the shape or slope of the curve. Commonly termed *ventricular compliance,* [131] [135] [188] [189] this change in pressure for a given change

in volume (DeltaP/DeltaV) is actually the reciprocal of compliance and is more accurately termed *ventricular elastance, distensibility,* or *stiffness.* A patient with an abnormally stiff ventricle will have a greater change in end-diastolic pressure for any given change in end-diastolic volume, and the converse is true for a patient with an abnormally compliant ventricle. By definition, *diastolic dysfunction* is present when ventricular pressure is abnormally elevated for any given ventricular volume.

The ventricular diastolic pressure-volume relation is influenced by intrinsic properties of the ventricle, such as the passive mechanical characteristics of cardiac muscle, chamber geometry, and relaxation. In addition, external forces exerted by the pericardium, the adjacent ventricle, coronary vasculature, and pleural pressure will further influence ventricular pressure-volume relations. [174] [175] [180] [182] [188] [189] [190] [191] One should not equate cardiac filling pressures with filling volumes when patients are functioning over wide ranges of their diastolic pressure-volume curve or under conditions in which diastolic stiffness is abnormal or changing rapidly.

In general, all intravascular pressures measured in clinical practice are referenced to ambient atmospheric pressure. (Indeed, the first step in pressure transducer setup is to zero the transducer by exposing it to atmospheric pressure and assigning this pressure a value of zero by pressing the zero pressure button on the attached monitor. See the earlier section *Technical Aspects of Direct Blood Pressure Monitoring.)* Thus, a cardiac filling pressure of 10 mm Hg is 10 mm Hg higher than ambient atmospheric pressure. Does this pressure value accurately represent the distending force across the cardiac chamber wall at end-diastole?

To answer this question, one needs to consider *transmural pressure.* The cardiac chambers are all contained within the pericardium and thorax. Clearly, changes in pressure in the structures surrounding the heart will influence pressures recorded within the heart. Transmural pressure is the difference between chamber pressure and juxtacardiac or pericardial pressure. This transmural pressure determines ventricular preload, end-diastolic volume, or fiber length. [131] [177] The same measured filling pressure, referenced to atmospheric pressure, can be associated with markedly different transmural pressures and chamber volumes, depending on whether juxtacardiac pressure is high or low. Although juxtacardiac pressure can be ignored under some circumstances, marked alterations in pleural and pericardial pressures occur commonly and must be considered when any cardiac filling pressure is interpreted. Transmural pressure is always the pressure of physiologic interest. Because juxtacardiac pressure is not measured routinely, one always must consider that the measured central vascular pressure, referenced to the ambient atmosphere, may be a poor estimate of transmural pressure. [160] [178]

Cardiac filling pressures are measured directly from a number of sites in the vascular system. CVP monitoring is the least invasive method, followed by PAP monitoring and left atrial pressure (LAP) monitoring. Proper interpretation of all cardiac filling pressures requires knowledge of normal values for these pressures, as well as pressures in the cardiac chambers and great vessels, and other measured and derived hemodynamic variables (Tables 30-1 and 30-2) . Methods for measuring CVP, PAP, and LAP will be described, along with indications, complications, and physiologic

interpretations of normal and pathologic waveforms encountered during monitoring.

Central Venous Cannulation

Indirect assessment of CVP, through physical examination of the neck veins, is a fundamental aspect of cardiovascular assessment but one that has many shortcomings. One real anatomic limitation to the physical assessment of jugular venous pulsations rests with the recent observation that competent venous valves exist in the internal jugular veins of most individuals. These valves are located approximately 0.5 to 2.0 cm above the junction of the internal jugular and subclavian veins bilaterally and withstand back pressures of 50 to 100 cm H_2O. [192] [193] [194] In addition, the jugular veins may be impossible to identify in 20 percent of patients, and the bedside diagnosis of low, normal, or high CVP may be inaccurate almost 50 percent of the time. [195] These general problems are compounded in the perioperative period, when

TABLE 30-2 -- Normal Hemodynamic Values

Cardiac output (L/min)	5.0	4.0-6.5
Stroke volume (mL)	75	60-90

Oxygen consumption (mL/min)	225	200-250

visualization of the neck veins is further obscured and acute, large changes in CVP occur in many patients. As a result, direct measurement of CVP is performed frequently in patients with advanced cardiovascular diseases and those undergoing major operations.

Cannulation of a large vein is the standard clinical method for monitoring CVP. In addition, central venous cannulation is performed to provide secure vascular access for administration of vasoactive drugs or to initiate rapid fluid resuscitation. Often the central venous location is the only site available for intravenous access of any kind. Patients at risk for venous air emboli may have central venous catheters placed for aspiration of entrained air. Central venous access is required to initiate transvenous cardiac pacing, temporary hemodialysis, or pulmonary artery catheterization for more comprehensive cardiac monitoring (Table 30-3) .

In certain patients, such as those with ischemic heart disease, the cardiovascular consequences of pain or anxiety during central venous or arterial cannulation may produce untoward hemodynamic changes. [196] Although some authors advocate postponing central venous catheterization until general anesthesia is established, [197] this is not a practical option in critically ill patients in intensive care, or in surgical patients who will not receive general anesthesia. Furthermore, safe vascular cannulation before induction of anesthesia is achieved easily through use of adequate local anesthesia, intravenous sedatives, and careful patient observation. [198] [199] In the end, the decision to perform central venous cannulation before or after induction of anesthesia is guided most often by individual patient and physician preferences or institutional practices. [197] [198] Perhaps of greatest importance, one should consider abandoning attempts at preoperative central venous cannulation in any patient who becomes overly sedated or uncooperative during the procedure. In most cases, the prudent course is to proceed with anesthetic induction and tracheal intubation as planned, then gain central vascular access under more controlled circumstances.

Among the numerous potential sites for central venous cannulation, the most popular are the right internal jugular vein and the subclavian veins. A common theme in many texts and articles describing cannulation techniques is the apparent preference of most anesthesiologists for the internal

jugular vein and of most surgeons for the subclavian vein. The advantages and disadvantages of each approach are considered next, along with a description of techniques to accomplish these procedures safely and successfully.

Right Internal Jugular Vein Cannulation

Many different techniques for internal jugular vein cannulation have been described, although the "central" approach described by Daily et al [200] is among the most popular and is described with minor modifications here. Careful positioning will make the patient comfortable, improve identification of surface landmarks, and increase the likelihood of successful venipuncture. The patient is placed in the supine position, with the head turned slightly to the left to expose the right side of the neck and keep the chin from interfering with the procedure. Pillows that cause the neck to be flexed should be removed, but forceful neck extension or extreme leftward rotation of the head should be avoided, because this may alter cervical vascular anatomy, cause the internal jugular vein to overlie the carotid artery, and increase the risk of carotid arterial puncture. [201]

Anatomic landmarks, including the sternal notch, clavicle, and sternocleidomastoid muscle, should be assessed before preparation and draping for the sterile procedure because these landmarks are appreciated better before they are covered by the sterile drape (Fig. 30-26) . The carotid artery should be palpated and its course determined as it lies lateral to the trachea, usually under the more medial sternal head of the sternocleidomastoid muscle. The internal jugular vein lies in the groove between the sternal and clavicular heads of the sternocleidomastoid muscle, lateral and slightly anterior to the carotid artery. In many patients, venous pulsations from the internal jugular vein are observed directly within this groove and further identify the approximate site for venipuncture.

The patient should be calm, sedated, and receiving supplemental oxygen if necessary, and monitored with an ECG, blood pressure monitor, and pulse oximeter. Owing to the frequency and potential morbidity of infectious complications from central venous catheterization, strict aseptic technique is required. Guidelines to reduce these complications, published by the U.S. Centers for Disease Control and Prevention, have been updated recently by the American Society of Anesthesiologists Task Force on Infection Control and provide prudent recommendations that should be followed during all but emergency basis catheterizations. [202]

1. Wash hands before the procedure.
2. Use a mask and sterile gloves and gown, even when placing the catheter in the operating room.
3. Cleanse the skin widely from earlobe to clavicle to sternal notch, using an appropriate antiseptic, such as 10 percent povidone-iodine.
4. Apply a sterile drape for maximal barrier precautions. A large drape that covers the entire patient is preferred when the central venous catheterization is intended for long-term catheter placement, although a smaller, disposable, fenestrated drape is generally used for more routine perioperative catheterizations.

Figure 30-26 Technique for right internal jugular vein central venous cannulation. (A) Important surface landmarks are identified. (B) The course of the internal carotid artery is palpated. (C) The internal jugular vein is punctured at the apex of the triangle formed by the two heads of the sternocleidomastoid muscle with the needle tip directed toward the ipsilateral nipple. (D) A guide wire is introduced through the thin-wall needle into the vein. (E) The central venous cannula is inserted over the guide wire, making sure that the proximal end of the guide wire protrudes beyond the catheter and is controlled by the operator. See text for greater detail.

Under these sterile conditions, the relevant anatomy is again identified, particularly the course of the carotid artery in the neck. An assistant then places the patient in a slight head-down (Trendelenburg) position to increase central venous pressure and jugular vein diameter in the neck. This step is omitted when physical examination indicates high venous pressure, and occasionally venipuncture must even be performed with the head slightly elevated in a patient who has markedly elevated CVP and cannot lie flat in bed. The intended venipuncture site is anesthetized by subcutaneous infiltration with a local anesthetic solution (typically 1% lidocaine), using a 25- or 26-gauge needle. The local anesthetic wheal should be generous enough to allow pain-free suturing of the catheter at the end of the procedure.

With the fingers of the left hand gently resting on the carotid artery pulse as a valuable anatomic landmark, venipuncture then proceeds using a 22-gauge, 1-1/2-in (3.8-cm) *finger needle* mounted on a 5-mL syringe (see Fig. 30-26) . The needle is inserted at the apex of the triangle formed by the two heads of the sternocleidomastoid muscle, at an angle of approximately 30v degrees from the plane of the skin, and directed at the ipsilateral nipple. Gentle aspiration will identify the jugular vein when dark venous blood enters the syringe. Although use of the small finder needle is an extra step in this procedure, it presumably increases the margin of safety, [203] because unintentional puncture of the carotid artery with this small needle is less likely to result in significant bleeding and hematoma formation. Although blood may have been aspirated earlier during injection of the local anesthetic, the color of the blood may not be appreciated when it mixes with the local anesthetic solution, thereby making it difficult to distinguish venous from arte-rial blood. Thus, it is important that the finder needle be attached to an empty syringe during this step.

If the blood is not aspirated as the finder needle is advanced and then withdrawn, additional needle passes may locate the internal jugular vein by fanning laterally in a small arc from the point where the needle enters the skin. As long as the carotid artery remains palpable medially, exploring in an orderly fashion with the finder needle directed slightly more laterally will often identify the vein, with little risk of carotid artery puncture. If the vein is not located after several needle passes, the finder needle is withdrawn completely and checked for patency, the anatomy is reassessed, and the puncture may then proceed with the needle entering the skin several millimeters closer to the palpated

carotid pulse but still directed in a sagittal or slightly lateral direction. Because of the normal anatomic relation between the carotid artery and the internal jugular vein, one should resist the temptation to explore with a medial or leftward direction of the finder needle when this technique for venipuncture is being used.

When the internal jugular vein is located with the finder needle, the needle is gently withdrawn, while the skin and surface anatomy remain fixed by the left hand. The vein is then repunctured with an 18-gauge 2-½-inch (6.4 cm) *thin-wall needle* attached to a 5-mL syringe, following the same track used with the finder needle, keeping in mind the location and depth of the identified internal jugular vein (see Fig. 30-26) . It is common that the lumen of the jugular vein is compressed as this

larger thin-wall needle is advanced, which causes the needle to pierce both front and back walls almost simultaneously. [204] [205] Consequently, the thin-wall needle should be inserted only slightly beyond the expected depth, then slowly withdrawn, maintaining gentle aspiration on the syringe. Frequently, a sudden gush of free-flowing venous blood is identified during needle withdrawal.

Successful puncture of the internal jugular vein is confirmed by the easy aspiration of dark venous blood into the 5-mL syringe. The hub of the thin-wall needle is fixed with the fingers of the left hand, the syringe is detached, and venous blood should slowly drip from the needle. A 0.035-inch (0.89-mm) guide wire is inserted through the needle, using either the J-shaped tip or the soft, flexible straight end (see Fig. 30-26) . The wire should advance easily into the vein with little resistance. The ECG is monitored continuously to observe arrhythmias, which are common, if the wire tip contacts the walls of the right atrium or ventricle. [206] From this point in the procedure, it is critical that the clinician maintain control over the guide wire and pay attention to its depth of insertion and continued sterility.

In preparation for placing the central venous catheter over the guide wire, the puncture site is enlarged, using a #11 scalpel blade, to the size required for the intended catheter. A firm, tapered-tip, vessel dilator may be inserted to dilate the subcutaneous tissues around the guide wire and allow a larger catheter to pass more smoothly. (When an introducer sheath is to be used for internal jugular vein cannulation, the dilator and sheath form one unit, and this separate dilation step usually is omitted.) The vessel dilator is removed, and the central venous catheter is inserted over the guide wire while traction on the skin is maintained. Again, the clinician must be attentive to the guide wire and ensure that a sufficient length protrudes from the catheter hub so that the wire may be extracted easily (see Fig. 30-26) . The catheter is inserted to an appropriate depth that will place the tip in the superior vena cava, above its junction with the right atrium. This depth is typically 15 to 18 cm if the catheter is placed using the technique described. However, the position of the catheter tip always must be confirmed radiographically, because catheter tips located within the heart increase the risk of cardiac perforation and tamponade, an often fatal complication. [207] [208] [209] [210] [211] Ideally, the catheter tip should lie within the superior vena cava, parallel to the vessel walls, and be positioned below the inferior border of the clavicles and above the level of the third rib, the T4 to T5 interspace, the azygos vein, or the tracheal carina. [209]

Finally, the guide wire is withdrawn, the catheter is attached by a Luer-Lok connector to the monitoring or infusion tubing and sutured in place, and a sterile gauze or transparent dressing is applied. Antibiotic ointment should not be applied to the insertion site, because this may increase the risk of catheter colonization with multidrug-resistant bacteria or *Candida.* [202] [212] Before monitoring or infusion commences, aspiration of blood should confirm intravenous location of the catheter and remove any residual air from the catheter-tubing system. Even in circumstances when the central venous cannulation is intended primarily for infusion, the venous pressure should be measured before infusion to document that the catheter is located in the jugular vein and not the carotid artery.

Choosing the Method, Catheter, and Site for Central Venous Cannulation

Since its introduction into clinical practice in the late 1960s, [200] [213] [214] , percutaneous venipuncture of the right internal jugular vein has been the method preferred by anesthesiologists for central venous cannulation. [215] Reasons for this preference include the following:

1. Consistent, predictable anatomic location.
2. Readily identified, palpable landmarks.
3. Short, straight course to the superior vena cava (which facilitates right heart catheterization).
4. Position at the patient's head, providing intraoperative accessibility to the anesthesiologist.
5. High success rate (90-99%). [200] [213] [215] [216] [217]

Numerous techniques have been described for percutaneous internal jugular vein cannulation. [218] [219] [220] Although it is unlikely that one single method will lead to the greatest success rate in the hands of all clinicians, it appears that certain techniques may result in a higher incidence of unintentional carotid artery puncture. [219] It seems prudent, therefore, to determine the location of the carotid pulse prior to attempted jugular vein cannulation and, when possible, to continue to palpate the pulse gently during the initial steps of venipuncture. This is easily done by a right-handed operator, but continued palpation of the carotid artery during jugular venipuncture is awkward when a left-handed individual is performing the procedure. In this instance, it is best to evaluate the course of the carotid artery prior to, but not during, the venipuncture.

Other adjunctive methods have been proposed to limit complications during central venous cannulation, particularly the frequency of carotid arterial puncture during attempted internal jugular cannulation. (Also see the later section, *Ultrasound-Guided Central Venous Cannulation.*) Many individuals substitute a 2-in, 18-gauge intravenous catheter for the 18-gauge thin-wall needle for venipuncture and guide wire placement. Although this catheter can be advanced completely into the vein, it is kinked more easily than a needle, thereby making it more difficult to recognize pulsatile arterial blood flow from unintentional arterial puncture. To confirm intravenous location of this catheter, several things may be done. The color of the aspirated blood is examined, and it may be compared with a simultaneously obtained arterial sample, or even sent for quantitative blood gas analysis. A quicker, simpler method is to transduce the pressure from the 18-gauge catheter, [221] or attach a sterile

intravenous extension tubing set to create a simple vertical fluid manometer to estimate the pressure and distinguish arterial from venous catheterization. [222] Although none of these safety measures are foolproof, they may provide a margin of safety and reduce the serious complications resulting from unintentional cannulation of the carotid artery with a large-bore catheter. Continuous pressure transduction of the thin-wall needle has been advocated as an even better method to detect arterial puncture and prevent arte-rial cannulation, because the needle will not kink and thereby provide a misleading pressure waveform. [217] [223]

Widespread adoption of guide wire-based vascular cannulation methods undoubtedly has increased the safety of central venous cannulation. These techniques, originally described by Seldinger, [224] allow initial vascular puncture with a smaller gauge needle, followed by guide-wire placement and subsequent vessel dilation and cannulation with a large-bore catheter. [225] This method has virtually replaced the "catheter through the needle" method, which requires vascular puncture with a needle larger than the catheter and results in more complications from cannulation site hemorrhage and shearing of the catheter if it is withdrawn inappropriately through the insertion needle. Some newer central venous catheter insertion kits contain a modified syringe that allows the guide wire to be placed directly through the syringe plunger, without disconnecting the syringe from the thin wall needle. However, when this technique is used, one of the most valuable signs of unintentional arterial puncture is virtually impossible to recognize--namely, the pulsatile return of bright red blood through the thin-wall needle. This may lead to erroneous arterial placement of a central venous catheter. [226]

Numerous types of central venous catheters are available. [227] [228] These vary according to the purpose of catheterization, whether for CVP monitoring or other therapeutic needs, and whether intended for short- or long-term use. [228] Catheters come in a variety of lengths, gauge, composition, and lumen number. This makes it critical for the physician to choose the best catheter for any given application and thereby reduce risk to the patient caused by improper catheter selection. Although multilumen catheters are very popular because they allow simultaneous continuous pressure monitoring and fluid or drug infusion, their use has been associated with a greater risk of infection than single-lumen catheters. [202] Furthermore, multilumen catheters may have a greater propensity to cause vascular perforation than single lumen catheters, because more septations and a stiffer plastic are required in the manufacturing process of a multilumen catheter. [227] A popular alternative method for multilumen central venous access uses a side-arm introducer sheath attached to a series of stopcocks for multiple drug infusions, with a single-lumen catheter inserted through the hemostasis valve for simultaneous continuous CVP monitoring. Although use of these larger introducer sheaths is not free from complications, [229] their use allows rapid placement of a pacing wire or pulmonary artery catheter for more intensive monitoring, without the need for additional central venipunctures or catheter exchanges over a guide wire.

In patients at risk for major intraoperative blood loss and hemodynamic instability, two central venous catheters frequently are inserted. Some physicians advocate double cannulation of the same central vein (usually the right internal jugular) with two catheters in close proximity. [230] With this technique, a guide wire is introduced into the internal jugular vein using the standard method. Then, before catheter placement, a second jugular venipuncture is performed, approximately 1 to 2 cm cephalad or caudad, and a second guide wire is introduced into the vein. Placing appropriate catheters over each guide wire and securing them at the skin in the normal fashion completes the procedure. Limited evidence suggests that the incidence of major complications with this double cannulation technique is no greater than with single central venous catheterization, although arrhythmias may be more common because of unintentional intracardiac placement of the guide wires. [230] However, it is not clear whether this approach is safer than central venous cannulation in two separate central veins. Serious reported complications of the double cannulation technique include facial vein avulsion, catheter entanglement, and catheter fracture. [230] [231] [232] Double central venous cannulation must be reserved for patients whose needs for venous access and hemodynamic monitoring cannot be met through single cannulation.

Selecting the best site for safe and effective central venous cannulation ultimately requires that the physician consider several important medical issues. These include the purpose of catheterization (pressure monitoring versus drug or fluid infusion), the patient's underlying medical condition, the intended operation, and the skill and experience of the physician performing the procedure. In patients with severe bleeding diatheses, it is best to choose a puncture site where bleeding from the vein or adjacent artery is easily detected and controlled with local compression. In this instance, an external jugular approach would be preferred to an infraclavicular subclavian catheterization. Patients with severe emphysema, or other patients who would be severely compromised by pneumothorax would be better candidates for right internal jugular cannulation than subclavian cannulation, owing to the higher risk of pneumothorax with the latter approach. If transvenous cardiac pacing were required in an emergency situation, catheterization of the right internal jugular vein is recommended, in that it provides the most direct course to the right ventricle. Trauma patients, with their necks immobilized in a hard cervical collar, are best resuscitated using femoral or subclavian cannulas; the latter may be placed even more safely if the risk of pneumothorax is obviated by prior placement of thoracostomy tubes. The physician must recognize that the length of catheter inserted to position the catheter tip properly in the superior vena cava will vary according to puncture site, being slightly (3-5 cm) longer when the left internal or external jugular veins are chosen, compared with the right internal jugular vein. [233] Finally, a physician's personal experience undoubtedly plays a significant role in determining the safest site for central venous cannulation, particularly when the procedure is performed under urgent or emergent circumstances.

Ultrasound-Guided Central Venous Cannulation

To increase the success and decrease the complications of central venous cannulation, different ultrasound-guided techniques have been described for cannulating the internal

jugular vein, [234] [235] [236] [237] [238] subclavian vein [239] [240] [241] [242] and femoral vein. [243] Some methods use dedicated devices, which are incorporated into the sterile field, to provide real-time twodimensional ultrasound images of the pertinent vascular anatomy, particularly the relation between the target vein and its adjacent artery. [234] [235] [238] [239] [243] Another approach employs the sophisticated ultrasound equipment that may already be available in the operating room to provide anatomic images immediately prior to the procedure and allow the surface anatomy to be marked appropriately. [237] [242] Finally, Doppler-based, nonimaging techniques provide a real-time, audible Doppler signal to guide venous cannulation, based on distinguishing the continuous audible hum of the vein from the pulsatile signal of the artery. [236] [241]

In general, these ultrasound-guided techniques appear to have several advantages. Invariably, with ultrasound assistance, fewer needle passes are required for successful venous cannulation. In addition, most investigators have shown that ultrasound guidance reduces the time required for catheterization, increases overall success rates, and results in fewer complications. In one of the largest controlled trials, Denys et al [235] used dedicated two-dimensional real-time imaging to cannulate the internal jugular vein in more than 900 patients and found that ultrasound-guided cannulation was successful in all patients and reduced the risk of carotid artery puncture (1.7 versus 8.3%), brachial plexus irritation (0.4 versus 1.7%), and hematoma (0.2 versus 3.3%) compared with landmark-guided techniques.

Although most published studies support the use of ultrasound guidance during central venous cannulation, most of these procedures are still performed with landmark-based techniques. This may be explained by the relatively high success rate and low morbidity of this procedure when performed by experienced individuals, as well as the additional cost and perceived inconvenience of acquiring or using an ultrasound device. However, increased use of ultrasound-guided venous cannulation has disclosed several pertinent technical insights that should lead to improved central venous cannulation in all patients, regardless of the technique employed.

The large central veins are distinguished readily from their accompanying arteries by their lack of pulsatility, marked enlargement during a Valsalva maneuver, and easy compressibility with the ultrasound probe. This provides several lessons for landmark-based venipuncture. When the internal jugular vein is not located easily with the finder needle, the clinician can increase the venous target size markedly by asking the patient to perform a Valsalva maneuver. In contrast, jugular venipuncture will be much more difficult if the vein is compressed during overzealous attempts to palpate and localize the carotid artery. Ultrasound imaging has demonstrated that both the subclavian [239] and internal jugular [235] veins are actually compressed, before vessel entry, by the cannulating needle as it advances. This observation explains the common clinical finding that venipuncture is recognized as often during needle withdrawal as during needle advancement. [204] [205] [235] Furthermore, in a significant number of patients, ultrasonography demonstrates that the internal jugular vein lies directly over the carotid artery, thereby increasing the risk of carotid artery puncture, unless the needle is directed more laterally [235] or lower in the neck where the internal jugular vein assumes a more lateral location. [238] Ultrasound-guided techniques may be particularly useful for increasing the success rate and decreasing complications when less experienced individuals and trainees perform central venous cannulation. [235] [239] Perhaps of greatest importance, ultrasound-guided central venous cannulation provides a method to salvage the procedure when landmark-based methods are unsuccessful, [235] [238] [239] making its use particularly attractive in high-risk patients in whom the clinician anticipates difficulties with vascular access.

Alternative Central Venous Cannulation Sites

Left Internal Jugular Vein

Left internal jugular vein cannulation may be accomplished using a technique similar to the one described earlier for the right internal jugular vein, although several anatomic details make the left side a less popular site for cannulation than the right. The cupola of the pleura is higher on the left than on the right, theoretically increasing the risk of pneumothorax. The thoracic duct may be injured during venipuncture, because it enters the venous system at the junction of the left internal jugular and subclavian veins. [244] The left internal jugular vein is often smaller than the right and demonstrates a greater degree of overlap of the adjacent carotid artery during head rotation. Catheters inserted from the left side of the patient must traverse the innominate (i.e., left brachiocephalic) vein and enter the superior vena cava perpendicularly, and their distal tips may impinge on the right lateral wall of the superior vena cava, thereby increasing the risk of vascular injury. (This anatomic disadvantage pertains to all left-sided catheterization sites and highlights the need for radiographic confirmation of proper catheter location.) In addition, because clinicians cannulate the left internal jugular vein much less often than the right, it is not surprising that cannulation of the left internal jugular vein is more difficult, more time-consuming, and associated with more complications than right internal jugular cannulation. [201] [245]

Subclavian Vein

The subclavian vein is an important site for central venous cannulation and is particularly popular among surgeons and other physicians who place central venous catheters for emergency volume resuscitation and long-term intravenous therapy, rather than for shorter-term monitoring purposes. [242] [246] [247] The advantages of subclavian venous cannulation include the following:

1. Lower risk of infection than jugular or femoral sites. [204] [247]
2. Ease of insertion in trauma patients who may be immobilized in a cervical collar.
3. Increased patient comfort, especially for long-term intravenous therapy, such as hyperalimentation and chemotherapy.

The most common technique used for subclavian vein cannulation is the infraclavicular approach. [247] The patient is placed in a slight head-down position with the arms kept to the side, the head is turned slightly away from the side of venipuncture, and a small bedroll is placed between the shoulder blades to expose the infraclavicular area fully. The skin is punctured 2 to 3 cm caudad to the midpoint of the clavicle, far enough from its inferior edge to avoid a downward angulation of the needle as it is walked under the posterior surface of the clavicle. The needle tip is directed toward the suprasternal notch, which may be constantly identified by the fingers of the operator's other hand. If the subclavian vein is not entered in the first pass, the needle may be withdrawn and a second pass attempted in a slightly more cephalad direction, while ensuring that the needle continues to hug the undersurface of the clavicle as it is advanced. Once the subclavian vein is punctured, catheterization proceeds in a similar manner to that described for jugular vein catheterization.

Several important technical details must be followed to ensure successful subclavian vein cannulation and avoid complications, particularly pneumothorax.

Venipuncture generally proceeds without first identifying the vein with a smaller gauge finder needle, because the depth of the subclavian vein is often beyond the reach of the standard 1-½-in 22-gauge needle. A thin-wall needle is preferred over an 18-gauge catheter for venipuncture and guide-wire placement because the 18-gauge catheter is easily kinked as it courses under the clavicle. Of greatest importance, however, the clinician should resist the temptation to make multiple needle thrusts if the subclavian vein is not punctured on the second or third attempt. It is clear that complications from this procedure, particularly the incidence of pneumothorax and subclavian arterial puncture, are directly related to the number of attempts at venipuncture and are more common when venipuncture is unsuccessful. [242] [247] [248] Bilateral attempts at subclavian venipuncture rarely should be undertaken, owing to the potential serious morbidity of bilateral pneumothoraces. Perhaps even more than in the case of internal jugular vein cannulation, the safety of subclavian venipuncture rests in the experience of the operator. In more practiced hands, the incidence of complications should be lower, with pneumothorax in fewer than 2 per-cent and arterial puncture in fewer than 5 percent of cases. [242] [247] [248]

External Jugular Vein

Both the right and left external jugular veins provide a safe alternative to internal jugular or subclavian vein cannulation. Because the external jugular veins are superficial structures, they allow central venous cannulation with essentially no risk of pneumothorax or unintended arterial puncture. [221] In most instances, it is best to use an 18-gauge catheter, rather than the thin-wall needle, to introduce the guide wire because of the tortuous course of the external jugular vein and the frequent need to manipulate the guide wire repeatedly to guide it into the superior vena cava. A J-tip guide wire should always be used, because it may be advanced under the clavicle into the central circulation more successfully than a straight-tip wire. [249] [250] When the guide wire does not advance as desired and appears to be moving peripherally into the subclavian vein, central venous passage may be facilitated by abducting the ipsilateral shoulder beyond 90 degrees prior to advancing the wire. Alternatively, the patient's ipsilateral arm is placed at the side, and an assistant applies mild caudad traction on the shoulder to straighten the course of the external jugular vein while the wire is advanced. Essentially the only factors that preclude use of the external jugular veins for CVP monitoring are an inability to visualize and cannulate the vessel in the neck and to advance a catheter into the central circulation. Unfortunately, these problems occur in approximately 20 percent of patients, thus limiting more widespread application of this technique. [221] [251]

Femoral Vein

Femoral vein cannulation provides a useful site for CVP monitoring when the more common jugular and subclavian sites are not accessible, as in patients with burns, trauma, or surgical procedures that involve the head, neck, and upper thorax. Use of the femoral venous site obviates many of the common complications of central venous catheterization, particularly pneumothorax and carotid or subclavian arterial injury. Femoral venipuncture is performed below the inguinal ligament just medial to the palpated femoral arterial pulse in a manner similar to that used for femoral arterial cannulation. Either a long (40-70 cm) catheter is positioned, using ECG guidance, in the inferior vena cava close to the cavoatrial junction, [252] or a shorter (15-20 cm) catheter is inserted from the femoral vein into the common iliac vein. [253] Both techniques provide intra-abdominal venous pressure measurements that agree closely with simultaneously obtained superior vena caval CVPs when these pressures are measured in mechanically ventilated, critically ill adults. [252] [253] However, it is unclear whether or not intra-abdominal venous pressure will reflect intrathoracic CVP in spontaneously breathing patients, those who are not supine, or in individuals with marked elevations in intrathoracic or intra-abdominal pressure. Potential disadvantages of the femoral venous route include increased risks of thromboembolic and infectious complications, although the magnitude of these risks has not been established. In addition, femoral arterial or venous injury during attempted cannulation may result in intra-abdominal hemorrhage.

Axillary and Other Peripheral Veins

In patients with extensive, severe burn injuries, the axillary region often is spared and provides a useful site for either arterial or venous pressure monitoring. [254] Standard 20-cm CVP catheters placed in the axillary veins, approximately 1 cm medial to the palpated axillary artery, will allow pressure measurement from the superior vena cava. Even more distal pressures measured from peripheral veins in the hand and forearm may provide a reasonably accurate estimate of CVP in selected surgical patients. [255] [256] Modified volumetric infusion pumps can measure in-line peripheral venous pressures without the need for additional transducers and monitoring equipment. [257] Although this method of measuring CVP

incurs no risk beyond that associated with placing any standard peripheral intravenous catheter, it has not been validated widely and clearly is no replacement for central venous cannulation in most circumstances when the latter is needed.

Peripherally inserted central venous catheters (PICC) have become a popular alternative to centrally inserted catheters in patients requiring long-term intravenous therapy. Advantages of the PICC include bedside placement under local anesthesia, extremely low risk of major insertion-related complications, and safe placement by nonphysicians (i.e., registered nurses and physician assistants). This technique may be particularly cost-effective, because it eliminates the need for a minor operative procedure in those patients who require a Hickman or Broviac central venous catheter. [258] Venous access for a PICC is obtained through an antecubital vein. Central catheter placement from the basilic vein is generally more successful than from the cephalic vein, in that the course of the latter is more tortuous, particularly at the clavipectoral fascia. Early reports described only modest success positioning PICCs in an appropriate central location as well as a considerable risk of venous thrombosis, [259] [260] [261] but improvements in catheter design and insertion technique now result in successful placement and few complications in most patients. [258] In current medical practice, most PICCs are placed for long-term therapeutic indications (chemotherapy or parenteral nutrition), using very flexible, nonthrombogenic silicone catheters. [258] Less commonly, a standard polyurethane 40-cm intravenous catheter is inserted peripherally and advanced to a central location for short-term infusion of vasoactive drugs or monitoring CVP or PAP. When these standard long venous catheters are inserted from an antecubital vein, the catheter tip may advance into the heart as the arm is abducted, thereby increasing the risk of cardiac perforation or arrhythmias. [208] [262] Whenever a PICC line is in place, the clinician should exercise caution when placing any additional central venous catheters because of the risk of shearing the PICC line within the central venous circulation.

Complications of Central Venous Cannulation and Pressure Monitoring

Complications of central venous cannulation have been recognized since this technique was introduced into clinical practice nearly 40 years ago. Although serious complications are infrequent when these procedures are performed by well-trained, experienced clinicians, significant morbidity and even fatal complications have been reported. [210] [211] Complications may be divided into those occurring during attempted venipuncture to gain central venous access, those occurring during placement of the venous catheter, those late complications associated with catheter residence in the body, and those associated with misuse of equipment and misinterpretation of data (Table 30-4) . This categorization is, however, somewhat arbitrary. Some complications, like nerve injury, may go unnoticed at the time of venipuncture but be clinically recognized days following the procedure. In contrast, cardiac perforation and tamponade usually occur in the days following successful central venous cannulation but may occur shortly after the initial catheterization procedure.

Clearly, the incidence of complications depends on various factors, including the site and techniques chosen for venipuncture and the patient's medical condition. Large retrospective and observational studies provide the best estimates of the most frequent complications. In general, unintended *arterial puncture* leads this list of adverse events. Shah et al [263] reported more than 6,000 central venous catheterizations over a 5-year period, with more than 95 percent performed via the internal jugular vein. In this series, the most common complication was carotid artery puncture, which occurred in 120 patients (1.9%) but did not result in any serious morbidity. Authors of other large studies report a somewhat higher incidence of arterial puncture during central venous catheterization, ranging from approximately 3 to 9 percent. [216] [217] [242] In all likelihood, the frequency of arterial puncture with a small-gauge finding needle is even higher. Although usually benign, on rare occasions even small-gauge-needle arterial punctures may lead to serious complications. [264]

If arterial puncture occurs during central venous cannulation, the needle is removed and external pressure is applied to the puncture site for at least 5 minutes or for as long as necessary to prevent hematoma formation. The most efficacious clinical management of unintentional cannulation of the carotid artery with a large-gauge catheter is less clear. In the large series of Shah and coworkers [263] arterial cannulation with a 7.5-French introducer sheath occurred in four patients. The sheath was removed immediately when its intra-arterial location was recognized by the high-pressure backflow of blood. External compression was applied for 5 minutes; there was no hematoma formation requiring further treatment in any patient. Other reports, however, emphasize that unintentional arterial cannulation may result in hematoma formation after catheter removal, with significant risk of airway compromise that may require urgent tracheal intubation and surgical exploration for hematoma evacuation or arterial repair. [121] [216] In summary, when unintentional carotid artery cannulation occurs, it can usually be managed conservatively by removing the catheter, applying local compression to the puncture site, and monitoring the patient's airway and neurologic status. Ideally, a vascular surgeon should be consulted promptly to help manage the complication. Under no circumstances should prolonged cannulation of the carotid artery be tolerated, because arteritis,

thrombus formation, and cerebral embolization may result. [265]

Pneumothorax is often cited as the most common complication of subclavian central venous cannulation, although it appears that unintended arterial puncture occurs more often than pneumothorax, even with the subclavian site of venipuncture. [121] [242] Mansfield et al [242] reported 821 patients who underwent attempted subclavian venous cannulation, with a 1.5 percent incidence of pneumothorax and a 3.7 percent incidence of subclavian arterial puncture. Pneumothorax occurs even less frequently with the internal jugular approach. Shah et al [263] reported an incidence of pneumothorax of 0.5 percent in their series of nearly 6,000 internal jugular catheterizations. This is likely a conservative overestimate, because most patients in this series underwent median sternotomy for cardiac surgery, a procedure that may

TABLE 30-4 -- Complications of Central Venous Pressure Monitoring

VENIPUNCTURE AND GAINING CENTRAL VENOUS ACCESS
Arterial puncture
Hematoma
Hemothorax
Hemomediastinum [1]
Arterial thromboembolism [2]
Airway compromise [3]
Pneumothorax
Subcutaneous, mediastinal emphysema
Chylothorax [4]
Nerve injury
Brachial plexus
Stellate ganglion
Phrenic nerve [5]
Vocal cord paralysis [6]
Chronic pain syndrome [7]
Tracheal puncture
Endotracheal tube cuff perforation [8]
CATHETERIZATION
Arterial cannulation [9] [1]
Venous injury, right facial vein avulsion [1]
Venous valve injury [1] [1]
Catheter shearing and embolization [1]
Guide-wire embolization [1]
Guide-wire-induced arrhythmias, heart block [1] [1]
Chlorhexidine hypersensitivity, anaphylaxis [1] [1]
Air embolism [2] [2] [2] [2]
CATHETER RESIDENCE (LATE COMPLICATIONS)
Delayed vascular injury
Aortoatrial fistula [2]
Venobronchial fistula [2] [2]
Pseudoaneurysm
Right atrial, right ventricular, superior vena caval perforation
Cardiac tamponade [2] [2] [2] [3] [3] [3] [3]
Venous thrombosis [3] [3]
Pulmonary embolism
Superior vena caval syndrome
Impaired venous drainage
Hydrothorax [3] [3]
Hydromediastinum [3]
Infection [3] [3] [4] [4] [4]
Phlebitis [4]
Cellulitis
Bacteremia, fungemia, sepsis
Catheter fracture, embolism
Catheter migration, malposition [4] [4]
Catheter-induced arrhythmias [1]
MISINTERPRETATION AND MISUSE [1] [3] [4] [4] [4]
