ANESTHESIA

FIFTH EDITION

Volume 1

Edited by

Ronald D. Miller M.D.
Professor and Chairman of Anesthesia and Perioperative Care
Professor of Cellular and Molecular Pharmacology
Department of Anesthesia
University of California, San Francisco
School of Medicine
San Francisco, California
Atlas of Regional Anesthesia Procedures illustrated by Gwenn Afton-Bird, M.S.

A Division of Harcourt Brace & Company
Philadelphia London Toronto Montreal Sydney Tokyo Edinburgh

Contributors

Hugo van Aken M.D., Ph.D.

Chairman and Professor of Anesthesiology
Westfalische Wilhelms-Universitat,
Munster, Germany

David D. Alfery M.D.

Department of Anesthesiology,
Centennial Medical Center,
Nashville, Tennessee

J. Jeffrey Andrews M.D.

Professor and Vice-Chair for Clinical Development,
Department of Anesthesiology,
University of Alabama at Birmingham
School of Medicine,
Birmingham, Alabama;

Chief, Anesthesiology Service,
Veterans Administration,
Birmingham VA Medical Center,
Birmingham, Alabama

Joseph F. Antognini M.D.

Associate Professor, Department of Anesthesiology,
University of California, Davis,
School of Medicine,
Davis, California

William P. Arnold III M.D.

Associate Professor, Department of Anesthesiology,
University of Virginia Health System,
University of Virginia School of Medicine,
Charlottesville, Virginia

Solomon Aronson M.D.

Associate Professor and Director of Cardiothoracic Anesthesia,
Department of Anesthesia and Critical Care,
University of Chicago Hospitals,
Chicago, Illinois

Michael J. Avram Ph.D.

Associate Professor, Department of Anesthesiology,
Northwestern University Medical School,
Chicago, Illinois

Jeffrey M. Baden F.R.C.A., M.R.C.P. (UK)

Professor, Department of Anesthesia,
Stanford University School of Medicine,
Stanford, California;

Staff Anesthesiologist,
Veterans Affairs Health Care System,
Palo Alto, California

Peter Bailey M.D.

Professor and Director, Cardiothoracic Anesthesia,
Department of Anesthesia,

**University of Utah, Health Sciences Center,
Salt Lake City, Utah**

Michael J. Banner Ph.D.

**Associate Professor, Department of Anesthesiology,
University of Florida, Shands Teaching Hospital,
Gainesville, Florida**

Steven J. Barker M.D.

**Professor and Chair, Department of Anesthesiology,
University of Arizona,
Tucson, Arizona**

Nathan M. Bass M.D., Ph.D.

**Professor, Department of Medicine,
University of California, San Francisco,
School of Medicine,
San Francisco, California;**

**Attending Physician,
Division of Gastroenterology,
University of California, San Francisco Medical Center,
San Francisco, California**

Jonathan L. Benumof M.D.

**Professor, Department of Anesthesiology,
University of California, San Diego, School of Medicine
La Jolla, California**

Susan Black M.D.

**Associate Professor,
Department of Anesthesiology,
University of Florida College of Medicine,
Gainesville, Florida**

Thomas J.J. Blanck M.D., Ph.D.

**Professor, Departments of Anesthesiology and Physiology and Biophysics,
Joan and Sanford I. Weill Medical College of Cornell University,
New York, New York;**

**Director, Department of Anesthesiology,
Hospital for Special Surgery,
New York, New York**

David L. Brown M.D.

**Professor and Head,
Department of Anesthesia,
University of Iowa College of Medicine,
Iowa City, Iowa;**

**Head, Department of Anesthesia,
University of Iowa Hospital and Clinics,
Iowa City, Iowa**

Michael K. Cahalan M.D.

**Professor, Department of Anesthesia,
University of California, San Francisco, School of Medicine;**

**Director of Anesthesia for Cardiac Surgery,
Moffitt and Long Hospitals,
San Francisco, California**

James E. Caldwell M.D.

**Professor and Director of Perioperative Medicine,
Department of Anesthesia,
University of California, San Francisco, School of Medicine,
San Francisco, California**

Enrico M. Camporesi M.D.

**Professor and Chair,
Department of Anesthesiology;
Professor of Physiology,
State University of New York Health Science Center at Syracuse College of Medicine,
Syracuse, New York**

Donald Caton M.D.

**Professor, Departments of Anesthesiology and Obstetrics and Gynecology,
University of Florida College of Medicine,
Gainesville, Florida**

Charles J. Cote M.D.

**Professor, Department of Anesthesiology and Pediatrics,
Northwestern University Medical School,
Chicago, Illinois;**

**Vice Chairman, Director of Research,
Department of Pediatric Anesthesiology,
Children's Memorial Hospital,
Chicago, Illinois**

Roy F. Cucchiara M.D.

**Professor, Department of Anesthesiology,
University of Florida College of Medicine,
Gainesville, Florida**

Bernard J. Dalens M.D.

**Pediatric Anesthesiologist,
University Hospital Hotel-Dieu,
Pavillon Gosselin,
Clermont-Ferrand, France**

Sudhir Diwan M.D.

**Instructor in Anesthesiology,
Joan and Sanford I. Weill Medical College of Cornell University,
New York, New York;**

**Assistant Attending Anesthesiologist,
Associate Director, Pain Service,
Department of Anesthesiology,
New York Presbyterian Hospital,
New York, New York**

Barbara A. Dodson M.D.

**Professor, Department of Anesthesia,
University of California, San Francisco,
School of Medicine,
San Francisco, California**

John V. Donlon Jr. M.D.

**Associate Clinical Professor, Anaesthesia,
Harvard Medical School,
Cambridge, Massachusetts;**

**Chief, Anesthesia Department,
Massachusetts Eye and Ear Infirmary,
Boston, Massachusetts**

John C. Drummond M.D.

**Professor and Chair,
Department of Anesthesiology,
University of California, San Diego, School
of Medicine
La Jolla, California;**

**Staff Anesthesiologist,
Department of Anesthesiology,
Veterans Administration Medical Center,
San Diego, California**

Talmage D. Egan M.D.

**Assistant Professor, Department of Medicine,
University of Utah School of Medicine,
Salt Lake City, Utah**

Edmond I. Eger II M.D.

**Professor, Department of Anesthesia,
University of California, San Francisco, School of Medicine
San Francisco, California**

Neil E. Farber M.D., Ph.D.

Associate Professor, Department Anesthesiology,

**Pharmacology and Toxicology, and Pediatrics;
Director of Pediatric Anesthesiology Research,
Medical College of Wisconsin,
Milwaukee, Wisconsin**

Ronald J. Faust M.D.

**Professor, Department of Anesthesiology,
Mayo School of Medicine,
Rochester, Minnesota;**

**Consultant in Anesthesiology,
Mayo Clinic,
Rochester, Minnesota**

Thomas W. Feeley M.D.

**Charles M. McBride Professor and Chairman,
Departments of Anesthesiology and Critical Care,
University of Texas
M.D. Anderson Cancer Center,
Houston, Texas**

John Feiner M.D.

**Assistant Professor, Department of Anesthesia,
University of California, San Francisco,
School of Medicine,
San Francisco, California**

Leonard Firestone M.D.

**Professor and Chairman,
Department of Anesthesiology and Critical Care Medicine,
University of Pittsburgh School of Medicine,
Pittsburgh, Pennsylvania**

Steven P. Fischer M.D.

**Assistant Professor, Department of Anesthesia,
Stanford University School of Medicine,
Stanford, California**

Dennis M. Fisher M.D.

**Professor, Departments of Anesthesia and Pediatrics,
University of California, San Francisco,
School of Medicine,
San Francisco, California**

Lee A. Fleisher M.D.

**Associate Professor, Department of Anesthesiology and Critical Care Medicine,
Joint Appointments in Medicine and Health Policy & Management,
The Johns Hopkins Medical Institutions,
Baltimore, Maryland;**

**Attending Anesthesiologist,
The Johns Hopkins Hospital,
Baltimore, Maryland**

Joseph F. Foss M.D.

**Assistant Clinical Professor, Department of Anesthesia and Critical Care,
University of Chicago Pritzker School
of Medicine,
Chicago, Illinois**

Robert J. Fragen M.D.

**Professor, Department of Anesthesiology,
Northwestern University Medical School,
Chicago, Illinois;**

**Staff Anesthesiologist,
Northwestern Memorial Hospital,
Chicago, Illinois**

Steven M. Frank M.D.

**Associate Professor,
Department of Anesthesiology and Critical Care Medicine,
The Johns Hopkins Medical Institutions,
Baltimore, Maryland**

David M. Gaba M.D.

**Associate Professor, Department of Anesthesia,
Stanford University School of Medicine,**

Stanford, California;

Staff Anesthesiologist,
Veterans Affairs Health Care System,
Palo Alto, California

Thomas J. Gal M.D.

Professor, Department of Anesthesiology,
University of Virginia Health Sciences Center,
Charlottesville, Virginia

Simon Gelman M.D., Ph.D.

Leroy D. Vandam/Benjamin G. Covino Professor of Anaesthesia,
Harvard Medical School,
Boston, Massachusetts;

Chairman, Department of Anesthesia,
Brigham and Women's Hospital,
Boston, Massachusetts

Peter S.A. Glass M.D.

Associate Professor, Department of Anesthesiology,
Duke University Medical Center,
Durham, North Carolina

Beth Glosten M.D.

Anesthesiologist,
Redmond, Washington

Christopher M. Grande M.D., M.P.H.

Professor, Department of Anesthesiology,
West Virginia University School of Medicine;
Director of Trauma Anesthesia,
Jon Michael Moore Trauma Center,
Robert C. Byrd Health Sciences Center,
Morgantown, West Virginia

Executive Director,
International Trauma Anesthesia
and Critical Care Society,
Baltimore, Maryland

William J. Greeley M.D.

Professor, Departments of Anesthesia and Pediatrics,
University of Pennsylvania
School of Medicine,
Philadelphia, Pennsylvania;

Chair, Department of Anesthesia and Critical Care Medicine,
Children's Hospital of Philadelphia,
Philadelphia, Pennsylvania

George A. Gregory M.D.

Professor, Departments of Anesthesia and Pediatrics,
University of California, San Francisco,
School of Medicine,
San Francisco, California

Alan Grogono M.D.

Merryl & Sam Israel Professor and
Chairman Emeritus, Department of Anesthesiology,
Tulane University Medical Center,
New Orleans, Louisiana;

Past President of the Association of Anesthesiology Program Directors

Gerald A. Gronert M.D.

Professor, Department of Anesthesiology,
University of California, Davis, School of Medicine,
Davis, California

Zaharia Hillel M.D., Ph.D.

Associate Professor of Clinical Anesthesiology,
Columbia University College of Physicians and Surgeons;

Director of Cardiothoracic Anesthesia,

**St. Luke's Roosevelt Hospital Center,
New York, New York**

Steven K. Howard M.D.

**Assistant Professor, Department of
Anesthesia,
Stanford University School of Medicine,
Stanford, California**

Carl C. Hug Jr. M.D., Ph.D.

**Professor, Departments of Anesthesiology and Pharmacology,
Emory University School of Medicine,
Atlanta, Georgia;**

**Attending Anesthesiologist,
Division of Cardiothoracic Anesthesiology and Critical Care Medicine,
Emory University Hospital,
Atlanta, Georgia**

Jean L. Joris M.D., Ph.D.

**Associate Professor,
Department of Anesthesia and Intensive Care Medicine,
CHU de Liege, Domaine du Sart Tilman,
Liege, Belgium**

Alan D. Kaye M.D., Ph.D.

**Professor and Chairman,
Department of Anesthesiology,
Texas Tech. University Medical Center,
Lubbock, Texas;**

**Professor, Department of Pharmacology,
Texas Tech. University Health Sciences Center,
Lubbock, Texas**

Frank H. Kern M.D.

**Professor and Chief of Pediatric Anesthesia,
Departments of Anesthesiology and Pediatrics,
Duke University Medical Center,
Durham, North Carolina**

Robert R. Kirby M.D.

**Professor of Anesthesiology,
University of Florida College of Medicine,
Gainesville, Florida;**

**System Chief, Anesthesiology Service,
Veterans Affairs Medical Center,
Gainesville, Florida**

Donald D. Koblin M.D., Ph.D.

**Professor, Department of Anesthesia and Perioperative Care,
University of California, San Francisco,
School of Medicine,
San Francisco, California;**

**Staff Anesthesiologist,
Department of Veterans Affairs
Medical Center,
San Francisco, California**

W. Daniel Kovarik M.D.

**Director of Pediatric Anesthesia,
Spectrum Medical Group,
Maine Medical Center,
Portland, Maine**

A. Joseph Layon M.D.

**Professor, Departments of Anesthesiology, Surgery, and Medicine,
University of Florida College of Medicine,
Gainesville, Florida;**

**Associate Director of Burn Center,
Shands Teaching Hospital, University
of Florida,
Gainesville, Florida**

David L. Lee M.D.

Assistant Professor of Anesthesiology,
Cornell University Medical College,
New York, New York;

Attending Anesthesiologist,
Hospital for Special Surgery,
New York, New York

Cynthia A. Lein M.D.

Associate Professor, Department of Anesthesiology,
New York Presbyterian Hospital,
Joan and Sanford I. Weill Medical College of Cornell University,
New York, New York

Lawrence Litt M.D., Ph.D.

Professor, Departments of Anesthesia and Radiology,
University of California, San Francisco,
School of Medicine,
San Francisco, California;

Attending Physician in Anesthesia,
Moffitt and Long Hospitals,
UCSF-Stanford Medical Center,
San Francisco, California

David A. Lubarsky M.D.

Associate Professor and Vice Chairman, Department of Anesthesiology,
Duke University Medical Center,
Durham, North Carolina

Alex Macario M.D.

Assistant Professor, Department of
Anesthesia,
Stanford University School of Medicine,
Stanford, California

Ronald A. Mackenzie D.O.

Assistant Professor, Department of Anesthesiology,
Mayo School of Medicine,
Rochester, Minnesota;

Consultant, Department of Anesthesiology,
Mayo Clinic,
Rochester, Minnesota

Michael E. Mahla M.D.

Associate Professor, Departments of Anesthesiology and Neurosurgery,
Associate Chairman for Education,
University of Florida College of Medicine,
Gainesville, Florida

Vinod Malhotra M.D.

Professor, Department of Anesthesiology,
Joan and Sanford I. Weill Medical College of Cornell University,
New York, New York;

Clinical Director of the Operating Rooms,
Department of Anesthesiology,
New York Presbyterian Hospital,
New York, New York

Jonathan B. Mark M.D.

Associate Professor of Anesthesiology;
Assistant Professor in Medicine,
Duke University Medical Center,
Durham, North Carolina;

Chief, Anesthesiology Service,
Durham Veterans Affairs Medical Center,
Durham, North Carolina

Jeevendra Martyn M.D.

Professor of Anaesthesia;
Director, Clinical and Biochemical Pharmacology Laboratory,
Harvard Medical School,
Massachusetts General Hospital,
Boston, Massachusetts

Mervyn Maze M.D.

Magill Professor of Anaesthetics,
Magill Department of Anaesthesia, Intensive Care, and Pain Management,
Imperial College School of Medicine,
Chelsea and Westminster Hospital,
Chelsea, London, England

William J. Mazzei M.D.

Clinical Professor, Department of Anesthesiology,
UCSD Medical Center,
San Diego, California

Joseph M. Messick Jr.

Former Professor, Department of Anesthesiology,
Mayo School of Medicine,
Rochester, Minnesota

Edward D. Miller Jr. M.D.

Dean of the Medical Faculty, CEO, Johns Hopkins Medicine, Professor, Department of Anesthesiology and Critical Care Medicine,
The Johns Hopkins University School of Medicine,
Baltimore, Maryland

Ronald D. Miller M.D.

Professor and Chairman of Anesthesia and Perioperative Care;
Professor of Cellular and Molecular Pharmacology,
Department of Anesthesia, University of California, San Francisco,
School of Medicine,
San Francisco, California

Charles S. Modell J.D.

Share Holder and Director,
Larkin, Hoffman, Daly and Lindgren,
Bloomington, Minnesota

Jerome H. Modell M.D.

Professor of Anesthesiology,
University of Florida College of Medicine,
Gainesville, Florida;

Associate Vice President for Health Affairs,
University of Florida,
Gainesville, Florida

Richard E. Moon M.D.

Professor, Department of Anesthesiology,
Associate Professor, Department of Pulmonary and Critical Care Medicine,
Duke University School of Medicine,
Durham, North Carolina;

Attending Anesthesiologist,
Attending Pulmonologist,
Duke University Medical Center,
Durham, North Carolina

Kenjiro Mori M.D.

Emeritus Professor, Department of Anesthesia,
Kyoto University Faculty of Medicine,
Kyoto, Japan;

Hospital Director,
Takamatsu Red Cross Hospital,
Takamatsu, Japan

Jonathan Moss M.D., Ph.D.

Professor, Department of Anesthesia and Critical Care;
Professor of the College;
Professor, Committee on Clinical Pharmacology,
Vice Chairman for Research,
University of Chicago
Pritzker School of Medicine,
Chicago, Illinois

Stanley Muravchick M.D., Ph.D.

Professor, Department of Anesthesia,
University of Pennsylvania School
of Medicine,

Philadelphia, Pennsylvania;

Staff Anesthesiologist,
Hospital of the University of Pennsylvania,
Philadelphia, Pennsylvania

Shin-ichi Nakao M.D., Ph.D.

Assistant Professor, Department of Anesthesiology,
Kansai Medical University, Moriguchi,
Osaka, Japan

Susan C. Nicolson M.D.

Professor of Anesthesia,
University of Pennsylvania School
of Medicine,
Philadelphia, Pennsylvania;

Director, Cardiac Anesthesiology,
The Children's Hospital of Philadelphia,
Philadelphia, Pennsylvania

Edward J. Norris M.D.

Assistant Professor, Department of Anesthesiology and Critical Care Medicine,
The Johns Hopkins University School of Medicine,
Baltimore, Maryland;

Attending Anesthesiologist,
Section Head, Vascular Anesthesia,
The Johns Hopkins Medical Institutions,
Baltimore, Maryland

Fredrick K. Orkin M.D.

Professor of Health Evaluation Sciences;
Professor, Department of Anesthesiology,
Pennsylvania State University College of Medicine,
Hershey, Pennsylvania;

Anesthesiologist,
The Milton S. Hershey Medical Center,
Penn State Geisinger Health System,
Hershey, Pennsylvania

P. Pearl O'Rourke M.D.

Director of Pediatric Intensive Care,
Children's Hospital Medical Center,
University of Washington School of Medicine,
Seattle, Washington

Paul S. Pagel M.D., Ph.D.

Associate Professor, Department of Anesthesiology,
Medical College of Wisconsin,
Milwaukee, Wisconsin

Dale A. Parks Ph.D.

Associate Professor, Department of Anesthesiology; Physiology and Biophysics; and Pediatrics; and Center for Free Radical Research,
University of Alabama at Birmingham School of Medicine,
Birmingham, Alabama

Piyush M. Patel M.D.

Associate Professor, Department of Anesthesiology,
University of California, San Diego, School of Medicine,
La Jolla, California;

Staff Anesthesiologist, Department of Anesthesiology,
Veterans Administration Medical Center,
San Diego, California

William T. Peruzzi M.D.

Associate Professor, Department of Anesthesiology,
Northwestern University Medical School,
Chicago, Illinois

Isaac N. Pessah Ph.D.

Professor, Department of Molecular Biosciences,
University of California, Davis, School
of Veterinary Medicine,

Davis, California

Ira J. Rampil M.D.

**Associate Professor, Department of Anesthesia and Perioperative Care,
University of California, San Francisco, School of Medicine,
San Francisco, California**

L. Brian Ready

**Professor, Department of Anesthesiology,
University of Washington School of Medicine,
Seattle, Washington;**

**Director, University of Washington Medical
Center Pain Service,
University of Washington Medical Center,
Seattle, Washington**

Cheryl Renz M.D.

**Fellow, Committee on Clinical Pharmacology,
Department of Anesthesia and Critical Care,
University of Chicago Pritzker School of Medicine,
Chicago, Illinois**

J. Gerald Reves M.D.

**Professor and Chairman, Department of Anesthesiology,
Duke University Medical Center,
Durham, North Carolina**

Susan A. Rice Ph.D.

**Department of Anesthesia,
Stanford University School of Medicine,
Stanford, California**

Michael F. Roizen M.D.

**Professor and Chairman, Department of Anesthesia and Critical Care;
Professor, Department of Medicine,
University of Chicago Pritzker School of Medicine,
Chicago, Illinois**

John C. Rowlingson M.D.

**Professor and Director, Pain Medicine Services,
Department of Anesthesiology,
University of Virginia Health System,
University of Virginia School of Medicine,
Charlottesville, Virginia**

Monica M. Sa Rego M.D.

**Resident in Anaesthesia,
Brigham and Women's Hospital,
Harvard Medical School,
Boston, Massachusetts**

John J. Savarese M.D.

**The Joseph F. Artusio Professor and Chairman,
Department of Anesthesiology,
New York Presbyterian Hospital,
Joan and Sanford I. Weill Medical College of Cornell University,
New York, New York**

Alan Jay Schwartz M.D.

**Professor and Chair, Department of Anesthesiology,
Professor of Pharmacology,
Hahnemann University School of Medicine,
Philadelphia, Pennsylvania;**

**Chair, Department of Anesthesiology,
City Avenue Hospital,
Hahnemann University Hospital,
Medical College of Pennsylvania Hospital,
Philadelphia, Pennsylvania**

Debra Schwinn M.D.

**Professor of Anesthesiology,
Department of Anesthesiology,
Duke University School of Medicine,
Durham, North Carolina**

Daniel I. Sessler M.D.

**Professor and Director, Outcomes Research,
Department of Anesthesia and Perioperative Care,
University of California, San Francisco,
School of Medicine,
San Francisco, California;**

**Professor, Ludwig Boltzmann Institute,
Vice-Chair, Department of Anesthesia,
University of Vienna,
Vienna, Austria**

Steven L. Shafer M.D.

**Associate Professor, Department of Anesthesia,
Stanford University School of Medicine,
Palo Alto, California**

**Staff Anesthesiologist,
Veterans Affairs Health Care System,
Palo Alto, California;**

Jack S. Shanewise M.D.

**Assistant Professor, Department of Anesthesiology,
Emory University School of Medicine,
Atlanta, Georgia;**

**Director, Intraoperative Echocardiography Service,
Emory University Hospital,
Atlanta, Georgia**

Robert E. Shangraw M.D., Ph.D.

**Associate Professor, Department of Anesthesiology,
Oregon Health Sciences University,
Portland, Oregon**

Barry A. Shapiro M.D.

**Professor and James E. Eckenhoff Chair, Department of Anesthesiology,
Northwestern University Medical School,
Chicago, Illinois**

Nigel E. Sharrock M.B.

**Assistant Clinical Professor, Department of Anesthesiology,
Joan and Sanford I. Weill Medical College of Cornell University,
New York, New York;**

**Senior Scientist and Attending Anesthesiologist,
The Hospital for Special Surgery,
New York, New York**

Koh Shingu M.D.

**Professor and Chairman, Department of Anesthesiology,
Kansai Medical University, Moriguchi,
Osaka, Japan**

Kelly A. Skinner Ph.D.

**Research Associate, Department of Physiology and Biophysics,
University of Alabama at Birmingham School of Medicine,
Birmingham, Alabama**

Robert N. Sladen M.B.

**Professor and Vice-Chair, Department of Anesthesiology,
College of Physicians and Surgeons of Columbia University,
New York, New York;**

**Medical Director, Cardiothoracic-Surgical Intensive Care Unit,
New York Presbyterian Hospital (Columbia Campus),
New York, New York**

Thomas F. Slaughter M.D.

**Assistant Professor, Department of Anesthesiology,
Duke University School of Medicine,
Durham, North Carolina;**

**Attending Physician,
Durham Veterans Affairs Medical Center,**

Durham, North Carolina

Peter Southorn M.D.

**Associate Professor, Department of Anesthesiology, Mayo School of Medicine,
Rochester, Minnesota;**

**Consultant, Mayo Clinic,
Rochester, Minnesota**

Theodore H. Stanley M.D.

**Professor, Department of Anesthesiology,
University of Utah School of Medicine,
University Hospital,
Salt Lake City, Utah**

Donald R. Stanski M.D.

**Professor, Departments of Anesthesia and Medicine,
Stanford University School of Medicine,
Stanford, California**

Linda Stehling M.D.

**Former Professor, Departments of Anesthesiology and Pediatrics,
State University of New York Health Sciences Center at Syracuse College of Medicine,
Syracuse, New York;**

**Medical Consultant,
Scottsdale, Arizona**

John K. Stene M.D., Ph.D.

**Associate Professor, Department of Anesthesiology,
Pennsylvania State University, College of Medicine,
Hershey, Pennsylvania;**

**Director of Trauma Anesthesia,
Co-Director of Surgical Intensive Care Unit,
Penn State Geisinger Health System,
Milton S. Hershey Medical Center,
Hershey, Pennsylvania**

Paul E. Stensrud M.D.

**Instructor in Anesthesiology,
Mayo School of Medicine,
Rochester, Minnesota;**

**Consultant in Anesthesiology,
Mayo Foundation,
Rochester, Minnesota**

James M. Steven M.D.

**Associate Professor, Departments of Anesthesia and Pediatrics,
University of Pennsylvania School of Medicine,
Philadelphia, Pennsylvania;**

**Associate Anesthesiologist-in-Chief,
The Children's Hospital of Philadelphia,
Philadelphia, Pennsylvania**

David J. Stone M.D.

**Professor, Departments of Anesthesiology and Neurological Surgery,
University of Virginia Health Sciences Center,
Charlottesville, Virginia**

Gary Strichartz M.D.

**Professor, Department of Anesthesia and Pharmacology,
Director, Pain Research Center,
Harvard Medical School,
Brigham and Women's Hospital,
Boston, Massachusetts**

Cheri A. Sulek M.D.

**Assistant Professor, Department of Anesthesiology,
University of Florida College of Medicine,
Gainesville, Florida;**

**Staff Anesthesiologist, Veterans Affairs Medical Center,
Gainesville, Florida;**

**Shands Teaching Hospital, University of Florida,
Gainesville, Florida**

James F. Szocik M.D.

**Assistant Professor, Department of Anesthesiology,
University of Michigan Medical Center,
Ann Arbor, Michigan**

Stephen J. Thomas M.D.

**Professor and Vice Chair, Department of Anesthesiology,
Joan and Sanford I. Weill Medical College of Cornell University,
New York, New York**

Daniel M. Thys M.D.

**Professor, Department of Anesthesiology,
Columbia University College of Physicians and Surgeons;
Director, Department of Anesthesiology,
St. Luke's Roosevelt Hospital Center,
New York, New York**

Kevin Tremper M.D., Ph.D.

**R.B. Suite Professor and Chair,
Department of Anesthesiology,
University of Michigan Medical School,
Ann Arbor, Michigan**

Leroy D. Vandam M.D.

**Professor Emeritus of Anesthesia,
Harvard Medical School,
Brigham and Women's Hospital,
Boston, Massachusetts**

Janet van Vlymen M.D.

**Associate Professor, Department of Anaesthesiology and Critical Care,
Queen's University Faculty of Medicine,
Kingston, Ontario, Canada**

Thomas C. Vary Ph.D.

**Professor, Department of Cellular and Molecular Physiology,
Pennsylvania State University,
College of Medicine,
Hershey, Pennsylvania**

Jorgen Viby-Mogensen M.D.

**Professor, Department of Anaesthesia,
Copenhagen University Hospital, Rigshospitalet,
Copenhagen, Denmark**

David C. Warltier M.D., Ph.D.

**Professor and Vice Chairman for Research,
Departments of Anesthesiology, Pharmacology and Toxicology, and Medicine (Division of Cardiovascular Diseases),
Medical College of Wisconsin,
Milwaukee, Wisconsin**

Denise J. Wedel M.D.

**Professor, Department of Anesthesiology,
Mayo Clinic,
Rochester, Minnesota**

Paul F. White M.D., Ph.D.

**Professor and Holder of the Margaret Milan McDermott Distinguished Chair in Anesthesiology,
Department of Anesthesiology and Pain Management,
University of Texas Southwestern Medical Center at Dallas,
Dallas, Texas**

Roger D. White M.D.

**Professor, Department of Anesthesiology,
Mayo School of Medicine,
Rochester, Minnesota;**

**Consultant in Anesthesiology,
Mayo Clinic,**

Preface to the Fifth Edition

The Fourth Edition of *Anesthesia* is widely recognized as the most complete and thorough analysis and presentation available on the specialty of anesthesiology. The consulting editors and I examined the Fourth Edition carefully to ensure that the entire specialty of anesthesiology in the Fifth Edition is adequately addressed in a scholarly, thorough, and contemporary manner. Each author was instructed to revise his or her chapter in a manner that ensured its being a contemporary treatment of the subject matter being described.

There are some modest changes in the subject matter and its reorganization in the Fifth Edition of *Anesthesia.* From a monitoring point of view, the use of transesophageal echocardiography is increasingly becoming a standard in anesthesia, not only for patients with cardiac surgery but also for many other patients with critical illnesses or procedures being performed. In that regard, we made the decision to have a separate chapter on transesophageal echocardiography (Chapter 31) written by Dr. Michael Cahalan, who is regarded as an international expert on this topic. We also recognized the increasing importance of information systems in the clinical setting in which we work. As a result, Dr. Ira Rampil added a chapter on "Finding Professional Information on the Internet" (Chapter 78). Also, recognizing the increasing requirement of assessing the effectiveness of clinical care, Dr. Dennis Fisher added a section on outcomes in his statistical analysis in Chapter 21.

As in previous editions, each chapter is written as a complete discussion of its topic and is fully referenced. As a result, there is some overlap from chapter to chapter. This overlap provides the reader with contrasting but equally valid views on many important areas in anesthesia. Also, there was an attempt to provide cross-referencing from one chapter to another on a particular topic.

With each new edition of *Anesthesia,* the number of pages and illustrations has progressively increased. This is a reflection of the increasing knowledge base that anesthesiologists need in order to have a complete understanding of the practice of anesthesiology. Therefore, a major emphasis in the Fifth Edition was to facilitate the overall understanding of the subject being discussed. In the Fourth Edition, color illustrations were inserted with regard to certain key illustrations. In the Fifth Edition, additional color was added, which should facilitate the ease of reading the text. Furthermore, a decision was made to develop a CD-ROM to provide a verbal and visual description of some of the more difficult technical procedures described in the text. It was our view that the addition of the CD-ROM would greatly enhance the understanding of some of the more technical aspects of our specialty. CD-ROM icons placed throughout both volumes indicate the related videos.

There is increasing recognition in health care delivery that standardization of health care not only increases quality but also tends to decrease cost. While one can debate this conclusion, there is no doubt that the practice of medicine is moving in a direction of standardization; anesthesiology is no exception. As a result, we are very grateful to the American Society of Anesthesiologists and Michael Todd, M.D., Editor-in-Chief of *Anesthesiology,* for allowing us to publish the ASA Practice Guidelines. The practice parameters described in these guidelines have been referenced to the appropriate chapters. This will allow the reader to compare leading experts' approaches to a particular topic with the standard recommendations of the American Society of Anesthesiologists.

As with the Fourth Edition, we believe that this text is truly peer-reviewed and that the review process by our consulting editors equals that of many excellent journals. I, therefore, especially thank Drs. Roy F. Cucchiara, Edward D. Miller, Jr., J. Gerald Reves, Michael F. Roizen, and John J. Savarese for their expertise and help in the development of the Fifth Edition of *Anesthesia.* Finally, I would like to acknowledge the support of Lewis Reines, President, and Allan Ross, Medical Editor, as well as the assistance of the editorial and production staff at W.B. Saunders Company, especially Ann Ruzycka, Senior Development Editor; Shelley Hampton, Production Editor; and Scott Filderman, Copy Editor.

INTRODUCTION

Anesthesia is considered an American invention, although innovations of such significance can hardly have arisen spontaneously. The individual's well-being was not genuinely considered until the need for surgical treatment of disease arose; attempts at relieving pain were previously sporadic. True, operations had been performed over the centuries but always for the superficial malady--a fracture, amputation, cataract extraction, trephination of the skull, or removal of bladder calculus. To these ends, the anesthetic properties of hypnosis and trance, pressure over peripheral nerves and blood vessels, application of cold, alcohol intoxication, or ingestion of herbal concoctions were used. A more influential approach to illness had been the galenic concept of disease, in which an imbalance among four cardinal body humors--blood, phlegm, and yellow and black bile--was said to exist; this concept survived well into the present century.

Section 1 - Introduction

Chapter 1 - History of Anesthetic Practice

Leroy D. Vandam

ANTECEDENTS OF MODERN ANESTHESIA

The gastrointestinal tract long remained the only avenue for medicinal therapy. The inhalation of vapors became an alternative approach. With techniques of anesthetic administration more or less divided into schools, the choice now lies between inhalational, intravenous, or regional techniques or combinations thereof. However, the seeds of all three methodologies were implanted during the Middle Ages. Although this chapter mainly considers subsequent developments and the birth of a new medical specialty, anesthesiology, it is worthwhile to look to the antecedents.

Inhalational Anesthesia

Around 1540, Paracelsus, a Swiss physician and alchemist, sweetened the feed of fowl with sweet oil of vitriol, a substance earlier prepared by Valerius Cordus, then named Aether by Frobenius--the familiar diethyl ether that would later be inhaled by most surgical patients over a span of 100 years or more. Paracelsus was led to exclaim, "... and besides, it has associated with it such sweetness that it is taken even by chickens and they fall asleep from it for a while but awaken later without harm."

Local Anesthesia

The coca leaf was believed to be a gift to the Incas from Manco Capac, son of the sun god, as a token of esteem and sympathy for their suffering. Initially used narrowly for religious and political purposes, the leaves achieved a more ominous significance with the destruction of the Incan civilization in the 16th century by Francisco Pizarro's conquistadores. The lower classes and slaves were paid off in coca leaves, an effective method of increasing and prolonging their productivity and ensuring low-cost, high-output labor. Customarily, coca leaves bound into a ball (cocada) with guano and cornstarch were chewed with lime or alkaline ash to release the active alkaloid. Anthropologic documentation of that era indicates that trephination was successful as the

operator permitted cocaine-drenched saliva to drip from the mouth onto the wound, thereby providing creditable local anesthesia.

Intravenous Anesthesia

One can construe that Harvey's studies of the circulation enabled both Percival Christopher Wren and Daniel Johann Major (Fig. 1-1) (Figure Not Available) to conceive the idea of injection of medicinals into the blood stream. Consequently, in 1665, Wren wrote that he could

> easily contrive a way to convey any liquid thing immediately into the circulating mass of blood; thus, in pretty big and lean dogs, by making ligatures on the veins and then opening them on the side of the ligature towards the heart; and by putting into them slender syringes or quills, fastened to bladders containing the matter to be injected ... whereof the success was that opium, being soon circulated into the brain did within a short time stupefy, though not kill the dog: but a large dose of the crocus metallorum, made another dog vomit up life and all.

The dried crocus or saffron was at the time employed as a stimulant, antispasmodic, and emmenagogue.

THE RISE OF INHALATIONAL ANESTHESIA

Primary observations on the physiology of the circulation and respiration eventually led to the discovery of gases and vapors and their experimental inhalation. In the mid-17th century, a Belgian, J. B. van Helmont, recognized a group of gases that were different from those of the atmosphere and attempted to classify them, and Harvey, during his studies on the circulation, noticed a difference in color, from dark to florid, when blood passed through the lungs. Robert Hooke opened the chest of a dog while sustaining lung inflation with a bellows, thereby proving that their rhythmic expansion is not immediately necessary for survival. A related conclusion was that some part of the atmosphere must enter the lungs, an essential ingredient named phlogiston by Stahl. Concurrently, Robert Boyle, in exhausting air from a bell jar containing a lighted taper and a living bird, extinguished the lives of both. In 1774, in the process of heating mercuric oxide, Joseph Priestley liberated oxygen, a gas with a "goodness" that sustained life, perhaps identical with the phlogiston of Becher and his pupil Stahl. Incidentally, Priestley also obtained nitrous oxide from nitric oxide. However, Antoine Lavoisier recognized phlogiston as the oxygen we breathe in the atmosphere. He concluded that only a smaller share of it was concerned in respiration, the larger share being irrespirable (nitrogen). He also observed that exhaled air precipitated lime water and concluded that it must also contain chalky air or carbon dioxide. Thus, the outlines of external respiration were delineated.

In the last decade of the 18th century, a center for the pneumatic treatment of disease was established in Birmingham, England. Joseph Priestley, James Watt, Josiah Wedgwood, Dr. Richard S. Pearson, and Thomas Beddoes were among the founders. Ether could be inhaled by a sufferer via a funnel to alleviate congestion and phlegm. Beddoes wrote that the medicinal use of these factitious airs was beneficial in the cure of bladder calculus, sea scurvy, and catarrhal fever. Realizing that more intensive experimentation was required, this group, with little knowledge of the causes of disease, established a Pneumatic Institute at Clifton, Bristol, and providentially appointed Humphry Davy, the youthful, brilliant chemist and physiologist, as superintendent. First, Davy disproved the theory proposed by the American Samuel Latham Mitchell that nitrous oxide was the contagium of disease. While breathing nitrous oxide for the relief of headache and the pain of an erupting third molar tooth, Davy experienced a "thrilling and an uneasiness swallowed up in pleasure." Thus originated his seminal pronouncement: "As nitrous oxide in its extensive operation appears capable of destroying pain, it may probably be used with advantage during surgical operations in which no great effusion of blood takes place." Not a surgeon, Davy failed to pursue the idea, but Henry Hill Hickman of Shifnal in Shropshire did so. Hickman was a practitioner and surgeon who lamented that "something had not been thought of whereby the fears [of a patient] may be tranquilized and suffering relieved." Having partially asphyxiated several animal species to a state of insensibility with carbon dioxide, Hickman in 1824 addressed his famous message to the Royal Society: "Letter on Suspended Animation--with the View of Ascertaining its Probable Utility in Surgical Operations on Human Subjects." Unfortunately and sadly, Hickman came the closest of all to the concept of surgical anesthesia, but utilizing an unlikely agent.

Davy's subjective experiences were duplicated among friends and visitors to the Institute and were soon taken up by the adventurous public in the form of frolics. In the United States, Crawford W. Long, while a student at the

University of Pennsylvania in the late 1830s, could very well have observed and participated in such fantasies. Sometime after his return to Jefferson, Georgia, as a general practitioner, Long probably not only introduced such frolics but also surely persuaded a young man, James M. Venable, to inhale ether while a growth was excised from the nape of his neck on March 30, 1842. Even though this venture was repeated several times, the matter was kept secret until the first report appeared in 1848 in the *Southern Medical and Surgical Journal,* several years delayed by influential physicians who were using mesmerism for surgical operations. Later it became known that William E. Clarke, a student at the Vermont Medical College, had employed ether for a tooth extraction in January 1842.

Within 2 years of this first clandestine surgical anesthetic, on December 10, 1844, Gardner Quincy Colton took his itinerant medicine show to Hartford, Connecticut, where an audience could experience the exhilarating effects of nitrous oxide inhalation. So intoxicated, Samuel A. Cooley did not notice at first that he had injured a leg in the melee, but in the audience, Horace Wells, a dentist, was quick to pick up the significance of this suggestion of analgesia. The next day, Wells had one of his own carious teeth painlessly extracted by a fellow dentist, while Colton administered the anesthetic. The anguish of dental pain could now be assuaged, and Wells set about to tell the world of his discovery. Circumstantially, a one-time student of Wells, William Thomas Green Morton, then in practice in Boston and enrolled in a course of lectures at Harvard Medical School, arranged for a demonstration by Wells in January 1845 before a group of medical students. However, the nitrous oxide demonstration proved a failure because a student screamed out in pain as his tooth came out, even though he later admitted to no recollection of pain. No doubt the time of induction was too brief and the gas reservoir too small to provide a surgical plane of anesthesia.

W.T.G. Morton, probably a witness to this abortive demonstration, also yearned to relieve pain because a dental prosthesis of his invention could be applied only after the rotted roots of teeth were extirpated, an experience few patients would venture to endure. As a domiciliary student with Charles T. Jackson, eccentric geologist and chemist, Morton learned from him that pure ether applied to the gums would, through evaporation, yield a degree of cold anesthesia. After experiments with inhalation of the vapor of ether in several animal species, Morton went a step further, and on September 30, 1846, in his Boston office, he painlessly removed a tooth from the mouth of Eben H. Frost, a merchant of that city. When notice of the operation appeared in a newspaper the next day, Henry Jacob Bigelow, a surgeon at the Massachusetts General Hospital, arranged to observe several additional anesthetics of the kind given by Morton. Suitably impressed and convinced of its surgical utility, Bigelow arranged for a trial of anesthesia at the hospital with John Collins Warren, a renowned surgeon, one-time dean of Harvard Medical School, and founder of the hospital in 1821 with several others. Warren was also an originator of the *Boston Medical and Surgical Journal,* now the *New England Journal of Medicine.* On October 16, 1846, using a hastily devised glass reservoir incorporating the drawover principle of vaporization, Morton anesthetized Edward Gilbert Abbott, a young printer, while Warren deftly ligated a congenital venous malformation in the left cervical triangle. This feat culminated in J.C. Warren's memorable remark to the assembled gallery, "Gentlemen, this is no humbug" (Fig. 1-2) (Figure Not Available) .

The Massachusetts General Hospital has, to this day, designated the incident as the first public demonstration, rather than discovery, and Oliver Wendell Holmes, professor of anatomy and literateur extraordiniare, chose the Greekderived noun "anaesthesia" to characterize the process. He had also considered "neurolepsis," a term employed today to describe the drugs used in one variety of balanced anesthesia. With a medical discovery of universal significance, it was only natural that a prolonged period of controversy would ensue as to who might be given the credit. Fortunately, such an outcome did not impede further application of the method, enhanced by the prestige of the hospital and its

Figure 1-2 (Figure Not Available) William Thomas Green Morton giving the first public demonstration of etherization at the Massachusetts General Hospital, Boston, October 16, 1846. Physicians around Edward Gilbert Abbott, patient, are from left to right: H.J. Bigelow, A.A. Gould, J. Mason Warren, J. Collins Warren, Morton, Samuel Parkman, George Hayward, and S.D. Townsend. *(From a steel engraving in Rice NP: Trials of a Public Benefactor, 1859.)*

Harvard-affiliated physicians, who knowledgeably reported on the pharmacology and physiology of the phenomenon.

In a situation of multiple discoveries as recounted here, sociologists of science would assert that the concept of anesthesia was "in the air," merely awaiting the appropriately receptive mind and social circumstance. Perhaps the Americans succeeded because of their pioneering spirit and lack of authoritative medical institutions. In England, on the brink of the industrial revolution, a medical hierarchy had already existed, made up of hospitals and societies, with public health a new concern and the general practitioner the dominant figure--here, a revolutionary therapy might not be adopted so readily.

W. Stanley Sykes, in an essay on "The Seven Foundation Stones, in Order of Merit," ranked the contenders for recognition in descending order of importance. First was Hickman, who "above all others had the idea of anaesthesia most deeply and spontaneously engrained in him." Second was Horace Wells, who "given the stimulus and the sight of a man partly under the influence of gas failing to notice an injury ... saw the possibility of it at once, as no one else had done." Third was W.T.G. Morton "to whom belongs the undoubted credit of introducing successful anaesthesia with sufficient publicity to ensure that it immediately achieved world-wide acceptance." Fourth, "Humphry Davy discovered the analgesic properties of nitrous oxide by inhaling it and made his famous suggestion that it could be used for surgical operations." Fifth was Crawford W. Long, "another pioneer who could easily have held a much higher place and had only himself to blame." "Long's place in the ranking order is low simply because of his extraordinary reticence." "There was no originality about James Young Simpson," and Charles T. Jackson, the last of the pioneers, "really does not deserve to be in the list at all. He did not have the idea of anaesthesia in the first place. All he did was to try and cash in upon it when it proved to be successful."

PROFESSIONAL ANESTHESIA IN ENGLAND: APPLICATION TO OBSTETRICS

John Snow, general practitioner, clinical investigator, and epidemiologist (who halted a cholera epidemic in London), became the first of a long line of British physician anesthetists, in contrast to America, where that species was to blossom only around the turn of the century (Fig. 1-3) (Figure Not Available) . In 1847, Snow's text on *The Inhalation of the Vapour of Ether* appeared, containing case reports and an elaborate description of the traditional signs and stages of ether anesthesia. An earlier tract on ether written by Robinson, a dentist, had appeared, as well as an account by Plomley of the stages of anesthesia, but Snow's pronouncements were definitive. Likewise, in Great Britain toward the end of 1847, James Young Simpson, obstetrician, who had first used ether to relieve the pain of labor, adopted chloroform for the purpose, as suggested to him by David Waldie (Ch. 57) . The compound had been independently synthesized by Samuel Guthrie of Sackett's Harbor, New York; Eugene Soubeiran, of France, and Justus von Liebig, of Germany. Although the clergy as well as other physicians opposed the concept of relieving pain during

Figure 1-3 (Figure Not Available) John Snow (1813-1858). Physician, epidemiologist, and first specialist in anesthesia. *(Reproduced from the Asclepiad, 1887, vol 4.)*

childbirth, the method took hold and achieved lasting status after Queen Victoria gave birth to Prince Leopold while being given chloroform at the hands of John Snow; this method was dubbed "anesthesia a la reine." To further strengthen the principle of obstetric anesthesia, Walter Channing, professor of midwifery and medical jurisprudence at Harvard, in 1847 wrote a *Treatise on Etherization in Childbirth,* the results of a survey to settle the important issue of safety. Although the validity of the study is questioned, Channing cited the use of morphine during labor and also included cases in which chloroform had been employed. Because of its less objectionable properties, more pleasant odor, and rapid induction and emergence, chloroform superseded ether in Great Britain. In 1858, a second text by Snow was published, *On Chloroform and Other Anaesthetics,* completed posthumously, with a biography added by Benjamin Ward Richardson, Snow's successor.

DEVELOPMENTS IN SURGERY

Surprisingly, the initial use of both ether and chloroform led to little alteration in surgical practice, which remained largely of an external nature: trephining of the skull, tapping of the chest for fluid removal, relief of strangulated hernia, extraction of bladder calculus, reduction of fracture, and amputation of extremities. Surgical writings and lectures then pertained mostly to anatomy. Moreover, with an increase in the number of hospitals and their consequent use rather than the home to treat illness, a new problem arose, that of infection, which came to be known as hospitalism. The initial solution, listerism, or surgical antisepsis using

carbolic acid, was not widely practiced until 1879, when it was acclaimed at an international conference. Then arose steam sterilization and true antisepsis.

Siegrist observed that the introduction of anesthesia was not the first attempt to render patients insensible to pain. Why then did surgery not have its great development before the mid-19th century, coincident with, rather, than resulting from, anesthesia? The answer lies in studies of the development of concepts of disease, "for surgery is only one method of treatment and like any other method is largely determined by the concept of disease prevailing at the time." As noted in the introduction to this chapter, for more than 2,000 years disease was considered to be the result of a disturbed balance of the cardinal humors of the body, which enjoyed health when in balance but showed symptoms of disease when upset.

Then, in the 18th and 19th centuries, with Morgagni describing the results of large numbers of autopsies, it was learned that organic lesions were responsible for disease. It seemed, then, that if an organ were abnormal, its function would also be abnormal. Consequently, it became the purpose of diagnostics to perceive anatomic changes in the living patient by the use of percussion and auscultation and by the use of bulbs and mirrors to look into the body cavities. Roentgenology was the ultimate triumph in this direction. By draining an abscess or excising an ulcer or tumor the surgeon was removing the disease and correcting the organ. Undoubtedly, however, surgery could not develop freely before the two bonds that enslaved it had been removed--pain and infection.

LOCAL ANESTHESIA

Cocaine began to receive attention in Europe and America during the mid-19th century (Ch. 13) . Around 1860, Albert Niemann, a pupil of Friedrich Wohler, isolated the alkaloid in crystalline form. Twenty years later, von Anrep wrote an extensive review on the physiologic and pharmacologic properties of cocaine, clearly citing the locally numbing effect on the tongue and dilation of the pupil, the former leading him to suggest that some day cocaine might become of medical importance. Later, Sigmund Freud of Vienna began to study the properties of the drug when given samples for trial by the Merck Company. As a result of reviewing *The Index Catalogue* of the Library of the Surgeon General's Office of the United States Army, which referenced some 25 papers and 10 monographs under the heading "Erythroxylin Coca," Freud, in 1884, wrote his classic paper "Uber Coca." Believing coca to be a worthy substitute for morphine, Freud first attempted to eliminate the morphine addiction of a close friend, Ernst von Fleischl-Marxow, who had long suffered from a painful posttraumatic thenar neuroma. von Fleischl-Marxow developed a new addiction as a consequence, as would many a cocaine user later on, but Freud himself never seemed to go down that path.

Sigmund Freud and Karl Koller

Sigmund Freud and Karl Koller, an intern in the Department of Ophthalmology at the Allgemeinen Krankenhaus in Vienna, used a dynamometer to study the effect of coca on muscle strength. Both researchers noticed the numbing effect on the tongue as they swallowed the experimental drug. Koller had a burning desire to anesthetize the cornea and conjunctiva for ophthalmologic operations and had already tried morphine and chloral bromide. In Freud's absence, he and Joseph Gartner dissolved a trace of the white powder in distilled water and instilled the solution into the conjunctival sac of a frog. After a minute or so, "the frog allowed its cornea to be touched and it also bore injury to the cornea without a trace of reflex action or defense." Koller wrote, "one more step had yet to be taken. We trickled the solution under each other's lifted eyelids. Then we placed a mirror before us, took pins, and with the head tried to touch the cornea. Almost simultaneously we were able to state jubilantly: I can't feel anything." A communication describing this finding, dated early September 1884, was read and a practical demonstration given by Joseph Brettauer at the Ophthalmological Congress at Heidelberg on September 15 of that year. Koller did not have the means to travel there. Koller gave full credit to Freud for the inspiration. Despite the latter's disappointment at not being first with the discovery, Freud is considered by many to be the founder of psychopharmacology because of his initial use of cocaine, the forerunner of mescaline, lysergic acid diethylamide, and the amphetamines to modify behavior and subsequently to relieve mental illness.

James Leonard Corning

After Koller, James Leonard Corning deserves citation for his analytic approach to local anesthesia in humans on the basis of laboratory experimentation. Having learned of Koller's report, Corning recalled the experiment in which strychnine is injected subcutaneously in the frog, causing the animal to have violent spasms as a result of an effect on the spinal cord. Because a much smaller quantity of strychnine injected beneath the membranes is equally effective following laminectomy, he assumed that the poison must act via vascular absorption. Cognizant of the presence of the many small veins, venae spinosum, about the spinal column and cord, Corning reasoned that it might be possible to utilize cocaine therapeutically. Accordingly, in a young dog, about 20 minims of a 2 percent solution of cocaine was injected between the spinous processes of the dorsal vertebrae. After some minutes, incoordination of the posterior extremities developed, followed by insensibility. These results were almost immediately applied to a patient, a man suffering from spinal weakness and seminal incontinence. "To this end, I injected 30 minims of a 3 percent solution of the hydrochloride of cocaine into the space situated between the spinous processes of the 11th and 12th dorsal vertebrae." After a lapse of 6 to 8 minutes, when nothing happened, the injection was repeated. Finally, 10 minutes later, anesthesia began to appear in the lower extremities, and a sound could be passed through the urethra without pain. Corning concluded his report with the statement, "Whether the method will ever find application as a substitute for etherization in genitourinary or other branches of surgery, further experience alone can show." This conclusion follows the pattern of statements made by Wren, Davy, and von Anrep

---

in relation to intravenous, inhalational, and local anesthesia, respectively, thereby further confirming the evolutionary aspects of science. Corning's textbook on local anesthesia, published in 1886, was the first devoted to the subject.

Regional Anesthesia Techniques and Agents: Procaine and Epinephrine

In juxtaposition to inhalational anesthesia, and because of toxicologic problems with chloroform, high anesthetic mortality, and lack of trained personnel to give general anesthesia, local anesthesia became highly popular with surgeons, especially in France and Germany, and to some extent in the United States. After a trial on himself that resulted in the first-known development of a lumbar puncture headache, August Bier of Germany began to give spinal anesthesia in 1898, followed by Matas in America and Tuffier in France. Then, because of the evident toxicity and tendency toward addiction of cocaine, a number of ester substitutes were synthesized, procaine (Novocain) by Einhorn becoming the more lasting of the group. As a result of pharmacologist John J. Abel's efforts at Johns Hopkins Medical School, epinephrine was isolated from the capsule of the suprarenal gland in 1897 and was ultimately crystallized by Takamine. Heinrich Braun, a German surgeon, advocated the use of cocaine in conjunction with epinephrine when, in 1903, he reported on its practical importance in inducing anemia of the mucosa in rhinolaryngologic and urologic surgery, thereby permitting the concentration of cocaine to be lowered and diminishing the dangers of intoxication.

Most currently used techniques of regional anesthesia were devised during that first decade: brachial plexus block, axillary and supraclavicular approaches, intravenous regional anesthesia (Bier), celiac plexus block, caudal anesthesia, hyperbaric and hypobaric techniques of spinal anesthesia, and all the presently employed nerve blocks about the head and neck that are applied in dentistry and plastic surgery. Thereafter, aside from technical innovation and understanding of some of the physiologic and toxicologic responses to local anesthetics, the great impetus to regional anesthesia came from the synthesis of the amide local anesthetics and an understanding of their pharmacodynamic and especially pharmacokinetic properties.

INTRAVENOUS ANESTHESIA

We have cited the experiments of Wren and Major in introducing medicinals into the circulation, quick upon Harvey's description of the circulation (Chs. 8 and 11) . Around the 1850s, the hypodermic hollow needle and glass and metal syringes were introduced via the inventions of Scotsmen Francis Rynd (1845) and Alexander Wood (1855) and Charles Gabriel Pravaz (1853). Although these improvements over the quill and bladder were to herald both intravenous and regional anesthesia, Rynd and Wood were making injections into the vicinity of nerves for the relief of neuralgia, and Pravaz injected ferric chloride via trocar into arterial aneurysms in an attempt to induce thrombosis.

Pierre-Cyprien Ore

W. Stanley Sykes, in a posthumously published essay, cited Pierre-Cyprien Ore as the true pioneer of intravenous anesthesia. Employing chloral hydrate for the purpose, his first report on the method was addressed to the Surgical Society of Paris in 1872. Utilizing a modification of the Pravaz syringe and needle, because he had found the latter likely to transfix the vein and cause the solution to be injected perivenously, Ore claimed that chloral hydrate was the most powerful of all anesthetics. As usual, opposition arose as critics raised the possibility of development of phlebitis and clotting. In a monograph published with a detailed account of 36 cases, some 18 for cataract surgery and others for treating tetanus, Ore claimed not to have encountered a single instance of clotting or phlebitis. Cardiac arrest occurred in one patient, an otherwise healthy, middle-aged man undergoing cataract extraction.

Anociassociation

Early in the 1900s, an essential concept was proposed toward the development of balanced anesthesia in which intravenous anesthesia is a major component. This was the anociassociation theory of George W. Crile, who in 1901 stated, "In conscious individuals, all noxious stimuli reach the brain. During general anesthesia only the traumatic stimuli are perceived centrally while with complete anociassociation all stimuli are blocked." Enlarged on by Harvey Cushing in 1902, the idea of anociassociation became the basis for the use of opioids intravenously, so prominent in practice today. Incidentally, George Crile, at the Cleveland Clinic, and the Mayo brothers, of Rochester, were the first to employ nurse anesthetists in their surgical practices. Cushing had a number of "firsts" relative to the development of anesthesia: coining the term "regional anesthesia," keeping anesthesia records, being the first in the United States to employ the Riva-Rocci technique for measurement of blood pressure intraoperatively, using a precordial stethoscope during operation, and being a surgeon who first appointed a physician, Walter M. Boothby, in charge of anesthesia at his clinic in Boston.

The Barbiturates

The major impetus for the subsequent development of intravenous anesthesia lay in the synthesis of the short-acting, water-soluble barbiturates. In 1903, long after von Baeyer had synthesized barbituric acid, or malonylurea (1864), Fischer and von Mering prepared the first sedative barbiturate, diethyl barbiturate, or barbital, a long-lasting hypnotic soon to be succeeded by the sodium salt of phenobarbital. Then, as other soluble compounds were devised, a number of barbiturates of short, medium, and long duration became available. Pernoston, a shorter-acting agent, was first given intravenously in 1927, in a 10 percent aqueous solution, and in 1928, John S. Lundy began to supplement inhalational anesthesia with amytal, then pentobarbital, intravenously, a procedure he designated balanced anesthesia. Because by current standards both drugs provide only a relatively slow onset

of action, the advent of hexobarbital, or Evipal, in 1932 (Weese) resulted in the first rapidly acting intravenous anesthetic to receive wide use. Ultimately, a sulfur derivative of barbituric acid yielded the necessary qualities, with the result that thiopental, a derivative of pentobarbital, was adopted both by Lundy, at the Mayo Clinic, and by Waters, at Wisconsin. Dundee noted how remarkable it is that this drug has survived and withstood the challenge of so many others. As in every intravenously given compound, no matter what the therapeutic ends, the lasting effects of such drugs depend on specific pharmacodynamic and pharmacokinetic properties, as first shown by Brodie and colleagues around 1950.

THE EVOLUTION OF PROFESSIONALISM IN AMERICA

The British were indeed fortunate in having physicians, beginning with John Snow, who specialized in anesthesia, a circumstance that eventually led to the formation of societies and publication of articles in the 1890s in such journals as *Lancet, British Medical Journal,* then the *Proceedings of the Royal Society of Medicine,* in which the subject of anesthesia had its own section. By definition, professionalism is a calling in which one professes to have acquired some special knowledge used by way of instructing, guiding, or advising others or in serving them in some art.

The Milieu

In America at the time of the first public demonstration, medicine was in a period of frontier expansion, in contrast to Great Britain. The general practitioner did all the work, and although the easterners began to loom as specialists and leaders, a good deal of emphasis was placed on practice as a business, with medical education at a low level. The only medium for scientific publication in the first part of the 19th century was the *Transactions of the Royal Society.* At the turn of the century, a class of physicians emerged that was clearly identified with anesthesia. Interestingly, the primordial group was made up mostly of midwesterners and Canadians, who may have had as peculiar characteristics, "their pioneering traditions, their common purpose, devotion to equality and their struggle for success." Of the pioneers, Ralph Waters was to remark in a reflective mood that "the development of a specialty could be traced in terms of men, publications and organizations." Three figures stand out in this regard, Waters among them.

Francis Hoeffer McMechan

F.H. McMechan, born in Cincinnati and son of a physician, excelled in college in oratory and dramatics and became a newspaper reporter on graduation, before matriculating at the Cincinnati Medical School. There, as would be the custom for many a decade, he was required to administer anesthetics, for his father as well, so that he became a devotee of the method. Between 1903 and 1910, he combined anesthesia with general practice, but progressively crippling arthritis forced abandonment of practice and his subsequent preoccupation with the organization of anesthesia and medical editing.

In 1912, in conjunction with Bainbridge, a surgeon, Yandell Henderson, a physiologist, and James T. Gwathmey, an anesthetist, McMechan founded the American Association of Anesthetists. As a result of his persuasion, the *American Journal of Surgery* began to publish a *Quarterly Supplement of Anesthesia and Analgesia* in 1914 (Fig. 1-4) , which survived until 1926, with McMechan as editor; he also served as editor of a *Year Book on Anesthesia and Analgesia.* His formation of one group after another in the United States and Canada led ultimately to the National Anesthesia Research Society, then to the International Society, whose medium of reporting in 1922 became *Current Researches in Anesthesia and Analgesia,* the first publication devoted solely to those subjects. Assisted in these endeavors by his wife, McMechan, who died in 1939, would have been gratified to know that the International Society and its publication, *Anesthesia and Analgesia,* still exist.

Elmer I. McKesson

The second of the trio, E.I. McKesson, was an innovator, teacher, and inventor, born in 1881 in Walkerton, Indiana. A teacher at first, McKesson was graduated from Rush Medical School and while an intern in Toledo became attracted to anesthesia. Later, he would found the University of Toledo,

Figure 1-4 "Quarterly Supplement of Anesthesia and Analgesia," Introductory Number, October 1914, edited by F. Hoeffer McMechan, as it appeared in the *American Journal of Surgery.*

where he served as associate professor of physiology and physiologic chemistry. McKesson invented and developed many pieces of apparatus: gas-oxygen machines, suction apparatus, metabolism-measuring devices, intermittent and demand gas flow valves, oxygen tents, and other instruments, all manufactured by the Toledo Technical Appliance Company. The Nargraf apparatus and the McKesson gas machine remained standard equipment until well into the 1950s.

Ralph M. Waters

Third, we have R.M. Waters, who left his mark on several generations of anesthetists by way of far-reaching vision, combining in no small measure all the stellar attributes of the other early American anesthetists. Born in 1883 in Bloomfield, Ohio, he was graduated from Western Reserve University Medical School, served as an intern in Cleveland, and then practiced privately in Sioux City, Iowa, with obstetrics as a chief interest. He began to give anesthesia for operations performed by the other practitioners, although some of them employed nurses for that purpose. Self-trained and with only a few specialized writings at his disposal-- *Proceedings of the Royal Society, McMechan*' *s Quarterly,* and Gwathmey and Baskerville's *American Text Book of Anesthesia*-- Waters wrote an article, "Why The Professional Anesthetist" in 1919. Such was his growing reputation that by 1927, he was invited to a post on the faculty of the University of Wisconsin as assistant professor of surgery in charge of anesthesia and was one of a group of luminaries in surgery, physiology, and pharmacology. For the first time, he established a resident training program in anesthesia coupled with an investigative effort that entailed, among other things, the examination of hydrocarbon-epinephrine cardiac arrhythmias, the pharmacology of cyclopropane, and a reexamination of the toxicology of chloroform. Many an apparatus arose from this clinical-investigative milieu, some rediscovered, others new: cuffed endotracheal tubes, laryngoscopic blades and pharyngeal airways, carbon dioxide absorption canisters, and precision-controlled liquid anesthetic vaporizers.

There were other outstanding innovators in American anesthesia, among them Arthur A. Guedel, John Silas Lundy, and a later generation of university chairmen-professors, including E.A. Rovenstine (New York University), R.M. Tovell (Hartford Hospital), H.K. Beecher (Harvard), S.C. Cullen (Iowa and San Francisco), John Adriani (Tulane), R.D. Dripps (Pennsylvania), E.M. Papper (Columbia-Presbyterian Hospital), P.P. Volpitto (Georgia), and L.D. Vandam (Harvard).

THE DEVELOPMENT OF MODERN ANESTHESIA

The American Society of Anesthesiologists

In 1905, a group of physicians, with Adolf F. Erdman as the catalyst, formed the Long Island Society of Anesthetists, "to promote the art and science of anesthesia." As the membership grew, the name of the organization was changed to the New York Society of Anesthetists in 1911, then augmented by out-of-state anesthetists so that by 1916, 60 members were enrolled. On the 25th anniversary (1930) of the founding of the Society, a 2-day scientific program was convened in New York City. In 1936, the name was once again changed to describe its breadth and character, The American Society of Anesthetists, Incorporated, with 484 adherents.

Over succeeding years, all the attributes of a specialty society were fulfilled, and the designation anesthesiologist replaced the nondescript term *anesthesia* to indicate that anesthesiologists are physicians who have received formal training in anesthesia. A certification committee was appointed that led to the acceptance of a section on anesthesiology into the hierarchy of the American Medical Association in 1940. That year marked the initial publication of its official journal, *Anesthesiology.* The stature of the Society was enhanced by incorporation of the Wood Library- Museum of Anesthesiology in 1950; to accommodate its multiple activities, a society headquarters was erected in Park Ridge, Illinois, in 1962, with an addition 2 years later to house the Library-Museum. The American Society of Anesthesiologists has dedicated itself to the following goals and endeavors: standards for equipment and patient care, education, repeated self-analysis via survey to crystallize the state and objectives of the Society, issues of manpower, affiliation with the World Federation of Societies of Anesthesiologists, and consideration of problems common to all kinds of medical practice. All these endeavors continue to progress with an eye toward discerning trends and future developments.

Progress Since 1940

After a gestational period of approximately 100 years, modern anesthesia began around the 1940s. At that time, as Lewis Thomas asserted, medicine was about to undergo a second revolution, from a mere art into a powerfully effective science. First, in the later 19th century, rebellion against the Galenical tradition had resulted in a practice in which the history, physical examination, and establishment of a diagnosis provided a basis for prognosis, not cure. This transition was succeeded in the late 1930s by the discovery of effective new drugs, initially the sulfonamides and then the antibiotics, for the treatment of infection. Inevitably, anesthesia would be caught up in the succeeding therapeutic and scientific ferment, as were all the specialties of medicine.

The first change in direction was the initial use during anesthesia of a curare product by Griffith and Johnson of Montreal in 1942. The muscle-paralyzing properties of the alkaloid derived from several preparations of South American plants had been known for centuries, and the site of action at the neuromuscular junction was graphically demonstrated by Claude Bernard. In the United States, crude extracts had been employed clinically to treat spasticity and to modify the convulsions induced during electroconvulsive therapy (ECT) for depression and other psychoses. Initially, when given the extract for experimental trial, S.C. Cullen, of Iowa City, and E.M. Papper, of New York, had independently deemed the paralytic effects to be too much a physiologic

trespass to be introduced to the anesthetic regimen. No one knows what subtle influence led Griffith to inject Intocostrin during the course of a cyclopropane anesthetic without prior experimentation. T.C. Gray of Liverpool, England, was reminded of John Hunter's advice to Edward Jenner in regard to vaccination: "Do not think--try." Perhaps Griffith was affected by the therapeutic revolution under way, even as Horace Wells in another era had perceived the concept of anesthesia while witnessing a demonstration of the mental effects of nitrous oxide.

The subsequent general use of curare had widespread repercussions. As a result of the muscle paralysis induced, tracheal intubation became necessary for manual control of pulmonary ventilation during anesthesia, followed rationally by the development of mechanical ventilators, obligatory studies on the physiology of central and peripheral respiration, and the invention of postanesthetic recovery rooms, where anesthesiologists would play a dominant role. In connection with this broadened participation in patient care, many physicians returning from World War II, during which they had had introductory experience with anesthesia, sought further training in this developing branch of medicine.

Anesthesiologists, as they now designated themselves, were soon impelled to scrutinize the safety of their performance, and the use of curare no doubt sharpened the focus. Thus, following the findings of several American anesthesia study commissions and reminiscent of the Hyderabad Chloroform Commissions of the late 19th century, H.K. Beecher, of Boston, initiated a prospective study of operating room deaths. This project incorporated the practice of some ten university-associated hospitals during the years 1948 to 1952. From a total of approximately 600,000 anesthetic administrations, the overall anesthetic-associated death rate was adjudged to be about 1:1560. In addition, many important epidemiologic data emerged. The most startling and controversial finding was a significantly higher mortality rate in patients given muscle relaxants, mainly curare, during anesthesia. Although Beecher ascribed this occurrence to an inherent drug toxicity, more likely the explanation was to be found in residual postanesthetic muscle paralysis and the associated respiratory insufficiency, which was inadequately treated or unrecognized in those days. One of the conclusions derived from this study suggests the state of anesthesia of that era: "Great changes in the use of anesthesia agents and techniques occurred within the five years of this study. This suggests that the practice of anesthesia is far as yet from achieving stability."

Also in the 1950s, following the admonition of W.T. Salter, a pharmacologist of Yale, that "without vision and research the professions die," research in anesthesia began, initially in conjunction with basic science departments in medical schools. Thus, S.S. Kety, of Philadelphia, and B.B. Brodie, of New York, inaugurated the science of pharmacokinetics in their respective studies on the uptake and distribution of inhaled anesthetics and the metabolism of thiopental. With this impetus, anesthesiologists enlarged on these basic concepts that today compose routine knowledge of the drugs we use. Soon thereafter, because of their unfavorable properties, most of the traditional inhaled anesthetics were replaced by the new anesthetics. Diethyl ether and cyclopropane were also abandoned, not only because of their flammability but also because of their poor pharmacodynamic and pharmacokinetic attributes. Only nitrous oxide maintained its place, and procaine was succeeded by local anesthetic agents of greater latitude.

The major inhaled anesthetic substitutions included the nonflammable, highly lipid-soluble and therefore potent, vapors; halogenated inhalants; more versatile neuromuscular blockers; and local anesthetics with the amide rather than ester structure. In some instances, there were unforeseen events, as when halothane was associated with development of postanesthetic fatal hepatic necrosis, a phenomenon previously well-documented for chloroform. A multiinstitutional cooperative endeavor supported by the National Institutes of Health led to the National Halothane Study. Although the conclusions of the survey were hotly debated, the data, derived from some 34 institutions based on approximately 850,000 anesthetic administrations, suggested an incidence of halothane-associated fatal hepatic necrosis approaching one in 10,000 anesthetics. Repeated administration of halogens for several anesthetics was an important contributing factor. Although an altered sensitivity to halothane was deemed responsible by some, a more convincing explanation implicated toxic metabolites induced by hypoxia as the cause. Only recently has evidence reappeared for an immunologic basis of the lesion (Ch. 6) .

Following these events, research on anesthesia began to reach its stride. First, the unsuspected fact emerged that inhaled anesthetics that were formerly considered

inert were indeed metabolized in various degrees; for example, halothane was 20 percent metabolized, and methoxyflurane was 50 percent metabolized. Not long after its introduction, methoxyflurane was discovered to induce a rare kind of renal failure with tubular necrosis, characterized by high urinary output that was unresponsive to vasopressin. Because of the pharmacokinetics and the production of a toxic metabolite, the free fluoride ion, a condition once described by the French as "diabetes insipidus fluorique," was found to occur after methoxyflurane anesthesia. Fluoroxene, another halogenated compound, was abandoned because of probable metabolite-induced hepatic necrosis. Investigations engendered by these events showed that the metabolism of halogenated anesthetics could be enhanced by hepatic enzymatic induction coincident with the use of barbiturates or phenytoin, with an actual proliferation of the endoplasmic reticulum and increase in cytochrome P-450. This discovery further emphasized the existing tenet that in their choice of anesthetics, anesthesiologists must remember the possibility of interactions with drugs of all kinds.

After the short-acting intravenous barbiturates were introduced, J.S. Lundy of Rochester coined the term "balanced anesthesia" to describe his use of these agents in conjunction with general or regional anesthesia. These practices were further advanced when, during the French-Indo-Chinese warfare of the late 1940s, Laborit and Huguenard of France used a "lytic cocktail" to prevent development of circulatory shock in the wounded. The resulting "artificial hibernation" induced by simultaneous injection of a barbiturate; an analgesic, meperidine; and the tranquilizer chloropromazine (L'Argactil), was typified by a state of stress-free suspended animation.

The tranquilizer was then succeeded by a butyrophenone, haloperidol, and meperidine was replaced by phenoperidine,

---

one of a new class of potent opioids. The concept was characterized as "neurolept-analgesia," a term Oliver Wendell Holmes had considered in 1846, before suggesting the term anaesthesia to describe the newly demonstrated phenomenon. In sequence, fentanyl (in combination with droperidol [Innovar]) was succeeded by the more potent opioids alfentanil and sufentanil. Purely intravenous anesthesia became possible, as practiced in clinics on the continent, and the potent analgesics were also given intraspinally (subarachnoid and epidural) to treat postoperative pain. This extra-anesthetic practice ushered in the era of anesthesiologists' concern with relief of acute postoperative pain, on the foundation of their previous pain treatment clinics that had mainly focused on chronic pain syndromes.

The profusion of unique agents and novel techniques introduced over the past 20 years naturally disclosed other unrecognized pharmacologic phenomena, some deleterious indeed. One category that pertains to all of drug therapy concerns pharmacogenetics, in which pharmacokinetic activity may be influenced by genetic factors. In this area, pharmacologists and anesthesiologists discovered that the metabolism of succinylcholine in plasma could be delayed or indeed prevented by the presence or absence of a variety of inherited pseudocholinesterases (Ch. 12) . Similarly, although elevations of body temperature and development of convulsions during ether anesthesia had long been noticed, a more malignant kind of hyperpyrexia came to be recognized. The malignant hyperthermia syndrome, often fatal, seemed to be triggered by a genetically determined response to agents such as succinylcholine and halothane (Ch. 27) .

Related to genetics is the fetal loss or development of fetal malformations that may occur when a pregnant woman is exposed to a variety of drugs, with some anesthetics suspect at least in animal experiments. One consequence of the putative adverse fetal effects was the initiation of epidemiologic studies that purported to show that the pregnant woman involved in operating room activities (nurses, anesthesiologists, and wives of anesthesiologists) could be exposed to trace anesthetic gases. A higher incidence of fetal loss was claimed, which led to the expensive installation of scavenging systems and the revival of closed-system anesthesia techniques with all of their complexities (Chs. 6 and 84) .

The development of contemporary anesthesia can be embellished by citing the improvement in anesthetic apparatus and monitoring systems toward greater safety or, on the pharmacologic side, continued search for the basis of narcosis at the molecular level. In this connection, a useful clinical yardstick was the concept of minimum alveolar concentration, which correlates closely with lipid solubility of anesthetics (Ch. 29) . Measurements of minimum alveolar concentration permitted comparison of studies on the physiologic effects of anesthetics in terms of their relative potencies. Parenthetically, there is the seemingly heretical suggestion that nitrous oxide should once and for all be abandoned because of the ever-present liability of hypoxemia, because of its effect on essential bone marrow metabolic enzymes, and last, because of its well-known nonpharmacologic properties in relation to air-containing body cavities.

The modern era of anesthesiology is reflected in the many respected scientific publications now devoted to that specialty the world over. Thus, the designation anesthesiologist may have been merited only after its adherents began to record their clinical experience and the results of laboratory investigations. We quote once more the lofty language of Salter's editorial, "The Leaven of the Profession," namely, "that professions do not live by service alone but rather by the words of wisdom which issue out of the mouths of those few demigods who in every generation lead and inspire the multitude of their professional associates."

We have suggested that modern anesthesia emerged about 100 years after the founding of clinical anesthesia. The events of the past decades have not been merely a parochial anesthetic excursion, but a manifestation of medicine's second revolution, which proceeds at an everquickening pace, anesthesiology included.

Section 2 - Scientific Principles

Chapter 2 - Basic Principles of Pharmacology Related to Anesthesia

Debra A. Schwinn
Steven L. Shafer

INTRODUCTION

Anesthesia involves administration of drugs to produce therapeutic effects while minimizing undesirable side effects or toxicity. Anesthesiologists give drugs to provide analgesia, amnesia, hypnosis, and muscle relaxation. They also administer drugs to manipulate major organ systems pharmacologically to maintain homeostasis and prevent injury. The therapeutic objective is to achieve adequate drug concentrations at specific sites of action to produce the desired effect. The anesthesiologist must select and administer appropriate drugs to provide tissue and receptor concentrations lower than those that produce unacceptable toxicity and higher than those that fail to provide effective therapy (i.e., within the therapeutic window).

The empiric approach to drug administration consists of selecting an initial dose and then titrating subsequent doses based on the clinical responses of the patient. The ability of the anesthesiologist to predict clinical response and hence to select optimal doses is, in part, the art of anesthesia. Continued research in the basic and clinical pharmacology of anesthetic drugs has produced guidelines by which the "science" of anesthesiology can enhance the art.

This chapter is divided into two sections: pharmacokinetic principles and pharmacodynamic principles. The pharmacokinetics section describes the relationship between drug administration and drug concentration at the site of action. Essential components of pharmacokinetics include volumes of distribution of drug within the tissues, binding of drugs to circulating plasma proteins, systemic clearance (usually hepatic metabolism for intravenous anesthetic drugs), biologic activity of metabolites, and transfer of drugs between plasma and tissues. Additionally, when drugs are administered by routes other than intravenous injection (e.g., transmucosal and transdermal fentanyl) the process of absorption is critical to the pharmacokinetic behavior of drugs. The first part of this chapter outlines how these processes determine the time course of drug concentration at the site of drug effect.

The pharmacodynamics section explores the relationship between drug concentration and pharmacologic effect. The broad areas of cellular mechanisms of drug action, clinical evaluation of drug effects, and variability in response are covered in this section.

An understanding of pharmacokinetic and pharmacodynamic principles provides the anesthesiologist with a scientific foundation for using drugs to achieve specific therapeutic objectives. These principles form the basis for the application of pharmacologic science to the practice of anesthesia.

PHARMACOKINETICS

Overview

Pharmacokinetics is the relationship between drug dose and plasma or effect-site drug concentration. The processes of absorption, distribution, and clearance govern this relationship. Absorption is not relevant to intravenously administered drugs, but it is highly relevant to all other routes of drug delivery. The pharmacokinetics of intravenously administered drugs is determined by distribution volumes and the processes of clearance. We first discuss the physiologic basis of pharmacokinetics, and then pharmacokinetic models that relate dose to plasma or tissue concentration.

Fundamental Pharmacokinetic Concepts

Volume of Distribution

The distribution of a drug throughout the plasma and tissues can be viewed as a process of dilution from the highly concentrated solution in the syringe to the dilute concentration in the plasma. This dilution follows the mixing of drug into a larger volume. The pharmacokinetic concept of volume is simply the apparent size of the tank required to explain the observed drug concentration. Figure 2-1 shows the dilution of administered drug into a tank of fluid. By definition, the concentration in the tank is the amount of drug administered divided by the volume of the tank. If we do not know the volume beforehand, but can measure the concentration, then we can rearrange the definition of concentration to tell us the volume of the tank:

Once the volume of the tank is known, the concentration following any bolus of drug can be calculated as the dose/volume. Just as the tank has a volume whether or not there is drug in it, the volume of distribution of a particular drug is an intrinsic property of the individual, whether or not any drug has been given. Unlike the tank in Figure 2-1 , the volume of distribution also depends on the properties of the drug.

Central Volume of Distribution

The central volume of distribution reflects the volume of the heart, great vessels, and the venous volume of the upper arm. It also reflects drug uptake by the lungs. For example, alfentanil is less lipophilic than fentanyl or sufentanil, resulting in less pulmonary uptake of alfentanil than of fentanyl or sufentanil. This results in a smaller central volume for alfentanil than for fentanyl or sufentanil. The central volume also reflects any metabolism that occurs between the venous injection site and the arterial sample.

Of the pharmacokinetic concepts that are introduced here, the central volume of distribution is the most problematic.

Figure 2-1 Volume represents the dilution of drug from the more concentrated form in the syringe to the dilute form in the blood.

The concept is based on an incorrect notion that the plasma concentration following bolus injection instantaneously mixes in this volume, resulting in an instantaneous peak at the moment of injection. Obviously, mixing is not instantaneous, and at the moment of intravenous injection, the arterial drug concentration is zero. The peak concentration is usually seen within 30 to 40 seconds of the injection. This 30- to 40-second delay is of no consequence for most therapeutics outside anesthesia, but within the field of anesthesia, the pharmacokinetic determinants of anesthetic induction are clinically important. The mathematics of the true time course including the time delay and recirculatory peaks have been worked out in detail by Krejcie et al, [1] as shown in Figure 2-2 .

Despite the assumption of instantaneous mixing, the concept of central volume of distribution is useful. The central volume represents the backward (and upward) extrapolation of the concentration versus time curve from its peak at about 30 seconds to the Y axis. It can be thought of as the initial concentration, had circulation been infinitely fast. Because of this backward extrapolation, estimates of the central volume are highly influenced by study design. A study with arterial samples has higher initial concentrations, and thus estimates a smaller central volume, than a study with venous samples. The timing of blood samples also influences the central volume of distribution. Over the first 2 or 3 minutes following bolus injection, the concentration of anesthetic drugs falls very rapidly. If the first sample is drawn at 30 seconds, the backward extrapolation of the concentration versus time curve to the Y axis predicts a high concentration at time 0, and thus a small central volume. If the first sample is drawn at 5 minutes, then the backward extrapolation of the concentration versus time curve to the Y axis predicts a much lower concentration and thus a larger central volume.

Total body water is decreased in elderly persons. One pharmacokinetic result is a reduced initial mixing volume. This smaller central volume of distribution leads to higher peak concentrations after a bolus or during the early part of an infusion. A decreased central volume of distribution partly accounts for the increased sensitivity of elderly patients to many anesthetic drugs.

Peripheral Volumes of Distribution

Anesthetic drugs distribute extensively into peripheral tissues. This distribution into the periphery is represented pharmacokinetically as additional volumes of distribution that are attached to the central volume. Peripheral volumes are linked to the central compartment (plasma) by blood flow, a process called "intercompartmental clearance." The linkage of peripheral volumes to a central volume is called a "mammillary" model. This name refers to the structure of the plumbing: peripheral piglets suckling off a central (mother) pig. At least, that is how the term was explained to us.

The size of the peripheral volumes of distribution reflects the drug's solubility in tissue relative to blood or plasma. The more soluble a drug is in peripheral tissues, relative to blood or plasma, the larger are the peripheral volumes of distribution. Because the tissue solubility of a drug depends on simple physiochemical constants, it would seem

Figure 2-2 A recirculatory model accounting for cardiac output (C.O.), transit delays and pulmonary uptake (Delay Elements--V_C), and nondistributive mixing pathways (V_{ND} and Cl_{ND}). All these components within the dashed circle are required to accurately model the central volume of distribution. In most situations, this complexity is not required, and the simpler approach of assuming instantaneous mixing within the central volume is an adequate approximation. Cl_{ND-F} and Cl_{ND-S}, fast and slow nondistributive clearances; Cl_{T-F} and Cl_{T-S}, fast and slow tissue clearances; V_{ND-F} and V_{ND-S}, fast and slow nondistributive volumes; V_{T-F} and V_{T-S}, fast and slow tissue volumes. *(From Krejcie TC, Auram MJ, Gentyw B et al: A recirculatory model of the pulmonary uptake and pharmacokinetics of lidocaine based on analysis of arterial and mixed venous data from dogs. J Pharmacokinet Biopharm 25:169, 1997)*

likely that peripheral volumes of distribution would be consistent from person to person. However, differences in body habitus and composition do occur, and these variations influence peripheral volumes of distribution. For example, aging is associated with decreased lean body mass, increased body fat, and decreased total body water. Because the lipid content of elderly patients is higher than that of young patients, elderly patients have more potential for lipophilic drugs to accumulate in peripheral volumes of distribution, leading to increased duration of effect for many anesthetic drugs.

Peripheral volumes of distribution explain the apparent dilution of the drug into all body tissues. We usually do not know the actual solubility of drugs in peripheral tissues. For the purpose of calculating drug dosage, a small true volume with high solubility is indistinguishable from a large true volume with low tissue solubility. The convention in pharmacokinetics is to assume that the solubility of the drug in tissue is the same as the solubility in plasma. This assumption does not compromise the role of peripheral compartments to characterize the dilution of drugs into tissues, but it does lead to very large volumes of distribution for highly soluble drugs (e.g., 5,000 L for propofol).

The volume of distribution at steady state (Vd_{ss}) is the volume that relates the plasma drug concentration at steady state (i.e., during a very long infusion) to the total amount of drug in the body. By rearranging the definition of concentration, we can calculate the Vd_{ss} as the total amount of drug in the body at steady state divided by the plasma drug concentration. The Vd_{ss} equals the central volume plus the peripheral volumes.

Clearance

Clearance is the process that removes drug from a volume. Systemic clearance permanently removes drug from the body, either by elimination or by transforming it into metabolites. Intercompartmental clearance moves drug from one compartment to another. Clearance is defined as the volume that is completely cleared of drug per unit of time. The units of clearance are therefore units of flow: volume per unit time (e.g., L/min). Clearance is most easily envisioned as flow to a clearing organ, as shown in Figure 2-3 (Figure Not Available) . [2] Clearance describes the body's capacity to remove drug. The actual rate of drug removal is the clearance times the concentration of the drug. If the clearance is 1 L/min, then the actual rate of drug elimination is zero if the concentration is zero, 1 mg/min if the concentration is 1 mg/L, 10 mg/min if the concentration is 10 mg/L, and so on.

Figure 2-3 (Figure Not Available) Clearance represents the flow of blood or plasma that is completely cleared of drug. If all the drug is extracted by the clearing organ (i.e., extraction ratio = 1), then clearance is simply the flow to the organ, as illustrated here. *(Modified from Shafer [2])*

Hepatic Clearance

Many drugs are cleared by hepatic biotransformation. The synthetic pathways for biotransformation are covered in detail in many biochemistry texts. Briefly, the liver metabolizes drugs through oxidation, reduction, hydrolysis, or conjugation. Oxidation and reduction occur in the cytochrome P-450 system. These enzymes can be induced by exposure to certain drugs, thus increasing the liver's intrinsic metabolic capacity. They can also be inhibited by drugs or hepatic disease. Routes of oxidative metabolism include hydroxylation, dealkylation, deamination, desulfuration, epoxidation, and dehalogenation. Conjugation and hydrolysis often occur outside the P-450 system, although glucuronidation involves the P-450 system as well. The effect of conjugation is to transform hydrophobic molecules into water-soluble molecules through addition of polar groups and thus to render the metabolites easier to excrete via the kidneys. The metabolites generated by the liver are generally inactive, although some drugs (e.g., morphine, midazolam) have metabolites that are as potent as the parent drug. Genetic polymorphism can occur in all these pathways, and this characteristic accounts for part of the variability in clearance in the population.

Systemic clearance of anesthetic drugs is generally via hepatic metabolism, although other mechanisms include plasma and tissue ester hydrolysis (remifentanil, succinylcholine, esmolol), renal elimination (pancuronium), and nonspecific "extrahepatic" metabolism for drugs whose clearance exceeds hepatic blood flow (propofol). The relationship between metabolism and clearance is complex, and although the following discussion assumes hepatic metabolism, the principles are valid for metabolism of drug in any tissue.

The rate of metabolism for most anesthetic drugs is proportional to the concentration of drug flowing into the liver. As shown later, this means that metabolic clearance is constant and independent of dose. This is such a common and fundamental assumption for anesthetic pharmacokinetics that we explore the conditions that must be satisfied for this to be valid. Of course, it cannot be true that metabolism is always proportional to concentration because the metabolic capacity of the liver is not infinite. At some rate of drug flow into the liver, the metabolic capacity becomes saturated, and the pharmacokinetics ceases to behave in a linear manner. To understand the rate of metabolism quantitatively, it is necessary to start with the simple observation that the rate at which drug flows *out* of the liver must be the rate at which drug flows *into* the liver less the rate of metabolism. The rate at which drug flows into the liver is liver blood flow (Q), times the concentration of drug flowing in (C_{inflow}). The rate at which drug flows out of the liver is Q times the concentration of drug flowing out ($C_{outflow}$). Putting this together, the rate of hepatic metabolism by the liver (R) is the difference between the C_{inflow} and $C_{outflow}$ times Q:

This relationship is illustrated in Figure 2-4 . Because hepatic metabolism does not have infinite capacity, the relationship between the rate of hepatic metabolism and concentration must be saturable. The saturation equation shows up repeatedly in pharmacokinetics and pharmacodynamics, so we inspect it carefully:

"Response" in this equation varies from 0 to 1, depending on the value of C. When C is 0, the response is 0. If C is greater than 0 but much less than C_{50}, then the response is nearly proportional to

. If C equals C_{50}, then the response is

, which is simply 0.5. That is where the term "C_{50}" comes from: it is the concentration associated with 50 percent response. As C becomes much greater than C_{50}, the equation approaches

, which is 1. The shape of this relationship is shown in Figure 2-5. . The relationship is linear at low concentrations, but at high concentrations, the response saturates

at 1.

We can model the relationship between hepatic metabolism and drug concentration using this equation for saturation. However, what concentration determines the rate of metabolism: the C_{inflow}, the average concentration within the liver, or $C_{outflow}$? All three have been used, but the most widely used model of metabolism views the rate of metabolism as a function of the $C_{outflow}$. This is discussed extensively by Wagner. [3]

Figure 2-4 The rate of metabolism can be computed as the rate of liver blood flow times the difference between the inflowing and outflowing drug concentrations. This is a common approach to analyzing metabolism or tissue uptake across an organ in mass-balance pharmacokinetic studies.

We can expand our equation of metabolism to include the observation that the rate of metabolism, R, approaches saturation at the maximum metabolic rate, V_m, as a function of $C_{outflow}$:

V_m is the maximum possible metabolic rate. The saturation part of this equation,

, determines fraction of the maximum metabolic rate. K_m, also called the Michaelis constant, is the concentration at which the metabolic rate is 50 percent of the maximum rate (V_m). This relationship is shown graphically in Figure 2-6 (Figure Not Available) . [2] The X axis is the outflow

Figure 2-5 The saturation equation,

. shows the decreasing incremental response as the system approaches saturation. Variations of this equation show up repeatedly in both pharmacokinetics and pharmacodynamics.

concentration, $C_{outflow}$, in units of K_m, the concentration that yields 50 percent of the maximum metabolic rate. The Y axis is the rate of drug metabolism, in units of V_m, the maximum rate of drug metabolism. By normalizing $C_{outflow}$ to K_m and the metabolic rate to V_m, the relationship in Figure 2-6 (Figure Not Available) is true for all values of V_m and K_m. Figure 2-6 (Figure Not Available) shows that as long as the $C_{outflow}$ is less than one-half of K_m, there is a nearly proportional change in metabolic rate with a proportional change in $C_{outflow}$. For most anesthetic drugs, the clinical concentrations do not exceed one-half of K_m, and so metabolism of anesthetic drugs is nearly proportional to concentration. We can also interpret Figure 2-6 (Figure Not Available) in terms of the metabolic rate (Y axis). As long as the metabolic rate is less than one-third of the maximum metabolic capacity, the rate of metabolism increases proportionally with concentration. The clinical message is that the metabolism is proportional to concentration, and thus pharmacokinetics remains linear, provided the rate of intravenous administration at steady state does not exceed one-third the maximum metabolic capacity.

So far, we have discussed the rate of metabolism and not hepatic clearance. If the liver could extract all the drug from the afferent flow, then clearance would equal Q. However, the liver cannot remove all the drug; there is always some drug in the effluent plasma. The fraction of inflowing drug extracted by the liver is

. This is called the extraction ratio. Clearance is the amount of blood completely cleared of drug per unit time. We can calculate clearance as Q times the extraction ratio:

With this basic understanding of clearance, let us divide each part of equation 4 by C_{inflow}:

Figure 2-6 (Figure Not Available) The relationship between concentration, expressed in units of K_m (Michaelis constant), and the rate of drug metabolism, in units of V_m (maximum rate). As long as the outflow concentration is less than half K_m, a change in concentration is matched by a proportional change in metabolic rate. This is true of nearly all anesthetic drugs. *(From Shafer [2])*

The third term is clearance: Q times the extraction ratio. Thus, each term must be equivalent to clearance. As such, each term brings insight into the process of clearance.

Consider the first term,

This indicates that clearance is a proportionality constant that relates arterial concentration to the rate of metabolism. If we want to maintain a given steady-state arterial drug concentration, we must infuse drug at the same rate that it is being metabolized. Thus, the infusion rate to maintain a given arterial concentration is the clearance times the desired arterial concentration.

What should we make of the third and fourth terms,

Taken together, these equations relate clearance to Q and the extraction ratio, as shown in Figure 2-7 (Figure Not Available) . [4] For drugs with an extraction ratio of nearly 1 (e.g., propofol), a change in Q produces a nearly proportional change in clearance. For drugs with a low extraction ratio (e.g., alfentanil), clearance is nearly independent of the rate of Q. This makes intuitive sense. If nearly 100 percent of the drug is extracted by the liver, this implies that the liver has tremendous metabolic capacity for the drug. In this case, the rate limiting step in metabolism is the flow of drug to the liver, and such drugs are said to be "flow limited." Any reduction in Q,

such as usually accompanies anesthesia, can be expected to reduce clearance. However, moderate changes in hepatic metabolic function per se have little impact on clearance, because hepatic metabolic capacity is overwhelmingly in excess of demand.

For many drugs (e.g., alfentanil), the extraction ratio is considerably less than 1. For these drugs, clearance is limited by the capacity of the liver to take up and metabolize the drug. These drugs are said to be "capacity dependent." Clearance changes in response to any change in the capacity of the liver to metabolize such drugs, such as could be caused by liver disease or enzymatic induction. However, changes in Q, as may be caused by the anesthetic state itself, usually have little influence on the clearance because the liver only handles a fraction of the drug it sees.

The last two components of equation 6 can also be used to show how the extraction ratio governs the response of clearance to changes in metabolic capacity (V_m). Figure 2-8 (Figure Not Available) shows the clearance for drugs with an extraction ratio ranging from 0.1 to 1, based on Q of 1.4 L/min. The extraction ratios were calculated for a $V_m = 1$. Changes in V_m, as could be caused by liver disease (reduced V_m) or enzymatic induction (increased V_m) have little effect on drugs with a high extraction ratio. However, drugs with a low extraction ratio have a nearly linear change in clearance with a change in intrinsic metabolic capacity (V_m).

So far, we have focused on linear pharmacokinetics, that is, the pharmacokinetics of drugs whose metabolic rate at clinical doses is less than $V_m/3$. The clearance of such drugs is generally expressed as a constant (e.g., propofol clearance = 1.6 L/min). Some drugs, such as phenytoin, exhibit saturable pharmacokinetics. The clearance of drugs with saturable metabolism is a function of drug concentration, rather than a constant.

Liver volume, Q, and hepatic metabolic capacity decrease with advancing age. These changes in hepatic physiology

Figure 2-7 (Figure Not Available) The relationship between liver blood flow (Q), clearance, and extraction ratio. For drugs with a high extraction ratio, clearance is nearly identical to liver blood flow. For drugs with a low extraction ratio, changes in liver blood flow have almost no effect on clearance. *(Modified from Wilkinson and Shand [4])*

Figure 2-8 (Figure Not Available) Corollary to Figure 2-7 (Figure Not Available) , showing the relationship between metabolic capacity, clearance, and extraction ratio (E.R.). Changes in maximum volume (V_m) have little effect on drugs with a high extraction ratio, but they cause a nearly proportional decrease in clearance for drugs with a low extraction ratio. *(From Shafer [2])*

account for the decreased clearance of opioids, hypnotics, benzodiazepines, and muscle relaxants and contribute to the increased sensitivity of elderly subjects to anesthetic drugs.

Renal Clearance

The kidneys clear drug from plasma by filtration at the glomerulus and direct transport into the tubules. Renal blood flow is inversely correlated with age, as is creatinine clearance, which can be predicted from age and weight [5] :

Men:

Women:
85% of the above

Equation 7 shows that age is an independent factor in predicting creatinine clearance. Thus, elderly people have decreased creatinine clearance, even in the presence of normal serum creatinine levels. Furthermore, inhalational anesthetics also decrease renal blood flow. Decreased renal clearance delays the offset of effect for renally excreted drugs. For instance, pancuronium is about 85 percent eliminated via renal clearance. The dose of pancuronium should be reduced in elderly patients on the basis of decreased clearance, even though they may have normal levels of creatinine.

Tissue Clearance

In some cases, anesthetic drugs are cleared in tissues, including blood, muscle, and lungs. For example, remifentanil is cleared by nonspecific esterases located primarily in muscle and intestines, whereas the lungs, liver, kidneys, and blood all contribute minimally to remifentanil clearance. Succinylcholine and mivacurium are all metabolized by plasma butyrylcholinesterases (formerly called pseudocholinesterase). The half-life ($t_{½}$) of succinylcholine and mivacurium in plasma is about 3 and 5 minutes, respectively. About half of atracurium's metabolism is hepatic, and the balance occurs in blood via nonspecific cholinesterases (but not by butyrylcholinesterases). Hofmann degradation is a spontaneous process in plasma at normal pH and temperature and does not depend on any circulating esterases. Hofmann degradation is a minor route of atracurium me-tabolism, but it is the major route of metabolism of cisatracurium, an isomer of atracurium. This is an important distinction: unlike atracurium and mivacurium, cisatracurium metabolism is unaffected by disease or genetic variants of cholinesterase metabolism.

Clearance by tissues other than blood can be analyzed using models similar to those for hepatic clearance. Tissue clearance can be flow limited, capacity limited, or both. Clearance within the blood itself cannot be flow limited and so is entirely dependent on intrinsic metabolic rate and capacity within the blood.

Distribution Clearance

Distribution clearance is the transfer of drug between the blood or plasma and the peripheral tissues. Unlike metabolic clearance, distribution clearance does not permanently remove drug from the body. Distribution clearance is a function of cardiac output, tissue blood flow, and the permeability of the capillary walls to the drug. For a drug that is avidly taken up in peripheral tissues, such as propofol, the sum of the metabolic clearance and the distribution clearance approaches cardiac output. For drugs that are metabolized directly in the plasma or in many peripheral tissues, such as succinylcholine and remifentanil, the sum of metabolic and distribution clearance can exceed cardiac output.

Tissue blood flow varies with cardiac output, which, in turn, changes with disease and in response to many drugs. Concurrently administered drugs can also raise or lower cardiac output or alter the distribution of cardiac output (i.e., redirect regional blood flow). Virtually all anesthetics decrease cardiac output, and so anesthesia likely decreases intercompartmental clearance.

Age, per se, only modestly reduces cardiac output in the absence of hypertension, coronary artery disease, valvular heart disease, or other cardiovascular disease. The net result is that advancing age modestly reduces intercompartmental clearance of anesthetic drugs.

The effect of decreased intercompartmental clearance is to increase initial plasma concentrations during drug administration. Following termination of drug administration, the role of decreased intercompartmental clearance is complex. In general, plasma concentrations decrease more rapidly following long infusions when intercompartmental clearance is decreased.

Protein Binding

Many drugs are bound to plasma proteins. The relationship between drugs and their binding proteins can be described as:

where [Free drug] is the free drug concentration, [Unbound protein binding sites] is the concentration of the available unbound protein binding sites, [Bound drug] is the concentration of drug bound to plasma proteins, k_{on} is the rate constant for binding of drug to plasma protein, and k_{off} is the rate constant for dissociation of bound drug from the plasma proteins. We can infer from this relationship that the rate of formation of bound drug is:

At equilibrium (which is nearly instantaneous), d[Bound drug]/dt = 0, permitting us to solve for k, the ratio of k_{on}/k_{off} , as:

Plasma proteins may have more than one binding site. Therefore, the total number of binding sites is the protein concentration, [Protein], times *n,* the average number of binding sites per protein molecule. For all the drugs used in anesthesia, the number of binding sites actually bound is only a trivial fraction of the total available binding sites, and so we can reasonably approximate [Unbound protein binding sites] by *n* [Protein]. Because *n,* the number of binding sites per molecule, is constant, we can just fold it into our rate constant, k, by defining the association constant, K_a , as:

Let us define f_u as the free fraction of drug:

When [Bound drug] = [Free drug], $f_u = 0.5$. Thus, we can think of a new term, $[\text{Free drug}]_{50}$, which is the free drug concentration associated with 50 percent binding. We could just as easily call it $[\text{Bound drug}]_{50}$, because [Bound drug] = [Free drug] when $f_u = 0.5$. Combining equations 10 and 11, we can solve for f_u in terms of the unbound drug concentration:

Two observations can be drawn from equation 12. First, the fraction bound to plasma protein solely depends only on the protein concentration, not on the drug concentration, within the approximation that [Bound drug] << *n*[Protein]. This approximation is always true for anesthetic drugs because of their potency. Even for thiopental, possibly the least potent drug used in contemporary anesthetic practice, [Bound drug] << *n*[Protein], and protein binding is independent of thiopental concentration.

Second, if we solve equation 12 for $f_u = 0.5$, we find that:

where $[\text{Protein}]_{50}$ is the concentration of protein at which the drug is half bound. Thus, another way of thinking about the K_a is that it is the inverse of the protein concentration associated with 50% binding. If we substitute

for K_a in equation 12, we have the relationship:

Figure 2-9 Relationship between plasma protein concentration as a fraction of the concentration associated with 50 percent binding and the fraction of drug that is unbound. This is another example of the saturation equation shown in Figure 2-5 .

This relationship is shown graphically in Figure 2-9 . On the left side of Figure 2-9 , [Protein] is much smaller than $[\text{Protein}]_{50}$. In this situation, the drug has little affinity for protein binding, so there is far less protein present than required to bind 50 percent of the drug. The drug is mostly free, and f_u is nearly 1. On the right side of Figure 2-9 , [Protein] is much greater than $[\text{Protein}]_{50}$. This means that there is far more protein present than would be required to bind 50 percent of the drug. The result is that drug is mostly bound to plasma proteins, and f_u is nearly 0.

K_a and its inverse, $[\text{Protein}]_{50}$, reflect the affinity of the drug for plasma proteins. They should not change in the presence of disease. However, [Protein] can change with disease, age, or concurrent drugs. Figure 2-10 (Figure Not Available) shows the relationship between changes in protein concentration and changes in the f_u of drug for drugs with different degrees of protein binding in normal clinical use. The lines on the graph correspond to different drugs whose f_u in normal plasma ranges from 1.0 (horizontal line) to
0.0 (straight diagonal line).

For drugs that are not bound ($f_u = 1.0$), there is no relationship between f_u and protein concentration, as indicated by the flat horizontal line. For drugs whose f_u is typically 90 percent, there is a small change in free drug concentration with changes in protein concentration. For drugs that are highly protein bound, the free drug concentration changes nearly in inverse with the change in protein concentration. As the percentage of binding approaches 100 percent (free drug
0.0), the relationship between change in protein concentration and change in fu becomes inversely proportional. Note that there is never a greater than proportional change in free drug concentration with change in plasma concentration. For example, the most that a 10 percent change in protein concentration would produce is a 10 percent

Figure 2-10 (Figure Not Available) The relationship between changes in protein concentration and changes in free fraction. The relationship depends on the free fraction in normal plasma with typical clinical doses. For a drug that is not bound (free fraction = 1), there is no change in free fraction with a change in protein concentration. For a highly bound drug with a free fraction that is nearly 0, any change in protein causes a nearly inversely proportional change in free fraction. *(From Shafer [z])*

change in free drug concentration, and that would only be the case if the drug were nearly 100 percent bound to plasma proteins.

The *in vitro* observation that changing protein concentration results in changing free drug concentration, as shown in Figure 2-10 (Figure Not Available) , does not necessarily apply to the *in vivo* situation. It is the free (e.g., unbound) drug that equilibrates between the plasma and the tissues. If protein binding is decreased, then the free drug concentration gradient between the plasma and peripheral tissues will increase. As a result, when protein binding decreases, equilibrium is achieved between the plasma and the tissue free drug concentrations at a lower total plasma drug concentration. This lower concentration gives the appearance that the drug has distributed into a larger total space. Thus, decreased protein binding causes an increase in the apparent volume of distribution when referenced to total, rather than free, drug concentration.

This explains why the increased Vd_{ss} seen with decreased plasma protein binding is mostly an illusion. Were only the unbound drug concentration measured, then for lipophilic drugs (such as most of those in anesthesia practice), there would be almost no change in the apparent volume of distribution because it is the partitioning of drug within peripheral tissues that primarily governs the free concentration of lipophilic drugs.

Changes in protein binding may affect the clearance of drugs. If a drug has a high extraction ratio, then the liver is going to remove nearly all the drug flowing to it, regardless of the extent of protein binding. However, if the drug has a low hepatic extraction ratio, then an increase in the f_u of drug will result in an increase in the driving gradient, with an associated increase in clearance. Protein binding also affects the apparent potency of a drug, when referenced to the total plasma drug concentration. An increase in f_u increases the driving pressure to the site of drug effect. Thus, a change in f_u increases the concentration at the effect site. Because of this change in apparent potency, decreased protein binding may decrease the dose required to produce a given drug effect even in the absence of pharmacokinetic changes.

Albumin and $alpha_1$ -acid glycoprotein are the primary sites of protein binding. Albumin concentration decreases with advancing age, hepatic disease, and malnutrition. In contrast, $alpha_1$ -acid glycoprotein concentration increases with advancing age and also with acute disease. Thus, the effects of age and disease on protein binding depend on which protein binds the drug. For example, because diazepam primarily binds to albumin, the f_u increases in elderly patients, and this may partly explain the increased sensitivity in elderly subjects. In contrast, lidocaine binds primarily to $alpha_1$ -acid glycoprotein, and in elderly patients increased $alpha_1$ -acid glycoprotein reduces the f_u , a factor that may contribute to the reduced clearance.

Stereochemistry

Typical pharmacokinetic analyses describe fictitious drugs. For example, the pharmacokinetics and pharmacodynamics of thiopental, fentanyl, and midazolam actually describe a drug that does not exist. The reason is that most

---

anesthetic drugs are chiral and are supplied as racemic mixtures. The body is a chiral environment, and drugs interact stereospecifically with enzymes, proteins, and receptors. The pharmacokinetics and pharmacodynamics of the enantiomers may differ. The enantiomers of bupivacaine and ketamine have been particularly well studied, in hopes of developing commercial products that lack the toxicity of the racemic mixtures. Although the importance of studying the pharmacokinetics and pharmacodynamics of individual stereoisomers is widely appreciated, the difficulty of doing such studies has precluded their wide-spread use.

Pharmacogenetics

Pharmacogenetics refers to the genetic diversity in the body's absorption, metabolism, and distribution of drugs (inborn pharmacokinetic variability) or to genetic diversity in the body's response to the drug, as may be caused by genetic differences in receptor structure (inborn pharmacodynamic variability). Most known pharmacogenetic variability refers to genetic diversity in drug metabolism. This may be because drug assays have been available for many years, whereas the molecular techniques to determine diversity in receptor populations have only recently been developed. Additionally, it is easy to understand how altered metabolism leads to higher or lower concentrations. It is much more difficult to understand how changes in receptor structure relate to differences in response to a drug.

However, there may be a biologic reason for pharmacogenetic variability in metabolism. It is probable that variability in drug metabolism is a natural adaptive response of animals to an environment that can present a huge variety of toxins. Enzymatic diversity is likely maintained through natural selection to ensure survival when species are confronted with novel environmental toxins.

In practical terms, this enzymatic diversity is rarely evident in the absence of drug therapy. In the presence of drug therapy, pharmacogenetic variation in metabolism is evident as unexpected toxicity, duration of action, or lack of efficacy to administered drugs. One of the best-studied pharmacogenetic variants is cytochrome P-450 2D6 (CYP2D6), also called debrisoquine hydroxylase. About 7 to 10 percent of whites are homozygous for an inactive variant of CYP2D6. This causes altered metabolism of at least 40 drugs. One of these drugs has potential interest to anesthesiologists: codeine. Codeine is a prodrug that is metabolized to morphine, the active drug, by CYP2D6. Patients who are homozygous for variant CYP2D6 do not have an analgesic response to codeine. Thus, the occasional patient who says that "codeine does nothing for me" is probably telling the truth--the patient is unable to convert codeine to morphine.

Anesthesiologists are familiar with the role of genetics in determining butyrylcholinesterase activity. Subjects with abnormal butyrylcholinesterase are at risk for prolonged paralysis from succinylcholine. Not surprisingly, there are ethnic differences in cholinesterase activity. For example, individuals of Middle Eastern descent are likely to have less butyrylcholinesterase activity than those of European descent. Molecular approaches have permitted extensive characterization of plasma cholines-terase variants. Many of these variants are not "all or none," but rather they reflect a spectrum of enzymatic activity.

Pharmacokinetic Models

Zero-Order and First-Order Processes

Zero-order processes and first-order processes are the basis of mathematical pharmacokinetic models. Processes such as the rotation of the earth or the flow of a river happen at a constant rate. These are called zero-order processes. The rate of change (dx/dt) for a zero-order process is:

Equation 15 simply states that the rate of change is constant. If x represents an amount of drug, and t represents time, then the units of k are amount/time. If we want to know the value of x at time t, x(t), we can compute it as the integral of the equation 15 from time 0 to time t:

where x_0 is the value of x at time 0. This is the equation of a straight line with a slope of k and an intercept of x_0.

Many other processes occur at a rate proportional to the amount. For example, the interest payment on a loan is proportional to the outstanding balance, and the rate at which water drains from a bathtub is proportional to amount of water in the tub. These are examples of first-order processes. The rate of change in a first-order process is only slightly more complex than for a zero-order process:

Here, the units of k are simply 1/time, because x on the right-hand side already includes the units for the amount. If we want to know the value of x at time t, x(t), again it can be computed as the integral from time 0 to time t:

where x_0 is the value of x at time 0. If k > 0, x(t) increases exponentially. If k < 0, x(t) decreases exponentially. In pharmacokinetics, k is negative because concentrations decrease over time. For clarity, the minus sign is usually explicit, so k is expressed as a positive number. Thus, the identical equation for pharmacokinetics, with the minus sign explicitly written, is:

Figure 2-11 shows the relationship between x and time, as described by equation 19. In Figure 2-11 , x continuously decreases over time, but the slope of the curve continuously increases (i.e., becomes less negative). Taking the natural logarithm of both sides of equation 19 gives:

Figure 2-11 Exponential decay curve, as given by $x(t) = x_0 e^{-kt}$, plotted on standard axes, with $x_0 = 10$ and $k = 0.5$.

This is the equation of a straight line, as shown in Figure 2-12 , where the vertical axis is ln(x(t)), the horizontal axis is t, the intercept is $\ln(x_0)$, and the slope of the line is -k.

How long will it take for x to go from some value, x_1 , to half that value, $x_1/2$? Because k is the slope of a straight line relating ln(x) to time:

where $t_{½}$ is the time required for a 50 percent decrease in x. We can simplify the numerator to:

This succinctly relates slope (or "rate constant"), k, to $t_{1/2}$:

Thus, if we measure the time it takes for x to fall by 50 percent, $t_{½}$, then we know the rate constant, k. If we know k from equation 23, we can easily deduce that the time it will take for x to fall by 50 percent is:

Physiologic Pharmacokinetic Models

It is possible to analyze volumes and clearances for each organ in the body and to construct models of pharmacokinetics by assembling the organ models into physiologically

Figure 2-12 The same exponential decay curve, $x(t) = x_0 e^{-kt}$, in Figure 2-11 , but now plotted on a log Y axis.

and anatomically accurate models of the entire animal. These models typically assume blood flows throughout the system as a zero-order process and drug transfers between the blood and tissues as a first-order process. Figure 2-13 (Figure Not Available) shows such a model for thiopental in rats. [6] Subsequent studies have shown that individual tissue volumes and blood flows can be scaled up from rats to humans, resulting in accurate models of human pharmacokinetics. This illustrates the potential utility of physiologically based pharmacokinetic models in developing human pharmacokinetic models from animal models.

Models that work with individual tissues are mathematically cumbersome and do not offer a better prediction of plasma drug concentration than models that lump the tissues into a few compartments. If the goal is to determine how to give drugs in order to obtain therapeutic plasma drug concentrations, then all that is needed is to relate dose to plasma concentration mathematically. For this purpose, conventional "compartmental" models are usually adequate.

Compartmental Pharmacokinetic Models

Compartmental models are built on the same basic concepts as physiologic models, but with gross simplifications. The "one-compartment model" seen in Figure 2-14 contains a single volume and a single clearance, as though we were built like buckets. For anesthetic drugs, we resemble several buckets connected by pipes. These are usually modeled using two- or three-compartment models, shown in Figure 2-14 . The volume to the right in the twocompartment model, and in the center of the three-compartment model, is the central volume. The other volumes are the peripheral volumes, and the sum of all the volumes is the Vd_{ss} . The clearance leaving the central compartment for the outside is the "central" or "metabolic" clearance. The clearances between the central compartment and the peripheral compartments are called "intercompartmental clearances."

Figure 2-13 (Figure Not Available) Physiologic model for thiopental in rats. The pharmacokinetics of distribution into each organ has been individually determined. The components of the model are linked by zero-order (flow) and first-order (diffusion) processes. *(From Ebling et al [6])*

One-Compartment Model

Bolus Pharmacokinetics

Think of the body as a bucket into which we pour drug. Let us call x_0 (x at time 0) the amount of drug that we pour into the bucket. The initial concentration, of course, is x_0 /V, where V is the volume of fluid in the bucket. Returning to equation 1, if we know the concentration we want to achieve, C_T (target concentration), and the volume in the bucket, we can calculate the dose to achieve C_T by rearranging the definition of concentration:

This is further discussed in Chapter 11 .

Let us assume that the fluid in the bucket is flowing out at a constant rate, which we call clearance, Cl. What is the rate, dx/dt, that drug is flowing out of the bucket? Because concentration is x/V, and Cl is the rate that the fluid in the bucket is flowing out, then the rate at which the drug is flowing out must be x/V times Cl. This rate is a first-order process if, and only if, it equals a constant, k, times the amount of drug in the bucket. Does it?

We stated earlier that the flow out of the bucket, Cl, was constant. The volume, V, is not a constant because it is shrinking as fluid flows from the bucket. So, let us open up a pipe at a rate that matches Cl to keep the V constant. Once V becomes a constant, the model looks like physiologic Cl

Figure 2-14 One-, two-, and three-compartment mammillary models.

(which does not require exsanguination). Because Cl and V are both constants,

is a constant. Referring back to equation 25, k, a constant by definition of first-order processes, equals

, a constant by the definition of Cl and V. This can be rearranged to yield the fundamental identity of linear pharmacokinetics:

What does this identity tell us about the relationship among $t_{½}$, V, and Cl? Rearranging the foregoing as

and remembering that

, we can conclude:

Figure 2-15 (Figure Not Available) shows a one-compartment model with an identical Cl but a bigger V than that seen in Figure 2-3 (Figure Not Available) It takes longer to clear drug from this bigger V, so the $t_{½}$ increases, as predicted by the foregoing equation. Figure 2-16 (Figure Not Available) shows a one-compartment model with an identical V but faster Cl than that seen in Figure 2-3 (Figure Not Available) . The concentrations fall more quickly (shorter $t_{½}$) with the larger Cl, as predicted by equation 27.

Because this is a first-order process, we know

, and the integral of this gives us the amount of drug at time t in terms of the amount at time 0, $x(t) = x_0 e^{-kt}$. If we divide both sides by V, and remember that x/V is the definition of concentration, we reach the equation that relates concentration following an intravenous bolus to time and initial concentration:

This equation defines the "concentration over time" curve for a one-compartment model, and it has the log-linear shape seen in Figure 2-12 . We can calculate Cl in one of two ways. First, we can calculate V by rearranging the definition of concentration, V = dose/initial concentration = dose/C_0 .

Figure 2-15 (Figure Not Available) A one-compartment model similar to Figure 2-3 (Figure Not Available) , but with an increased volume of distribution. Following drug administration, concentrations will fall more slowly in this model than in the model shown in Figure 2-3 (Figure Not Available) . *(Modified from Shafer [2])*

Referring back to equation 26, we can then calculate Cl as k × V. A more general solution is to consider the integral of the concentration over time curve, equation 28, known in pharmacokinetics as the area under the curve, or AUC:

We can rearrange equation 29 to solve for Cl:

Because x_0 is the dose of drug, Cl equals the dose divided by the AUC. This fundamental property of linear pharmacokinetic models applies to one-compartment models, multicompartment models, and to any type of intravenous drug

Figure 2-16 (Figure Not Available) A one-compartment model similar to Figure 2-3 (Figure Not Available) , but with increased clearance. Following drug administration, concentrations will fall faster in this model than in the model shown in Figure 2-3 (Figure Not Available) . *(Modified from Shafer [2])*

dosing (provided the *total* dose is used as the numerator). It directly follows that AUC is proportional to dose for linear models (i.e., models in which Cl is constant).

Infusion Pharmacokinetics

If you give an infusion at a rate of I (for input), the plasma concentration will rise as long as the rate of drug going in the body, I, exceeds the rate at which drug leaves the body, C × Cl, where C is the drug concentration. Once, I = C × Cl, drug is going in and coming out at the same rate, and the body is at steady state. We can calculate the concentration at steady state by observing that the rate of drug going in must equal the rate of drug coming out of the body. From equation 6, we know that rate of drug metabolism at steady state is:

where C
 is the arterial concentration at steady state. Because by definition at steady state the infusion rate must equal the metabolic rate, the infusion rate, I, at steady state must be I = C
Cl, where I is the rate of the drug infusion. Solving this for the concentration at steady state, C
gives

. Thus, the steady-state concentration during an infusion is the rate of drug input divided by Cl. It follows that if we want to calculate the infusion rate that will achieve a given C_T , at steady state, then the infusion rate must be C_T × Cl. This is discussed further in Chapter 11 .

is similar in form to the equation describing the concentration following a bolus injection:

. Thus, volume is a scalar relating bolus to initial concentration, and Cl is a scalar relating infusion rate to steady-state concentration. It follows that the initial concentration following a bolus is independent of Cl, and the steady-state concentration during a continuous infusion is independent of V.

During an infusion, the rate of change in the amount of drug, x, is rate of inflow, I, minus the rate of outflow, k times x.

We can calculate x at any time t as the integral from time 0 to time t. Assuming that $x_0 = 0$ (i.e., we are starting with no drug in the body), the result is:

As t

, e^{-kt}
 0, and equation 33 reduces to:

Let us say that we want to reach 50 percent of that amount, that is,

. From equation 34, we know that

. Substituting

for x(t) in equation 33, we have:

Solving equation 35 for t, we get:

. In equation 24, we found that the $t_{½}$ following a bolus injection was

. Here again, we have a parallel between boluses and infusions. With an infusion, the time to reach 50 percent of the steady-state concentration is one $t_{½}$. Similarly, it takes two $t_{½}$ to reach 75 percent, three $t_{½}$ to reach 88 percent, and five $t_{½}$ to reach 97 percent of the steady-state concentration. By four to five $t_{½}$, we typically consider the patient to be at steady state, although the concentrations only asymptotically approach the steady-state value.

Absorption Pharmacokinetics

In intravenous drug delivery, all the drug reaches the systemic circulation. When drugs are given by a different route, such as orally, transdermally, epidurally, or intramuscularly, the drug must first reach the systemic circulation. Oral drugs may be metabolized by first-pass hepatic metabolism before reaching the systemic circulation. Transdermally applied drugs may be sloughed off with the stratum corneum without being absorbed. We cannot assume that the dose given to the patient is the same as the dose that reaches the systemic circulation when working with alternative routes of drug delivery. The systemic dose is the administered dose times f, the fraction that is "bioavailable."

Alternative routes of drug delivery are often modeled by assuming that the drug is absorbed from a reservoir or depot, usually modeled as an additional compartment with a monoexponential rate of transfer to the systemic circulation:

where A(t) is the absorption rate at time t, f is the fraction bioavailable, D_{ora} is the dose taken orally (or intramuscularly or applied to the skin), and k_a is the absorption rate constant. Because the integral of $k_a e^{-k_a t}$ is 1, the total amount of drug absorbed is f times D_{ora}. To compute the concentrations over time, we first reduce the problem to differential equations, (e.g., equations 17 and 32) and then integrate. The differential equation for the amount, x, with oral absorption into a one-compartment disposition model is:

This is simply the rate of absorption at time t, A(t), minus the rate of exit, k x(t). To solve for the amount of drug, x, in the compartment at time t, we integrate this from 0, to time t, knowing that x(0) = 0:

Equation 38 describes the amount of drug in the systemic circulation when absorbed from some depot, such as the stomach, intramuscular injection, the skin, or even an epidural dose. To describe the concentrations, rather than amounts, of drug, it is necessary to divide both sides of equation 38 by Vd, the volume of distribution.

This covers the standard pharmacokinetic equations for one-compartment models. The one-compartment model introduces the concepts of rate constants and $t_{½}$ and relates them to the physiologic concepts of V and Cl. *Unfortunately, none of the drugs used in anesthesia can be accurately characterized by one-compartment models.* Distribution of anesthetic drugs into and out of peripheral tissues plays a crucial role in the time course of anesthetic drug effect. To describe intravenous anesthetics, we must extend the one-compartment model to account for distribution into tissues.

Multicompartment Models

The plasma concentrations over time following an intravenous bolus resemble the curve in Figure 2-17 . In contrast to Figure 2-12 , Figure 2-17 is not a straight line, even though it is plotted on a log Y axis. This curve has the characteristics

Figure 2-17 Concentration versus time relationship showing a very rapid initial decline after bolus injection. The terminal log-linear portion is only seen after most of the drug has left the plasma. This is characteristic of most anesthetic drugs. Different line types highlight the rapid, intermediate, and slow (log-linear) portions of the curve.

common to most drugs when given by intravenous bolus. First, the concentrations continuously decrease over time. Second, the rate of decline is initially steep, but it continuously becomes less steep, until we reach a portion that is "log-linear." During this log-linear phase, the slope continues to decrease over time. However, if we plot the log of concentration against time, the terminal part of the curve will appear linear.

For many drugs, three distinct phases can be distinguished, as suggested by Figure 2-17 . There is a rapid "distribution" phase (solid line in Fig. 2-17) that begins immediately after the bolus injection. Very rapid movement of the drug from the plasma to the rapidly equilibrating tissues characterizes this phase. Often, there is a slower second distribution phase (dashed line in Fig. 2-17) that is characterized by movement of drug into more slowly equilibrating tissues and return of drug to the plasma from the most rapidly equilibrating tissues (i.e., those that reached equilibrium with the plasma during phase 1). The terminal phase (dotted line in Fig. 2-17) is a straight line when plotted on a semilogarithmic graph. The terminal phase is often called the "elimination phase" because the primary mechanism for decreasing drug concentration during the terminal phase is drug elimination from the body. The distinguishing characteristic of the terminal elimination phase is that the relative proportion of drug in the plasma and peripheral volumes remains constant. During this "terminal phase," drug returns from the rapid and slow volumes to the plasma, and it is permanently removed from the plasma by metabolism or excretion.

The presence of three distinct phases following bolus injection is a defining characteristic of a mammillary model with three compartments. It is possible to develop hydraulic models, as shown in Figure 2-18 (Figure Not Available) , [7] for intravenous drugs. In this model, there are three tanks, corresponding (from left to right) with the slowly equilibrating peripheral compartment, the central compartment (the plasma, into which drug is injected), and the rapidly equilibrating peripheral compartment. The horizontal pipes represent intercompartmental clearance or (for the pipe draining onto the page) metabolic clearance. The volumes of each tank

correspond with the volumes of the compartments for fentanyl. The cross-sectional areas of the pipes correlate with fentanyl systemic and intercompartmental clearances. The height of water in each tank corresponds to drug concentration.

Figure 2-18 (Figure Not Available) A hydraulic model of fentanyl pharmacokinetics. Drug is administered into the central tank, from which it can distribute into two peripheral tanks, or it may be eliminated. The volume of the tanks is proportional to the volumes of distribution. The cross-sectional area of the pipes is proportional to the clearance. *(Modified from Youngs and Shafer [7])*

Using this hydraulic model, we can follow the processes that decrease drug concentration over time following bolus injection. Initially, drug flows from the central compartment to both peripheral compartments through intercompartmental clearance and completely out of the model through metabolic clearance. Because there are three places for drug to go, the central compartment concentration decreases very rapidly. At the transition between the solid line and the dashed line in Figure 2-18 (Figure Not Available) , there is a change in the role of the most rapidly equilibrating compartment. At this transition, the central compartment concentration falls to less than the concentration in the rapidly equilibrating compartment, and the direction of flow between them is reversed. After this transition (dashed line in Fig. 2-18) (Figure Not Available) , drug in the plasma only has two places to go: flow into the slowly equilibrating compartment and metabolic clearance. These processes are partly offset by the return of drug to the plasma from the rapidly equilibrating compartment. The net effect is that once the rapidly equilibrating compartment has come to equilibration, the central compartment concentration falls far more slowly than before.

Once the concentration in the central compartment falls to less than both the rapidly and slowly equilibrating compartments (dotted line in Fig. 2-18) (Figure Not Available) , then the only method of decreasing the plasma concentration is metabolic clearance. The return of drug from both peripheral compartments to the central compartment greatly slows the rate of decrease in plasma drug concentration.

Curves that continuously decrease over time, with a continuously increasing slope (i.e., curves that look like Figs. 2-17 and 2-18) (Figure Not Available) , can be described by a sum of exponentials. In pharmacokinetics, one way of denoting this sum of exponentials is to say that the plasma concentration over time is:

where t is the time since the bolus, C(t) is the drug concentration following a bolus dose, and A, alpha, B, beta, C, and gamma are parameters of a pharmacokinetic model. A, B, and C are called coefficients, whereas alpha, beta, and gamma are called exponents. Following a bolus injection, all six of the parameters in equation 39 are greater than zero.

The main reason that polyexponential equations are used is that they describe the concentrations observed after bolus injection (except for the misspecification in the first minute). Compartmental pharmacokinetics is strictly empiric: the models describe the data, not the processes by which the observations came to be. Fortunately, polyexponential equations permit us to use many of the one-compartment ideas just developed, with some generalization of the concepts. This involves translating equation 39 into a model of V and Cl that has an appealing, if not necessarily accurate, physiologic flavor.

Equation 39 states that the concentrations over time are the algebraic sum of three separate functions: $Ae^{-alpha\,t}$, $Be^{-beta\,t}$, and $Ce^{-gamma\,t}$. Typically, alpha > beta > gamma by about 1 order of magnitude. We can graph each of these functions separately, as well as their sum, as shown in Figure 2-19 . At time 0 (t = 0), equation 39 reduces to:

The sum of the coefficients A, B, and C, equals the concentration immediately following a bolus.

Special significance is often ascribed to the smallest exponent. This exponent determines the slope of the final log-linear portion of the curve. When the medical literature refers to the $t_{½}$ of a drug, unless otherwise stated, the $t_{½}$ is the terminal $t_{½}$ (i.e., 0.693/smallest exponent). However, the terminal $t_{½}$ for drugs with more than one exponential term is nearly uninterpretable. The terminal $t_{½}$ is merely

Figure 2-19 The disposition of a three-compartment model (i.e., triexponential model) consists of the sum of three monoexponential functions. See text for an explanation of the equations.

the upper limit on the time required for the concentrations to decrease by 50 percent after drug administration. Usually, the time for a 50 percent decrease is much faster than that upper limit. This is discussed further in Chapter 11 .

Constructing pharmacokinetic models represents a tradeoff among accurately describing the data, having confidence in the results, and mathematical tractability. Adding exponents to the model usually provides a better description of the observed concentrations. However, adding more exponent terms usually decreases our confidence in how well we know each coefficient and exponential and greatly increases the mathematical burden of the models. This is why most pharmacokinetic models are limited to two or three exponents.

Part of the continuing popularity of polyexponential models of pharmacokinetics is that they can be mathematically transformed from the admittedly unintuitive exponential form in equation 39 to a more easily intuited compartmental form, as shown in Figure 2-14 . Microrate constants, expressed as k_{ij} , define the rate of drug transfer from compartment i to compartment j. Compartment 0 is a compartment outside the model, so k_{10} is the microrate constant for those processes acting through biotransformation or elimination that irreversibly remove drug from the central compartment (analogous to k for a one-compartment model). The intercompartmental microrate constants (e.g., k_{12} , k_{21}) describe the exchange of drug between the central and peripheral compartments. Each compartment has at least two microrate constants, one for drug entry and one for drug exit. The microrate constants for the two- and three-compartment models can be seen in Figure 2-14 . The differential equations describing the rate of change for the amount of drugs in compartments 1, 2, and 3, follow directly from the microrate constants. For the two-compartment model, the differential equations for each compartment are:

For the three-compartmental model, the differential equations for each compartment are:

where I is the rate of drug input. An easy way to model pharmacokinetics is to convert the foregoing differential equations to difference equations, so that dx becomes Deltax, and dt becomes Deltat. With a Deltat of 1 second, the error from linearizing the differential equations is less than 1 percent. In this way, desktop computers

can simulate hours worth of pharmacokinetics in a matter of seconds using a spreadsheet.

For the one-compartment model, k was both the rate constant and the exponent. For multicompartment models, the relationships are more complex. The interconversion between the microrate constants and the exponents becomes exceedingly complex as more exponents are added, because every exponent is a function of every microrate constant and vice versa. Individuals interested in such interconversions can find them in the Excel spreadsheet "convert.xls," which can be downloaded over the World Wide Web at the following address: http://pkpd.icon.palo-alto.med.va.gov.

Time Course of Drug Effect

The plasma is not the site of drug effect for anesthetic drugs. There is a time lag between plasma drug concentration and effect-site drug concentration. For example, one significant difference between fentanyl and alfentanil is the more rapid onset of alfentanil drug effect. The black bar in the top graph of Figure 2-20 (Figure Not Available) shows the duration of a fentanyl infusion. [8] Rapid arterial samples document the rise in

Figure 2-20 (Figure Not Available) Fentanyl and alfentanil arterial concentrations (circles) and electroencephalographic (EEG) response (irregular line) to an intravenous infusion. With each drug, there is a time lag between the rise and fall in arterial concentration and the EEG response, but the time lag is much greater for fentanyl than for alfentanil. *(Modified from Scott et al [6])*

Figure 2-21 A three-compartment model with an added effect site to account for the equilibration delay between the rise and fall of arterial drug concentrations and the onset and offset of drug effect.

fentanyl concentration. The time course of electroencephalographic (EEG) effect lags about 2 minutes behind the rapid rise in arterial concentration. This lag is called hysteresis. The plasma concentration peaks at the moment the infusion is turned off. Following the peak plasma concentration, the fentanyl concentration rapidly decreases. However, the offset of fentanyl drug effect again lags well behind the decrease in concentration. The lower graph in Figure 2-20 (Figure Not Available) shows the same study in a patient receiving alfentanil. Because of alfentanil's rapid blood-brain equilibration, there is less hysteresis with alfentanil than with fentanyl.

Typically, the relationship between the plasma and the site of drug effect is modeled with an "effect-site" model, as shown in Figure 2-21 . The site of drug effect is connected to the plasma by a first-order process, as described earlier. The equation that relates effect-site concentration to plasma concentration is:

where Ce is the effect site concentration and Cp is the plasma drug concentration. k_{e0} is the rate constant for elimination of drug from the effect site. It is most easily understood in terms of its reciprocal, $0.693/k_{e0}$, the half-time for equilibration between the plasma and the site of drug effect.

The constant k_{e0} has a large influence on the rate of rise of drug effect, the rate of offset of drug effect, and the dose that is required to produce the desired drug effect. The mathematical basis of these relationships is explored in Chapter 11 .

Summary

Pharmacokinetics involves fundamental physiologic proc-esses, including metabolism, protein binding, tissue distri-bution, and drug transport into the site of drug effect. Pharmacokinetic models are mathematical relationships between dose and concentration, either in the plasma or at the site of drug effect. Such models can be used to determine how best to give drugs to achieve a therapeutic objective, but only when the relationship between drug concentration and drug effect is understood.

PHARMACODYNAMICS

Overview

Pharmacodynamics describes the relationship between plasma drug concentration and pharmacologic effect. Simply stated, pharmacodynamics attempts to explain what a drug does to the body. Although the study of clinically important drug effects is multifaceted, pharmacodynamics may be divided into three general areas. These areas are transduction of biologic signals, clinical evaluation of drug effects, and biologic variability. Each of these aspects of pharmacodynamics is explored in detail in the following sections.

Transduction of Biologic Signals

Receptor Theory

Definition

In the broadest sense, a receptor is a component of a cell that interacts selectively with an extracellular compound to initiate a biochemical change or a cascade of biochemical alterations that represent observed effects of the compound. Binding of drug to a receptor determines (1) the quantitative relationship between a given dose of a drug and the effect produced, (2) selectivity of a given drug's activity and effect,

---

and (3) an explanation of the pharmacologic activity of receptor agonists, antagonists, and inverse agonists. Receptors therefore serve to mediate or amplify the effect of a drug on the biologic system.

Historical Perspective

Although the overall concept of receptors is generally attributed to Paul Erhlich (1854-1915), earlier work performed by Claude Bernard (1813-1878) paved the way for receptor theory. This earlier work is of particular interest to anesthesiologists because it centered on elucidation of the mechanism of action of curare, an arrow poison. In his experiments, Claude Bernard ligated vessels leading to one hindlimb of a frog while leaving nerve input intact; he then administered intravenous curare. Pinching the paralyzed hindlimb produced reflex movements in the opposite unparalyzed vessel-ligated hindlimb. These experiments and others demonstrated for the first time the separation between sensory and motor nervous systems and also revealed that circulating "substances" produce selective effects on organ systems, a concept important in the development of receptor theory.

The concept of selectivity of effect eventually led Paul Erhlich to his conclusion that "agents cannot act unless they are bound," a cornerstone of receptor theory. Although Erhlich is attributed with discovering this concept, his contemporary J.N. Langley (1852-1926) coined the phrase "receptive substance" (or receptor). Langley extended Claude Bernard's work by showing that nicotine and curare have mutually antagonistic effects on the same receptive substance that is neither nerve nor muscle. Today, we recognize this "receptive substance" as the nicotinic acetylcholine receptor in the neuromuscular junction. Several decades of research have refined receptor theory to the point that receptors are now recognized as discrete excitable proteins.

Classic Receptor Theory

The binding of a ligand (drug molecule) to its receptor follows the laws of chemical reactions (analogous to Michaelis Menten enzyme kinetics) and can be summarized by the relationship:

where k_{on} is the rate constant for the ligand binding to the receptor, k_{off} is the rate constant for the ligand disassociating from the receptor, [L] is the concentration of the ligand, [R] is the concentration of the unbound receptor, and [LR] is the concentration of the bound receptor. Note that units for k_{or} are units of [L] multiplied by the units of [R] over time; typically, units of L are nanomoles per liter. The units for k_{off} are the units of [LR] over time. The term K_d, or dissociation constant, defines characteristics of ligand/receptor interactions at equilibrium. Mathematically,

The units of K_d are the units of [L], that is, units of concentration. When enough drug is administered to occupy exactly 50 percent of the receptors, the measured K_d is equal to the drug concentration. A low K_d indicates that less drug is required to occupy 50 percent of the receptors (because each molecule of drug is tightly associated with the receptor); a high K_d indicates that more drug is required to occupy 50 percent of receptors. The K_d has been determined for many of the drugs currently administered during anesthesia. The reciprocal of K_d is K_a, the association constant, which is exactly analogous to the K_a defined for protein binding. K_a is a measure of the affinity of the drug for the receptor. Hence, a drug with a low K_d constant has a high K_a and therefore high affinity for the receptor.

In practice, it is difficult to measure precise drug-receptor occupancy. It is often assumed that the drug-receptor complex represents an intermediate step in the production of a specific effect; therefore, many investigators apply pharmacodynamic theory to compare a given dose of a drug with a resulting effect. An effect can be any biochemical or physiologic variable that is measurable. A measured effect can be an alteration in a biochemical compound, an enzyme level, a physiologic variable such as heart rate or blood pressure, or a response to any graded input into the biologic system. For example, in evaluating the pharmacodynamics of muscle relaxants, the measured effect is not a direct measurement of drug-receptor complexes, but rather a response to a neuromuscular stimulus as delivered by a nerve stimulator.

From the discussion of pharmacokinetics, it is clear that the delivery of a drug to a given receptor is time- and dose-dependent. If the receptor is located within the

central compartment, there may be nearly instantaneous equilibration after an intravenous injection, and hence the peak effect may occur immediately. If drug must cross from the central compartment to the site of drug effect, this will cause a delay. The onset of drug effect can also be delayed by the time required for the body to respond to the drug. This delay may occur anywhere on the path between drug-receptor binding and clinical manifestation of drug effect. Examples of post-transduction time delays are drug-receptor complex- induced secondary messenger changes, increased enzyme synthesis, and the time required for physiologic change (e.g., reduced fluid content).

Receptor Agonists and Antagonists

Agonist drugs induce an effect that mimics endogenous hormones or neurotransmitters when bound to a receptor. This effect may be stimulatory or inhibitory. As described earlier, the term *affinity* as related to a given agonist is a measure of the attraction between the given drug and receptor. A drug with low affinity for a given receptor tends not to bind to the receptor, hence produces little or no effect. An agonist drug that binds avidly (or with high affinity) to a given receptor produces the receptor-determined effect at a lower given dose.

Full agonists completely activate a receptor, whereas partial agonists only partially activate a receptor (Fig. 2-22) . The difference between full and partial agonists results from differing intrinsic efficacy for each drug. Efficacy should not be confused with affinity. Two drugs can have

Figure 2-22 Effect of various types of ligands on receptor responses. Full agonist binding results in complete (100%) activation of a receptor, whereas partial agonist binding results in less than 100 percent activation. A neutral antagonist has no activity of its own, but it blocks agonist binding; hence, antagonists result in prevention of agonist responses. Inverse agonists can be thought of as "super antagonists" because binding of these compounds results in decreased responsiveness below the baseline response measured in the absence of drug. If the physiologic effect of the baseline levels of activated receptor (R*) is small, then the antagonists and inverse agonists may not be clinically distinguishable.

identical affinity for a receptor (and therefore bind to the same extent at a given drug concentration), yet they may produce different levels of activation of the receptor. Both are agonists, yet the drug that produces the maximal receptor activation is called a full agonist and has high efficacy, whereas the drug that produces less than a maximal receptor-mediated response is called a partial agonist with less intrinsic efficacy. The mechanisms underlying one drug's producing full versus partial agonist effects remain shrouded in mystery, but they may be related to the ability of the drug to stabilize the high-affinity state of the receptor (R*; see later).

Antagonist drugs inhibit or prevent receptor-mediated agonist effects by competing for receptor occupancy. A competitive antagonist can generally be displaced from the receptor complex by the administration of a large enough concentration of receptor agonist, thus permitting the agonist to produce the expected effect in spite of the presence of antagonist (see the clinical example later). However, a noncompetitive antagonist usually binds irreversibly to the receptor complex, producing loss of the expected effect that cannot be reproduced by concurrent administration of high-dose receptor agonist. Most antagonist drugs used in clinical medicine are competitive antagonists.

For example, vecuronium, a nondepolarizing muscle relaxant of moderate duration, is a competitive antagonist of acetylcholine. Acetylcholine mediates muscle contraction via the postsynaptic nicotinic acetylcholine receptor at the neuromuscular junction. When vecuronium binds to the post-synaptic acetylcholine receptor, acetylcholine agonism is blocked, and neuromuscular transmission is inhibited. The result is flaccid paralysis. Neuromuscular transmission may be reinstated by administering an acetylcholine esterase inhibitor. Acetylcholine esterase inhibitors prevent breakdown of acetylcholine, thus effectively raising the concentration of the agonist, acetylcholine, at the receptor, which then displaces vecuronium from the receptor complex. When enough vecuronium is displaced, muscle contraction is reinstated. This general principle is commonly used in anesthesia to reverse drug-induced muscle relaxation at the end of a surgical procedure.

Inverse agonists can be thought of as "superantagonists" because they decrease receptor responses to less than baseline (see Fig. 2-22). An example of concentration-response relationships for four different benzodiazepines and EEG response is shown in Figure 2-23 (Figure Not Available) . Note that in this example, EEG responses represent a surrogate clinical end point for binding of benzodiazepines to the $_{A}$ subunit of gamma-aminobutyric acid ($GABA_A$) ligand-gated ion channel complex with resultant modulations of ion fluxes in the central nervous system (CNS).

Receptor States

Classic receptor theory describes interaction between li-gand and receptor based on the laws of mass action. At a molecular level, this interaction has been interpreted over the years to suggest that binding of agonist to receptor initiates a change in receptor conformation, changing the receptor from an inactive (R) to an activated (R*) state (Fig. 2-24) . [2] [9] In this model, the change in receptor conformation facilitates activated receptor coupling to intermediary proteins (e.g., guanine nucleotide [G] proteins) or second messengers (effectors, E) which then initiate a rapid cascade of cellular responses.

Transgenic animal experiments have shed light on ligand and receptor interactions. In an elegant set of experiments in which beta $_{2}$ -adrenergic receptors were massively overexpressed in mouse myocardium, second messenger responses were increased *in the absence of ligand* when compared with normal mouse myocardium. In fact, adenylyl cyclase activity (the second messenger most commonly studied for $beta_2$ -adrenergic receptors) is identical at baseline in transgenic animals (in the absence of drug) compared with normal mice stimulated with isoproterenol (a beta $_{2}$ -adrenergic receptor agonist). Furthermore, isoproterenol stimulation of transgenic animals is unable to increase adenylyl cyclase activity higher than this elevated baseline. This finding suggests that, in these transgenic animals, a subpopulation of receptors is already fully activated. One way to analyze these findings is to consider that at baseline a small percentage (e.g., 1%) of receptors spontaneously exists in the activated (R*) state. Because this equilibration is the normal balance of the receptors in that tissue, the activity of these R* receptors is part of the baseline effect measured in the absence of drug. However, once massive overexpression of beta $_{2}$ -adrenergic receptors occurs (as in a transgenic animal), one percent of the total receptors becomes a very large number of activated receptors. This mimics

Figure 2-23 (Figure Not Available) The concentration-electroencephalographic (EEG) response relationship for four benzodiazepines: midazolam (full agonist), bretazenil (partial agonist), flumazenil (antagonist), and R0 19-4063 (an inverse agonist). The maximum effect seen in the EEG correlates with clinical action (full agonist > partial agonist > antagonist > inverse agonist). *(From Shafer, [2] based on Mandema et al [5])*

the effect of a maximal dose of drug, which would produce similar numbers of receptors in the R* state.

These findings have broad implications for understanding receptor states and drug-receptor interactions. Instead of ligand binding's causing a change from R to R* (as suggested by Fig. 2-24) , these data suggest spontaneous conversion from the R to the R* state (Fig. 2-25). In most tissues, the concentration of R* represents a small fraction of total overall receptor (hence the large arrow pointing toward R in Fig. 2-25). However, baseline receptor responses are known to differ among tissues, a finding suggesting that the absolute concentration of R* (and hence spontaneous conversion rates between R and R*) may be tissue-dependent. This finding is clinically important because inverse agonists, which drive receptors toward R and hence decrease responses to less than "baseline" to the true zero baseline, would be predicted to be most efficacious in tissues in which higher concentrations of spontaneous R* exist. Figure 2-23 (Figure Not Available) illustrates a tissue (CNS) in which enough activated $GABA_A$ ligand-gated ion channels (R*) are present to see EEG changes with an inverse agonist; this finding provides a rationale for the inverse agonist antiepileptic drugs currently being developed. Finally, it is important to note that the discussion thus far assumes only two receptor states, R (completely inactive) and R* (fully activated). More recent experimental evidence suggests the existence of intermediate transition states between R and R* (hence the use of curved lines in addition to straight lines in Fig. 2-25) . However, in the interest of simplicity, further discussion in this chapter utilizes only R and R*.

The discovery of spontaneous conversion between R and R* has implications for understanding the action of ligands (agonists, antagonists, inverse agonists). Instead of agonists' causing conversion from R to R*, it is now thought that li-gands stabilize a given receptor state. Specifically, as shown in Figure 2-26 , agonists stabilize (or energetically favor) R* and inverse agonists stabilize R, whereas neutral antagonists bind equally to R and R*. Binding of ligand to receptor removes the receptor from the equation because rapid coupling to second messengers occurs, thus driving (by mass action) the equation toward that specific state (Fig. 2-27) .

For example, once agonists bind to R*, the activated receptor-ligand complex is capable of activating second messenger pathways, so it is removed from the equation, driving the R
R* equation to the right to replace R*. Hence, the probability of being in the R* state increases in the presence of agonist. Conversely, inverse agonists drive the equation to the left, stabilizing the R configuration. Because baseline receptor

Figure 2-24 Schematic of classic receptor activation. For years, binding of ligand was thought to cause receptors to change from an inactive state (R) to an activated state (R*). The activated receptor then interacts with intermediary guanine nucleotide (G) proteins and/or directly with second messenger cascades (effectors, E). More recent information suggests a more complicated equilibrium between R and R*, as shown in Figure 2-27 .

responses represent a balance between R and R*, an inverse agonist often causes receptor response to fall to less than baseline to a true zero response level (see Fig. 2-22). Because antagonists are neutral (by definition), they bind equally to R and R*, thus preventing agonist responses but not changing the equilibrium between R and R*; hence, antagonists do not change the baseline response (see Fig. 2-22) . Many classic "antagonists" have now been tested and found to be inverse agonists rather than neutral antagonists. For example, "inverse efficacy" of common beta-adrenergic receptor antagonists has been determined as follows: timolol
propranolol > alprenolol
pindolol > labetalol > dichloroisoproterenol. Because inverse agonists may have theoretical advantages in treating certain diseases (e.g., seizures, congestive heart failure), clinicians should critically evaluate recent pharmacologic data prior to using an antagonist to distinguish whether the drug is an antagonist or an inverse agonist.

Figure 2-25 Spontaneous conversion of receptors from an inactive (R) to an active (R*) state. In most tissues, R* represents a small fraction of the total receptor population.

Figure 2-26 Ligand stabilization of receptor states. Agonists stabilize active receptors (R*), inverse agonists stabilize inactive receptors (R), and neutral antagonists bind equally to R and R* without affecting the equilibrium between the two receptor states.

Receptor Structure

General Principles

Receptors are located in many places in the cell--outer cell membrane, cytoplasm, intracellular organelle membranes, and nucleus. The overall physical structure of a receptor depends on the type of receptor considered as well as its location. For example, membrane receptors have structures different from those of cytoplasmic receptors. In general, cytoplasmic receptors (and/or nuclear receptors) bind ligands that readily traverse cell membrane lipid bilayers to reach the cytoplasm or nucleus. These ligands must therefore

Figure 2-27 Equilibrium between inactive receptors (R) and active receptors (R*) is tissue specific and depends on the type of ligand administered. By stabilizing R*, agonists drive the equilibrium to the right. In contrast, inverse agonists stabilize R, driving the equilibrium to the left. Because neutral antagonists bind equally to R and R*, they do not affect tissue specific equilibrium between R and R*.

Figure 2-28 Schematic of four types of membrane associated drug targets: membrane (G protein-coupled) receptor, ligand-gated ion channel, voltage-sensitive ion channel, and an enzyme. Potential sites of drug action are shown. betaAR, beta-adrenergic receptor; $GABA_A$, gamma-aminobutyric acid.

contain significant hydrophobic components. Examples of cytoplasmic and nuclear receptors include steroid and thyroid hormone receptors. In contrast, most receptors important to the anesthesiologist are excitable cell-membrane proteins, such as membrane receptors, ligand-gated ion channels, and voltage-gated ion channels (Fig. 2-28) . Many endogenous hormones and exogenous drugs are water soluble (hydrophilic and charged) and are unable to cross cell-membrane lipid bilayers. Therefore, a mechanism is required to transduce drug binding at the extracellular surface into changes in intracellular physiology. Membrane receptor structure depends on whether coupling to second messengers via intermediary proteins is required or whether the receptor is part of a larger ion channel complex (e.g., ligand-gated ion channels). Each of these types of membrane receptors has a role in mediating the action of various drugs important in anesthesiology. It is beyond the scope of this review to list all currently identified receptor proteins. However, prototypical examples are used to illustrate important pharmacodynamic principles.

Guanine Nucleotide (G) Protein-Coupled Receptors

One of the most common methods by which membrane receptors translate agonist occupancy into intracellular "action" is via intermediary G proteins. As a result, G protein-coupled receptors are the most abundant type of receptor known to date. The overall structure of G protein- coupled receptors is shown schematically in Figure 2-29 . Two-dimensional representation of G protein-coupled receptors reveals an extracellular amino terminus containing glycosylation sites, an intracellular carboxyl terminus, a fatty acid attachment (usually via palmitoylation or myristoylation) of a carboxyl terminal cysteine residue, three extracellular loops, and four intracellular loops. Major sites of G protein interactions with the receptor occur in the third and fourth (and to a lesser extent second) intracellular loops, whereas major sites of phosphorylation (important in desensitization, or dampening of receptor responses) generally occur in the third intracellular loop and carboxyl terminus.

Although a two-dimensional schematic is shown in Figure 2-29 , it is important to remember that G protein-coupled receptors are three-dimensional structures with transmembrane segments coalescing around a central binding pocket (Fig. 2-30) (Figure Not Available) . [10] Although transmembrane amino acids must be hydrophobic overall (in order to be energetically favored in the lipid membrane), side chains on individual amino acids may be charged. Specific amino acids therefore act as counterions to anchor charged (water-soluble) hormone or

Figure 2-29 Schematic of G protein-coupled receptors. A twodimensional version of receptor structure is shown with seven transmembrane domains, an extracellular amino (NH_2) terminus (with associated glycosylation sites [Y]), an intracellular carboxyl (COOH) terminus, palmitoylated cysteine residue (denoted by crooked line extending into membrane), three extracellular loops, and four intracellular loops. Major sites of G protein interactions with the receptor are speckled; potential sites of phosphorylation in the third intracellular loop and carboxyl terminus are enclosed in boxes.

Figure 2-30 (Figure Not Available) Schematic of the three dimensional structure of the beta $_2$ -adrenergic receptor (a prototypical G protein-coupled receptor), looking from the outside of the cell inward. Transmembrane domains (denoted by cylinders and numbered with Roman numerals) coalesce to form a binding pocket. The correct orientation of the agonist norepinephrine is shown. Note that agonist affinity is determined by specific amino acids located in transmembranes III, IV, and VII. These critical sites in transmembrane domains have been determined experimentally using chimeric receptor and mutagenesis approaches combined with sophisticated computer modeling techniques. Ultimate confirmation of these structures will require crystallographic data; this is currently being attempted by several laboratories. *(From Stapelfeldt [10])*

drug to the receptor. Therefore, structure-activity relationships between drug and the three-dimensional configuration of the receptor binding site are critically important. Although perhaps obvious, the chemical structure of a drug must match the three-dimensional configuration of the binding area of a receptor. Hence, subtle changes in drug structure may dramatically alter the ability of a drug to bind to a specific receptor population. In addition, two drugs with seemingly unrelated two-dimensional chemical structures may bind to the same receptor if their three-dimensional structures and charged areas are similar.

Ion Channels

In addition to membrane receptors, pharmacologic agents act on other excitable cell-membrane proteins, such as ion channels. These channels mediate neural signaling by modulating ion permeability in electrically excitable membranes. Because many drugs act directly or indirectly through ion channels, it is important for the anesthesiologist to understand their general function. Classic ion channels such as the sodium channel have charged regions that span the cell membrane. The formation of ion pairs between many positive and negative charges helps to stabilize the channel in the membrane. Voltage-dependent gating of the sodium channel is made possible by the presence of a voltage sensor--a collection of charges that moves under the influence of the cell-membrane electrical field, hence the name voltage-gated ion channels. During depolarization, these charges presumably move outward, causing conformational changes and rearrangement of ion pairs that result in sodium permeability. Blockade of sodium channels by local anesthetics is a major mechanism underlying pain insensibility. This concept is discussed in more detail in Chapter 13 .

In addition to classic voltage-gated ion channels, many drugs in anesthesiology act via ligand-gated ion channels. Both the nicotinic acetylcholine receptor and the $GABA_A$ receptor are receptor-ion channel complexes. The combination of a classic receptor protein plus an ion channel results in a ligand-gated ion channel, giving rise to the unique ability of certain drugs to alter membrane permeability to ions directly. This coupling is revealed in the physical structure of the receptor itself (Fig. 2-31) (Figure Not Available) . [11] [12] Whereas membrane receptors have hydrophobic transmembrane regions, and ion channels have a central charged transmembrane region, ligand-gated ion channels have both hydrophobic and central charged transmembrane regions. It is interesting to note that the binding of drugs to receptors in ligand-gated ion channel complexes usually enhances or dampens an already existing neurotransmitter ion flux. For example, the neurotransmitter GABA binds to its receptor within the $GABA_A$ ligand-gated ion channel complex and causes the movement of chloride ions intracellularly; this action results in lowered membrane potential, a hallmark of inhibitory neurotransmission. Drugs binding to other receptor sites in the GABA $_A$ ligand-gated ion channel (e.g., benzodiazepines, barbiturates, alcohols) facilitate the action of endogenous GABA. This process results in increased inhibitory chloride ion flux in the CNS (see Fig. 2-31) (Figure Not Available) .

Ion Pumps

Another type of excitable membrane protein is the ion pump. The sodium-potassium-adenosine triphosphatase (ATPase) pump is perhaps the most familiar ion pump to the anesthesiologist because it is inhibited by the drug digitalis. Extracellular fluid is high in sodium and low in potassium, whereas intracellular fluid is high in potassium and low in sodium. Action potentials activate sodium channels, allowing sodium to rush intracellularly. The sodium-potassium-ATPase pump then rapidly pumps sodium out of the cell in exchange for potassium, returning the cell to its original cation composition and electrical gradient. Drugs that act on ion pumps therefore alter intracellular/extracellular cation ratios, resulting in altered membrane electrical potential. This action accounts for some drug effects.

For example, the mechanism of action of digitalis is inhibition of sodium-potassium-ATPase pump function. This is of special importance in the myocardial cell, where sodium-potassium-ATPase exchange is replaced by slower sodium-calcium exchange, thereby increasing intracellular calcium concentrations. Because calcium increases myocardial contractility, improved myocardial pump function results. This is the basis of digitalis use in the treatment of congestive heart failure.

Second Messengers

The binding of a hormone or drug to its receptor does not instantly produce clinical effects. Instead, a series of rapid biochemical events couples receptor binding to ultimate clinical effects. These biochemical events are called second messengers. Because alterations in second messenger coupling can alter the effectiveness of a drug, it is important

Figure 2-31 (Figure Not Available) Schematic of the gamma-aminobutyric acid (GABA)-benzodiazepine receptor complex (a prototypical ligand-gated ion channel complex). Binding of benzodiazepine agonists to the $GABA_A$ ligand-gated ion channel facilitates the action of endogenous GABA. This results in increased inhibitory chloride ion flux in the central nervous system. (A) Schematic of the $GABA_A$ ligand-gated ion channel complex showing receptor sites for benzodiazepines and GABA, as well as distinct receptor sites for barbiturates and alcohol. *(From Berkowitz, [11] with permission)* (B) Model of the $GABA_A$ receptor-chloride ion channel protein complex composed of a heterooligomer of five subunits, including alpha, beta, and gamma, as well as delta or rho polypeptides. Each subunit has four putative membrane-spanning domains (numbered 1-4, represented by cylinders). *(From Firestone et al [12])*

that the anesthesiologist understand the general principles of second messenger action.

Many membrane receptors couple to their primary second messenger via G proteins, which are intermediate regulatory molecules. The coupling of G proteins to receptor-hormone complexes requires energy in the form of guanosine triphosphate (GTP). Once the receptor interacts with the G protein, the biochemical reaction in the effector cascade is triggered. There are stimulating (e.g., Gs, Gq) and inhibitory (e.g., Gi, Go) G proteins, and the physiologic effect is determined by the specific G protein and subsequent cellular response. G proteins are heterotrimeric, composed of three subunits--alpha, beta, and gamma. Receptor-G protein interactions result in dissociation of the G protein subunits into alpha and betagamma. The alpha subunit of most G proteins confers specificity between receptor and effectors. Although betagamma subunits were originally thought simply to anchor G proteins to the cell membrane, it is now clear that dissociated

betagamma subunits are capable of directly stimulating second messengers. In addition, betagamma subunits play a role in anchoring regulatory kinases to the cell membrane, leading to enhanced phosphorylation of membrane receptors.

Several receptor second messenger systems produce biologic effects in humans. One of the best understood second messenger systems is the adenylyl cyclase system. In this system, stimulatory G protein-receptor-hormone complexes increase activity of the enzyme adenylyl cyclase, resulting in increased levels of cyclic adenosine 3
,5
-monophosphate (cAMP) in the cell (Fig. 2-32) . Inhibitory G protein-receptor-hormone complexes decrease the activity of adenylyl cyclase, thus resulting in decreased levels of cellular cAMP. In general, increased levels of intracellular cAMP activate protein kinases that phosphorylate various proteins, ion channels, and second messenger enzymes. For example, beta-adrenergic receptor stimulation results in stimulation of adenylyl cyclase activity, increasing production of intracellular cAMP, which activates protein kinase A, which, in turn, phosphorylates the L-type calcium channel in myocardium to produce increases in intracellular calcium,

ultimately leading to increased inotropy. Examples of drugs or hormones that activate adenylyl cyclase include glucagon and histamine. In contrast, muscarinic (M_2, M_4) agonists, alpha$_2$-adrenergic agonists, and adenosine generally inhibit adenylyl cyclase.

Another example of a second messenger system is the phosphatidylinositol system. Here, hydrolysis of phospha-tidylinositol-4,5-bisphosphate (PIP_2) in the cell membrane, catalyzed by Gq activation of phospholipase C, generates two second messenger molecules, inositol-1,4,5-trisphosphate (IP_3) and 1,2-diacylglycerol (DAG). IP_3 then mobilizes intracellular calcium from nonmitochondrial intracellular stores by interacting with distinct IP_3 receptors on the surface of these organelles. The resulting increase in intracellular calcium levels produces biologic effects such as smooth muscle contraction. Examples of drugs that mediate phosphatidylinositol hydrolysis include alpha$_1$-adrenergic, endothelin, and muscarinic (M_1, M_3, M_5) agonists.

Stimulation of receptors and second messengers ultimately leads to physiologic effects in a given tissue. The specific physiologic effects produced depend on the presence of specific receptor subtypes, G proteins, and second messen-gers within that tissue. An example of the wide-ranging cardiovascular

Figure 2-32 Schematic of the beta-adrenergic receptor signal transduction cascade. betaAR, beta-adrenergic receptor; Gsalpha, alpha subunit of the stimulatory G protein (Gs); betagamma, stimulatory G protein betagamma subunit; ATP, adenosine triphosphate; cAMP, cyclic adenosine monophosphate.

Figure 2-33 Adrenergic receptor subtype physiology. HR, heart rate; NE, norepinephrine.

effects produced by a single hormone-- norepinephrine, the predominant sympathetic neurotransmitter-- can be seen in Figure 2-33. Effects of sympathetic stimulation vary according to tissue. For example, acute effects of beta$_2$-adrenergic receptor-mediated vasodilation enhance skeletal muscle blood flow, beta-adrenergic receptor-mediated inotropic effects improve myocardial performance, and adrenergic effects in the CNS result in enhanced alertness; all these effects enable effective performance during stressful situations. Chronic stimulation of stress responses, however, leads to other adrenergically mediated effects, some maladaptive, such as alpha$_1$-adrenergic receptor-mediated hypertrophy, hypertension, and dampening of myocardial function.

Developments in Molecular Pharmacology

The field of molecular pharmacology is rapidly advancing understanding of excitable membrane proteins and their mechanisms of action. Prior to the advent of molecular biology, most pharmacology research utilized ligand binding and protein purification techniques to elucidate the structure and mechanism of action of various drugs and receptors. Although important, these studies were tedious because tissues contain more than one receptor subtype, and protein purification of receptors to homogeneity is a lengthy and complicated process. Molecular biology techniques provide a unique opportunity to study receptors and their structure at the DNA level. Many receptors and receptor subtypes have been discovered, paving the way for more receptor-specific pharmacologic agents. Future drugs for perioperative use will likely target receptor and receptor subtypes discovered using molecular approaches. For this reason, the general field of molecular pharmacology is briefly described.

Molecular pharmacology takes advantage of the finding that all proteins, including excitable membrane proteins, are encoded in the human genome as nucleic acids. Every amino acid present in a protein is encoded by a specific combination of three nucleotides in DNA. Therefore, if the DNA sequence that encodes a receptor protein can be determined, then the putative primary structure of the receptor can be deduced. In addition, these fragments of DNA (genes) can be inserted into special cells that will express (manufacture, assemble, and deliver to the appropriate location

in the cell) receptor protein in high quantity. This has several advantages.

First, studies on the receptor itself can be performed. By changing (mutating) nucleotide sequences, an abnormal (synthetic or "designer") receptor can be created. This abnormal receptor can then be compared with the original receptor to see whether the changes made affect binding of drug to the receptor or its coupling to second messengers. In this manner, precise portions of the receptor responsible for drug binding and/or second messenger coupling can be elucidated. This type of information is often called structure-activity relationships. G proteins and second messengers can be investigated in a similar manner.

The second advantage of using molecular techniques in pharmacology includes potential discovery of new receptors and receptor subtypes by searching for DNA sequences similar to those of known receptors. Once these new receptors are discovered, they can be easily characterized, because high expression in cells enables them to be screened by various pharmacologic agents.

Finally, and perhaps the most immediately clinically relevant, new investigational drugs can be rapidly screened for effects on various receptors. In this way, pharmacologic effects of individual receptors can be studied in a controlled manner, isolated from other receptors and receptor subtypes. Such studies have the potential to lead to development of new drugs for use in the perioperative period.

In addition to studying individual receptors expressed in cells, molecular pharmacology now includes creation and study of whole animals (usually mice) with altered physiologic features using transgenic and knock-out technology. In simplistic terms, transgenic animals overexpress a specific gene, whereas knock-out animals are missing a targeted gene. The physiologic consequence of such altered protein expression is then examined. Details of these technologies are beyond the scope of this chapter. The reading list at the end of this chapter includes several excellent reviews of the subject.

In order to interpret data from transgenic and knock-out animals correctly, it is important to consider several potential limitations of this technology. First, the genetic background of animals created should be carefully examined. If not carefully controlled, altered phenotypes may result from differences in animal "strain" (or genetic background), rather than from an overexpressed or knocked-out gene product. Second, elimination of specific receptors may be compensated for by alterations of other gene products. In this case, the final phenotype represents the net alteration of several genes; this is of particular concern when elimination of a gene is lethal because surviving progeny by definition have compensated in a way that enhances survival and therefore may not be representative of the results of a single gene knock-out. Finally, some receptors and proteins have different tissue localization in humans versus other animal species. Therefore, results from transgenic and knock-out animal studies should be interpreted cautiously in this circumstance lest incorrect conclusions be drawn regarding implications for human physiology.

In spite of these potential limitations, transgenic and knock-out animal models have proved very important in elucidating novel functions of receptors and proteins. Many unexpected physiologic roles for gene products have been discovered, and important physiologic questions have been answered and confirmed using these approaches. As an example, Table 2-1 lists conclusions drawn from transgenic and knock-out mice based on alterations of adrenergic receptors

TABLE 2-1 -- Summary of Results From Knockout and Transgenic Mice Illustrating Adrenergic Receptor Signaling Pathways

MODEL	TARGET	RESULT
Transgenic	beta$_2$ AR	basal AC, LV fn, atrial contractility, supraventricular premature beats, HR variability
Knock-out	beta$_1$ AR	70% prenatal death, survivors: nl AC, ISO-stim

Transgenic	GRK2	AC activity, fn betaARs, ISO-stim
Transgenic	GRK5	Enhanced betaAR desens, but not AngII desens
Transgenic	GRK2 inhib (net: GRK2)	Enhanced cardiac contractility with ISO
Knock-out	GRK2	Lethal phenotype, gestational hyperplasia LV, LVEF <70% in embryos
Transgenic	Gs	No Delta baseline EF, ISO-stim, myocardial fibrosis
Knock-out	phospholamban	betaAR-mediated contractile responses
Transgenic	$alpha_{1b}$ AR (*)	Myocardial hypertrophy
Transgenic	$alpha_{1b}$ AR (WT)	No myocardial hypertrophy
Transgenic	Gq	Myocardial hypertrophy 4-fold overexpression, higher expression gives heart failure
Transgenic	Gq inhib (net: Gq)	Prevention of myocardial hypertrophy
Knock-out	$alpha_{2a}$ AR	Presynaptic $alpha_2$ AR, mediates sedation/hypnosis, BP (central hypotension), analgesia, regulation of DA/5-HT, antiepileptogenic effects of NE
Knock-out	$alpha_{2b}$ AR	Mediates BP (peripheral vasoconstriction)
Knock-out	$alpha_{2c}$ AR	Mediates hypothermia, DA synthesis/metabolism

and their signal transduction cascade. Novel functions for specific adrenergic receptor subtypes (e.g., the role of alpha $_{2c}$ -adrenergic receptors in temperature control, $alpha_{2b}$ -adrenergic receptors in mediating vasoconstriction, and alpha $_{2a}$ -adrenergic receptors in sedation and CNS-mediated hypotension) have been discovered. Furthermore, Table 2-1 illustrates that alterations in adrenergic receptor signal transduction pathways and modulating kinases have physiologic consequences in the whole animal.

Clinical Evaluation of Drug Effects

General Principles

Once pharmacologic agents have stimulated excitable cell-membrane proteins and have produced a physiologic effect, it is important to evaluate this effect clinically. This section focuses on methods of evaluating drug effects such as dose-response curves, efficacy, potency, the median effective dose (ED $_{50}$), the median lethal dose (LD_{50}), and the therapeutic index.

Concentration Versus Response Relationships

The standard comparison of a drug with its clinical effect is the concentration versus response curve, shown in Figure 2-34 . The relationship shown is the time-independent relationship between dose, concentration, or some other measure of exposure to the drug (X axis) and the measured effect

Figure 2-34 Dose-response relationships. A sigmoidal dose-response curve is generated when the log drug concentration is plotted against the clinical response or effect (curve A). The dose-response curve is shifted to the right in the presence of a competitive antagonist or when it is generated by another agonist with lower receptor affinity (K $_{a}$) and/or potency (curves B and C). Of note, desensitization also results in a shift of the doseresponse curve to the curve to the right.

(Y axis). The measured effect can be an absolute response (e.g., twitch height), a normalized response (e.g., percentage of twitch height depression), or a population response (e.g., fraction of subjects moving at incision). The standard equation for this relationship is the "Hill" equation, sometimes called the "sigmoid-E $_{max}$ relationship":

This is another example of the saturation equation shown in Figure 2-5 . In equation 44, E_0 is the baseline effect in the absence of drug, and E $_{max}$ is the maximum possible drug effect. C is typically concentration or dose, although other measures of drug exposure (e.g., AUC) can be used. C $_{50}$ is the concentration associated with 50 percent of peak drug effect and is a measure of drug potency. The exponent gamma relates to the sigmoidicity and steepness of the curve. If gamma = 1, and the curve is plotted on a standard X axis, then the curve appears hyperbolic (see Fig. 2-5). If gamma is greater than 1, then the curve appears sigmoidal, as in Figure 2-34 . If the X axis is plotted on a log scale, then the curve will always appear sigmoidal, regardless of the value of gamma.

Effect of Receptor Agonists and Antagonists on Dose-Response Relationships

Dose-response relationships can be modified by both agonists and antagonists. If two agonists have identical affinity (K $_{a}$) for a given receptor and identical effectiveness in coupling to second messengers, their resultant dose-response curves should be superimposable. However, if two agonists have different receptor affinities, in spite of identical effectiveness in coupling to second messengers, then their dose-response curves will be parallel (with the rightward shifted curve corresponding to the drug with lower receptor affinity; see Fig. 2-34 , curves B and C). When two agonists are administered simultaneously, one could predict that the

clinical effect would be dependent on the total amount of drug-receptor complexes generated; note that this implies a direct linear relationship between receptor-drug complex and measured effect. However, this is not always the case in biologic systems. For example, in neuromuscular transmission, measured change in effect on twitch height is not linear when receptor occupancy declines from 100 to 90 percent, as compared with the change from 80 to 70 percent occupancy. A further distinction between agonist effect is based on achievement of the maximum measured pharmacologic response or effect.

As stated earlier, full agonists produce maximal responses, whereas partial agonists produce less than maximal response at the same receptor occupancy. The precise molecular mechanism that explains this blunting of the maximal response by partial agonists is not known, but it may relate to the ability of full agonists to stabilize R* most effectively. Finally, the addition of a competitive antagonist shifts the dose-response curve to the right (higher agonist concentration is required to achieve effect; see Fig. 2-34 , curves B and C). The dose-response curve generated by the addition

of an agonist in the presence of a noncompetitive antagonist fails to demonstrate attainment of maximal response at any dose because blockade of effect (antagonism) cannot be reversed.

Effective Dose and Lethal Dose

The ED_{50} is the dose of a drug required to produce a specific effect in 50 percent of individuals to whom it is administered. The LD_{50} is the dose of a drug required to produce death in 50 percent of patients (or, more often, animals) to whom it is administered. The therapeutic index of a drug is the ratio between the LD_{50} and the ED_{50} (LD_{50}/ED_{50}). Hence, the higher the therapeutic index of a drug, the safer the drug is for clinical administration because the LD_{50} is far higher than the ED_{50}. The relationship among ED_{50}, LD_{50}, and therapeutic index is shown in Figure 2-35 .

Efficacy and Potency

Efficacy is a measure of the intrinsic ability of a drug to produce a given physiologic or clinical effect. Efficacy is influenced by receptor coupling to G proteins, activation of second messengers, and the ability to generate ultimate physiologic responses. The scale used to describe intrinsic efficacy at a given receptor ranges from 0 to 1. Efficacy for full agonists is 1.0, for neutral antagonists is 0, and for partial

Figure 2-35 Relationship between median effective dose (ED_{50}), median lethal dose (LD_{50}), and therapeutic index. These curves were generated from data in which animals were injected with varying doses of a sedative-hypnotic and clinical responses determined. ED_{50} is the dose of drug required to produce a specific effect (hypnosis) in 50 percent of animals to which it is administered (left curve). LD_{50} is the dose of drug required to produce death in 50 percent of animals to which drug is administered (right curve). The therapeutic index of the drug is the ratio between LD_{50} and ED_{50} (LD_{50}/ED_{50}).

agonists ranges between 0 and 1.0. In contrast, the term *potency* refers to the quantity of drug that must be administered to produce a specific effect. Two drugs may have the same efficacy, but if one drug produces the maximum effect at 1 mg while the second drug produces the maximum effect only at 100 mg, then the second drug is less potent. Figures 2-34 and 2-36 demonstrate the relationship among efficacy, potency, and the dose-response curve.

Desensitization

Desensitization is broadly defined as waning of physiologic responsiveness to a drug over time. In the perioperative period, acute desensitization of vasodilator responses to nitroprusside occurs; therefore, in order to achieve desired vasodilation, it is often necessary to increase the concentration of nitroprusside infusion over time. In general, stimulation of receptor pathways results in activation of kinases (e.g., protein kinase A, G protein-coupled receptor kinases, protein kinase C) that phosphorylate specific regions of the receptor, thus preventing further interaction of the receptor with G proteins and/or second messengers. Thus, desensitization provides a negative-feedback mechanism to receptor stimulation. Although desensitization was initially thought to occur only at the receptor level, it is now well recognized that alterations of G proteins and second messengers also occurs in response to agonist stimulation. Effectively, desensitization shifts the dose-response curve to the right (see Fig. 2-34 , curves B or C compared with curve A) and/or decreases maximal drug effect; hence, both efficacy and potency can be diminished by desensitization.

Desensitization of receptor responses is a feature of many diseases present in the aging population and therefore is relevant to consider during the perioperative period. Common diseases in which desensitization is important include

Figure 2-36 Relationship among efficacy, potency, and individual variability is shown as they relate to a typical sigmoidal dose-response curve.

congestive heart failure, hypertension, and diabetes; a hallmark of each of these diseases is elevation of hormone (agonist) concentrations. In the case of congestive heart failure, poor cardiac output induces compensatory sympathetic nervous system stimulation, resulting in a doubling of circulating catecholamine concentrations (specifically norepinephrine). On a long-term basis, this results in desensitization of the myocardial beta-adrenergic receptor signal transduc-tion pathway; specifically, $beta_1$-adrenergic receptor density and function decreases (
75%) with relative sparing of $beta_2$-adrenergic receptors (
25%). Gi levels also increase without change in Gs. Furthermore, G protein-coupled receptor kinase concentrations increase and modulation of adenylyl cyclase isoforms occurs. Physiologic effects of changes important in desensitization of myocardial beta- adrenergic receptors have been examined using transgenic and knock-out mice (see Table 2-1 and the earlier discussion of molecular pharmacology). In order to break the cycle of elevated agonist exposure and resultant desensitization, long-term low-dose beta-adrenergic receptor antagonists (
1/10 the usual dose for hypertension or myocardial ischemia) are now cautiously utilized by cardiologists in patients with congestive heart failure; this therapy has been shown to improve functional classification and longevity.

Increased Receptor Sensitivity

The opposite of desensitization is increased receptor sensitivity. Long-term exposure to a drug often results in compensatory responses by the receptor system. For example, when a receptor antagonist is administered on a long-term basis, receptor number (density) often increases. If the receptor antagonist is suddenly discontinued, exaggerated responsiveness to agonist may occur. This is the rationale for continuing long-term beta-adrenergic receptor antagonists during the perioperative period. Abrupt discontinuation of these drugs leaves the myocardium vulnerable to exaggerated heart rate and inotropic responses to routine procedures such as tracheal intubation, potentially leading to myocardial ischemia and infarction. Therefore, careful consideration should be given prior to discontinuing a long-term medication before surgery.

Biologic Variability

Individual variation in response to an identical dose of administered drug is a phenomenon observed daily by the anesthesiologist. Individual variation in response to a drug can occur as a result of differences in pharmacokinetic parameters such as absorption, distribution, metabolism, and excretion of a drug. Individual variation can also be due to differences in pharmacodynamic parameters. In this circumstance, an identical number of drug molecules present at an effector site produces different responses in different patients. The relationship between patient variability and a typical dose-response curve is shown in Figure 2-36 . In addition to

desensitization (discussed earlier), factors that affect pharmacodynamic responses include age, genetic variability, and concurrent diseases.

Age

Although important age-related pharmacokinetic differences have been investigated in detail, there is a paucity of data addressing pharmacodynamic differences among age groups. Overall, the presence or absence of age-related pharmacodynamic differences appears to depend on the drug. For example, both antiepileptic agents and digoxin have been examined in adults and children, and the effective plasma concentration is the same. This finding suggests that for these two types of drugs, no age-related differences in pharmacodynamic responses occur. However many drugs with CNS effects (e.g., benzodiazepines, opioids, propofol) appear to be intrinsically more potent in the elderly. In other words, the concentration associated with a given level of drug effect is reduced in elderly subjects. Pharmacodynamic models have quantified the influence of age on the potency of anesthetic drugs. Present research is now directed toward understanding the biologic basis of increased sensitivity in the elderly to anesthetic drugs.

Genetic Variability

Genetic variability also can affect pharmacodynamic parameters. If a receptor or second messenger is defective or hyperactive, then pharmacodynamic alterations in drug effect will be noted. The most striking example of genetic variability resulting in pharmacodynamic differences in anesthesia is the disease *malignant hyperthermia.* Malignant hyperthermia is manifested in approximately 1 in 20,000 anesthetic regimens. Various anesthetics, especially halothane, seem to trigger an abnormal hypermetabolic response that results in an uncontrolled rise in body temperature, muscle rigidity, metabolic acidosis, hyperkalemia, and hypercapnia. Although the exact cause of malignant hyperthermia is unknown, it appears to be related to abnormal calcium release and uptake by the sarcoplasmic reticulum within cells. Because the disease does not influence the uptake and distribution of drug, but is manifest once the drug interacts at the cellular level, it represents a classic genetic pharmacodynamic abnormality.

Disease States

Various diseases contribute to variation in drug response. Although diseases frequently result in pharmacokinetic variations (e.g., decreased perfusion in heart failure or decreased elimination in renal failure), pharmacodynamic variation is also observed. Diseases such as diabetes, thyroid disease, adrenal disease, myasthenia gravis, and hypertension alter receptor function and therefore represent pharmacodynamic effects. Alteration of receptor function resulting from elevated agonist concentration is described earlier in the desensitization section. In addition to desensitization, other changes can occur at receptors that result in diminished function. For example, in patients with myasthenia gravis, antibodies to the postsynaptic nicotinic acetylcholine receptor effectively decrease the number of receptors pres-ent. Muscle weakness characterizes the disease. As a result, these patients are exquisitely sensitive to muscle relaxants,

---

which act via the nicotinic acetylcholine receptor. Clinically, muscle relaxant dose must be decreased or these drugs must be eliminated in this patient population.

Summary

This chapter reviews general pharmacology by examining basic principles of pharmacokinetics and pharmacodynamics. Careful consideration of these principles should permit the anesthesiologist to understand drug movement from the site of administration through various body compartments to the site of action, and the mechanisms by which drugs act on receptors to bring about the desired clinical effect. Many factors may alter the pharmacokinetic and pharmacodynamic processes by which drugs exert their effects, including age, disease, and concurrent drug therapy. Understanding the basic pharmacologic processes, and how these may be altered in individual patients, should facilitate drug titration for each patient. There is a biologic basis for finding just the right drug, in just the right dose, to provide safe and effective patient care.

Chapter 3 - Mechanisms of Action

Donald D. Koblin

/das/book/view/29494766/875/23.html

INTRODUCTION

Although currently popular inhaled anesthetics include nitrous oxide, isoflurane, and sevoflurane, a far greater variety of inhaled agents can produce anesthesia (Fig. 3-1) . The properties of these anesthetics vary considerably. For example, cyclopropane and diethyl ether are no longer used because of their explosiveness and flammability. Halothane is nonflammable but possesses a permanent dipole moment, can form hydrogen bonds, and is metabolized by the liver. Xenon, an anesthetic more potent than nitrous oxide in humans, [1] is essentially inert and undergoes no known transformation in the body. The molecular size of inhaled anesthetics may differ by a factor of about 10.

The structural diversity of the inhaled anesthetics suggests that they all do not interact directly with a single specific receptor site. However, some correlations of the potencies of anesthetics with their physicochemical properties do suggest a common (unitary) mechanism of general anesthetic action. An example is the striking (albeit imperfect) relationship between anesthetic potency and lipid solubility (see *Physicochemical Nature of the Site of Anesthetic Action*). Although such correlations do not provide a detailed mechanism of anesthesia, they have been helpful in defining the environment in which anesthetics act.

Any molecular hypothesis of anesthesia must explain the effects of anesthetics on the whole organism. For instance, because anesthetic administration can rapidly induce unconsciousness, and awakening can quickly occur following the discontinuation of anesthesia, physical or biochemical changes important to the mechanism of anesthesia must occur within seconds. Similarly, physical or biochemical alterations

Figure 3-1 Chemical structures of various inhaled anesthetics. Anesthetics with asymmetric carbon atoms [indicated by (*)] are mixtures of the optical isomers.

caused by anesthetics are meaningful only at clinical doses and physiologic temperatures and not at high anesthetic levels. [2] High levels may produce toxic effects unrelated to the mechanism by which inhaled anesthetics act. Furthermore, anesthetic requirement does not change [3] (or only decreases slightly [4]) with increasing duration of anesthesia. Thus, any physical or biochemical change causally related to anesthesia should be stable for a period of hours or days.

Finally, the mechanism(s) by which inhaled anesthetics act may overlap the mechanism(s) of action of intravenous anesthetics (Chs. 8 - 10), local anesthetics (Ch. 13) , and even of alcohols. [5] This chapter considers only the inhaled agents.

MEASUREMENT OF ANESTHETIC POTENCIES

An exploration of the mechanism by which anesthetics act requires a knowledge of relative anesthetic potencies for each of the agents. The best estimate of anesthetic potency is the minimum alveolar concentration (MAC) (at 1 atm) of an agent that produces immobility in 50 percent of those subjects exposed to a noxious stimulus. [6] For determination of MAC in humans, the stimulus is a surgical skin incision. (Variations on the MAC concept may be used to estimate the potency of other anesthetic end points. For example, lack of response to verbal command [MAC awake] occurs at lower anesthetic concentrations, and lack of response to endotracheal intubation [MAC intubation] occurs at higher anesthetic concentrations than those needed to prevent movement to surgical skin incision [Ch. 29]). In animals, the noxious stimulus is usually produced by clamping the tail or by passing electrical current through subcutaneous electrodes. The advantage of measuring the alveolar concentration is that after a short period of equilibration, this concentration directly represents the partial pressure of anesthetic in the central nervous system (CNS) and is independent of the uptake and distribution of the agent to other tissues (Chs. 4 and 29) . Another advantage of MAC is its consistency for a given animal or species or between different species or classes of animals. [6] [7] This consistency makes it possible to discern small changes in anesthetic requirement, which may give a clue as to how anesthetics act.

The anesthetic concentration that abolishes the righting reflex in 50 percent of the animals is often used to measure anesthetic potencies in smaller animals, that is, it is an anesthetic 50 percent effective dose (ED_{50}). Because the inspired rather than the alveolar concentrations are measured, the method applies best to rapidly equilibrating (poorly blood-soluble) agents. Only with equilibration can it be assumed that the partial pressure of the inspired gas equals that at the site of action. The use of small animals and inspired concentrations facilitates work with agents at very high pressures (i.e., tens or hundreds of atmospheres). The anesthetic ED_{50} in the mouse, as determined by the rolling response (i.e., the righting reflex), correlates closely with MAC in humans over a 500-fold change in anesthetic requirements (Fig. 3-2) .

It must be noted, however, that the tail-clamp ED_{50} (MAC) and the righting-reflex ED_{50} are not identical. The

Figure 3-2 A close correlation exists between the MAC of various anesthetics, preventing a response to surgical incision in humans and the inspired dose of an anesthetic (ED_{50}) required to abolish the righting reflex in the mouse. *(Data from references [6] and [5])*

tail-clamp ED_{50} is higher than the righting-reflex ED_{50} , and the ratio of these measurements averages approximately 1.8 (Table 3-1) [8] [9] [10] . This ratio varies slightly with the anesthetic examined, implying that the righting reflex is depressed, at least in part, by a different mechanism from that which depresses the response to application of a tail clamp. [8] [9] [10] Thus, the absolute and relative potencies of inhaled anesthetics depend on the end point measured. [11]

ALTERATIONS IN ANESTHETIC REQUIREMENT PERTINENT TO THEORIES OF NARCOSIS

Effects of Temperature

In mammals, MAC decreases with decreasing body temperatures for all anesthetics, but the reduction (
2-5%) per degree decrease in body temperature varies slightly from agent to agent. [6] [12] Although the gas phase potencies of inhaled

Diethyl ether	--	1.25

Data from Deady et al, [8] Koblin et al, [9] and Kissin et al [10]

agents increase with decreasing temperature, there is an associated increase in anesthetic solubility with a decrease in temperature so that the aqueous phase potencies remain relatively constant with changes in temperature (Fig. 3-3) (Figure Not Available) . [13] For *in vitro* experiments involving clinical volatile anesthetics, aqueous concentrations equivalent to 1 MAC range from
200 to 600 mum. [13]

Effects of Pressure

The exposure of whole organisms to increasing hydrostatic pressures often increases the anesthetic dose required to bring about unresponsiveness, a phenomenon termed the *pressure reversal of anesthesia.* [14] In experiments with mammals, pressure is increased by the addition of helium because helium does not produce anesthesia and possesses little or no inherent anesthetic effect at high pressures. At a total pressure of 100 atm, a 30 to 60 percent increase in the partial pressure of inhaled anesthetics is required to abolish the righting reflex in the mouse. [15] However, not all species exhibit a pressure reversal of anesthesia. The reduction in swimming activity of freshwater shrimp induced by halothane, chloroform, and diethyl ether is not reversed by the application of high pressure. [16] It remains debatable whether pressure reversal represents a specific antagonism at the site of anesthetic action or is simply a generalized phenomenon that counteracts a global depression produced by anesthetics.

Effects of Age

In humans, MACs of volatile agents are maximal in infants at approximately 6 months of age (Fig. 3-4) . MAC gradually decreases with increasing age, and MAC in the octogenarian is approximately one-half that in the infant. The increase in potency (decrease in MAC) with increasing age is seen for all inhaled anesthetics and averages
6 percent change per decade of age. [17] Thus, the greater susceptibility of older patients to CNS depression by inhaled anesthetics is not related to the absolute potency of the agent. Animal models may be useful for studying the mechanisms of change in anesthetic potency with age because comparison of mice and humans over similar life-spans shows the decrease in anesthetic requirement of mice to parallel that clinically seen in humans (see Fig. 3-4) .

Effects of Ion Concentrations

Hypernatremia increases sodium proportionately in cerebrospinal fluid (CSF) and increases halothane MAC in dogs by as much as 43 percent. [6] Conversely, hyponatremia dilutes cerebrospinal fluid sodium and reduces halothane MAC. [6]

Hyperkalemia in dogs does not alter cerebrospinal fluid potassium or MAC. [6] Furthermore, intracerebroventricular injection of drugs (cromakalim, pinacidil) that enhance flow of ions through potassium channels does not change MAC in rats. [18]

Calcium infusions in dogs increase serum and CSF calcium by 2.6 and 1.3 times, respectively, without influencing halothane MAC. [19] However, calcium entry blockers (at relatively high concentrations) augment the potency of inhaled anesthetics. [20]

A 5-fold increase in serum magnesium is associated with a 12 percent increase in CSF magnesium in dogs and does not alter halothane MAC. [19] In rats, a 10-fold increase in plasma magnesium concentration above control levels decreases halothane MAC by approximately 60 percent. [21]

Alterations in anion concentrations via infusion of hydrochloric acid or sodium bicarbonate have little influence on MAC in spite of marked changes in arterial pH. [6] However, intrathecal or intracisternal administration of drugs that block chloride ion transport increases the MACs of isoflurane [22] and halothane [23] in rats.

Figure 3-3 (Figure Not Available) Plot of halothane MAC (in dogs) versus temperature. When measured as a function of the gas-phase partial pressure, MAC decreases with decreasing temperature. In contrast, when measured as a function of calculated aqueous concentrations, MAC remains relatively constant with changes in temperature from 28 to 43°C. *(From Franks and Lieb [15])*

Figure 3-4 Age-dependent alterations in halothane requirement (MAC) in humans and nitrous oxide requirement (righting-reflex ED_{50}) in mice over similar life spans. *(Data for halothane in humans are from Lerman et al [Anesthesiology 59: 421, 1983] and Gregory et al [Anesthesiology 30:488, 1969]. Data for nitrous oxide in mice are from Koblin et al [Anesthesiology 58:428, 1983].)*

These effects of temperature, pressure, aging, and ion concentrations may be used to test the various models of anesthetic action. Any valid theory of anesthetic action must account for the influence of these physical and physiologic parameters on anesthetic requirement.

ACTIONS OF INHALED ANESTHETICS IN THE CNS

Brain

Inhaled anesthetics may act by altering neuronal activity in selected regions of the CNS. Because the brain stem reticular formation plays a role in altering the state of consciousness and alertness and in regulating motor activity, it is often suggested that this structure is an important site of anesthetic action. Although the idea that anesthesia results from a decrease in "tone" in the ascending reticular system may be correct, it is most likely an oversimplification. [24] The effect of anesthesia on neuronal activity in the reticular formation is variable and can be increased, unchanged, or decreased, depending on the agent and the neuronal unit examined. [25]

General anesthetics interrupt transmission in the CNS at sites other than the reticular formation. Clinical concentrations of inhaled agents may alter spontaneous and evoked activity inthe mammalian cerebral cortex [26] and hippocampus. [27] Although inhaled anesthetics usually depress excitability of brain neurons, situations can be found in which anesthetics enhance excitability (Fig. 3-5) (Figure Not Available) . [27] In addition, inhibitory transmission may be influenced by volatile agents. For example, halothane prolongs gamma-aminobutyric acid (GABA)-induced inhibition in the hippocampus, [28] and volatile anesthetics may either enhance the amplitude and duration of inhibitory postsynaptic currents [29] or selectively depress inhibitory postsynaptic potentials. [30] Neuronal pathways between various brain regions and consisting of both excitatory and inhibitory components may also be influenced by inhaled agents. The transfer of sensory information from the thalamus to certain cortical regions is thought to be particularly sensitive to anesthetics. [31]

Spinal Cord

Both excitatory and inhibitory neurotransmission in mammalian spinal cord may be altered by inhaled anesthetics. [32] Anesthetic effects depend on the concentration of the agent and on the particular spinal cord pathway examined. Inhaled anesthetics alter responses of the spinal dorsal horn (sensory) to both noxious and nonnoxious stimuli. [32] Volatile anesthetics also depress spinal motor neurons. Clinical inhaled agents depress the F-wave amplitude (a measure of the excitability of spinal motor neurons) in rats [33] and humans. [34] Thus, both a reduction in the sensory processing and an inhibition of motor neuron excitation are likely to be involved in the anesthetic-induced lack of movement in response to a noxious stimulus. In addition to a direct action on the spinal cord, inhaled agents may indirectly influence activity of spinal neurons by altering the tonic input received from descending modulatory systems from the brain. [32] [35]

Sites of CNS Action and Anesthetic End Points

Traditionally, most investigators assumed that surgical anesthesia resulted from a supraspinal event. Although it remains probable that an interaction of inhaled anesthetics with various brain structures is required for the production

Figure 3-5 (Figure Not Available) The effects of halothane (left) and isoflurane (right) on three excitatory synaptic pathways in the rat hippocampal slice. The potential recordings were produced from stimulation of three discrete regions of the hippocampal slice: the stratum radiatum (RAD), the stratum oriens (OR), and perforant path (PP) fibers. Each superimposed series of records shows control (C) responses before (solid line) and after washout (light dotted line) together with two or three concentrations of anesthetic (numbers refer to volume percent). The horizontal calibration bar represents 20 ms and the vertical calibration bar represents 2.0 mV. These studies demonstrate that the ability of inhaled agents to depress or enhance neuronal excitability depends on the anesthetic, the anesthetic concentration, and the particular brain region examined. *(From MacIver and Roth [27])*

of amnesia, the ability of anesthetics to prevent a motor response to noxious stimulation likely results from a site of action in the spinal cord and not in the brain.

A focal cryogenic lesion that destroys much of the left parietal cortex in rats has no influence on halothane MAC in rats. [36] Moreover, isoflurane MAC in rats is not altered by bilateral decerebration (including removal of thalamus and hippocampus [37]) (Fig. 3-6) (Figure Not Available) nor by high thoracic spinal cord transection and functional separation of the rat brain from the spinal cord. [38] The cerebral blood supply of the goat allows for the preferential anesthetization of its forebrain, which results in an isoflurane MAC that is more than twice the value found when anesthetic is administered via the goat's native circulation. [39] This finding in a second species confirms the importance of extracranial structures in anesthesia as defined by MAC.

Thus, if anesthesia is defined as consisting of (at least) two components, amnesia and immobility in response to a noxious stimulus, there must be two separate anatomic sites of inhaled anesthetic action: a supraspinal site involved in the production of amnesia and a spinal site involved in the prevention of movement to noxious stimuli. [40] Given that the human CNS consists of billions of neurons, each having thousands of synapses, the discovery of the exact nature of these sites of anesthetic action presents a formidable challenge. Attempts to reduce this complexity have led to experiments on isolated neuronal preparations.

INTERRUPTION OF NEURONAL TRANSMISSION BY INHALED ANESTHETICS

Peripheral Receptors

The action of inhaled anesthetics cannot be explained by depression of peripheral receptors. Anesthetizing concentrations of clinical agents do not alter cutaneous receptor responses

Figure 3-6 (Figure Not Available) Decerebration does not alter anesthetic requirement, as measured by MAC. Removal of brain tissue rostral to the heavy black line does not alter isoflurane MAC in rats. Thl = thalamus; RN = red nucleus; PAG = periaqueductal gray; RF = reticular formation. *(From Rampil et al [37])*

to touch or movement of hair and can even sensitize and promote excitation of nociceptors in mammalian A and C fibers. [41] Moreover, a selective perfusion technique allowing for minimal (
0.2% atm) isoflurane concentration at the site of peripheral noxious stimulus in dogs while maintaining higher concentrations in the rest of the body results in no change in isoflurane MAC and demonstrates that the peripheral effects of isoflurane do not influence the response to a noxious stimulus. [42]

Highly Sensitive Neurons

From the previous discussion it is apparent that inhaled agents can alter excitability in many different anatomic regions of the brain or spinal cord. However, within each discrete area of the CNS there may exist a relatively small number of neurons that are exquisitely sensitive to anesthetics. The existence of such highly sensitive cells is demonstrated in molluscan ganglia having endogenous firing activity. [43] [44] The firing activity may be completely inhibited in selected neurons at halothane concentrations of
1 MAC (Fig. 3-7) (Figure Not Available) [43] [44] , with other neighboring neurons exhibiting little alteration in neuronal firing activity. There may even exist supersensitive sites in the CNS (i.e., sites that are maximally inhibited at anesthetic concentrations substantially less than MAC) that are related to the anesthetic-induced production of amnesia. [45]

Axonal Versus Synaptic Transmission

Concentrations of inhaled anesthetics that alter synaptic transmission typically have a smaller effect on axonal transmission, with synaptic events being
5-fold more sensitive to inhibition than impulse conduction. [46] Nevertheless, at near-clinical concentrations, inhaled anesthetics may alter transmission through axons, and even a partial decrease in action potential propagation could decrease the amount of neurotransmitter secreted and thereby influence synaptic transmission. That is, an apparent effect at the synapse may simply reflect depression of axonal transmission. Smalldiameter axons may exhibit enhanced susceptibility to inhaled anesthetics. In the rat hippocampus, isoflurane (1.4% atm) depresses the activity of thin (0.16 mum) unmyelinated fibers but has little influence on the larger-diameter (1 mum) myelinated fibers. [47]

The frequency at which axons transmit impulses may alter anesthetic potency. At low-impulse frequencies, volatile anesthetics produce a constant level of action potential block, whereas at relatively high frequencies, conduction block by volatile agents increases progressively. That is, the blockade is use-dependent. [48] The branch points of axons may be particularly sensitive to high-frequency conduction block.

Synapses

Anesthetics may disrupt normal synaptic transmission by interfering with the release of neurotransmitter from the presynaptic nerve terminals into the synaptic cleft by altering the reuptake of neurotransmitter following its release, by changing the binding of neurotransmitter to receptor sites on the postsynaptic membrane, or by influencing the ionic conductance change that follows activation of the postsynaptic receptor by neurotransmitter. [46]

Figure 3-7 (Figure Not Available) Certain molluscan neurons having endogenous firing activity are extremely sensitive to volatile agents. The figure shows a continuous intracellular recording of membrane potential before, during (bar), and after exposure of a sensitive cell to normal saline solution containing halothane at a partial pressure of 0.0080 atm. *(From Franks and Lieb [43])*

Presynaptic Action

A presynaptic site of inhaled anesthetic action may be implied from electrophysiologic recordings that compare postsynaptic potentials obtained via presynaptic stimulation versus those generated with direct application of neurotransmitter. For example, in mouse hippocampal slices, glutamatergic excitatory postsynaptic currents are reduced
50 percent by
1 MAC halothane, whereas halothane (even at concentrations of
5 MAC) has no effect on the currents induced by bath application of glutamatergic agonists. [49]

A presynaptic site of action is also implied from studies that demonstrate an influence of anesthetics on neurotransmitter release. [46] [50] Clinical concentrations of inhaled agents reduce depolarization-evoked release of norepinephrine but not acetylcholine from slices of rat cerebral cortex. [51] In the rat striatum, isoflurane and halothane increase spontaneous dopamine release [52] but decrease nicotine-evoked release of dopamine and have no effect on potassium-induced GABA release. [53] Inhaled agents do not alter basal glutamate release in guinea pig [54] or rat [55] cerebrocortical synaptosomes but are reported to either depress (in the guinea pig [54]) or have no effect on (in the rat [55]) potassium-evoked glutamate release from synaptosomes. Thus, the ability of anesthetics to alter neurotransmitter release depends on the biologic preparation examined, the method employed to evoke neurotransmitter release, the neurotransmitter, and the anesthetic and its concentration.

In addition to an effect on the presynaptic release of neurotransmitters, it is conceivable that inhaled anesthetics may alter the duration of neurotransmitter action by influencing the reuptake of neurotransmitter into the nerve terminal. Halothane and isoflurane inhibit the uptake of choline, [56] 5-hydroxytryptamine, [57] and dopamine [58] (but not GABA [59] [60]) by rat brain synaptosomes in a concentration-dependent manner. An anesthetic-induced increase in the uptake of glutamate [60] [61] has been

speculated to decrease excitatory transmission and contribute to the action of volatile agents.

Postsynaptic Action

Evidence is also available for postsynaptic effects of inhaled anesthetics on both excitatory and inhibitory neurons. Postsynaptic sites of anesthetic action may be studied by application of putative neurotransmitters thought to act directly on postsynaptic membrane receptors. [46] Depending upon the particular neuronal preparation and neurotransmitter examined, anesthetics may depress, have little influence on, or enhance the postsynaptic response. In the lamprey, halothane decreases synaptic response to bath-applied glutamate to the same extent that it decreases the excitatory postsynaptic potential, implying a postsynaptic site of action. [62] Halothane and isoflurane (0.5-2.5 MAC) reduce the depolarizing responses to iontophoretic applications of acetylcholine or glutamate to dendrites in guinea pig neocortical slices, with the acetylcholine response being depressed more than the glutamate response. [63] In contrast, halothane and isoflurane have little or no effect on the response induced by iontophoretic application of GABA to perikaryons in these neocortical slices. [63] In hippocampal neurons [64] and in neurons dissociated from the nucleus tractus solitarius of the rat, [65] volatile anesthetics enhance the currents produced by application of GABA (Fig. 3-8) (Figure Not Available) .

A postsynaptic action is also evident from the ability of clinical concentrations of inhaled agents to modulate current flow through a variety of ion channels found on postsynaptic membranes [66] (see *Membrane Proteins*). The enhancement of neuromuscular blockade by inhaled anesthetics observed in the clinical setting probably results from a reduced effectiveness of acetylcholine at the postsynaptic motor endplate. [67]

In summary, inhaled anesthetics act on synaptic regions, including afferent axons at the nerve terminal. Inhaled agents alter axonal and synaptic transmission in isolated mono- and polysynaptic neuronal systems and may have both pre- and postsynaptic effects. Clinical concentrations of inhaled agents can depress, leave unchanged, or enhance presynaptic neurotransmitter release and the postsynaptic response. The effect depends on the biologic preparation,

Figure 3-8 (Figure Not Available) (A) Effects of halothane (Hal), enflurane (Enf), and the convulsant hexafluorodiethyl ether [flurothyl] (HFE) on current responses evoked by GABA (3×10^{-6} M) application to dissociated CNS neurons of the rat. Responses are normalized to the peak current induced by 3×10^{-6} M GABA alone. (B) The GABA concentration-response curve is shifted to the left by halothane and to the right by HFE. Peak response was normalized to that evoked by 3×10^{-6} M GABA (*). *(From Wakamori et al [65])*

the frequency of neuronal transmission, the particular neurotransmitter, and the anesthetic examined.

ALTERATIONS IN NEUROREGULATORS ASSOCIATED WITH ANESTHESIA

The list of CNS transmitters is rapidly expanding. In addition to the "classic" transmitters(e.g., acetylcholine), endogenous amino acids and peptides may act as neurotransmitters or modulate the action of other neurotransmitters. Furthermore, the postsynaptic action of neurotransmitters may result in the formation of second messengers that mediate changes in neuronal transmission. Limited information is available concerning the relationship between the levels of neuroregulators in the CNS and the inhaled anesthetic requirement.

Acetylcholine

Inhaled anesthetics do not alter acetylcholine concentrations in macroscopic structures (e.g., cortex) of rat brain [66] but may increase [69] or decrease [70] acetylcholine content in specific brain nuclei. Inhaled agents decrease acetylcholine turnover rate, with the magnitude of the decrease varying with the brain region examined. [68] Synthesis of acetylcholine in brain is impaired by inhaled agents and is associated with an anesthetic-induced inhibition of choline uptake. [56] A hypothesis that depressed cholinergic neurotransmission plays a role in the mediation of the anesthetic state is supported by the finding that intracerebroventricular injection of hemicholinium-3 (which reduces synaptic levels of acetylcholine) decreases isoflurane MAC in rats. [71]

Catecholamines

Rats anesthetized with halothane or cyclopropane have unaltered norepinephrine concentrations in most brain regions but may have an elevated norepinephrine content in the nucleus accumbens, locus caeruleus, and central gray catecholamine areas. [72] Although anesthesia does not deplete brain norepinephrine, a change in norepinephrine availability significantly influences anesthetic requirement. Drugs that decrease central levels of norepinephrine result in a dose-related decrease in halothane MAC, whereas drugs that elevate central norepinephrine levels increase anesthetic requirement. [73] The ablation of certain norepinephrine-rich brainstem areas in rats lowers MAC by 16 to 35 percent compared with sham-operated littermate controls. [74]

In contrast to those of norepinephrine, central levels of dopamine appear to be inversely related to anesthetic requirement. Administration of levodopa to mice increases striatal dopamine content and decreases halothane MAC, [75] and an increase in striatal dopamine content is associated with halothane anesthesia. [76] Conversely, chemical destruction of dopaminergic neurons lowers dopamine content and increases halothane MAC. [75]

The administration of alpha$_2$ -adrenergic agonists markedly lowers inhaled anesthetic requirement in animals and humans. Dexmedetomidine, an agonist that is more selective for the alpha$_2$ -adrenoreceptor than clonidine, produces a remarkable decrease in halothane [77] MAC in dogs to less than 10 percent of the control value (Fig. 3-9) (Figure Not Available) . This effect appears to be highly specific for the alpha $_2$ -adrenoreceptor because the optical isomer L-medetomidine does not alter MAC (see Fig. 3-9) (Figure Not Available) . In isolated hippocampal neurons, dexmedetomidine exhibits only a small potentiation of the effects of isoflurane, [78] suggesting that hippocampal neurons are not representative of the CNS site(s) at which alpha $_2$ -adre-nergic agonists lessen anesthetic requirement *in vivo.*

Serotonin

Serotonin levels are unaltered in most brain regions of rats anesthetized with halothane orcyclopropane but may increase in specific brain structures (e.g., substantia nigra, nucleus raphedorsalis). [79] Destruction of the serotonin-rich nucleus raphe dorsalis in rats decreasesanesthetic requirement by as much as 25 percent. [74]

Adenosine

Administration of adenosine or an adenosine analogue to dogs [80] or rats [81] decreases halothane MAC by about 50 percent. The mechanism of this lowering in anesthetic requirement is probably related to an adenosine-induced decrease in CNS noradrenergic transmission. [80] [81] Although exogenous adenosine reduces anesthetic requirement, small alterations of endogenous adenosine concentrations do not substantially alter MAC. [80]

GABA

Although rats administered 1 to 4 percent atm halothane for 30 minutes exhibit no change in whole brain GABA content, [82] anesthesia may alter GABA levels in selected regions of brain. Treatment of rat cerebral cortex slices with 3 percent atm halothane inhibits the metabolism and increases the content of the inhibitory transmitter GABA but does not affect the uptake or release of GABA. [83] If the accumulation of GABA in inhibitory neurons is associated with an increase in inhibitory activity, the resulting decrease in synaptic transmission might contribute to the anesthetic state. [83] Findings consistent with this hypothesis include the production of anesthesia by a GABA analogue [84] and the ability of GABA antagonists to lessen the antinociceptive action of halothane [85] in rodents.

Excitatory Amino Acids

A role for excitatory amino acids in anesthesia is implied by the depression in glutamate-induced neurotransmission by inhaled anesthetics and the decreased requirements for volatile anesthetics after administering inhibitors of excitatory amino acid transmission. [86] Anesthesia does not result

---

Figure 3-9 (Figure Not Available) The D- stereoisomer (closed squares) of the alpha$_2$ -adrenergic agonist medetomidine causes a dose-dependent decrease in halothane MAC in dogs, whereas the L-stereoisomer (open squares) has little or no influence on halothane MAC. Asterisks indicate values that are significantly different from the controls. *(From Vickery et al [77])*

from a depletion of excitatory amino acids because rats anesthetized with halothane have an increased whole brain content of aspartate and glutamate. [82] It has been suggested that the ability of enflurane to enhance glutamate release from synaptosomes may provide an explanation for clinically observed enflurane-induced convulsions. [87]

Cyclic Nucleotides

The production of cyclic nucleotides may be influenced by neurotransmitters and anesthetics, and cyclic nucleotides may serve as second messengers in altering neurotransmission. The effect of anesthetics on cyclic adenosine monophosphate (cAMP) content varies with the species and tissues examined. [88] Most (but not all) studies demonstrate an increase in brain cAMP content of rodents during the administration of volatile anesthetics, with the magnitude of the increase varying among species and among brain regions. [88] In contrast, levels of cyclic guanosine monophosphate (cGMP) in brain are decreased by volatile agents. [89] Nitric oxide

activates adenyl cyclase to form cGMP and, in turn, nitric oxide production can be enhanced by excitatory neurotransmitters. It has been suggested that volatile anesthetics decrease brain cGMP by interfering with the neuronal nitric oxide-cGMP pathway. [89] Such alterations in brain cyclic nucleotide content may chemically alter (e.g., via phosphorylation) macromolecules that are important in neurotransmission.

Calcium

Calcium is mentioned as a neuroregulator because there is evidence that inhaled anesthetics alter intracellular concentrations of calcium and because changes in intracellular calcium may influence neuronal excitability [90] (e.g., via a calcium-dependent release of neurotransmitter). Inhaled anesthetics usually [90] (but not always [54]) increase resting cytoplasmic calcium concentration, and it has been proposed that the depressant action of halothane in rat hippocampal slices involves enhancement of GABA-mediated inhibition through release of intraneuronally stored calcium. [91] In contrast, increases in intraneuronal calcium evoked by various stimuli are often prevented by inhaled agents. [54] The mechanisms for the attenuation of the calcium rise by inhaled anesthetics may depend on the anesthetic and tissue examined and include impairment of calcium influx into cells [54] [90] and modulation of intracellular calcium release via action on inositoltriphosphate-dependent pathways. [92]

Endogenous Opiates

In the late 1970s, it was hypothesized that inhaled anesthetics may work through an action on the opiate receptor. [93] [94] Consistent with this hypothesis are the clinical observations and experimental findings that synthetic narcotics partially decrease the requirement for inhaled anesthetics. Furthermore, the administration of naloxone (a narcotic antagonist) partially reverses the action of inhaled anesthetics either when given intravenously [93] [94] or given into the cerebral ventricle. [94] [93] However, this antagonistic effect of naloxone can be explained by a minor shift in the anesthetic dose-response curve. Anesthetic requirement, as measured by lack of response to a noxious stimulus [96] or by the ability to abolish the righting reflex, [97] is altered no more than a small percentage by narcotic antagonists, even at doses of naloxone as high as 250 mg/kg. [96] The mild antagonism of inhalational

anesthesia by high doses of naloxone probably results from a general increase in CNS excitation and not by pharmacologic competition for opiate receptors. [97]

Another prediction of the opiate theory of anesthesia is that inhaled agents may release an endogenous opiate-like substance in the CNS. Data are available to support and refute this prediction. Nitrous oxide markedly increases proenkephalin-derived endogenous opioid peptides in canine third ventricle cerebrospinal fluid. [98] The lowering of halothane MAC in rats by transcranial electrical stimulation is reversed by naloxone, suggesting that release of endogenous opioids mediated the decrease in halothane requirement. [99] In patients anesthetized with a combination of halothane and nitrous oxide [100] or isoflurane, [101] there is no elevation in opioid peptides in cerebrospinal fluid. Thus, any contribution of the endogenous opiate system to the production of general anesthesia in humans does not appear to require the release of opioid peptides.

Nitric Oxide

Nitric oxide is now recognized as a neuromodulator and has been hypothesized to play a role in mediating consciousness. Although the short half-life (milliseconds to seconds) of nitric oxide makes it a difficult compound to study, administration of nitric oxide synthase inhibitors decreases (by 30-50%) MAC and righting-reflex ED_{50} s of halothane and isoflurane in rodents. [102] [103] However, sparing of anesthetic requirement by nitric oxide synthase inhibitors is not found in all experiments. [104] As noted before, [85] nitric oxide is involved in cellular communication processes via production of cGMP and various neurotransmitter pathways, processes that may be important to the anesthetic state.

In summary, the predominant effects of inhaled anesthetics cannot at present be explained by the depletion, production, or release of a single neuromodulator in the CNS. In all likelihood, the anesthetic state involves a balance between many different neuromodulator systems.

PHYSICOCHEMICAL NATURE OF THE SITE OF ANESTHETIC ACTION

The preceding sections suggest that anesthetics may act at several gross (e.g., spinal cord versus reticular activating system) or microscopic (e.g., presynaptic versus postsynaptic) sites. The varied nature of these sites, however, does not preclude a unique action at a molecular level. For instance, depression of presynaptic neurotransmitter release and blockade of current flow through the postsynaptic membrane may arise from an anesthetic perturbation at an identical molecular site, even though the geographic locations of these sites differ. The concept that all inhaled anesthetics have a common mode of action on a specific molecular structure is called the *unitary theory of narcosis.* The nature of this presumed common site has been explored by correlating the physical properties of anesthetics with their potencies. The rationale behind this approach is that the best correlation between anesthetic potency and a physical property will suggest the nature of the anesthetic site of action. For example, the correlation of MAC and lipid solubility (see below) implies that the site of action is hydrophobic. Note that the correlations that depend on forces exerted between anesthetic molecules (e.g., the boiling point of an anesthetic) are not important to the study of anesthetic mechanisms, as such intermolecular forces cannot be representative of a single site of action. That is, such correlations are defined by the interaction of each anesthetic with itself rather than with a common site.

Hydrophobic Site: The Meyer-Overton Rule

The physical property that correlates best with anesthetic potency is lipid solubility [105] [106] [107] [108] (Table 3-2 and Fig. 3-10) . This correlation is termed the *Meyer-Overton rule,* after its two discoverers. For the majority of inhaled agents, the product of the anesthetizing partial pressure and its olive oil/gas partition coefficient varies little over approximately a 100,000-fold range of anesthetizing partial pressures (see Table 3-2 and Fig. 3-10) . For the correlation to be perfect, this product would have to be the same for all anesthetics for a given animal. Within a given species, the product of anesthetizing partial pressure and oil/gas partition coefficient varies only slightly (see Table 3-2) . The closeness of this correlation implies a unitary molecular site of action and suggests that anesthesia results when a specific number of anesthetic molecules occupy a crucial hydrophobic region in the CNS. This finding has led many investigators to look for the molecular basis of anesthetic action in cellular hydrophobic regions.

Further Characterization of the Hydrophobic Site of Anesthetic Action

The correlation of potency to solubility in olive oil (see Fig. 3-10 and Table 3-2) suggests that olive oil closely mimics the anesthetic site of action and that anesthesia occurs when a critical anesthetic concentration is attained at that site. However, because olive oil is a mixture of oils and is not very well characterized from a physicochemical point of view, attempts have been made to examine anesthetic solubility in simpler solvents in order to better define the nature of the site of anesthetic action. A pure solvent may be characterized by a solubility parameter, which is a measure of the intermolecular forces in that solvent. [105] Anesthetic potency correlates best with solubility in solvents having solubility parameters of about 8 to 11 (calories/cm ^{3})^{½} [105] [109] . These values are representative of a solvent such as ben-zene and again imply a hydrophobic site of anesthetic action. However, even better correlations between anesthetic potency and solubility may be obtained when octanol [110] (having a solubility parameter of approximately 10 [calories/cm ^{3}]^{½}) or lecithin [111] (an amphipathic compound with hydrophobic and polar components) is used as the model solvent.

Figure 3-10 Correlation of MAC in humans and dogs and the righting-reflex ED_{50} in mice with lipid solubility (i.e., the olive oil/gas partition coefficient.) Values are taken from Table 3-2 .

Additive Effects of Inhaled Anesthetics

The Meyer-Overton rule postulates that it is the number of molecules dissolved at the site of anesthetic action, and not the types of molecules present, that causes anesthesia. Thus, 0.5 MAC of one agent and 0.5 MAC of another agent should have the same effect as 1.0 MAC of either agent. In general, this prediction has been confirmed for clinically employed agents in animals and humans, [112] although slight antagonistic effects are also occasionally observed.

Apparent Exceptions to the Meyer-Overton Rule

Isomers

In spite of the close correlation between lipid solubility and anesthetic potency, deviations from this correlation do exist. For example, enflurane and isoflurane are structural isomers (see Fig.3-1) having approximately the same oil/gas partition coefficient, yet anesthetic requirement for enflurane is 45 to 90 percent greater than that for isoflurane (see Table 3-2) . These differences in anesthetic requirements for agents having similar oil/gas partition coefficients suggest that the potency of an agent depends on factors other than lipid solubility.

Several of the commonly used inhaled anesthetics (Fig. 3-1 A) exist as mixtures of two stereoisomers (nonsuperimposable compounds that are mirror images of each other, having identical physicochemical properties except for the direction in which they rotate polarized light). For isoflurane stereoisomers in rats, the (+)-isomer is 17 [113] to 53 percent [114] more potent than the (-)-isomer. Thus, the differential effects of the inhaled anesthetic stereoisomers are relatively modest.

Convulsant Gases

Another apparent exception to the Meyer-Overton rule is the ability of certain lipid-soluble compounds to produce convulsions. Indeed, complete halogenation (or full halogenation of the end-methyl groups) of alkanes and ethers tends to decrease the anesthetic potencies of these agents and to enhance convulsant activity. [115] Flurothyl ($CF_3 CH_2 OCH_2 CF_3$) produces convulsions at concentrations an order of magnitude less than those predicted to be anesthetic by the Meyer-Overton rule. [116] Although the loss of righting reflex in the mouse at very high flurothyl concentrations implies an anesthetic effect, 3 to 4 percent atm flurothyl only marginally decreases isoflurane MAC in dogs. [116]

Compound 485 (Fig. 3-1 C) possesses completely halogenated end-methyl groups and is a structural isomer of enflurane and isoflurane. It occasionally produced convulsions in dogs at concentrations near 6 percent atm. [117] As an isomer of enflurane and isoflurane, it was predicted to have similar potency and solubility characteristics; however, its MAC was found to be 12.5 percent atm. This high MAC value was balanced by an 4-fold lower oil/gas partition coefficient [117] (see Table 3-2) .

Convulsant halogenated ethers may have different physical properties from the anesthetic halogenated ethers because the convulsants are characterized by a low solubility parameter. [118] For example, flurothyl has a solubility parameter of 6.9, whereas the anesthetic halogenated ethers have values of approximately 8.0. [118] Furthermore, halogenated compounds that are anesthetics and convulsants may have different effects on synaptic transmission. Anesthetic agents block the excitatory glutamate response but not inhibitory transmission mediated by GABA at the crab neuromuscular junction, whereas convulsant agents block inhibitory but not excitatory transmission. [119] In dissociated rat brain neurons, halothane and enflurane enhance the response to GABA, whereas flurothyl decreases GABA response (see Fig. 3- 8) (Figure Not Available) . [65]

Cutoff Effect

There has been a long-standing impression that the highly lipid soluble paraffin hydrocarbon *n*-decane was nonanesthetic in animals, even though less soluble paraffin homologues such as *n*-pentane caused anesthesia. This decrease in anesthetic potency in the higher members of a homologous series is known as the *cutoff effect.* [120] However, detailed reexamination of this issue has revealed the cutoff for *n*-alkanes may be explained by limited delivery of the larger alkanes due to decreasing volatility. Although decane does not anesthetize rats when given alone at its saturated vapor pressure, anesthetic properties are demonstrated by an ability to decrease requirement for isoflurane. [121] In the fruitfly *Drosophila melanogaster,* anesthetic ED_{50} values (using lack of coordination and mobility as an end-point) can be measured for decane and undecane when given alone. [122] A surprising result of these studies was the finding that *n*-alkanes did not obey the Meyer-Overton rule, [122] [123] independent of the solvent used to measure alkane partitioning. [123]

A "true" cutoff exists for the perfluoroalkanes. [124] Perfluoromethane (CF_4) produces anesthesia in rats (MAC 60 atm), but perfluoroethane ($CF_3 CF_3$) and longer-chain perfluorinated derivatives are nonanesthetic despite being soluble in hydrophobic solvents and in tissues. [124]

Nonanesthetics (Nonimmobilizers)

In addition to the nonanesthetic perfluoroalkane gases noted previously, certain volatile polyhalogenated agents that are even more lipid-soluble yet lack anesthetic properties have also been discovered. [125] [126] Examples of such "nonanesthetics" are given in Figure 3-11 . These nonanesthetics do not produce anesthesia when administered alone (even when administered at partial pressures greater than those predicted to have an anesthetic effect by the Meyer-Overton hypothesis), and they do not lower MAC for conventional anesthetics. [125] [126]

These nonanesthetics are not inert. They quickly reach the brain, produce excitable behavior, and typically cause convulsions when administered at high enough partial pressures. [125] [126] [127] Because MAC is used as the end-point to

Figure 3-11 Examples of nonanesthetics (nonimmobilizers). Although these compounds have oil/gas partition coefficients (43.5 for 1,2-dichlorohexafluorocyclobutane; 25 for 2,3-dichlorooctafluorobutane) similar to those of conventional anesthetics (Table 3-2) , they completely lack anesthetic properties (as determined by MAC measurements). [125]

define a nonanesthetic, it may be more appropriate to call these compounds "nonimmobilizers" rather than nonanesthetics. It is possible that such nonanesthetics fail to produce immobility in response to a noxious stimulus but do cause amnesia. [40] [128]

The nonimmobilizers may be helpful in identifying anesthetic sites and mechanisms of action. Physiologic or biochemical/biophysical changes produced by conventional anesthetics in a model system thought to be important for the anesthetic state (as measured by MAC) should not be produced by the nonimmobilizers.

Hydrophilic Site

The suggestion of a possible nonhydrophobic anesthetic site of action is not new. For example, Pauling [129] suggested that anesthesia might be caused by the ability of anesthetics to precipitate the formation of hydrates. These hydrates are cage-like structures of water molecules surrounding a central anesthetic molecule, and it was speculated that hydrate microcrystals could alter the transmission of electrical charge through a neuron. [129] However, a unitary hydrate theory of anesthesia seems unlikely because there is a poor correlationbetween the ability of anesthetics to form hydrates and their anesthetic potency. [105]

Another hypothesis is that certain inhaled anesthetics act by disrupting hydrogen bonds. [130] (This cannot be a unitary hypothesis because compounds like xenon and argon are anesthetics but do not form hydrogen bonds.) One suggestion is that general anesthetic target sites have, in addition to an overall hydrophobicity, a polar component that is a relatively poor hydrogen bond donor but that accepts a hydrogen bond about as well as water. [130] If hydrogen bonds are important in anesthesia, then substitution of hydrogen for deuterium atoms in anesthetic molecules might alter the hydrogen bonding capabilities of a compound and change its anesthetic potency. However, the findings of identical anesthetic potencies of chloroform and deuterated chloroform [131] and of halothane and deuterated halothane [132] do not support this prediction.

Volume Expansion by Inhaled Anesthetics

Although the Meyer-Overton rule postulates that anesthesia occurs when a sufficient number of anesthetic molecules dissolve at a certain site, it does not explain why anesthesia results. Mullins [109] took the lipid solubility correlation one step further and hypothesized that anesthesia occurs when the absorption of anesthetic molecules expands the volume of a hydrophobic region beyond a critical amount *(critical volume hypothesis).* Such an expansion might produce anesthesia by obstructing ion channels or by altering the electrical properties of neurons.

One prediction of the volume expansion hypothesis was that anesthetizing partial pressures of inhaled agents should produce a consistent volume expansion in a model hydrophobic system. Indeed, anesthetizing doses of inhaled agents cause hydrophobic solvents to undergo a significant increase in volume. [133] The hypothesis also predicts that anesthesia should be reversed by compressing the volume of the expanded hydrophobic region, and high pressures do reverse many effects of anesthetics *in vivo.*[14] [15] However, the influence of body temperature on anesthetic requirement (see Fig. 3-3) (Figure Not Available) , a nonlinear pressure antagonism for certain anesthetics, and the fact that not all lipid-soluble compounds are anesthetics are findings that are difficult to explain. Thus, although the critical volume hypothesis is a useful model for estimating the interactions between pressure and inhaled anesthetics, it probably is an oversimplified view of the way in which anesthetics act.

THE MEMBRANE AS THE SITE OF ANESTHETIC ACTION

The electrical activity (i.e., transfer of ions) immediately underlying the transmission of nervous impulses occurs principally at the plasma membranes of nerves. Because inhaled agents disrupt this transmission, synaptic and/or axonal membranes are usually assumed to be the primary sites of anesthetic action. A membrane site of action is also consistent with the hydrophobic/amphipathic theories of anesthesia because plasma membranes consist largely of hydrophobic/amphipathic components.

Electrophysiologic studies reveal the effects of anesthetics on the flow of ions through excitable membranes. In isolated axons, the conduction of the nervous impulse requires the sequential flow of sodium and potassium ions through selective transmembrane channels. Excitation produces a rapid increase in sodium conductance to a peak (the activation process) followed by a slower decline in sodium conductance to zero (the inactivation process). Although channels in peripheral neurons tend to be relatively insensitive to anesthetics, [2] clinical concentrations of inhaled anesthetics may decrease the magnitude of both sodium [134] and potassium [135] currents in channels isolated from brain.

Electrophysiologic recordings of single membrane channels activated by neurotransmitter can be obtained by forming a seal between the tip of a glass micropipette and a membrane patch of a few square micrometers. Using this "patch clamp" technique, unitary acetylcholine receptor

channel currents have been measured in the absence and in the presence of inhaled anesthetics (Fig. 3-12). (Figure Not Available) [67] [136] [137] . Isoflurane decreases the average open duration of this membrane channel, and such an accelerated decay of the membrane current may decrease the net charge transferred across the membrane and impair transmission (see Fig. 3-12). (Figure Not Available) [67] [136] [137]

In contrast to the inhibitory effects of anesthetics on ion flow through membranes described earlier, other experiments suggest that anesthetics may act by enhancing the conductance of certain ions through membranes. Volatile anesthetics enhance the inhibitory current responses produced by GABA (see Fig. 3-8) (Figure Not Available) , [64] [64] [65] presumably by increasing the flow of chloride ions through GABA receptor-channel complexes in neuronal membranes. [138] Inhaled agents may also enhance potassium conductance, resulting in membrane hyperpolarization. [26] Molluscan neurons that are highly sensitive to volatile agents (see Fig. 3-7) (Figure Not Available) exhibit a halothane-induced activation of potassium current that is associated with a marked hyperpolarization of the cell membrane and an inability to initiate firing of action potentials. [43] [44] However, the finding that anesthetic effects on resting membrane potential are voltage-dependent and agent-specific [139] indicates that changes in membrane potential are not a universal feature of anesthetic action on CNS neurons.

The requirement of an intact plasma membrane for the transmission of nervous impulses and the abilities of anesthetics to disrupt the flow of ions through plasma membranes point to a membrane site of anesthetic action. Nevertheless, anesthetics could act indirectly at a cytoplasmic site. For example, anesthetics might alter the calcium-accumulating activity of cellular organelles (e.g., mitochondria [90]) and thereby alter the levels of intracellular free calcium. Such alterations in intracellular free calcium could in turn influence the conductance properties of excitable membranes and alter the presynaptic release of neurotransmitters. [90]

This discussion strongly suggests but does not prove that anesthesia results from an association of inhaled agents with plasma membranes of nerves. If so, which components of the plasma membrane are altered by the anesthetics? Biological membranes consist of a cholesterol-phospholipid bilayer matrix having a thickness of approximately 4 nm. Peripheral proteins are weakly bound to the exterior hydrophilic membrane, and integral proteins (such as ion channels) are deeply embedded in or pass through the lipid bilayer (Fig. 3-13) (Figure Not Available) . Synaptic plasma membranes are approximately half protein and half lipid by weight. If (as implied by the Meyer-Overton rule) inhaled agents bind to hydrophobic sites, anesthetics could act on the nonpolar interior of the lipid bilayer, at hydrophobic pockets in proteins extending outside or embedded into the lipid bilayer, or at the hydrophobic interface between intrinsic membrane proteins and the lipid matrix (see Fig. 3-13) (Figure Not Available) .

Attempts to better understand the penetration of inhaled agents into and their interaction with membrane sites have led to an examination of isolated membrane components.

Figure 3-12 (Figure Not Available) Examples of unitary acetylcholine receptor channel currents before, during, and after local microperfusion with 5 mM isoflurane. Channel openings are represented by downward directions of the current trace. When isoflurane is removed (bottom panel), the channels are indistinguishable from those observed under control conditions. *(From Brett et al [136])* Note that pre-equilibrated and 10-fold lower concentrations of isoflurane also decrease the average open duration of acetylcholine receptor channel currents. [67] [137]

Figure 3-13 (Figure Not Available) Four possible target sites for inhaled anesthetic molecules ( ) in a neuronal membrane include (a) the lipid bilayer as a whole, (b) lipids at a protein/lipid interface, (c) a protein site bounded by lipid, and (d) a protein site exposed to an aqueous environment. *(Modified from Franks and Lieb, [106] with permission of Elsevier Science.)*

These experiments were greatly aided by the discovery that phospholipids dispersed in an aqueous medium spontaneously form bilayers comprising the surface of spherical structures (liposomes). These phospholipid bilayers act as a permeability barrier to ions and are similar to those found in biomembranes. In contrast, membrane proteins are often difficult to isolate and purify, and membrane proteins typically exhibit an impaired function unless surrounded by a boundary layer of lipid. Nevertheless, recent advances have resulted in the biochemical characterization of several protein receptor/ionophores thought to permit the passage (tunneling) of ions through membranes during excitation. However, only limited information is available concerning the interaction of inhaled agents with these membrane protein ionophores, and many experiments that examine anesthetic-protein interactions employ soluble proteins as model systems. Such proteins are easy to prepare in reasonable quantities but may not mimic precisely the natural proteins responsible for ion translocation.

INTERACTION OF INHALED ANESTHETICS WITH MEMBRANE LIPIDS

Binding of Anesthetics to Membrane Lipids

The solubilities of gaseous and volatile agents in membrane lipids tend to correlate with their anesthetic potencies. This correlation is as good [140] as or better [111] than that obtained when olive oil is the model solvent. The incorporation of cholesterol into phospholipid model membranes decreases the partitioning of inhaled agents but does not alter the good correlation between anesthetic potency and lipid membrane solubility. [140] The degree of saturation of lipid acyl chains [140] or the length of the acyl chains [141] has little effect on the partition coefficient. On the other hand, a decrease in temperature increases the partitioning of anesthetics into phospholipid membranes. [140] At anesthetic concentrations close to 1.0 MAC, lipid membranes may contain as many as 80 phospholipid molecules for every anesthetic molecule. [108]

The interaction of inhaled agents with membrane lipids is a dynamic process, and anesthetic molecules may rapidly exchange between the membrane and aqueous phases. Although anesthetics may penetrate to all depths of the lipid bilayer, current evidence indicates a preferential anesthetic distribution at the membrane interface [142] [143] [144] where regions of the lipid membrane contact the aqueous environment. In contrast, the "nonimmobilizers" 1,2-dichlorohexafluorocyclobutane and 2,3-dichlorooctafluorobutane (see Fig. 3-11) exhibit a preferential location in the lipid membrane hydrocarbon core. [143] [144] It has been speculated that the interfacial site may be associated with anesthetic-induced immobility in response to noxious stimuli and that the production of amnesia may be associated with anesthetic penetration into the nonpolar interior of a phospholipid bilayer. [40]

Effects on Membrane Permeability

Inhaled agents increase the cation permeability of liposomes in a dose-related manner. [105] [145] These anesthetic-induced increases in cation permeability occur both in the presence and absence of ionophores that facilitate the transport of ions through membranes. The magnitude of the increase depends on the composition of the liposome and on the anesthetic examined. [105]

Inhaled anesthetics also increase the flow of protons across lipid vesicles. [146] The rate of proton transfer across the membrane may depend on lipid composition. It has been suggested that anesthetics may act by increasing proton permeability across synaptic vesicles, collapsing the pH gradient required for retention of catecholamines in their charged form and thereby depressing neurotransmission by releasing catecholamines from synaptic storage vesicles. [147] However, this hypothesis seems unlikely because (1) marked depletion of brain catecholamines lowers MAC by a maximum of 40 percent (see *Alterations in Neuroregulators Associated with Anesthesia*), (2) clinical concentrations of

inhaled agents release only a small fraction of catecholamines trapped in vesicles, [146] and (3) not all anesthetics increase proton conduction across lipid vesicles.

Alterations in Membrane Dimension

Lipid monolayers adsorb inhaled agents, resulting in an increase in the lateral pressure of the monolayer that parallels the potency of the anesthetic. [148] This finding is consistent with the notion that anesthetics might expand membranes and exert pressure on the ionic channels needed for impulse transmission--a variation of the volume expansion theory of anesthesia--and thereby inhibit the opening or accelerate the closure of ionic channels.However, precise volume measurements show only a small (0.1%) expansion when suspensions of membranes in aqueous media are combined with inhaled agents at concentrations near 1.0 MAC. [149] Direct microscopic visualization of the erythrocyte surface shows an area of expansion ranging from 0.13 to 0.62 percent for clinical anesthetics at concentrations of one to four times MAC, [150] but long-chain alcohols that are not anesthetics also expand red cell surface area. This finding casts doubt on the role of membrane area expansion in anesthesia. [150] In addition, most studies indicate little or no effect of clinical concentrations of inhaled agents on membrane thickness. [140]

According to the critical volume hypothesis, an increase in pressure or a decrease in temperature should reverse anesthesia because these physical changes should compress membranes. However, a decrease in body temperature consistently decreases MAC (see Fig. 3-3) (Figure Not Available) . This apparent contradiction is partly resolved by the increased partitioning of anesthetics into membranes at lower temperatures. Moreover, the expansion of membranes by anesthetics and an increase in temperature may not be equivalent. For example, anesthetics might expand membranes without changing thickness. [140]

Alterations in Membrane Physical State

Further studies of the molecular changes occurring on the insertion of anesthetic molecules into lipid membranes led to the suggestion that anesthetics increase the mobility of membrane components (the *fluidization theory* of anesthesia). The ability of an anesthetic to *fluidize* a lipid bilayer depends on the agent examined and the composition of the lipid bilayer. [140] The incorporation of cholesterol [140] or gangliosides [151] into neutral phospholipid membranes enhances the membrane-disordering effects by a given partial pressure of inhaled anesthetic. At clinical concentrations, the increase in lipid fluidity by inhaled agents can be as small as 0.5 percent or as large as 31 percent, [152] depending on the lipid system examined and the method of fluidity measurement. Moreover, the anesthetic-induced changes in fluidity may even depend on membrane position. Inhaled agents can produce a small *decrease* in the fluidity of palmitoyloleoylphosphatidylcholine membranes near the headgroup region and increase fluidity in regions deep in the membrane bilayer. [144] [153] Of note are the findings that the nonimmobilizers 1,2-dichlorohexafluorocyclobutane and 2,3-dichlorooctafluorobutane (see Fig. 3-11) do not fluidize membrane lipids. [144] [153]

It has been suggested that even small changes in lipid fluidity may profoundly change membrane function. Some investigators have speculated that the increased decay rate of postsynaptic currents and accelerated decay rate of open membrane channels (see Fig. 3-12) (Figure Not Available) caused by inhaled agents may result from an increased fluidity of the postsynaptic membrane, allowing a more rapid relaxation (i.e., return to the closed configuration) of the proteins involved in the conductance change after activation. However, incompatible with this hypothesis is the fact that hypothermia (which lessens mobility of membrane lipids) potentiates anesthesia and that the raising of temperature does not mimic the pattern of accelerated channel closing rates produced by an inhaled agent. [136]

Liposomes composed of a single type of phospholipid undergo a *phase transition;* that is, a sudden conversion of the lipids from a solid or gel phase to a liquid or fluid phase as temperature increases past a critical point. Clinical concentrations of inhaled agents typically decrease this phase transition temperature by 0.5° C, although the composition and charge of the lipid bilayer determines the magnitude of the decrease in the phase transition temperature by anesthetics. [155] According to one hypothesis, lipids surrounding an excitable membrane channel are normally exclusively in the more rigid gel phase, thereby helping maintain patency of the channel. It has been speculated that adding anesthetic may fluidize these lipids, impair the surrounding structural support, and allow the channel to close. If a major phase transition is important in the production of anesthesia, one would predict a discontinuity in the relationship between temperature and anesthetic

potency. However, there is no such discontinuity (see Fig. 3-3) (Figure Not Available) .

An alternative hypothesis (the *lateral phase separation hypothesis*) proposes that neuronal membrane lipids coexist in both fluid and gel forms and that the expansion of a protein to allow passage of ions through channels requires conversion of lipids from a fluid to a gel phase. [156] Anesthetic molecules are thought to sustain lipids in their fluid phase, block the formation of the low volume gel phase, and thereby prevent the protein from changing its conformation to the open channel state. [156] However, both the fluidization and lateral phase separation theories are compromised by the fact that small increases (
1°C) in temperature increase membrane fluidity to approximately the same extent as clinical concentrations of inhaled anesthetics and therefore should but do not augment anesthesia.

Other theories of anesthetic action on lipids include anesthetic-induced alterations in membrane electrical properties or membrane pressures. Inhaled agents (at
1 MAC) can alter dipole potentials at a lipid membrane interface by
10 mV, and it has been suggested that such changes in membrane potential could modulate conformational transitions of membrane channel proteins. [157] Insertion of inhaled anesthetics into a lipid bilayer is predicted to increase lateral pressure at the membrane interface. [158] If ion channel opening increases the cross-sectional area of the protein channel more near the aqueous interface than in the middle of the bilayer, then the anesthetic-induced increase in lateral pressure

near the interface would tend to favor the closed state of the ion channel. [158]

INTERACTION OF INHALED AGENTS WITH PROTEINS

Most investigators agree that the ultimate action of inhaled anesthetics is on specific neuronal membrane proteins that permit the translocation of ions during membrane excitation. It remains a matter of debate, however, whether inhaled agents disrupt ion flow through membrane channels by an indirect action on the surrounding lipids or via a second messenger or by a direct and specific binding to channel proteins. Immobilized [159] and saturable binding sites for inhaled anesthetics in brain imply but do not prove a direct interaction of anesthetics with neuronal proteins. Because of the complexity involved in searching for specific anesthetic binding sites in whole brain or brain homogenate, attempts have been made to simplify this search by examining the interaction of anesthetics with isolated proteins.

Soluble Proteins

Distinct anesthetic binding sites have been identified in several soluble proteins, including hemoglobin, myoglobin, and albumin. [107] [160] [161] Anesthetics move rapidly between their binding sites in soluble proteins and the surrounding aqueous solvent and bind to albumin with an average lifetime of about 200 mus. [160] Discrete binding sites for halothane, involving aromatic amino acid residues, have been identified in albumin. [161]

The interaction of inhaled anesthetics with soluble enzymes may be reflected indirectly by changes in enzyme activity. Many enzymes, including several glycolytic enzymes and serum cholinesterase, are resistant to even saturated solutions of volatile agents. However, other soluble enzymes are highly sensitive to clinical anesthetic concentrations. The purified firefly luciferase enzyme combines with its substrate (luciferin) to produce a photon of light, and a variety of inhaled anesthetics (at
1.0 MAC) inhibit the activity (light intensity) of this enzyme by competing with luciferin. [162] However, it needs to be noted that these results apply only to firefly luciferase; studies with the bacterial form of the enzyme show poor agreement between the anesthetic concentrations required to inhibit bacterial luciferase and MAC. [163]

Membrane Proteins

Two major obstacles are encountered when one attempts to study the influence of inhaled anesthetics on the purified protein ionophores involved in the membrane translocation of ions. First, the biochemical purification of such protein ionophores in adequate quantities is a difficult and time- consuming process. Second, even when these membrane proteins can be isolated, they need to be reincorporated into lipids for measurement of their functional ability to translocate ions. This reincorporation of the purified ionophore into a lipid membrane makes it difficult to distinguish whether an anesthetic affects ion flow through a direct action on the membrane protein or via an indirect action on surrounding lipids.

Ligand-Gated Ion Channels

The binding of neurotransmitter alters membrane permeability of ligand-operated channels to specific ions. The muscle-type nicotinic acetylcholine receptor-ionophore complex is the best characterized of these membrane proteins with regard to interaction with inhaled anesthetics; it is the only channel complex that has been bichemically isolated in large enough quantities to be studied. This protein complex is composed of five containing four hydrophobic amino acid domains spanning the membrane) that form the wall of the membrane channel. Each subunit of the acetylcholine receptor binds halothane (as measured by a radioligand-binding assay following photoactivation of radioactive halothane). [164] Volatile agents stabilize the acetylcholine receptor in a conformational form that binds agonists with high affinity and may be associated with a desensitized and thus inactive (closed-channel) state. [165] Volatile anesthetics promote desensitization at clinically relevant concentrations, [165] [166] and desensitization is associated with (but probably not caused by) membrane lipid disordering. [167] Although the pharmacologies of inhaled anesthetic-induced acetylcholine receptor desensitization and general anesthesia are similar, it is unlikely that anesthesia results from desensitization of acetylcholine receptors. [167]

Additional information concerning anesthetic action on the nicotinic acetylcholine receptor-ionophore may be made by examining ion flow through channels of defined subunit composition incorporated (via cDNA or mRNA injection) into cellular systems. Such studies have revealed a markedly enhanced sensitivity of neuronal (as compared with muscular) nicotinic acetylcholine receptors to inhaled anesthetics [168] [169] (Fig. 3-14) (Figure Not Available) . Because neuronal nicotinic acetylcholine receptors can be inhibited at inhaled anesthetic concentrations as low as 0.1 MAC (see Fig. 3-14) (Figure Not Available) , these receptors may play some role in the behavioral and physiologic effects observed at subanesthetic concentrations. [45] [168] [169] The ability of specific amino acid mutations in the pore-forming domain of the acetylcholine receptor to enhance sensitivity to inhaled agents (with increased sensitivity associated with increased hydrophobicity of amino acid substitution) is consistent with a mechanism by which anesthetics bind within the pore of the nicotinic acetylcholine receptor. [170]

Other neurotransmitter-gated ion channels including the $GABA_A$, glycine, ionotropic glutamate, and $5\text{-}HT_3$ serotonin receptors have considerable overlap with the nicotinic acetylcholine receptor in amino acid sequence and have similar subunit structures. Interactions of anesthetics with particular subunits of these ligand-gated ion channels can be studied by molecular cloning and expression in cells that do not endogenously contain these receptors. [66] The dependence of GABA receptor subunit composition on the ability of inhaled anesthetics to alter ligand binding [171] or potentiate GABA-activated chloride currents [154] [172] implies specific GABA subunit binding sites for anesthetics. Interaction of

Figure 3-14 (Figure Not Available) The figure on the left shows the current from an oocyte that expresses the predominant nicotinic acetylcholine receptor subtype (alpha4beta2) found in the central nervous system. Isoflurane (320 muM) reduces the peak current obtained in response to 1 muM acetylcholine from 2.4 muA to 1.1 muA (46% of control). The graph on the right shows the dose-response curve of the inhibition of alpha4beta2 receptor subtype current by isoflurane. Note that some inhibition of receptor function occurs even at isoflurane concentration of 0.1 MAC. *(From Flood et al [168])*

anesthetics with the GABA receptor is also indicated by a direct (but small) activation by halothane in receptors of particular subunit composition, an effect that is reversed by GABA antagonists. [173] Inhaled anesthetics enhance the function of glycine [174] [175] and $5\text{-}HT_3$ [176] [177] serotonin receptors, but the degree of enhancement is not related to anesthetic potency. Inhaled anesthetics produce subunit-selective actions on excitatory glutamate receptors, with GluR3 (AMPA subtype) receptors being inhibited or unaffected by anesthetics, whereas GluR6 (kainate subtype) receptor function is enhanced by volatile agents. [178]

The nonimmobilizers 1,2-dichlorohexafluorocyclobutane and 2,3-dichlorooctafluorobutane (see Fig. 3-11) have little or no effect on GABA, [154] glycine, [175] $5\text{-}HT_3$, [176] and glutamate [178] receptor function and are minimally effective in producing desensitization of nicotinic acetylcholine receptors. [166] However, these nonimmobilizing agents are highly effective in blocking currents through the nicotinic acetylcholine receptor pore, [179] consistent with the concept that anesthetic action on nicotinic acetylcholine receptors might be important for anesthetic-induced behavioral changes (e.g., amnesia) but not important for preventing response to surgical

stimulation.

Voltage-Gated Ion Channels

The flux of ions through voltage-gated ion channels is controlled by the electric field across the membrane. These channels share structural similarities and include sodium and potassium channels involved in the propagation of neuronal action potentials and calcium channels that control entry of calcium through presynaptic membranes and eventual neurotransmitter release. Although voltage-gated ion channels are often found to be insensitive to even high anesthetic concentrations, [2] [180] it is recognized that pharmacologic effects on a particular channel may vary from tissue to tissue or among channel subtypes. Thus, 2 percent atm isoflurane inhibits voltage-gated calcium currents in rat hippocampal pyrimidal neurons [181] ; clinical concentrations of volatile anesthetics suppress sodium current through rat brain sodium channels expressed in a cell line [134] ; and 1 to 4 percent atm halothane inhibits potassium currents through rat brain potassium channels. [135] A protein site of anesthetic action is suggested by the lesser ability of halothane to block currents through potassium channels that have had 318 amino acids removed from their cytoplasmic C-terminus. [135]

Metabotropic Receptors and G Proteins

In contrast to the ionotropic multiple subunit ligand-gated ion channels where membrane ion permeabilities change within a few milliseconds of agonist binding, metabotropic receptors consist of a single subunit, are coupled to G proteins, and evoke changes in neuronal excitability over hundreds of milliseconds. The ability of halothane but not isoflurane to inhibit muscarinic signaling activated by acetylcholine indicates a variable effect of anesthetics and suggests that muscarinic inhibition might be more relevant to side effects of anesthetics than to anesthetic action per se. [182] The 5-hydroxytryptamine type 2A receptor is coupled to G proteins and is inhibited by both inhaled anesthetics and the nonimmobilizer 1,2-dichlorohexafluorocyclobutane (see Fig.3-11) , implying that this receptor is not important for the immobility component of anesthesia but may relate to anesthetic-induced behavioral changes. [183]

G proteins are potential membrane sites where anesthetics exert their functional effects. G proteins are guanine nucleotide-binding neuronal membrane proteins that couple many neurotransmitter receptors to ion channels in the brain. That is, the binding of a neurotransmitter to its receptor

can influence the activation state of a G protein, which in turn can control the opening or closing of an ion channel. Evidence for an anesthetic target site on G proteins is supported (but not proved) by the abilities of clinical concentrations of volatile anesthetics to alter interactions of G proteins with some (but not all) receptors and impair the ability of guanine nucleotides to depress the high affinity binding of agonists to receptors. [184]

Membrane Enzymes and Transporters

Photoaffinity labeling of radioactive halothane demonstrates a direct binding of halothane to Ca^{2+}-ATPase, [185] an enzyme found in synaptic membranes that is 20 to 30 percent inhibited by inhaled anesthetics at 1 MAC. [186] A direct anesthetic-protein interaction may also be inferred by the ability of inhaled agents to compete with ligands known to have specific binding sites on proteins. The Na^{+}-K^{+}-Cl^{-} cotransporter (a plasma membrane protein that simultaneously transports sodium, potassium, and chloride ions into the cell) is inhibited by halothane but not by other clinical anesthetics, possibly because this membrane protein contains a hydrophobic pocket of circumscribed dimensions that allows binding of halothane but not other inhaled agents. [187]

Protein kinase C is an enzyme involved in the phosphorylation of proteins and may modulate neurotransmission through effects on transmitter release and conductance of ions through membrane channels. Alteration protein kinase C activity by volatile anesthetics and the lowering of anesthetic requirement by a protein kinase C inhibitor (staurosporine) raises the possibility that protein kinase C inhibition may play a role in the production of general anesthesia. [188] However, protein kinase C exists in several isoforms, and anesthetic effects on this enzyme are complicated, with enzyme activity depending on the isoform and tissue examined, the presence of endogenous enzyme activators, and the particular anesthetic and its duration of treatment. [189]

USE OF ANIMAL MODELS: ATTEMPTS TO RELATE SUSTAINED ALTERATIONS IN ANESTHETIC POTENCY WITH NEUROCHEMICAL COMPOSITION

One approach to the mechanism of anesthetic action is to relate alterations in anesthetic requirement with biochemical and biophysical changes occurring in the CNS. A correlation between changes in anesthetic requirement and a structural change in the nervous system might indicate the critical properties of the anesthetic site of action and how anesthetics affect that site.

Dietary Studies

Mice fed diets of different fatty acid composition (saturated versus unsaturated) from birth have large alterations in certain synaptic membrane fatty acid components. [190] The most notable changes occur in the synaptic membrane phosphatidylethanolamine and phosphatidylserine fractions in mice fed the saturated fat diet; these mice exhibit a relative decrease in docosahexaenoic (22:6omega3) and increase in eicosatrienoic (20:3omega9) fatty acids. However, these alterations in synaptic membrane fatty acid composition have little or no influence on the righting-reflex ED_{50} for N_2O and isoflurane. [190] In contrast, diet-induced alterations in rat brain fatty acid composition can be correlated with alterations in anesthetic potency. [191] Compared with rats on a control diet, rats maintained on a fat-free diet exhibit lower levels of whole brain arachidonic acid (20:4omega6) and docosahexaenoic acid and an increase in eicosatrienoic acid. The fat-deprived animals exhibited a 10 to 33 percent decrease in MAC for methoxyflurane, halothane, isoflurane, and cyclopropane as compared with control rats. [191] Furthermore, the enhanced sensitivity of the fat-deprived rats to inhaled agents could be reversed by supplementing the fat-deprived animals with linoleic acid (18:2omega6). [191] The alterations in anesthetic potency are correlated with changes in brain arachidonyl-phosphatidylinositol content, and one speculation is that such changes in arachidonyl-phosphatidylinositol content might alter the ability of neurotransmitters to synthesize chemical second messengers, thus altering neuronal excitability and anesthetic requirement. [192]

Tolerance Studies

Chronic Tolerance

Inhaled anesthetic requirement can be increased by the chronic exposure of mice to subanesthetic levels of N_2O. [193] [194] [195] [196] The maximal increase in the N_2O righting-reflex ED_{50} for mice placed under 40 to 70 percent N_2O is approximately 0.25 atm and occurs after 2 weeks of continuous exposure. Tolerance disappears within 6 days of removing the mice from the subanesthetic N_2O environment. [193] [194] Mice tolerant to N_2O are also more tolerant to cyclopropane, [195] isoflurane, [195] and nitrogen. [196]

One possible mechanism for the tolerance that develops is that the continuous exposure to anesthetic alters the physical state of neuronal membranes and that the animals might adapt to this perturbation by adjusting the neuronal membrane lipid composition so that the physical state of the membrane is returned to that prior to anesthetic exposure. However, no significant differences in membrane order or in the composition of purified synaptic membrane fatty acid, phospholipid, or cholesterol occur in mice tolerant to N_2O. [193] [194] [197] Nevertheless, preliminary evidence indicates a lesser anesthetic-induced perturbation of membranes isolated from tolerant than from nontolerant animals. [197] Other possible mechanisms behind tolerance development include alterations in neurotransmitter levels or their receptors. Prolonged exposure of rats to N_2O decreases brain-stem opiate receptor density by approximately 20 percent and may in part account for the tolerance to the analgesic action of N_2O. [198]

Acute Tolerance

In humans, a tolerance to the analgesic effect of N_2O is seen in some but not all patients within 10 to 60 minutes of

administration. [199] A rapidly developing tolerance to the anesthetic effects of gaseous agents is also seen in mice, [200] and this is associated with a withdrawal syndrome that occurs when animals are removed from the anesthetic environment. [201] This syndrome may be related to the emergence delirium occasionally seen in patients after general anesthesia. Although an involvement of calcium channels is suggested by the ability of a calcium entry blocker to prevent N_2O tolerance and withdrawal seizures, [201] the mechanistic bases of the acute tolerance and the withdrawal syndrome remain to be determined.

Genetic Studies

Genetic approaches to anesthetic mechanisms involve the development of lines of animals or the discovery of mutants that are markedly sensitive or resistant to anesthetics and examination of the physiologic (cellular) and molecular changes in these selected animals that explain their altered anesthetic sensitivities. Most genetic studies have involved three different types of organisms: nematodes *(C. elegans),* fruit flies *(Drosophila),* and mice. Nematodes and fruit flies are advantageous in genetic studies because of their well-mapped genomes, defined nervous systems, short life cycles, and relatively low cost. However, the behavioral assays used to assess anesthetic potencies in these simpler organisms may be difficult to relate to the anesthetic-induced immobility and amnesia in patients during surgical anesthesia.

C. elegans

The potencies of inhaled agents in wild-type *C. elegans* parallel those found in higher animals. [202] [203] Although certain behavioral end points (e.g., mating, chemotaxis, coordinated movement) are disrupted at clinical anesthetic concentrations, [203] anesthetic-induced immobility of nematodes requires anesthetic concentrations of
10 MAC. [202] [203] Mutants of *C. elegans* have been developed that are hypersensitive to clinical anesthetics, and additional mutations were discovered that could suppress this hypersensitivity to some but not all anesthetics. [202] A genetic pathway was described that controls the sensitivity to volatile anesthetics in *C. elegans,* and it was suggested that at least three different sites of anesthetic action exist in this organism. [202] The molecular bases of these sites remain to be determined.

Drosophila

Potencies of inhaled anesthetics in wild-type *Drosophila*(measured by either response to mechanical [204] or heat [205] stimuli or disruption of coordinated movement [122]) approximate those required for surgical anesthesia. Mutant have been obtained that are resistant and sensitive to various anesthetics, [204] [205] with anesthetic sensitivity depending on the agent examined and end point measured. [205] Mutations that affect ion channels change the sensitivity of *Drosophila* to volatile

anesthetics in a manner suggesting an agentspecific action through different neuronal pathways. [206]

Mice

With selective breeding, use is made of the fact that anesthetic requirement varies slightly among animals of a given species and that members resistant and vulnerable to anesthesia may be found in a normal population. Mice can be selected from a normal population with consistently high and consistently low N_2O righting-reflex ED_{50}. [207] Repeating the process of selection, breeding, and testing for N_2O requirement through 15 generations produced two lines of mice with N_2O requirements separated by as much as 1 atm (Fig. 3-15). [9] [207] Mice resistant to N_2O also have a higher requirement for other inhaled anesthetics, but the separation in righting-reflex ED_{50} values between the two lines is inversely related to the lipid solubility of the anesthetic. [9] N_2O ED_{50} values of offspring produced by cross-mating animals of the resistant and vulnerable lines approximate the average value of the parents, implying that the genetic control of resistance or susceptibility probably involves many genes. [208] The differences in N_2O requirement between these lines of mice could not be explained by an alteration in synaptic membrane fatty acid, phospholipid, or cholesterol composition [207] but may be explained, at least in part, by a higher

Figure 3-15 Nitrous oxide righting-reflex ED_{50} values for male (closed symbols) and female (open symbols) offspring of mice selectively bred for resistance (HI group, circles) or susceptibility (LO group, triangles) to nitrous oxide anesthesia. The nitrous oxide requirements for HI and LO mice became progressively more separated over 15 generations of selective breeding. Standard errors about most points are less than 0.03 atm. Values for generations 1 through 10 are taken from references [9] and [207].

TABLE 3-3 -- Possible Sites of Anesthetic Action

ANATOMIC LEVEL	SITE OF ACTION	COMMENTS
Macroscopic	Central Nervous System	
	Brain vs. Spinal Cord	Anesthetics disrupt transmission throughout the CNS; decerebration does not alter MAC.
Microscopic	Axons vs. Synapses	Higher concentrations of inhaled anesthetic are typically required to disrupt axonal synaptic than transmission.
	Excitatory vs. Inhibitory Synapses	Anesthetics may block excitatory and enhance inhibitory transmission.
	Presynaptic vs. Postsynaptic	Anesthetics may alter presynaptic release of neuro-transmitter (perhaps via changes in intracellular Ca^{++}) and modify flow of ions through postsynaptic channels.
Molecular		*Meyer-Overton Rule* implies a hydrophobic site of action.
	Membrane	*Critical volume hypothesis* purports anesthetic action through membrane expansion. Possible importance of membrane/aqueous interface.
	Lipid vs. Protein	Lipid *fluidization* theories cannot account for the production of the anesthetic state. Evidence accumulating for direct binding of anesthetics to "excitable" membrane proteins.

brain norepinephrine content in resistant as compared with susceptible mice. [209]

An alternative genetic approach is to "knock out" a gene in embryonic stem cells thought to be important for the anesthetic state and examine anesthetic sensitivity in mice that lack functional genes. Targeted disruption of the neuronal nitrous oxide synthase gene has no influence on isoflurane MAC or isoflurane righting-reflex ED_{50} in knock-out compared to wild-type mice. [102] Unlike wild-type mice, acute administration of nitrous oxide synthase inhibitors does not decrease anesthetic

requirement in these knock-out mice, suggesting that other non-nitrous oxide mechanisms exist in the knock-out mice to compensate for the mutation. [102] Gene knock-out of the a6 subunit of the GABA receptor does not alter MAC or righting-reflex ED_{50} for enflurane or halothane, implying that this particular subunit of the GABA receptor is not important in the behavioral responses to volatile anesthetics. [210]

SUMMARY

We remain uncertain of the site of anesthetic action at the macroscopic, microscopic, and molecular levels (Table 3-3) . We do know that inhaled anesthetics disrupt neuronal transmission in many areas of the CNS. They may either enhance or depress excitatory or inhibitory transmission through axons or synaptic regions. Both pre- and postsynaptic effects have been found. Regardless of the macroscopic site of action, the ultimate action of inhaled agents is on neuronal membranes. Although a direct neuronal plasma membrane interaction seems likely, the possibility remains that inhaled anesthetics act indirectly via production of a second messenger. The correlation between lipid solubility and anesthetic potency suggests that anesthetics have a hydrophobic or amphipathic site of action. The discovery of "nonimmobilizers," lipid-soluble compounds that do not alter MAC, implies the site of action is different for different anesthetic end points. Anesthetics bind to and perturb both membrane lipids and proteins, but it is presently uncertain which of these components is most important and how such perturbations might lead to the anesthetic state. Future advances in anesthetic mechanisms will go hand in hand with the development of molecular biology techniques used to clone and characterize excitable membrane channels and biophysical and biochemical advances used to study neuronal interactions. The development of animal models with sustained alterations in anesthetic potency will allow for the testing of hypotheses that specific molecular changes in selected regions of the CNS are important in the production of anesthesia.

Chapter 4 - Uptake and Distribution

Edmond I. Eger II

INTRODUCTION

The modern anesthetist expeditiously develops and then sustains a brain anesthetic concentration sufficient for surgery, doing so with agents and techniques that usually permit a rapid recovery from anesthesia. Producing an adequate brain anesthetic concentration for surgery requires sufficient anesthetic delivery to the patient that does not impose excessive depression. Knowledge of the factors that govern the relationship between the delivered and brain (or heart or muscle) concentrations is indispensable to the optimum conduction of anesthesia.

THE INSPIRED TO ALVEOLAR ANESTHETIC RELATIONSHIP

Of the steps between delivered and brain anesthetic partial pressures, none is more pivotal than that between the inspired and alveolar gases. The alveolar partial pressure governs the partial pressures of anesthetic in all body tissues: all must approach and ultimately equal the alveolar partial pressure. By use of high inflow rates (and hence conversion to a nonrebreathing system), the anesthetist can precisely control the partial pressure of anesthetic that is inspired.

The Effect of Ventilation

Two factors determine the rate at which the alveolar concentration of anesthetic (F_A) rises toward the concentration being inspired (F_I): the inspired concentration (see The Concentration Effect) and alveolar ventilation. Ventilation exerts a powerful effect. On induction, the unopposed effect of ventilation rapidly increases the alveolar concentration (i.e., F_A/F_I quickly approaches 1). This occurs with preoxygenation to achieve high alveolar concentrations of oxygen. Normally, a 95 percent or greater washin of oxygen occurs in 2 minutes or less when a nonrebreathing (or high inflow rate) system is used (Fig. 4-1) (Figure Not Available) .

However, inhaled anesthetics do not mimic the rapid washin of oxygen. The solubility of anesthetics is far higher than that of oxygen (or nitrogen), and the higher solubility causes the transfer of substantial quantities of anesthetic to

Figure 4-1 (Figure Not Available) The washin of oxygen was determined in two patients breathing from a mask. Note that a 63% change is obtained in about a half minute, an 86% change in about a minute, and a 95- 98% change in 2 minutes. *(From Eger [unpublished data])*

the blood passing through the lung. This uptake opposes the effect of ventilation to increase the alveolar anesthetic concentration. At low inspired concentrations, the F_A/F_I ratio is ultimately determined by the balance between the delivery of anesthetic by ventilation and its removal by uptake. The relationship is a simple one. For example, if uptake removes one-third of the inspired anesthetic molecules, F_A/F_I equals two-thirds; if uptake removes two-thirds of the inspired molecules, F_A/F_I equals one-third.

Anesthetic Uptake Factors

Anesthetic uptake itself is the product of three factors: solubility (lambda), cardiac output (Q), and alveolar to venous partial pressure difference (P_A-P_V). [1] That is:

Uptake = (lambda) × (Q) × (P_A-P_V) divided by barometric pressure

The fact that uptake is a product of the three factors rather than a sum means that if any factor approaches zero, uptake must approach zero, and ventilation is free to rapidly drive the alveolar concentrations upward. Thus, if solubility is small (as in the case of oxygen), if cardiac output approaches zero (as in profound myocardial depression or death), or if the alveolar to venous difference becomes inconsequential (as might occur after an extraordinarily long anesthetic), uptake would be minimal, and F_A/F_I would quickly equal 1.

Solubility

The blood/gas partition coefficient (lambda, or "blood solubility") describes the relative affinity of an anesthetic for two phases and hence how that anesthetic partitions itself between the two phases when equilibrium has been achieved. For example, isoflurane has a blood/gas partition coefficient of 1.4, indicating that at equilibrium, isoflurane's concentration in blood is 1.4 times its concentration in the gas (alveolar) phase. "Equilibrium" means that no difference in partial pressure exists (i.e., a blood/gas partition coefficient of 1.4 does not indicate that the partial pressure in blood is 1.4 times that in the gas phase). The partition coefficient may be thought of in another way--it indicates the relative capacity of the two phases. Thus, a value of 1.4 means that each milliliter of blood holds 1.4 times as much isoflurane as a milliliter of alveolar gas.

A larger blood/gas partition coefficient produces a greater uptake and hence a lower F_A/F_I ratio. Because the anesthetic partial pressure in the alveoli is transmitted to the arterial blood and thence to all tissues (especially the brain), the development of an adequate brain anesthetic partial pressure may be delayed in the case of highly blood-soluble agents, such as ether and methoxyflurane (Table 4-1) [1] . Indeed, the delay in development of an anesthetizing cerebral partial pressure contributed to the elimination of such highly blood-soluble agents from anesthetic practice. Even the moderate solubility of enflurane, isoflurane, or halothane would slow induction of anesthesia with these agents were it not for the use of anesthetic overpressure--that is, we compensate for the uptake of anesthetic by delivering a higher concentration than we hope to achieve in the alveoli. For example, on induction of anesthesia, we may use 4 to 5 percent halothane to produce an alveolar concentration of 1 percent. The use of overpressure can eliminate differences among anesthetics that otherwise would result as a consequence of differences in solubility. For example, induction of anesthesia with 5 percent halothane is essentially as rapid as induction with 8 percent sevoflurane, despite a nearly fourfold greater solubility of halothane. [2]

TABLE 4-1 -- Partition Coefficients at 37°C

ANESTHETIC	BLOOD/GAS	BRAIN/BLOOD	LIVER/BLOOD	KIDNEY/BLOOD	MUSCLE/BLOOD	FAT/BLOOD
Desflurane	0.45	1.3	1.4	1.0	2.0	27
Nitrous oxide	0.47	1.1	0.8	--	1.2	2.3
Sevoflurane	0.65	1.7	1.8	1.2	3.1	48
Isoflurane	1.4	1.6	1.8	1.2	2.9	45
Enflurane	1.8	1.4	2.1	--	1.7	36
Halothane	2.5	1.9	2.1	1.2	3.4	51
Diethyl ether	12	2.0	1.9	0.9	1.3	5
Methoxyflurane	15	1.4	2.0	0.9	1.6	38

Data from Eger et al, [1] [81] [83] [86] [87] Cromwell and Eger, [82] Yasuda et al, [84] and Lerman et al [85]

Cardiac Output

The effect of altering cardiac output is intuitively obvious. A greater passage of blood through the lungs removes more anesthetic and thereby lowers the alveolar anesthetic concentration. To the beginning student of uptake and distribution, this may appear to produce a conflict. It would seem that if more agent were taken up and delivered more rapidly to the tissues, the tissue anesthetic partial pressure should rise more rapidly. In one sense this is true: an increase in cardiac output does hasten the equilibration of tissue anesthetic partial pressure with the partial pressure in arterial blood. [3] What this reasoning ignores is the fact that the anesthetic partial pressure in arterial blood is lower than it would be if cardiac output were normal.

The effect of a change in cardiac output is analogous to the effect of a change in solubility. As already noted, doubling solubility doubles the capacity of the same volume of blood to hold anesthetic. Doubling cardiac output also would double capacity, but in this case by increasing the volume of blood exposed to anesthetic.

The Alveolar to Venous Anesthetic Gradient

The alveolar to venous anesthetic partial pressure difference results from tissue uptake of anesthetic. Were there no tissue uptake, the venous blood returning to the lungs would contain as much anesthetic as it had when it left the lungs as arterial blood. That is, the alveolar (which equals arterial) to venous partial pressure difference would be zero. The presumption that alveolar and arterial anesthetic partial pressures are equal is reasonable in normal patients who have no barrier to diffusion of anesthetic from alveoli to pulmonary capillary blood and who do not have ventilation/perfusion ratio abnormalities. Later, we shall consider the effect of ventilation/perfusion ratio abnormalities on anesthetic uptake.

The factors that determine the fraction of anesthetic removed from blood traversing a given tissue parallel the factors that govern uptake at the lungs: tissue solubility, tissue blood flow, and arterial to tissue anesthetic partial pressure difference. Again, uptake is the product of these three factors. If any one factor approaches zero, uptake by that tissue becomes inconsequential. The succeeding paragraphs discuss the characteristics of each of these factors and then how uptake by individual tissues can be summed to give the venous component of the alveolar to venous anesthetic partial pressure difference.

Blood/gas partition coefficients span a range of values extending from 0.45 for desflurane to 15 for methoxyflurane (see Table 4-1) . In contrast, tissue/blood partition coefficients (i.e., tissue solubility) for lean tissues are close to 1, ranging from slightly less than 1 to a maximum of 3.4 (see Table 4-1) --that is, different lean tissues do not have greatly different capacities per milliliter of tissue. Put another way, a given anesthetic has roughly the same affinity for lean tissues and blood. As with blood/gas partition coefficients, tissue/blood partition coefficients define the concentration ratio of anesthetic at equilibrium. For example, a halothane brain/blood partition coefficient of 1.9 means that 1 mL of brain can hold 1.9 times as much halothane as 1 mL of blood having the same halothane partial pressure.

Lean tissues differ in the volume of tissue relative to the volume of blood passing that tissue. A larger volume of tissue relative to flow has two implications. First, the large tissue capacity increases the transfer of anesthetic from blood to tissue. Second, it takes longer to fill up a tissue with a large capacity (i.e., it takes longer for the tissue to equilibrate with the anesthetic partial pressure being delivered in arterial blood). That is, a large tissue volume relative to blood flow sustains the arterial to tissue anesthetic partial pressure difference (and hence uptake) for a longer time. With its high perfusion per gram, brain equilibrates rapidly with the anesthetic partial pressure brought to it in arterial blood. Per milliliter of tissue, muscle has about one-twentieth the perfusion of brain, and thus muscle takes about 20 times as long as brain to equilibrate. Uptake of anesthetic by muscle continues long after uptake by brain has ceased.

Fat has a tissue/blood coefficient that is significantly greater than 1, particularly for more potent anesthetics (see Table 4-1) . Fat/blood coefficients range from 2.3 (nitrous oxide) to 51 (halothane) to 61 (methoxyflurane). That is, each milliliter of fat tissue contains 2.3 times more nitrous oxide or 51 times as much halothane than a milliliter of blood having the same nitrous oxide or halothane partial pressure. This enormous capacity of fat for anesthetic means that most of the anesthetic contained in the blood perfusing fat is transferred to the fat. Although most of the anesthetic moves from the blood that perfuses fat into the fat, the anesthetic partial pressure in that tissue rises very slowly. Both the large capacity of fat and the low perfusion per milliliter of tissue prolong the time required to narrow the anesthetic partial pressure difference between arterial blood and fat.

Tissue Groups

The algebraic sum of uptake by individual tissues determines the alveolar to venous partial pressure difference and hence the uptake at the lungs. However, we do not need to analyze the effect of individual tissues to arrive at the algebraic sum; instead, we can group tissues in terms of their perfusion and solubility characteristics (i.e., in terms of those features that define the duration of a substantial arterial to tissue anesthetic partial pressure difference). Four tissue groups result from such an analysis (Table 4-2) . [1]

The vessel-rich group (VRG) is composed of the brain, heart, splanchnic bed (including liver), kidney, and endocrine glands. These organs make up less than 10 percent of the body weight but receive 75 percent of the cardiac output. This high perfusion confers several features. Access to a large flow of blood permits the VRG to take up a relatively large volume of anesthetic in the earliest moments of induction. However, the small volume of tissue relative to perfusion produces a rapid equilibration of this tissue group with the anesthetic delivered in arterial blood. The time to half equilibration (i.e., the time at which the VRG anesthetic partial pressure equals half that in arterial blood) varies from about 1 minute for nitrous oxide to 2 minutes for halothane. The longer time to equilibration with halothane results from its higher tissue/blood partition coefficients (see Table 4-1) . Equilibration of the VRG with the anesthetic partial pressure in arterial blood is over 90 percent complete in 4 to 8

TABLE 4-2 -- Tissue Group Characteristics

	VESSEL-RICH	GROUP		*VESSEL-POOR*
		MUSCLE	*FAT*	
Percentage of body mass	10	50	20	20
Perfusion as percentage of cardiac output	75	19	6	0

Adapted from Eger [1]

minutes. Thus, after 8 minutes, uptake by the VRG is too small (i.e., the arterial to VRG anesthetic partial pressure difference is too small) to significantly influence the alveolar concentration. For a substantial period after 8 minutes, uptake is principally determined by the muscle group.

Muscle and skin, which make up the muscle group, have similar blood flow and solubility (lean tissue) characteristics. The lower perfusion (about 3 mL of blood per 100 mL of tissue per minute) sets this group apart from the VRG (70 mL per 100 mL per minute). Although about half of the body bulk is muscle and skin, this volume receives only 1 L/min blood flow at rest. That is, this tissue group receives one-quarter the amount of anesthetic delivered to the VRG and initially takes up only approximately one-quarter as much anesthetic. The large bulk relative to perfusion means two things: (1) during induction, most of the anesthetic delivered to the muscle group is removed from the muscle group blood flow, and (2) the muscle group continues to remove anesthetic from its blood supply for a long time. The time to half equilibration ranges from 20 to 25 minutes (nitrous oxide) to 70 to 80 minutes (sevoflurane or halothane). Thus, long after equilibration of the VRG has taken place, muscle continues to take up substantial amounts of anesthetic. This tissue approaches equilibration in 2 to 4 hours.

Once equilibration of muscle is complete, only fat (i.e., the fat group) continues to serve as an effective depot for uptake. In a normal lean patient, fat occupies one-fifth of the body bulk and receives a blood flow of about 400 mL/min (i.e., the perfusion per 100 mL of fat nearly equals the perfusion per 100 mL of resting muscle). Thus, during the initial delivery of anesthetic to tissues, fat has access to only 40 percent of the anesthetic that is delivered to the muscle group (i.e., blood blow to the fat group is 40 percent of that to the muscle group). Fat also differs from muscle in its higher affinity for anesthetic, a property that greatly lengthens the

time over which it absorbs anesthetic. The half-time to equilibration of fat ranges from 70 to 80 minutes for nitrous oxide to 30 hours for sevoflurane and halothane. Equilibration with fat does not occur in the course of an ordinary halothane or enflurane anesthetic.

One tissue group, the vessel-poor group, remains to be defined. This group consists of ligaments, tendons, bone, and cartilage (i.e., those lean tissues that have little or no perfusion). The absence of a significant blood flow means that this group does not participate in the uptake process despite the fact that it makes up one-fifth of the body mass.

Synthesis of the Factors Governing the Rise of the F_A/F_I Ratio

We may now consider the combined impact of ventilation, solubility, and distribution of blood flow on the development of the alveolar anesthetic partial pressure. The initial rate of rise of F_A/F_I is rapid for all agents, regardless of their solubility (Fig. 4-2) [4] [5] . The rapidity of this upswing results from the absence of an alveolar to venous anesthetic partial pressure difference (there is no anesthetic present in the lung to create a gradient) and hence the absence of uptake in the first moment of induction. Thus, the effect of ventilation to generate a sudden rise in F_A/F_I is unopposed. Obviously, delivery of more and more anesthetic to the alveoli by ventilation produces a progressively greater alveolar to venous partial pressure difference. The resulting increase in uptake increasingly opposes the effect of ventilation to drive the alveolar concentration upwards. Ultimately, a rough balance is struck between the input by ventilation and the removal by uptake. The height of the F_A/F_I ratio at which the balance is struck depends on the solubility factor in the uptake equation (see equation for anesthetic uptake, earlier). A higher solubility produces a greater uptake for a given alveolar to venous partial pressure difference. Hence, the initial rapid rise in F_A/F_I is halted at a lower level with a more soluble agent. This results in the first "knee" in the curve--higher for desflurane than for sevoflurane, higher for sevoflurane than for isoflurane, and higher for isoflurane than for halothane. The position of nitrous oxide is discussed later (see The Concentration Effect).

The balance struck between ventilation and uptake does not remain constant. F_A/F_I continues to rise, albeit at a slower rate than seen in the first minute. This rise results from the progressive decrease in uptake by the VRG, a decrease to an inconsequential amount after 8 minutes. Thus, by about 8 minutes, three-quarters of the cardiac output returning to the lungs (i.e., the blood from the VRG) contains

Figure 4-2 The rise in alveolar (F_A) anesthetic concentration toward the inspired (F_I) concentration is most rapid with the least soluble anesthetics, nitrous oxide and desflurane, and slowest with the most soluble anesthetic, halothane. All data are from human studies. *(Data from Yasuda et al [1] [2])*

nearly as much anesthetic as it had when it left the lungs. The consequent rise in venous anesthetic partial pressure decreases the alveolar to venous partial pressure difference and hence the uptake, allowing ventilation to drive the alveolar concentration upward to the second knee at roughly 8 minutes.

With the termination of effective uptake by the VRG, muscle and fat become the principal determinants of tissue uptake. The slow rate of change of the anesthetic partial pressure difference between arterial blood and muscle or fat produces the relatively stable terminal portion of each curve in Figure 4-1 (Figure Not Available) . In fact, this terminal portion gradually ascends as muscle and, to a lesser extent, fat progressively equilibrate with the arterial anesthetic partial pressure. If the graphs were extended for several hours, a third knee would be found that indicates equilibration of the muscle group. Uptake after that time would principally depend on the partial pressure gradient between arterial blood and fat.

The Concentration Effect

The aforementioned analysis ignores the impact of the concentration effect on F_A/F_I. The inspired anesthetic concentration influences both the alveolar concentration that may be attained and the rate at which that concentration may be attained. [6] [7] Increasing the inspired concentration accelerates the rate of rise. At an inspired concentration of 100 percent, the rate of rise is extremely rapid because it is dictated solely by the rate at which ventilation washes gas into the lung; that is, at 100 percent inspired concentration, uptake no longer limits the level to which F_A/F_I may rise. The cause of this extreme effect is readily perceived. At 100 percent inspired concentration, the uptake of anesthetic creates a void, which draws gas down the trachea. This additional inspiration replaces the gas taken up. Because the concentration of the replacement gas is 100 percent, uptake cannot modify the alveolar concentration. This explains why the rise of nitrous oxide shown in Figure 4-2 is more rapid than the rise of desflurane, despite the identity of their blood/gas partition coefficients.

The concentration effect results from two factors, a concentrating effect and an augmentation of inspired ventilation. [8] Both are illustrated in Figure 4-3 (Figure Not Available) . The first rectangle represents a lung containing 80 percent nitrous oxide. If half of this gas is taken up, the residual 40 volumes of nitrous oxide exist in a total of 60 volumes, yielding a concentration of 67 percent Figure 4-3 (Figure Not Available) A. That is, uptake of half the nitrous oxide does not halve the concentration, because the remaining gases are "concentrated" in a smaller volume. If the void created by uptake is filled by drawing more gas into the lungs (an augmentation of inspired ventilation), the final concentration equals 72 Figure 4-3 (Figure Not Available) B.

This explanation has been criticized as overly simplistic, as ignoring the realities of some aspects of ventilation. [9] For example, if ventilation is controlled with a volume-limited respirator, an augmentation in inspired ventilation is limited to the period of the expiratory pause. If ventilation is spontaneous, this limitation is minimized. In any event, the reader needs to be aware that although Figure 4-3 (Figure Not Available) describes the basic factors governing the concentration (and second gas effects--see later), the actual situation is more complex.

The impact of the concentration effect on F_A/F_I may be thought of as identical to the impact of a change in solubility [10] ; as the inspired concentration increases, the effective solubility decreases. Thus, at 50 percent inspired nitrous oxide, the F_A/F_I rises as rapidly as the F_A/F_I of an anesthetic that has half the solubility of nitrous oxide and is given at 1 percent inspired concentration, and 75 percent inspired nitrous oxide acts as does an anesthetic given at 1 percent that has one-quarter the solubility of nitrous oxide.

The Second Gas Effect

The factors that govern the concentration effect also influence the concentration of any gas given concomitantly. [8] [11] This second gas effect applies to halothane or enflurane when it is administered with nitrous oxide. The loss of volume associated with the uptake of nitrous oxide concentrates the halothane or enflurane (see Fig. 4-3 (Figure Not Available) A). Replacement of the gas taken up by an increase in inspired ventilation augments the amount of halothane or enflurane present in the lung (see Fig. 4-3 (Figure Not Available) B).

Both the concentration effect and the second gas effect were demonstrated by the following experiments. [11] Dogs were given 0.5 percent halothane in either 10 percent nitrous oxide or 70 percent nitrous oxide. The F_A/F_I for nitrous oxide rose more rapidly when 70 percent nitrous oxide was inspired than when 10 percent was inspired (the concentration effect) (Fig. 4-4) (Figure Not Available) . Similarly, the F_A/F_I ratio for halothane rose more rapidly when 70 percent nitrous oxide

Figure 4-3 (Figure Not Available) The rectangle to the left represents a lung filled with 80% nitrous oxide plus 1% of a second gas. (A) Uptake of half the nitrous oxide does not halve the concentration of nitrous oxide, and the reduction in volume thereby increases the concentration of the second gas. (B) Restoration of the lung volume by addition of gas at the same concentration as that contained in the left-most rectangle will increase the nitrous oxide concentration and add to the amount of the second gas present in the lung. *(Modified from Stoelting and Eger [6])*

Figure 4-4 (Figure Not Available) In dogs, administration of 70% nitrous oxide produces a more rapid rise in the F_A/F_I ratio of nitrous oxide than administration of 10% (concentration effect, upper two curves). The F_A/F_I ratio for 0.5% halothane rises more rapidly when given with 70% nitrous oxide than when given with 10% (second gas effect, lower two curves). *(Modified from Epstein et al [11])*

was inspired than when 10 percent was inspired (second gas effect).

Percutaneous Anesthetic Loss

I have ignored three possible avenues by which anesthetics may be lost: (1) transcutaneous movement, (2) transvisceral movement, and (3) metabolism. Although transcutaneous movement occurs, the movement is small. [12] [13] [14] [15] The greatest loss per alveolar anesthetic percent occurs with nitrous oxide. Loss of nitrous oxide might equal 5 to 10 mL/min with an alveolar concentration of 70 percent. The movement of anesthetic across visceral or pleural surfaces during abdominal or pulmonary surgery is larger than the movement across skin, but such visceral losses are usually small relative to total uptake. [16]

Metabolism of Anesthetic

Although percutaneous loss of anesthetic may not appreciably affect anesthetic uptake, loss of anesthetic by biodegradation can produce significant changes, particularly with agents that undergo extensive biodegradation. Berman et al [17] found that phenobarbital pretreatment in rats decreased the arterial level of methoxyflurane. Carpenter et al [18] found biodegradation of as much as half of the halothane and three-quarters of the methoxyflurane that was taken up. They speculated that this biodegradation could explain the finding that the alveolar concentration of halothane decays more rapidly on recovery from anesthesia than the alveolar concentration of isoflurane, an anesthetic that is significantly less soluble in blood. [19] [20] Two reasons suggest that agents such as isoflurane and desflurane are less likely to be affected: first, they are not metabolized as readily as halothane or methoxyflurane, [21] [22] and second, anesthetizing concentrations appear to saturate the enzymes responsible for anesthetic metabolism. [23] Saturation of enzymes particularly may limit the impact of metabolism during the washin as opposed to the washout of anesthetic. The combined effect of these factors remains to be determined, but it appears that metabolism is not a significant determinant of F_A/F_I during anesthesia with isoflurane or desflurane. [4] [5] A small influence on the kinetics of sevoflurane may exist, explaining why there is a more substantial difference between the F_A/F_I for desflurane versus sevoflurane during induction and maintenance of anesthesia than for the parallel washout curves (F_A/F_{AO}) during recovery. [24]

Intertissue Diffusion

Carpenter et al [19] [20] examined the washin and washout of isoflurane, enflurane, halothane, and methoxyflurane given simultaneously for fixed periods of time to healthy young patients. Washout was examined for several days after discontinuation of anesthetic administration. Analysis suggested that a model with five compartments best explained the resulting data for all the anesthetics (i.e., the model was independent of solubility and anesthetic metabolism). The half-times of four of these compartments were consistent with the model used earlier in this chapter. Thus, these compartments could be related to washin and washout of the lungs, the VRG, the muscle group, and the fat group.

However, an additional important compartment was more difficult to explain. This compartment had a half-time of roughly 300 minutes, which is between those for muscle and for fat. This additional compartment, which was important because it accounted for almost one-third of the anesthetic taken up, could in part be explained by uptake by highly perfused fat, such as that found in bone marrow. However, the perfusion of such tissue is not sufficient to account for the major portion of uptake by this compartment. Carpenter et al [19] [20] speculated that this uptake resulted from diffusion of anesthetic from lean tissue to an adjacent thin layer of fat tissue. Such diffusion could be from the heart to pericardial fat, from the kidney to perirenal fat, from the intestine to mesenteric and omental fat, and from the dermis to subcutaneous fat. Yasuda et al [4] [5] confirmed these findings, extending them to desflurane and sevoflurane.

FACTORS MODIFYING THE RATE OF RISE OF F_A/F_I

Alteration of those factors that govern the rate of delivery of anesthetic to the lungs or its removal from the lungs alters the alveolar concentration of anesthetic. We have seen the importance of differences in solubility (see Fig. 4-2) . The succeeding sections examine the impact of differences in ventilation and circulation and the interaction of these differences with factors such as solubility.

The Effect of Ventilatory Changes

By augmenting delivery of anesthetic to the lungs, an increased ventilation accelerates the rate of rise of F_A/F_I [1] [25]

Figure 4-5 (Figure Not Available) The F_A/F_I ratio rises more rapidly if ventilation is increased. Solubility modifies this impact of ventilation: the effect on the anesthetizing partial pressure is greatest with the most soluble anesthetic (ether) and least with the least soluble anesthetic (nitrous oxide). *(Modified from Eger [9])*

(Fig. 4-5) (Figure Not Available) . A change in ventilation produces a greater relative change in F_A/F_I with a more soluble anesthetic. In Figure 4-5 (Figure Not Available) , an increase in ventilation from 2 to 8 L/min triples the ether concentration at 10 minutes, only doubles the halothane concentration, and scarcely affects the nitrous oxide concentration.

The impact of solubility may be explained as follows. With a poorly soluble agent, such as nitrous oxide, the rate of rise of F_A/F_I is rapid, even with hypoventilation. Because F_A normally cannot exceed F_I, there is little room for an augmentation of ventilation to increase F_A/F_I. With a highly soluble agent, such as ether and methoxyflurane, most of the anesthetic delivered to the lungs is taken up, so that if the uptake at 2 L/min ventilation equaled X, the uptake at 4 L/min would approach 2X. Thus, if cardiac output is held constant, ventilation of 4 L/min produces an arterial ether concentration that is nearly twice the concentration produced by a ventilation of 2 L/min. Because arterial and alveolar concentrations are in equilibrium, our example suggests that doubling ventilation must nearly double the concentration of a highly soluble anesthetic in lung or blood.

These observations imply that imposed alterations in ventilation (e.g., an increase produced by conversion from spontaneous to controlled ventilation) produce greater changes in anesthetic effect with more soluble agents. Because such effects include both anesthetic depth and depression of circulation, greater caution must be exercised when ventilation is augmented during anesthesia produced with a highly soluble agent.

Anesthetics themselves may alter ventilation and thereby alter their own uptake. [3] [26] Modern potent agents (desflurane, enflurane, halothane, isoflurane, sevoflurane) are profound respiratory depressants, whose depression of ventilation is inversely related to anesthetic dose. [27] [28] [29] [30] [31] At some dose, all inhaled anesthetics probably produce apnea, a feature that must limit the maximum alveolar concentration that can be obtained if ventilation is spontaneous.

Thus, administration of an anesthetic concentration that produces significant respiratory depression progressively decreases delivery of anesthetic to the alveoli. [3] [32] As a result, doubling the inspired concentration does not double the alveolar concentration attained at a given point in time. At high inspired concentrations, further increases in inspired concentration produce little absolute change in the alveolar concentration (Fig. 4-6) (Figure Not Available) . Anesthetics can thereby

Figure 4-6 (Figure Not Available) An increase in inspired halothane concentration does not produce a proportional increase in the alveolar concentration because of the progressively greater depression of ventilation which occurs as alveolar halothane is increased. The initial "overshoot" seen with 10 to 20% inspired halothane results from the delay in the transfer of alveolar halothane partial pressure to the brain. *(From Munson et al [5])*

exert a negative feedback effect on their own alveolar concentration, an effect that increases the safety of spontaneous ventilation by limiting the maximum concentration that is attained in the alveoli.

The Effect of Changes in Cardiac Output

The discussion in the previous section assumed a constant cardiac output and examined the effect of changes in ventilation. In this section, the reverse process is discussed. An increase in cardiac output augments uptake and thereby hinders the rise in F_A/F_I. [1] [33] As with a change in ventilation, a change in cardiac output scarcely affects the alveolar concentration of a poorly soluble agent; the alveolar concentration of a highly soluble agent is much more influenced (Fig. 4-7) (Figure Not Available) . The reason for the impact of a change in solubility is similar to the reason explaining the effect of a change in ventilation. A decrease in cardiac output can do little to increase the F_A/F_I ratio of a poorly soluble agent because the rate of rise is rapid at any cardiac output. In contrast, nearly all of a highly soluble agent is taken up, and a halving of blood flow through the lungs must concentrate the arterial (equals alveolar) anesthetic, nearly doubling its partial pressure in the case of an extremely soluble agent.

This effect of solubility suggests that conditions that lower cardiac output (e.g., shock) may produce unexpectedly high alveolar anesthetic concentrations if highly soluble agents are used. The higher F_A/F_I ratio should be anticipated and

Figure 4-7 (Figure Not Available) If unopposed by a concomitant increase in ventilation, an increase in cardiac output will decrease alveolar anesthetic concentration by augmenting uptake. The resulting alveolar anesthetic change is greatest with the most soluble anesthetic. *(Modified from Eger [9])*

the inspired anesthetic concentration lowered accordingly to avoid further depression of circulation. Shock presents a two-pronged problem: (1) an increase in ventilation usually accompanies the circulatory depression, and (2) both an increase in ventilation and a decrease in cardiac output accelerate the rise in F_A/F_I. Perhaps this is why such heavy reliance is placed on the use of nitrous oxide in patients in shock. In contrast to more soluble anesthetics (e.g., halothane), the alveolar concentration of nitrous oxide would be little influenced by the associated cardiorespiratory changes.

Anesthetics also affect circulation. Usually, they depress cardiac output, [34] [35] although stimulation may occur with some agents (e.g., nitrous oxide). In contrast to the negative feedback that results from respiratory depression, circulatory depression produces a positive feedback: depression decreases uptake, and this increases the alveolar concentration, which in turn further decreases uptake. A potentially lethal acceleration of the rise in F_A/F_I results from the depression of cardiac output (Fig. 4-8) (Figure Not Available) [3] [26] [32] . The impact of this acceleration increases in importance with increasing anesthetic solubility. High inspired concentrations of

agents such as enflurane and halothane should be administered with considerable caution, particularly if ventilation is controlled.

The Effect of Concomitant Changes in Ventilation and Perfusion

The preceding considerations of the effects of ventilatory and circulatory alterations presume that only one of these variables was changed while the other was held constant. In fact, both may change concomitantly. If both ventilation and cardiac output increase proportionately, an intuitive expectation

Figure 4-8 (Figure Not Available) Dogs given a constant ventilation demonstrate different rates of rise of F_A/F_I. The rates of rise depend on the inspired halothane concentration. The two higher concentrations accelerated the rate of rise by depressing cardiac output and thereby decreasing uptake. *(Modified from Gibbons et al [32])*

Figure 4-9 (Figure Not Available) Proportional increases in alveolar ventilation (VA) and cardiac output (Q) will increase the rate at which F_A/F_I rises. As indicated in the illustration, the effect is relatively small if the increase in cardiac output is distributed proportionately to all tissues (i.e., if cardiac output is doubled, all tissue blood flows are doubled). The greatest effect occurs with the most soluble anesthetic. *(From Eger et al [36])*

might be that F_A/F_I would be little altered. After all, uptake equals the product of solubility, the cardiac output, and the alveolar to venous anesthetic partial pressure difference (see anesthetic uptake equation, earlier). In the absence of other changes, doubling cardiac output doubles uptake, and this should exactly balance the influence of doubling of ventilation on F_A/F_I. That is, a doubling of both delivery of anesthetic to the lungs and removal of anesthetic from the lungs should produce no net change in the alveolar concentration.

This reasoning ignores one other factor in the equation that defines uptake. By accelerating the rate at which tissue equilibration occurs, an increase in cardiac output accelerates the narrowing of the alveolar to venous partial pressure difference [36] and thereby reduces the impact of the increase in cardiac output on uptake. Thus, a proportional increase in ventilation and cardiac output increases the rate of rise of F_A/F_I.

The magnitude of the acceleration of rise in F_A/F_I depends in part on distribution of the increase in cardiac output. If the increase is distributed proportionately to all tissues (e.g., if a doubling of output doubles flow to all tissues), the increase is fairly small (Fig. 4-9) (Figure Not Available) [36] [37] . Thus, conditions such as hyperthermia and thyrotoxicosis would only slightly influence the development of an anesthetizing anesthetic concentration through their influence on F_A/F_I. However, if the increase in cardiac output is diverted to the VRG, a greater effect is seen. Perfusion of the VRG is normally high and results in rapid equilibration. Further increases in perfusion only hasten the rate of equilibration. Because blood returning from the VRG soon has the same partial pressure as it had when it left the lungs, it cannot remove more anesthetic from the lungs. Thus, after a few seconds or minutes, the increase in ventilation is not matched, even in part, by an increase in uptake. The result is a considerable acceleration in the rise in F_A/F_I. This effect may be seen in a comparison of the F_A/F_I curves for children and adults (Fig. 4-10) (Figure Not Available) . Children (especially infants) have a relatively greater perfusion of the VRG and consequently show a significantly faster rise in F_A/F_I (Ch. 59) . [38] A clinical result of this accelerated rise is a more rapid development of anesthesia in young patients. The higher perfusion of the brain further accelerates the development of anesthesia.

Ventilation/Perfusion Ratio Abnormalities

Up to this point, I have assumed that alveolar and arterial anesthetic partial pressures are equal (i.e., that the alveolar gases completely equilibrate with the blood passing through the lungs). For normal patients, this assumption is approximately

Figure 4-10 (Figure Not Available) The alveolar rate of rise of halothane is more rapid in children (upper curve) than in adults (lower curve.) The difference probably results from the greater ventilation and perfusion per kilogram of tissue in children and the fact that a disproportionate amount of the increased perfusion is devoted to the vessel-rich group. *(Modified from Salanitre and Rackow [38])*

correct, but diseases such as emphysema and atelectasis, as well as congenital cardiac defects, produce substantial deviations from equilibration. The associated ventilation/perfusion ratio abnormality does two things: (1) increases the alveolar (end-tidal) anesthetic partial pressure and (2) decreases the arterial anesthetic partial pressure (i.e., a partial pressure difference appears between alveolar gas and arterial blood). The relative change depends on the solubility of the anesthetic. With a poorly soluble agent, the end-tidal concentration is slightly increased, but the arterial partial pressure is significantly reduced. The opposite occurs with a highly soluble anesthetic. [39]

The considerable decrease in the arterial anesthetic partial pressure that occurs with poorly soluble agents may be explained as follows. Ventilation/perfusion ratio abnormalities increase ventilation relative to perfusion of some alveoli, whereas in other alveoli, the reverse occurs. With a poorly soluble anesthetic, an increase in ventilation relative to perfusion does not appreciably increase alveolar or arterial anesthetic partial pressure issuing from those alveoli (see effect for nitrous oxide in Fig. 4-5) (Figure Not Available) . However, when ventilation decreases relative to perfusion, a significant effect can occur, particularly when ventilation is absent, as in a segment of atelectatic lung. Blood emerges from that segment with no additional anesthetic. Such anesthetic-deficient blood then mixes with the blood from the ventilated segments containing a normal complement of anesthetic. The mixture produces an arterial anesthetic partial pressure that is considerably below normal.

With highly soluble agents, a different situation results from similar ventilation/perfusion ratio abnormalities. In alveoli receiving more ventilation relative to perfusion, the anesthetic partial pressure rises to a higher level than usual (see Fig. 4-5 (Figure Not Available) for effect with diethyl ether). That is, blood issuing from these alveoli has an increased anesthetic content, the increase being nearly proportional to the increased ventilation. Assuming that overall (total) ventilation remains normal, this increase in the anesthetic contained by blood from the relatively hyperventilated alveoli compensates for the lack of anesthetic uptake in unventilated alveoli.

These effects are illustrated in Figure 4-11 (Figure Not Available) for a condition that may be iatrogenically produced, endobronchial intubation. Because all ventilation now is directed to the intubated lung, this lung is hyperventilated relative to perfusion. F_A/F_I for this lung is slightly increased (above that obtained in the absence of endobronchial intubation) with the poorly soluble cyclopropane and greatly increased with the highly soluble ether. As indicated earlier, the increase with ether compensates for the absence of uptake from the unventilated lung, a compensatory mechanism that is not available with cyclopropane. The result is that the cyclopropane arterial partial pressure is well below normal, whereas the ether arterial partial pressure is scarcely changed.

These concepts have been confirmed experimentally by comparing the rate of arterial anesthetic rise with and without endobronchial intubation in dogs. [40] Endobronchial intubation significantly slowed the arterial rate of rise of cyclopropane but did not influence the rise with methoxyflurane. An intermediate result was obtained with halothane (Fig. 4-12) (Figure Not Available) . These data suggest that in the presence of ventilation

Figure 4-11 (Figure Not Available) When no ventilation/perfusion abnormalities exist, the alveolar (P_A or P_{ET}) and arterial (Pa) anesthetic partial pressures rise together (continuous lines) toward the inspired partial pressure (P_I). When 50% of the cardiac output is shunted through the lungs, the rate of rise of the end-tidal partial pressure (dashed lines) is accelerated while the rate of rise of the arterial partial pressure (dot-dashed lines) is retarded. The greatest retardation is found with the least soluble anesthetic, cyclopropane. *(From Eger and Severinghaus [39])*

/perfusion ratio abnormalities, the anesthetic effect of agents such as nitrous oxide, desflurane, and sevoflurane may be delayed more than the anesthetic effect of isoflurane or halothane.

Figure 4-12 (Figure Not Available) In dogs, when only the right lung was ventilated, the rise of the very soluble anesthetic methoxyflurane in arterial blood was normal (i.e., did not deviate from control), while the rise for the poorly soluble anesthetic cyclopropane was significantly slowed. *(From Stoelting and Longnecker [40])*

THE EFFECT OF NITROUS OXIDE ON CLOSED GAS SPACES

Volume Changes in Highly Compliant Spaces

During the course of anesthetic administration, appreciable volumes of nitrous oxide can move into closed gas spaces. Although this transfer does not influence F_A/F_I, it may have important functional consequences. There are two types of closed gas spaces in the body, those enclosed by compliant walls and those enclosed by noncompliant walls. The former (bowel gas, pneumothorax, or pneumoperitoneum) are subject to changes in volume secondary to the transfer of nitrous oxide into these spaces. [41] These spaces normally contain nitrogen (from air), a gas whose low solubility (blood/gas partition coefficient, 0.015) limits its removal by blood. Thus, the entrance of nitrous oxide (whose solubility permits it to be carried by blood in substantial quantities) is not countered by an equal loss, and the result is an increase in volume. The theoretical limit to the increase in volume is a function of the alveolar nitrous oxide concentration, because it is this concentration that is ultimately achieved in the closed gas space. That is, at equilibrium, the partial pressure of nitrous oxide in the closed gas space must equal its partial pressure in the alveoli. An alveolar concentration of 50 percent might double the gas space volume, and a 75 percent concentration might produce a fourfold increase.

These theoretic limits may be approached if equilibrium is rapidly achieved, as with pneumothorax or gas emboli. Administration of 75 percent nitrous oxide in the presence of a pneumothorax may double the pneumothorax volume by 10 minutes and may triple it by 30 minutes (Fig. 4-13) (Figure Not Available) [41] . This increase in volume may seriously impair

Figure 4-13 (Figure Not Available) The volume of a pneumothorax created by air injection is little affected when oxygen subsequently is breathed (filled triangle and circles). However, if 75% nitrous oxide is breathed, the volume doubles in 10 minutes and triples in a half-hour (open circles, squares, and triangles). *(From Eger and Saidman [41])*

cardiorespiratory function, [42] and the use of nitrous oxide is contraindicated in the presence of a significant pneumothorax.

A still more rapid expansion of volume occurs if air is inadvertently allowed to enter the blood stream in a patient anesthetized with nitrous oxide. Expansion may be complete in seconds rather than minutes. Munson and Merrick [43] demonstrated that the lethal volume of an air embolus was decreased in animals breathing nitrous oxide as opposed to air (Fig. 4-14) (Figure Not Available) . The difference could be entirely explained by expansion of the embolus in the animals breathing nitrous oxide (i.e., the predicted total volume of air plus nitrous oxide in the embolus equaled the volume of air needed to produce death in animals breathing only air). These studies suggest caution in the use of nitrous oxide for procedures in which air embolization is a risk (e.g., posterior fossa craniotomies, laparoscopy). They also suggest that if air embolization is suspected, nitrous oxide administration should be immediately discontinued. Conversely, a nitrous oxide "challenge" may be used to test whether air embolization has occurred. [44]

The endotracheal tube cuff normally is filled with air. It, too, is susceptible to expansion by nitrous oxide [45] ; the presence of 75 percent nitrous oxide surrounding such a cuff can double or triple the volume of the cuff. The result may be an unwanted increase in pressure exerted on the tracheal mucosa. Similarly, nitrous oxide may expand the cuffs of balloon-tipped (e.g., Swan-Ganz) catheters [46] [47] when the balloons are inflated with air. The expansion is rapid, and a doubling of volume may occur within 10 minutes.

Figure 4-14 (Figure Not Available) An air embolus equaling 0.55 mL/kg killed 50% of rabbits breathing oxygen. If the inspired gas mixture contained 75% nitrous oxide, only 0.16 mL/kg was required to kill half the animals. *(Modified from Munson and Merrick [43])*

Pressure Changes in Poorly Compliant Spaces

Pressure can be produced by the entrance of nitrous oxide into gas cavities surrounded by poorly compliant walls. Unwanted increases in intraocular pressure may be imposed by nitrous oxide administration after intravitreal sulfur hexafluoride injection. [48] Other examples include the gas space created by pneumoencephalography (now rare as a deliberate procedure) and the natural gas space in the middle ear. Pressures in the head or middle ear may rise by 20 to 50 mm Hg owing to the ingress of nitrous oxide at a faster rate than air can be removed. [49] [50] Recognition of this problem has decreased the use of nitrous oxide for tympanoplasty because the increased pressure may displace the graft. Increase in middle ear pressure may cause adverse postoperative effects on hearing. [51] The capacity of nitrous oxide to expand the gas in the middle ear has also been used to elevate an adherent atelectatic tympanic membrane off the promontory and the ossicles. [52]

ANESTHETIC CIRCUITRY

The previous discussions generally considered that the alveolar anesthetic concentration (F_A) was moving toward a constant inspired anesthetic concentration (F_I). In practice, the inspired concentration is usually not constant, because a nonrebreathing system is not used. The rebreathing that results from the use of an anesthetic circuit causes the inspired concentration to be less than that in the gas delivered from the anesthetic machine. The inspired concentration thus is influenced by the delivered concentration, by the need to "wash in" the circuit and by the depletion of anesthetic in rebreathed gases produced by uptake of anesthetic.

Washin of the Circuit

To begin anesthesia, anesthetic must be washed into the volume of the circuit. At inflow rates of 1 to 5 L/min and a circuit volume of 7 L (3-L bag, 2-L carbon dioxide absorber, and 2 L of corrugated hoses and fittings), the washin of the circuit is 75 to 100 percent complete in 10 minutes (Fig. 4-15) (Figure Not Available) . Higher inflow rates produce a more rapid rise in the inspired concentration, which suggests that induction can be accelerated and made more predictable by use of high inflow rates.

Figure 4-15 (Figure Not Available) The rate at which the inspired anesthetic concentration (F_{INS}) rises toward the inflowing concentration (F_{INF}) is determined by the inflow rate and circuit volume. In the case illustrated here, the circuit volume is 7 L. *(From Eger [91])*

Anesthetic Loss to Plastic and Soda Lime

Uptake of anesthetic by several depots also constitutes a hindrance to the development of an adequate inspired anesthetic concentration. The rubber or plastic components of the circuit may remove agent [53] [54] this was a significant problem with the obsolete anesthetic methoxyflurane, which has a high solubility in rubber and plastic (Table 4-3) . A minor problem exists for halothane and isoflurane, and no problem results from the solution of nitrous oxide, desflurane, or sevoflurane. [55]

Normal (moist) carbon dioxide absorbents containing 13 to 15 percent water can slightly increase the sevoflurane, and, to a lesser extent, the halothane requirement by degrading each of these anesthetics. [56] Degradation results in the removal of hydrogen fluoride and the production of unsaturated compounds. Nitrous oxide, desflurane, and isoflurane are not materially degraded. For sevoflurane and halothane, degradation is of concern because the unsaturated compounds produced are toxic (e.g., compound A from sevoflurane is nephrotoxic). [57]

TABLE 4-3 -- Rubber/Gas and Plastic/Gas Partition Coefficients

ANESTHETIC	POLYETHYLENE (CIRCUIT TUBE)	RUBBER (BAG)	POLYVINYL CHLORIDE (ENDOTRACHEAL TUBE)	
Nitrous oxide	--	1.2	--	
Desflurane	16	19		35
Sevoflurane	31	29		68
Isoflurane	58	49		114
Enflurane	--	74	--	
Halothane	128	190		233
Methoxyflurane	118	742	--	

Data from Titel and Lowe, [53] Eger et al, [54] [89] Targ et al, [55] and Munson and Eger. [88]

In contrast to normal (moist) carbon dioxide absorbents, desiccated absorbents materially degrade all potent inhaled anesthetics. [58] Degradation of sevoflurane materially increases anesthetic requirement. [59] In addition, dehydration of Baralyme increases compound A production from sevoflurane, but dehydration of soda lime does the opposite. [59] Desiccated absorbents degrade all anesthetics containing the CHF2-O- moiety (i.e., desflurane, enflurane, and isoflurane), the degradation product of concern being carbon monoxide. [58] Degradation by soda lime is minimal at hydrations approximately one-tenth those found in normal soda lime.

The Effect of Rebreathing

Inspired gas actually consists of two gases: that delivered from the anesthetic machine and that previously exhaled by the patient and subsequently rebreathed. Because the patient has removed (taken up) anesthetic from the rebreathed gas, the amount taken up and the amount rebreathed influence the inspired anesthetic concentration. An increase in uptake or rebreathing lowers the inspired concentration of a highly soluble gas more than the inspired concentration of a poorly soluble gas. This effect of uptake can be diminished by decreasing rebreathing, which is accomplished by increasing the inflow rate. With a ventilation of 5 L/min, rebreathing can be essentially abolished by use of a 5-L/min inflow rate. [60]

High inflow rates (i.e., 5 L/min or greater) have the advantage of increasing the predictability of the inspired anesthetic concentration, but they have the disadvantages of being wasteful and of increasing atmospheric pollution. High inflow rates may be unacceptably costly because of the attendant greater consumption of expensive volatile anesthetics. High inflow rates also may result in drier inspired gas and greater difficulty in estimating ventilation from excursions of the rebreathing bag. These several disadvantages lead us to consider techniques that avoid the use of high inflow rates.

/das/book/view/29494766/875/42.html

THE LOW-FLOW OR CLOSED-CIRCUIT TECHNIQUE

Much of the previous discussion assumed the use of a nonrebreathing system and a fixed inspired concentration of anesthetic. Although this approach does not invalidate the principles described earlier, it also does not reflect the variety of approaches applied in practice. Practice often deviates in two ways: (1) most anesthetists use lower inflow (fresh gas flow) rates in order to provide a more economical delivery of anesthesia, and (2) most anesthetists apply a constant alveolar, rather than a constant inspired, concentration because a constant alveolar concentration more closely reflects a constant level of anesthesia.

A low inflow rate results in several advantages and a few disadvantages, the latter particularly applying to kinetics. The advantages of low inflow administration (defined as fresh gas flows of less than half the minute volume, usually less than 3 L/min) or closed-circuit anesthesia (defined as delivery of gases in amounts sufficient to replace the gases--oxygen and anesthetic--removed by the patient) include lower cost, increased humidification, reduced heat loss, decreased release of anesthetic to the environment, and better capacity to assess physiologic variables, such as ventilation. On the debit side, one must be more concerned about oxygen levels (especially if nitrous oxide is used, but the patient also contributes nitrogen from stores in the body, and such nitrogen can slightly decrease the inspired concentration of oxygen), about increasing concentrations of carbon monoxide, and about rebreathing of toxic products from the breakdown of volatile anesthetics. Regarding this last point, carbon dioxide absorbents can degrade both halothane and sevoflurane to toxic unsaturated compounds. [61] [62] However, the debit of most immediate concern is the lack of control that low flows and, especially, closed circuits offer.

Closed-Circuit Anesthesia

The use of a closed circuit represents an extreme of anesthetic administration, one that is infrequently accomplished because few systems completely eliminate leakage of gas from the circuit. Indeed, anesthetists often apply a deliberate leak of approximately 200 mL/min by sampling gases for oxygen, carbon dioxide, and anesthetic analyses.

Usually, closed-circuit anesthesia requires replacement of three gases: (1) oxygen, (2) nitrous oxide, and (3) a potent volatile anesthetic. Each replacement implies somewhat different considerations. Oxygen replacement remains constant unless metabolism changes as a consequence of sympathetic response to stimulation, alteration in body temperature, or shivering. Replacement of nitrous oxide follows a fairly predictable course, in part because the concentration applied does not usually vary. Furthermore, it is the least soluble of anesthetics, especially in fat, and is the most prone to percutaneous loss (a constant value). Of most interest and potential variability are the uptakes of the potent inhaled anesthetics.

Uptake of potent anesthetics may be estimated from the values (constants) obtained by Yasuda et al [4] [5] in human volunteers. These values may be applied to obtain uptake at a constant alveolar concentration. To provide an appropriate level for comparison, I have assumed an alveolar concentration equal to the minimum alveolar concentration (MAC). The resulting figure (Fig. 4-16) reveals parallel shapes for each anesthetic, shapes dictated by the perfusion and solvent characteristics of the three major tissue compartments (plus intertissue diffusion). Thus, a large initial uptake rapidly decreases to a much lower level in 5 to 10 minutes, reflecting the high initial uptake of the VRG (high because of its large perfusion) and the rapid decrease in uptake imposed by a short time constant. The subsequent slower decrease primarily results from the longer time constant of the muscle group, which dominates this period until its uptake declines below that provided by fourth compartment and fat groups.

Although the curves for each anesthetic do not differ in shape, they differ in position. The height of each curve (i.e., uptake) is directly proportional to two factors: (1) solubility and (2) MAC. This relationship tends to minimize differences among anesthetics because solubility and MAC tend

Figure 4-16 The uptake (in milliliters per minute), as illustrated in this graph, resulted from the application of the constants calculated by Yasuda et al [4] [5] from their measurements in human volunteers. The application also assumes that the alveolar concentration equals maximum alveolar concentration (MAC). Uptake is a function of both MAC and solubility of the anesthetic in blood and tissues. Thus, the fivefold higher MAC for desflurane versus isoflurane is offset by a threefold lower solubility, producing less than a twofold difference in uptake at any point in time. Uptake for all anesthetics initially declines rapidly as a function of the rate at which the vessel-rich group equilibrates. The further decline after 5 to 10 minutes is a function of the approach to equilibration of the muscle group. *(Data from Yasuda et al [4] [5]*

to move inversely. For example, although the MAC for desflurane is five times that for isoflurane, its uptake is less than twice that of isoflurane because of its lower solubility in both blood and tissues.

Uptake may be estimated from the "square-root-of-time rule," first proposed by Severinghaus [63] and expanded greatly by Lowe and associates [64] [65] in their classic descriptions of closed-circuit anesthesia. This rule states that uptake at any point in time may be estimated as uptake during the first minute of anesthesia divided by the square root of time in minutes. Making certain assumptions permits an estimate of uptake during the first minute. In general, uptake equals the product of blood solubility, cardiac output, and alveolar to venous anesthetic partial pressure difference. Several sources supply standard values for solubility and cardiac output, and alveolar to venous anesthetic partial pressure difference may be estimated if we determine what alveolar partial pressure we wish and assume that venous anesthetic partial pressure is inconsequential. An inconsequential venous partial pressure is reasonable because no anesthetic can appear in venous blood before recirculation (about a half a minute) and even the anesthetic that appears is small because tissue uptake is maximal during the first minute. Thus, we might estimate isoflurane uptake in a normal adult as 1.4 times 5,400 times 0.0115, or 87 mL, where 1.4 is the blood/gas partition coefficient; 5,400 is a reasonable cardiac output, and 0.0115 is MAC as a fraction of one atmosphere (1 atm). By 4 minutes, uptake would equal 87 mL/2; by 9 minutes 87 mL/3; and by 64 minutes 87 mL/8.

Hendrickx et al [66] questioned the accuracy of the square root of time rule, suggesting that the rule overestimates the decrease in uptake with the passage of time. Eger [67] considered whether the evidence provided by Hendrickx overturns the square root of time rule, and the matter continues to be debated.

Replacement of anesthetic taken up may be accomplished by infusion of liquid anesthetic directly into the anesthetic circuit, either continuously or as boluses. A continuous infusion requires a pump of some sort, and an elegant solution uses a computer to direct a progressive decrease in infusion rate as a function of time. Bolus injection from a syringe has an elegant simplicity but has two disadvantages: (1) the circuit concentration modestly oscillates, and (2) the anesthetist is required to remember when and how much to inject. A further disadvantage accrues to the injection of desflurane by either pump or syringe. The high vapor pressure of desflurane (about 1 atm at room temperature) results in the unpredictable formation of bubbles of desflurane gas and a potential for a marked variability in the rate of infusion or injection, especially when smaller volumes of liquid are to be injected.

An alternative solution to injection of liquid applies a variable bypass (Tec-type) vaporizer, one capable of accurate delivery of a range of concentrations at low inflow rates (e.g., 200 mL/min). This solution may not be applicable in the initial delivery of anesthesia, because the demand for vapor may exceed the capability of presently

available vaporizers. For example, the maximum output of a conventional isoflurane vaporizer is 5 percent, and at a 200 mL/min flow of oxygen, only approximately 10 mL of isoflurane vapor can be produced per minute, far less than the 87 mL estimated earlier. Even after 1 hour of anesthesia, an isoflurane vaporizer is barely capable of meeting the demand for anesthetic (Fig. 4-17 A). This difficulty may be overcome in several ways. If a concentration less than MAC is acceptable, a lesser delivery of vapor is required. Thus, the concurrent use of nitrous oxide decreases the demand on the vaporizer. In addition, the use of nitrous oxide also increases the total fresh gas flow to compensate for the considerable uptake of nitrous oxide. If the fresh gas flow increases to 1,500 mL/min, 79 mL of isoflurane vapor can be produced. Another solution is to select an anesthetic having a vaporizer capability closer to demand. Such a solution tends to be available for less soluble anesthetics. For example, we calculate the uptake for desflurane in the first minute of anesthesia to be 0.45 × 5,400 × 0.06, or 146 mL. At a 200-mL/min flow of oxygen, the 18 percent maximum output of a desflurane vaporizer permits delivery of 44 mL. Although still inadequate to meet demand in the first minute, this figure is 2.6 times closer to meeting that demand than the isoflurane vaporizer, and within 10 minutes, the desflurane vaporizer can supply the required volume (see Fig.4-17 A).

Figure 4-17 A suggests one of the major difficulties associated with the closed-circuit approach, namely, control. Clearly, there is an enormous difference between delivered (i.e., vaporizer dial) and alveolar concentrations. The differences decrease with less soluble anesthetics, but even with an anesthetic such as desflurane and even after the initial high-uptake period is passed, the dialed concentration markedly exceeds the alveolar concentration that it sustains. This means that changes in uptake (e.g., secondary to the increase in cardiac output that may result from surgical stimulation) can cause considerable alterations in alveolar concentration unless the delivered concentration is altered. The alveolar concentration changes for two reasons: (1) assuming

Figure 4-17 (A-D) The ratio of delivered to alveolar concentrations (F_D/F_A) required to sustain the alveolar concentration constant at, for example, MAC, is a function of several factors. First, it is determined by uptake (see Fig. 4-16) . Second, it is determined by rebreathing. Thus, the ratio decreases with increasing inflow rates. Although these graphs have the same shape, notice the progressive decrease in the scale on the ordinate as inflow rate increases. The lowest values for any anesthetic result from a nonrebreathing system (i.e., when the inflow rate equals minute ventilation).

a constant ventilation, the difference between the alveolar and inspired concentrations varies directly with uptake (e.g., a greater uptake increases the difference), and (2) because of the rebreathing, the inspired concentration varies inversely with the uptake (e.g., an increased uptake lowers the inspired concentration). Thus, the sum of these effects either decreases or increases the alveolar concentration. A closed circuit has an inherent element of instability not present in an open circuit.

Low-Flow Anesthetic Delivery

The instability of the closed circuit may be greatly mitigated by the use of low-flow (less than half the minute ventilation) anesthetic delivery. Low-flow delivery may provide most of the advantages of closed systems without the attendant instability while retaining considerable advantages over open systems in economy, maintenance of humidification and temperature, and limited atmospheric pollution. Low-flow delivery also diminishes the disadvantages of the closed circuit in the areas of constancy of oxygen and anesthetic levels and elimination of carbon monoxide and toxic anesthetic breakdown products.

In a low-flow delivery system, two factors control the relationship between the concentration delivered from a vaporizer (F_D) and that in the alveoli (F_A), a relationship that may best be described as the ratio (F_D/F_A) of the two variables. First, we have already seen that uptake governs this ratio in a closed system (see Fig. 4-17 A). Thus, F_D/F_A is higher for more soluble anesthetics, and regardless of solubility, the ratio is highest early in anesthetic administration and decreases rapidly in the first 5 to 10 minutes of anesthesia (as uptake by the VRG of tissues decreases to the point of near-equilibration)

and more slowly thereafter (as uptake by tissue groups with longer time constants, such as muscle, the fourth compartment, and fat decreases).

Second, inflow rate also governs F_D/F_A. The relationship is inverse: the higher the inflow rate, the lower the ratio (compare Figs. 4-17 B-D with Fig. 4-17 A). An increase in inflow rate decreases F_D/F_A by decreasing rebreathing. Rebreathing is important because uptake of anesthetic depletes the anesthetic concentration in rebreathed gases, and the concentration in the delivered gases (F_D) must be sufficient to compensate for this depletion. The higher the inflow rate, the less the compensation required because rebreathing is less.

However, increases in inflow rate do not produce proportional decreases in F_D/F_A (compare Figs. 4-17 A-D). The greatest reduction in F_D/F_A comes with but modest increases in inflow rate. Thus, a large decrease occurs when the inflow rate is changed from that needed for a closed circuit to a 1-L/min inflow rate, whereas only a small decrease occurs when the inflow rate is increased from 2 to 4 L/min. Once the inflow rate exceeds minute ventilation (i.e., a nonrebreathing system exists), further increases in inflow rate have no effect on F_D/F_A, and F_D/F_A is the same as the ratio of inspired (F_I) to alveolar concentrations (i.e., $F_D/F_A = F_I/F_A$).

I have used the term anesthetic tether as a metaphor for the F_D/F_A ratio. [68] A large ratio equates to a long tether, one permitting considerable freedom or variability in the alveolar concentration. With a long tether, changes in uptake secondary to changes in physiologic variables (e.g., an increase in cardiac output consequent to surgical stimulation) can appreciably alter the alveolar concentration and thus the level of anesthesia. In the example just cited, there is positive feedback because by increasing uptake, surgical stimulation decreases the alveolar concentration and thereby increases the perception of that stimulation. Most anesthetists prefer a short anesthetic tether because a short tether provides a tighter control over the level of anesthesia. A shorter tether is produced by the use of less soluble anesthetics and higher inflow rates.

Another benefit to a short tether accrues to the anesthetist who does not have access to an agent-specific analyzer. In the absence of such an analyzer, some anesthetists would rely on the dial setting of the vaporizer to indicate the concentration of anesthetic in the patient's lungs (i.e., would assume that F_D equaled F_A). Although the vaporizer setting may correlate with the concentration in the lungs, the correlation may be a distant one. The correlation is poor: (1) early in anesthesia for all agents, (2) later in anesthesia for closed circuits or very low inflow rates, and (3) later in anesthesia for more soluble agents, such as isoflurane, even at higher inflow rates. Note that with poorly soluble anesthetics, such as sevoflurane and desflurane, by 30 to 60 minutes after the inception of anesthetic administration, the delivered concentration from the vaporizer may be less than 20 percent greater than that in the alveoli (i.e., the F_D/F_A ratio is 1.2), even at inflow rates of 1 to 2 L/min (Figs. 4-17 B and C).

Economic concerns increasingly dictate the practice of anesthesia. The reader may wish to appreciate the differences in anesthetic consumption as a function of the choice of inflow rate, the duration of anesthesia, and the choice of anesthetic. The reports by Yasuda et al [4] [5] provide constants that may be used to estimate the uptake of commonly available potent inhaled anesthetics. By using the gas laws and published values for specific gravities, the values for uptake of vapor may be converted to milliliters of liquid taken up. Combining this information with a knowledge of the function of circuit rebreathing systems [60] allows an estimate of the amounts of liquid in milliliters that must be delivered at various inflow rates to provide a constant alveolar concentration equal to MAC (Table 4-4) (Table Not Available) . [69] The relative costs of anesthesia may be estimated by applying the price of the anesthetic of interest to the number of milliliters needed to sustain anesthesia.

If both economy and a low F_D/F_A ratio are desirable, the aforementioned considerations suggest that a good compromise is the use of a low-flow delivery system after an initial period of higher flows. Higher flows (4 to 6 L/min) might be applied early in anesthesia (i.e., at the times of highest uptake) and then decreased progressively as uptake decreases. Flows of 2 to 4 L/min might be given for the period from 5 to 15 minutes after inducing anesthesia, and flows of 1 to 2 L/min may be given thereafter. If the average inflow rate were 2 L/min, 1 hour of anesthesia with the four potent anesthetics listed in Table 4-4 (Table Not Available) would require administration of 9.0 to 46.0 mL of liquid. This fivefold range of values is smaller than the eightfold range of potency (MAC) values because the amount of anesthetic delivered must account for more than potency. The amount delivered also must compensate for uptake and losses of anesthetic through the overflow valve. The relatively smaller uptake and losses of

TABLE 4-4 -- Milliliters of Liquid Anesthetic at Various Inflow Rates Needed to Sustain an Alveolar Concentration Equal to Minimum Alveolar Concentration

(Not Available)

Modified from Weiskopf and Eger [65]

the less soluble desflurane and sevoflurane are what account for the reduction from eightfold to fivefold. An even smaller range is found at lower inflow rates, decreasing to about twofold for a closed circuit. However, such flows should not be used with sevoflurane because of the greater concentrations of compound A that result.

RECOVERY FROM ANESTHESIA

General Principles

Nearly all the factors that govern the rate at which the alveolar anesthetic concentration rises on induction apply to recovery. Thus, the immediate decline is extremely rapid because the washout of the functional residual capacity by ventilation is as rapid as the washin. Only 2 minutes is required to eliminate 95 to 98 percent of nitrogen from the lungs when pure oxygen is breathed.

Nitrogen, however, is a poorly soluble gas relative to the inhaled anesthetics. As ventilation sweeps anesthetic from the alveoli, an anesthetic partial pressure gradient develops between that partial pressure in the returning venous blood and the partial pressure in the alveoli. This gradient drives anesthetic into the alveoli, thereby opposing the tendency of ventilation to lower the alveolar concentration. The effectiveness of the venous to alveolar gradient in opposing the tendency of ventilation to decrease the alveolar anesthetic partial pressure is in part determined by the solubility of the anesthetic. A highly soluble agent, such as methoxyflurane, opposes the elimination produced by ventilation more effectively than does a poorly soluble agent, such as nitrous oxide, because a greater reserve exists in blood for the highly soluble agent--that is, far more methoxyflurane is available at a given partial pressure for transfer to the alveoli. Thus, the fall in the alveolar partial pressure of methoxyflurane is slower than the fall with halothane, and the latter, in turn, is less rapid than the fall with nitrous oxide. The rate at which recovery occurs is similarly affected: it is rapid with nitrous oxide and may be slow with methoxyflurane. The rapidity of recovery thus largely depends on the solubility of the anesthetic. [70]

Differences Between Induction and Recovery

Recovery differs from induction in two crucial ways. First, on induction, the effect of solubility to hinder the rise in alveolar anesthetic concentration could be overcome by increasing the inspired anesthetic concentration (i.e., by applying overpressure). No such luxury is available during recovery; the inspired concentration cannot be reduced below zero. Second, on induction, all the tissues initially have the same anesthetic partial pressure--zero. On recovery, the tissue partial pressures are variable. The VRG has a pressure that usually equals that required for anesthesia; that is, the VRG has come to equilibrium with the alveolar anesthetic partial pressure. The muscle group may or may not have the same partial pressure as that found in the alveoli. A longer anesthetic (2 to 4 hours) might permit equilibrium to be approached, but a shorter case would not. The high capacity of fat for all anesthetics except nitrous oxide precludes equilibration of the fat group with the alveolar anesthetic partial pressure with hours or even days of anesthesia.

The failure of muscle and fat to equilibrate with the alveolar anesthetic partial pressure means that these tissues initially cannot contribute to the transfer of anesthetic back to the lungs. In fact, as long as an anesthetic partial pressure gradient exists between arterial blood and tissue blood, that tissue will continue to take up anesthetic. Thus, for the first several hours of recovery from halothane anesthesia, fat continues to take up halothane and by so doing accelerates the rate of recovery. Only after the alveolar (equals arterial) anesthetic partial pressure falls below that in a tissue can the tissue contribute anesthetic to the alveoli.

The failure of several tissues to reach equilibration with the alveolar anesthetic partial pressure means that the rate of decrease of alveolar anesthetic on recovery is more rapid than its rate of increase on induction, and that recovery depends in part on the duration of anesthesia (Fig. 4-18) (Figure Not Available) . [71] [72] A longer anesthetic puts more anesthetic into the slowly filling muscle and fat depots. Obviously, these reservoirs can supply more anesthetic to the blood returning to the lungs

Figure 4-18 (Figure Not Available) Both solubility and duration of anesthesia affect the fall of the alveolar concentration (F_E) from its value immediately preceding the cessation of anesthetic administration (F_{EO}). A longer anesthetic slows the fall, as does a greater solubility. *(From Stoelting and Eger [72])*

Figure 4-19 (Figure Not Available) The time to decrease the partial pressure in the alveoli or vessel-rich group by a certain fraction directly depends on several factors, primary among which are the solubility of the anesthetic and the duration of anesthesia. If between 80% of the anesthetic must be elimination to permit awakening, awakening from isoflurane will be delayed for progressively longer times as the duration of anesthesia is increased, but awakening from desflurane or sevoflurane will be minimally affected. If 90% of the anesthetic must be eliminated, awakening from both sevoflurane and isoflurane will be delayed more and more as the duration of anesthesia increases (isoflurane more than sevoflurane), but awakening from desflurane will be minimally affected. *(Modified from Bailey [73])*

when they are filled than when they are empty and thereby can prolong the time to recovery. [70]

Solubility influences the effect of duration of anesthesia on the rate at which the alveolar anesthetic partial pressure declines. [72] The decline of the partial pressure of a poorly soluble agent such as nitrous oxide is rapid in any case, and thus the acceleration imparted by a less than complete tissue equilibration cannot significantly alter the rate of recovery. The approach to equilibration becomes important with halothane and becomes even more important with methoxyflurane (see Fig. 4-18) (Figure Not Available) . Recovery may be rapid after a short methoxyflurane anesthetic but may be slow after a prolonged anesthetic. This is one of the reasons why nitrous oxide is usually a component of an inhaled (or for that matter, an injected) anesthetic regimen. The rapid elimination of this component permits at least a portion of recovery to be rapid. The recovery from anesthesia with desflurane and sevoflurane is more rapid than with more soluble agents, such as isoflurane and halothane. [70]

The importance of solubility and duration of anesthesia to the rate of recovery may be appreciated by the use of context-dependent times to reach particular levels of washout. [73] Regardless of duration of anesthesia, the alveolar concentrations of poorly soluble anesthetics (nitrous oxide, desflurane, sevoflurane) and moderately soluble anesthetics (isoflurane, halothane) decrease by 50 percent in roughly the same period of time. If recovery were reached at a 50 percent decrease, the choice of anesthetic would matter little to the time to recovery from anesthesia. The impact of solubility and anesthetic duration becomes evident if greater levels of washout are required to achieve recovery. If 80 percent washout is required, then increasing duration of anesthesia markedly affects recovery from isoflurane, but little affects recovery from desflurane and sevoflurane (Fig. 4-19) (Figure Not Available) . If 90 percent washout is required, then increasing duration of anesthesia affects both isoflurane and sevoflurane but not the less soluble desflurane (see Fig. 4-19) (Figure Not Available) . Indeed, the 90 percent washout may be of importance if anesthesia is maintained primarily with the potent inhaled anesthetic. After 2, 4, or 8 hours of anesthesia with 1.25 MAC sevoflurane versus desflurane, initial (Fig. 4-20) (Figure Not Available) and later (Fig. 4-21) (Figure Not Available) recovery is nearly twice as rapid with desflurane, and the difference between the recovery times appears to increase with increasing duration of anesthesia. [24]

Can I Have My Cake and Eat It Too?

The less soluble new inhaled anesthetics desflurane and sevoflurane offer a more rapid recovery from anesthesia than the more soluble older agents, such as isoflurane. However, this rapid recovery comes at a price: the new anesthetics are more expensive. Might it be possible to have the best of both worlds by using

isoflurane for the major portion of anesthesia, reserving desflurane (or sevoflurane) for the final

Figure 4-20 (Figure Not Available) The possibility of a differential time to awakening suggested by the analysis in Figure 4-19 (Figure Not Available) is shown to occur after 2, 4, or 8 hours of anesthesia at 1.25 MAC for desflurane versus sevoflurane. Awakening to response to command or to orientation is nearly twice as rapid after anesthesia with the less soluble desflurane. *(From Eger et al [24])*

Figure 4-21 (Figure Not Available) The differential suggested by Figure 4-19 (Figure Not Available) extends to measures of more subtle degrees of awakening such as the digit symbol substitution test (DSST), a measure of judgment and cognition. Note that there appears to be a greater spread between the results after 2 versus 8 hours of anesthesia. *(From Eger et al [24])*

minutes? The premise would be that such an approach would provide the economy of isoflurane and the rapid recovery of desflurane. Neumann et al [74] tested this premise. Volunteers were anesthetized for 2 hours on three occasions: once with 1.25 MAC of isoflurane; once with 1.25 MAC of desflurane; and once with 1.5 hours of 1.25 MAC of isoflurane followed by 0.5 hours of a combination of desflurane and isoflurane ("crossover"). The combination provided a total of 1.25 MAC (i.e., desflurane was added as the isoflurane was eliminated, the addition being sufficient to sustain a total of 1.25 MAC). To ensure economy, all anesthetics were delivered at a 2 L/min inflow rate.

The premise was not realized. Recovery after the crossover was no faster than recovery after isoflurane alone (Fig. 4-22) . Recovery after desflurane alone was considerably faster than recovery after either isoflurane or the crossover from isoflurane to desflurane.

Impact of Metabolism

Saturation of the enzymes responsible for the metabolism of anesthetics may limit the ability of metabolism to significantly alter the rate at which the alveolar anesthetic partial pressure rises. This limitation does not exist on recovery, and metabolism may be an important determinant of the rate at which the alveolar anesthetic partial pressure declines. The importance of metabolism to recovery is implied by results from Munson et al, [75] who showed that contrary to what might be predicted from their respective solubilities, the alveolar washout of halothane is more rapid than that of enflurane, a result later confirmed by Carpenter et al. [18] [19] This agrees with the relative ease with which these two agents are metabolized: 15 to 20 percent of the halothane taken up during the course of an ordinary anesthetic can be recovered as urinary metabolites, [76] whereas only 2 to 3 percent of enflurane can similarly be recovered. [77] Thus, there are two major routes by which halothane can be eliminated, the lung and the liver. With enflurane, elimination via the liver is relatively minor, which explains why Munson et al [75] found a more rapid fall in alveolar halothane. These results also apply to desflurane, isoflurane, and sevoflurane. Metabolism of desflurane and isoflurane is too small to accelerate their elimination, but metabolism of sevoflurane is sufficient to narrow the difference between its washout and that of desflurane. [24]

Diffusion Hypoxia

The uptake of large volumes of nitrous oxide on induction of anesthesia gives rise to the concentration and the second gas effects. On recovery from anesthesia, the outpouring of large volumes of nitrous oxide can produce what Fink [78] called diffusion anoxia. These volumes may cause hypoxia (Fig. 4-23) (Figure Not Available) in two ways. First, they may directly affect oxygenation by displacing oxygen. [78] [79] [80] Second, by diluting alveolar

Figure 4-22 Volunteers were anesthetized for 2 hours on three occasions: once with 1.25 MAC isoflurane; once with 1.25 MAC desflurane; and once with 1.5 hours of 1.25 MAC isoflurane followed by 0.5 hours of a combination of desflurane and isoflurane ("crossover"). The combination provided a total of 1.25 MAC (i.e., desflurane was added as the isoflurane was eliminated, the addition being sufficient to sustain a total of 1.25 MAC). All anesthetics were delivered at a 2-L/min inflow rate. At the end of 2 hours, anesthetic administration was discontinued and a nonrebreathing system applied. The digit symbol substitution test (DSST) was applied at 15-minute intervals, and the results are displayed as a percentage of the control (preanesthesia) results. Recovery of judgment and cognition as defined by the DSST was more rapid at 15, 30, and 45 minutes with desflurane given alone (asterisks indicate significant differences from isoflurane or crossover results). *(Data from Neumann et al [74])*

Figure 4-23 (Figure Not Available) At time zero, the inspired gas was changed from 21% oxygen/79% nitrous oxide to 21% oxygen/79% nitrogen. Arterial oxygen subsequently fell in association with the outpouring of nitrous oxide. *(Modified from Sheffer et al [79])*

carbon dioxide, they may decrease respiratory drive and hence ventilation. [80] Both of these effects require that large volumes of nitrous oxide be released into the alveoli. Because large volumes of nitrous oxide are released only during the first 5 to 10 minutes of recovery, this is the period of greatest concern. This concern is enhanced by the fact that the first 5 to 10 minutes of recovery also may be the time of greatest respiratory depression. For these reasons, many anesthetists administer 100 percent oxygen for the first 5 to 10 minutes of recovery. This procedure may be particularly indicated in patients with preexisting lung disease or in those in whom postoperative respiratory depression is anticipated (e.g., after a nitrous oxide-narcotic anesthetic).

Impact of the Anesthetic Circuit

The anesthetic circuit may limit the rate of recovery just as it limits induction. If the patient is not disconnected from the circuit on cessation of anesthetic delivery, the patient may continue to inspire anesthetic. To reduce the inspired level to zero or near-zero, several factors must be taken into account. The anesthetic within the circuit must be washed out. In addition, the rubber or plastic components of the circuit and the soda lime within the circuit will have absorbed anesthetic (see Table 4-3) that can be released back into the gas phase, [54] and this, too, must be washed out. Finally, the patient's exhaled air contains anesthetic that cannot be rebreathed if the inspired anesthetic concentration is to approach zero. The effect of each of these factors to raise the inspired anesthetic concentration can be overcome by the use of high inflow rates of oxygen (i.e., 5 L/min or greater).

Chapter 5A - Cardiovascular Pharmacology

Paul S. Pagel
Neil E. Farber
David C. Warltier

INTRODUCTION

This chapter will comprehensively describe the cardiovascular pharmacology of modern volatile anesthetics, nitrous oxide, and xenon. The actions of inhaled anesthetics on cardiovascular function, cardiac electrophysiology, the coronary circulation, and autonomic nervous system control of the circulation will be examined in detail.

VOLATILE ANESTHETICS AND CARDIOVASCULAR FUNCTION

Myocardial Contractility

All modern volatile anesthetics, including desflurane and sevoflurane, depress contractile function in normal myocardium *in vitro* and *in vivo.*[1] Investigations conducted in the 1960s demonstrated that halothane causes dose-related depression of force-velocity relations and Frank-Starling curves in isolated cardiac muscle preparations [2] [3] and in intact, closed-chest dogs, [4] respectively. These findings supported clinical observations of circulatory depression during halothane anesthesia in humans. [5] [6] [7] [8] Enflurane [9] and isoflurane [10] have also been shown to produce direct negative inotropic effects as indicated by decreases in maximal velocity of shortening, peak developed force, and maximal rate of force development during isotonic contraction in isolated feline papillary muscles. These reductions in intrinsic myocardial contractility by enflurane and isoflurane contribute to the cardiovascular depression observed with these agents in humans. [11] [12]

The relative degree of myocardial depression produced by different volatile anesthetics *in vivo* has been more difficult to establish because simultaneous alterations in systemic and pulmonary hemodynamics and autonomic nervous system activity often complicate assessment of left ventricular (LV) systolic function. Early studies using isovol-umic and ejection phase measures of myocardial contractility demonstrated that enflurane and halothane caused very similar negative inotropic effects in dogs [13] [14] [15] [16] and humans. [11] These findings were subsequently confirmed using the slope (E_{es}) of the LV end-systolic pressure-mid-axis diameter relation

as a relatively heart rate- and load-independent index of inotropic state in chronically instrumented dogs. [17] Equianesthetic concentrations of enflurane and halothane depress myocardial contractility to similar degrees *in vivo.*[17] In contrast, studies in experimental animals have repeatedly demonstrated that isoflurane produces less myocardial depression than does halothane or enflurane. Halothane caused greater reductions in LV peak-positive dP/dt than isoflurane when equianesthetic concentrations were directly compared in the presence and absence of autonomic nervous system function, [16] [18] [19] suggesting that differences in myocardial depression caused by these agents occurred independently of autonomic nervous system activity. [16] Differences in the negative inotropic effects of halothane and isoflurane have been quantified using the slope (M_w) of the regional preload recruitable stroke work relation derived from a differentially loaded series of LV pressure-segment length diagrams. [20] [21] In these studies conducted in chronically instrumented dogs, isoflurane maintained contractility an average of 20% greater as compared with an equi-MAC (minimum alveolar concentration) of halothane. [20] [21] Differences in the relative degree of myocardial depression produced by halothane and isoflurane have also been inferred in humans, using isovolumic and ejection phase measures of contractile function. [12] [22] [23] The negative inotropic actions of isoflurane (Fig. 5-1) (Figure Not Available) and halothane are exacerbated by hypocalcemia, [24] calcium (Ca^{2+}) channel blockers, [25] [26] [27] and $beta_1$-adrenoceptor antagonists [25] and can be reversed by administration of exogenous Ca^{2+} [24] [28] [29] [30] cardiac phosphodiesterase fraction III inhibitors, [31] [32] $beta_1$-adrenoceptor agonists, [1] Ca^{2+} channel agonists, [27] and myofilament Ca^{2+} sensitizers. [33] Importantly, the differential effects of halothane and isoflurane on myocardial contractility in dogs are maintained during depression or augmentation of inotropic state produced by these vasoactive drugs. [1]

Desflurane causes systemic and coronary hemodynamic effects that are remarkably similar to those produced by isoflurane. [34] Desflurane and isoflurane have been shown to depress myocardial function to equivalent degrees, using isovolumic and ejection phase measures of contractility in dogs, [16] [35] pigs, [36] and humans. [37] [38] These observations have been verified using both end-systolic pressure-volume relations and regional and global preload recruitable stroke work (Fig. 5-2) (Figure Not Available) in the presence and absence of autonomic nervous system activity *in vivo.*[9] [10] [11] [12] [13] [14] [15] [16] [17] [18] [19] [20] [21] [22] [23] [24] [25] [26] [27] [28] [29] [30] [31] [32] [33] [34] [35] [36] [37] [38] [39] [40] [41] However, the unique cardiovascular stimulation associated with rapid increases in inspired desflurane concentration in humans [42] may lead to transient increases in myocardial contractility resulting from augmentation of sympathetic nervous system tone. [43] [44] [45]

The effects of sevoflurane on myocardial contractility have been shown to be also virtually indistinguishable from those produced by isoflurane in dogs. [46] [47] Another study conducted in pigs suggested that sevoflurane may produce less myocardial depression than an equi-MAC concentration of halothane. [48] Sevoflurane produces less myocardial depression than enflurane in volunteers as assessed by the heart rate-corrected velocity of circumferential fiber shortening versus left ventricular end-systolic wall stress relation derived from echocardiography. [49] Sevoflurane decreased contractile function to approximately 40 to 45 percent of control values at 1.75 MAC in the presence and absence of autonomic nervous system tone, using regional preload recruitable

Figure 5A-1 (Figure Not Available) End-systolic pressure-volume (top panel) and stroke work-end-diastolic volume relations (bottom panel) before (control 1; C_1), during 0.6, 0.9, and 1.2 MAC, and after isoflurane (control 2; C_2) in an experiment in an open-chest dog. *(From Hettrick et al [41])*

stroke work in dogs. [47] This magnitude of myocardial depression agrees with previous data for isoflurane and desflurane, using an identical experimental model. [39] [40] Thus, volatile anesthetics appear to depress contractile state in normal ventricular myocardium in the following order: Halothane = enflurane > isoflurane = desflurane = sevoflurane.

The effects of volatile anesthetics on LV systolic function in animal models of or patients with LV dysfunction have not been comprehensively studied. Early *in vitro* studies demonstrated that isoflurane [10] and enflurane [50] cause greater reductions in maximum shortening velocity and the peak rate of force development in feline papillary muscles from failing hearts subjected to chronic pressure overload than in those from normal hearts. Halothane also produced more pronounced myocardial depression in ischemic as compared with normal myocardium. [51] [52] More recently, isoflurane and halothane were shown to cause greater negative inotropic effects in ventricular myocardium obtained from cardiomyopathic as compared with normal hamsters (Fig. 5-3) (Figure Not Available) [53] These findings suggested that myocardial depression caused by volatile anesthetics in failing myocardium were accentuated; they provided indirect evidence that patients with underlying contractile dysfunction

Figure 5A-2 (Figure Not Available) Preload recruitable stroke work (PRSW) slope for chronically instrumented dogs during control and at 1.0 and 1.5 end-tidal MAC of desflurane (top) and isoflurane (bottom). may be more sensitive to the negative inotropic effects of volatile agents. This hypothesis has not been extensively examined *in vivo,* however.

In experimental models of myocardial ischemia [51] or infarction, [54] volatile anesthetic-induced declines in contractile function were well tolerated and did not precipitate frank systolic dysfunction. In fact, volatile anesthetics exert important beneficial effects on mechanical function during myocardial ischemia and reperfusion injury. Volatile anesthetics reduce experimental myocardial infarct size, [55] [56] preserve metabolic and structural integrity during regional ischemia and reperfusion, [57]

[58] [59] enhance the functional recovery of postischemic-reperfused ("stunned") myocardium, [60] and improve indices of LV diastolic performance during brief coronary artery occlusion. [61] Halothane and isoflurane also produce beneficial decreases in LV preload and afterload in patients with heart failure and coronary artery disease, respectively. [62] [63] [64] These improvements in loading conditions in patients with compromised LV function may serve to partially offset the direct negative inotropic effects of anesthetics [62] and contribute to relative maintenance of cardiac performance by optimizing the operating range of the heart on the Starling curve or by improving LV diastolic function. Isoflurane and halothane have recently been demonstrated to produce dose-related depression of myocardial contractility in a canine model of

Figure 5A-3 (Figure Not Available) Comparison of the effects of halothane (left) and isoflurane (right) on isometric active force (AF) of papillary muscles from healthy hamsters (solid circles) and those with cardiomyopathy (open circles). moderate LV dysfunction induced by chronic rapid LV pacing (Fig. 5-4) (Figure Not Available) [65] Nevertheless, isoflurane or halothane anesthesia was relatively well tolerated and did not precipitate frank LV failure in dogs with pacing-induced cardiomyopathy. These findings were attributed to simultaneous improvements in LV loading conditions and filling dynamics that contributed to relative maintenance of cardiac output in the setting of moderate LV dysfunction despite concomitant reductions in contractility. [65] The influence of volatile anesthetics on LV systolic function in the presence of overt heart failure remains to be defined, however. Halothane caused greater depression of contractile function than isoflurane in cardiomyopathic dogs, [66] [65] observations that are similar to those described in normal myocardium in experimental animals and humans. These results contrast with those in isolated ventricular myocardium obtained from cardiomyopathic hamsters, demonstrating that isoflurane and halothane produce similar negative inotropic effects. [53] Differential actions on autonomic nervous system tone caused by the volatile anesthetics may be responsible for the discrepancy in these findings *in vivo* and *in vitro.*

Cellular Mechanisms of Myocardial Depression

Volatile anesthetics depress myocardial contractility via alterations of intracellular Ca^{2+} homeostasis at several subcellular targets in the normal cardiac myocyte. [67] [68] Volatile agents cause dose-related inhibition of the transsarcolemmal

Figure 5A-4 (Figure Not Available) Histograms depicting the slope (M_w ; top panel) and length intercept (L_w ; middle panel) of the regional preload recruitable stroke work relation and the time constant of isovolumic relaxation (tau bottom panel) in the conscious state before (C; open bar) and after pacing (P) and during 1.1, 1.4, and 1.7 MAC (end-tidal concentration) isoflurane (hatched bars) and halothane (solid bars). [a] Significantly ($P < 0.05$) different from P; [b] significantly ($P < 0.05$) different from 1.1 MAC; [c] significantly ($P < 0.05$) different from corresponding isoflurane value. *(From Pagel et al [65])*

Ca^{2+} transient [69] [70] by affecting both L- and T-type Ca^{2+} channels. [69] [71] [72] [73] Isoflurane appears to cause less pronounced reductions in the intracellular Ca^{2+} transient than does halothane or enflurane, [69] although this contention remains somewhat controversial when equianesthetic concentrations of these agents are considered. [74] [75] The structural conformation and functional integrity of the voltage-dependent Ca^{2+} channel are directly altered by volatile anesthetics as indicated by attenuated binding of the dihydropyridine and phenylalkylamine Ca^{2+} channel blockers nitrendipine [76] [77] and galopamil, [78] respectively. The partial inhibition of Ca^{2+} influx via sarcolemmal Ca^{2+} channels has several important consequences, including declines in the availability of Ca^{2+} for contractile activation, depression of Ca^{2+} -dependent Ca^{2+} release from the sarcoplasmic reticulum (SR), and reduction of the amount of Ca^{2+} that can be subsequently stored in the SR. [75] [79] [80] [81] [82] Halothane and enflurane, [80] [82] but not isoflurane, [82] [83] [84] also stimulate Ca^{2+} release from the SR, a caffeine-like action that may cause transient, modest increases that precede subsequent, more profound reductions in contractility. [80] [85] [86] Unlike isoflurane, halothane and enflurane directly activate ryanodine-sensitive SR Ca^{2+} release channels, [87] [88] thereby reducing SR Ca^{2+} storage. Volatile anesthetics also provoke a nonspecific leak of Ca^{2+} from the SR, [89] [90] contributing to further decreases in accumulation of Ca^{2+} available for release during contraction. When combined with decreases in transsarcolemmal Ca^{2+} flux, these alterations in SR function represent important mechanisms by which halothane and enflurane depress the intracellular Ca^{2+} transient and reduce myocardial contractility to a greater extent than equianesthetic concentrations of isoflurane. [69] The partial preservation of the myocardial positive frequency staircase effect observed with isoflurane at physiologic excitation rates *in vitro*[75] [91] may also be attributed to the relative maintenance of SR function by this volatile agent, in contrast to halothane and enflurane.

Recent evidence indicates that volatile anesthetics may also depress contractile function by inhibiting sodium (Na^+)-Ca^{2+} exchange and reducing intracellular Ca^{2+} concentration independent of the voltage-dependent Ca^{2+} channel *in vitro.*[92] [93] [94] This effect may be particularly important in neonatal myocardium [92] because this tissue has been shown to be more sensitive to the negative inotropic actions of volatile anesthetics than adult myocardium. [95] However, the relative contribution of Na^+ -Ca^{2+} exchanger inhibition to anesthetic-induced depression of myocardial contractility in the intact heart has yet to be defined. Halothane, enflurane, and isoflurane may also exert direct effects on the contractile apparatus and the sensitivity of the myofilaments to activator Ca^{2+} . Volatile anesthetics decrease tension development of skinned cardiac myofibrils [96] [97] [98] and directly reduce myofibrillar ATPase activity, [95] [100] actions that may contribute to declines in actin-myosin cross-bridge kinetics during contraction. [101] In addition, volatile anesthetics either do not affect [102] or may decrease [103] the troponin C (TnC) affinity for Ca^{2+} , suggesting that myofilament Ca^{2+} sensitivity is not altered [104] or modestly reduced, [69] respectively, by these agents. Nevertheless, although volatile anesthetic-induced reductions in myofilament Ca^{2+} sensitivity have been implicated in some studies, this mechanism probably plays a relatively minor role in the negative inotropic effects of these agents at clinically relevant concentrations *in vivo.*[68]

The cellular mechanisms responsible for volatile anesthetic-induced depression of myocardial contractility in failing myocardium have not been extensively studied. It is very likely that alterations of intracellular Ca^{2+} regulation produced by volatile anesthetics in normal myocardium will also occur at similar subcellular targets in failing myocardium. Profound abnormalities in intracellular Ca^{2+} homeostasis are characteristic features of failing myocardium, [105] and it is likely that volatile anesthetics will cause further reductions in contractile function by producing additive or synergistic effects on Ca^{2+} metabolism.

Diastolic Function

Definitions of heart failure based solely on contractile dysfunction have been rendered inadequate by the recognition that LV function during diastole significantly influences overall cardiac performance. The heart serves dual roles,

Figure 5A-5 (Figure Not Available) Effects of desflurane, isoflurane, and halothane on the time constant of isovolumic relaxation (T_0). *Significantly ($P < 0.05$) different from control; significantly ($P < 0.05$) different from 1.0 MAC. *(From Pagel et al [114])*

propelling blood into the high-pressure arterial vasculature during systole and collecting blood from the low-pressure venous circulation during diastole. Thus, heart failure may occur not only from impaired contractility but also from altered LV diastolic function. The timing, rate, and extent of LV filling are determined by several major factors including the rate and degree of myocardial relaxation, the intrinsic mechanical properties of the LV itself and those imposed by external constraints, and the structure and function of the left atrium, the pulmonary venous circulation, and the mitral valve. [106] Although abnormalities in LV diastolic function may be linked to decreases in myocardial contractility, heart failure may result from primary diastolic dysfunction in the absence of or before the appearance of alterations in LV systolic function [107] [108] [109] in a variety of pathologic conditions including ischemic heart disease, pressure- or volume-overload hypertrophy, hypertrophic obstructive cardiomyopathy, and restrictive disease processes. [110] [111]

The effects of volatile anesthetics on diastolic function in the normal and diseased heart have been incompletely studied. Volatile anesthetics produce dose-related prolongation of isovolumic relaxation *in vivo* (Fig. 5-5) (Figure Not Available) [47] [112] [113] [114] This delay of isovolumic relaxation may be associated with declines in early LV filling [27] [30] [32] [47] but is probably not of sufficient magnitude to affect LV chamber stiffness. The significance of anesthetic-induced delays in isovolumic relaxation to early coronary blood flow has not been thoroughly investigated; however, coronary blood flow is highest during this phase of diastole, and delays in relaxation lead to impairment of flow during halothane anesthesia. [112] Prolongation of LV relaxation probably occurs as a result of simultaneous depression of myocardial contractility and not because of a direct negative lusitropic effect. [115] In fact, isoflurane, enflurane, and halothane have been shown to modestly enhance isotonic relaxation of isolated ferret myocardium *in vitro.*[116]

Volatile anesthetics cause concentration-related decreases in the rate and extent of early LV filling concomitant with negative inotropic effects. Isoflurane and halothane also reduce LV filling associated with atrial systole. [30] Isoflurane, desflurane, and sevoflurane do not alter invasively derived indices of regional myocardial or chamber stiffness, indicating that LV distensibility is unaffected by these volatile agents (Fig. 5-6) (Figure Not Available) [47] [114] Although some indirect evidence suggests that halothane affects LV compliance, [117] [118] [119] more recent studies [17] [114] [120] using invasively derived measures of LV passive elasticity and myocardial stiffness have indicated that this is not the case. Halothane increases LV enddiastolic pressure, indicating that the LV operates on a steeper, less compliant region of the LV end-diastolic

Figure 5A-6 (Figure Not Available) Left ventricular (LV) diastolic transmural pressure-Lagrangian strain relations in a conscious (squares) and halothane-anesthetized (triangles) dog. The pressure-strain relation was not altered by halothane anesthesia, indicating that this volatile anesthetic does not affect intrinsic myocardial stiffness. alpha = gain; beta = modulus of myocardial stiffness. *(From Van Trigt et al [17])*

pressure-volume relation; however, this volatile agent does not directly alter the intrinsic viscoelastic properties of the myocardium. [1]

The effects of isoflurane and halothane on LV diastolic function in a canine model of dilated cardiomyopathy have recently been described. [65] In contrast to the findings in dogs with normal LV function, isoflurane improved several indices of LV relaxation and filling in cardiomyopathic dogs despite producing simultaneous negative inotropic effects. In addition, halothane did not exacerbate preexisting dia-stolic dysfunction inherent to this experimental model. The findings with isoflurane and halothane were most likely related to favorable reductions in LV preload produced by these volatile agents and not because of direct positive lusitropic effects. [65] These data further suggest that isoflurane-induced improvements of LV isovolumic relaxation and filling dynamics may contribute to relative maintenance of cardiac output in the presence of LV dysfunction despite simultaneous reductions in contractility. [65] The findings in cardiomyopathic dogs supported earlier clinical observations [62] [64] reporting that patients with severe ischemic heart disease or congestive heart failure tolerated isoflurane or halothane anesthesia without acute hemodynamic decompensation.

Recent investigations have demonstrated that the afterload dependence of LV relaxation is markedly enhanced in failing myocardium. [121] [122] This observation has important clinical consequences because afterload reduction may not only increase LV systolic performance by decreasing impedance to LV ejection but may also increase the rate of LV relaxation and contribute to improvements in LV diastolic filling and compliance. [123] The effects of isoflurane and halothane on the afterload dependence of LV relaxation have recently been explored in dogs before and after the development of rapid LV pacing-induced cardiomyopathy. [66] The afterload dependence of LV relaxation was unaffected by isoflurane and halothane anesthesia in dogs with dilated cardiomyopathy (Fig. 5-7) (Figure Not Available) , further indicating that these volatile agents do not exert direct actions on LV isovolumic relaxation in failing myocardium.

Left Ventricular - Arterial Coupling and Mechanical Efficiency

Optimum transfer of stroke volume from the LV to the arterial circulation requires appropriate matching of these mechanical systems. Left ventricular-arterial coupling has most often been described using a series elastic chamber model of the cardiovascular system (Fig. 5-8) (Figure Not Available) [124] The elastances of the contracting LV (E_{es}) and the arterial vasculature (E_a) are determined from LV end-systolic pressure-volume and end-systolic arterial pressure-stroke volume relations, respectively. [124] [125] [126] The ratio of E_{es} to E_a defines coupling between the LV and the arterial circulation [124] [125] and provides a useful technique for assessment of the actions of drugs, including volatile anesthetics, on LV-arterial matching *in vivo.* [127] [128] Analysis of the pressure-volume relation also creates a framework for the study of LV mechanical efficiency defined by the ratio of stroke work (SW) to pressure-volume area (PVA). [129]

Figure 5A-7 (Figure Not Available) Linear relationship between the time constant of isovolumic relaxation (tau) and left ventricular end-systolic pressure (P_{es}) during inferior vena caval occlusion (left panels) in a typical dog before (open squares) and after (solid squares) the development of pacing-induced cardiomyopathy in the conscious state and during isoflurane and halothane anesthesia. The histograms on the right illustrate the slope (R) of the tau-versus P_{es} -relationship in the conscious state (top right panel) and during isoflurane (middle right panel) and halothane (bottom right panel) anesthesia before (open bars) and after (solid bars) pacing. [a] Significantly ($P < 0.05$) different from normal myocardium. *(From Pagel et al [66])*

The influence of volatile anesthetics on LV-arterial coupling and mechanical efficiency have been studied in the normal canine cardiovascular system but have yet to be described in models of heart failure. LV-arterial coupling may theoretically be maintained during anesthesia because declines in LV afterload may balance simultaneous reductions in myocardial contractility. Low concentrations of halothane (1 MAC), but not isoflurane, reduced E_{es}/E_a in barbiturate-anesthetized, acutely instrumented dogs, consistent with depression of mechanical coupling between the LV and arterial circulation. [130] However, isoflurane also decreased E_{es}/E_a at 2 MAC, suggesting that the vasodilating effects of this anesthetic were unable to compensate for the relatively greater declines in contractility. More recently, desflurane, sevoflurane, and isoflurane were shown to maintain optimum LV-arterial coupling and mechanical efficiency as evaluated by E_{es}/E_a and SW/PVA at low anesthetic concentrations (
0.9 MAC) by producing simultaneous declines in myocardial contractility and LV afterload (Fig. 5-9) (Figure Not Available) [41] However,

Figure 5A-8 (Figure Not Available) Left ventricular (LV) pressure-volume diagrams during inferior vena caval occlusion and the definition of LV-arterial coupling. The LV maximal elastances of each pressure-volume diagram are used to calculate the slope (E_{es}) of the end-systolic pressure-volume relation. Effective arterial elastance (E_a) is determined as the ratio of end-systolic arterial pressure and stroke volume during steady-state hemodynamic conditions. In the pressure-volume plane, E_a represents the magnitude of the slope connecting end-systole to end-diastole. *(From Hettrick et al [44])*

mechanical matching between the LV and the arterial vasculature and efficiency of total LV energy transfer to external stroke work degenerates at higher anesthetic concentrations, indicating that anesthetic-induced reductions in contractility are not appropriately balanced by declines in afterload. Halothane (<1.0 MAC) has also been shown to reduce the ratio of oscillatory to mean hydraulic power *in vivo,* indicating that this agent decreases LV mechanical efficiency as well. [131] Detrimental alterations in LV-arterial coupling produced by volatile anesthetics contribute to reductions in overall cardiac performance observed with these agents *in vivo.*

Left Ventricular Afterload

Although a definition of LV afterload that describes the mechanical properties of the arterial vasculature opposing LV ejection is intuitively clear, [132] quantitative evaluation of afterload *in vivo* remains difficult. Systemic vascular resistance, calculated as the ratio of mean arterial pressure to cardiac output, is the most commonly used estimate of LV afterload. However, systemic vascular resistance inadequately describes LV afterload [133] because this index ignores the mechanical characteristics of the blood and arterial walls, fails to account for the frequency-dependent, phasic nature of arterial blood pressure and blood flow, and does not consider the potential effects of arterial wave reflection. As a result, systemic vascular resistance cannot be reliably used to quantify changes in LV afterload produced by drugs,

Figure 5A-9 (Figure Not Available) Histograms depicting left ventricular-arterial coupling (E_{es}/E_a ; top panel) and mechanical efficiency (SW/PVA; bottom panel) before (control 1; C_1), during 0.6, 0.9, and 1.2 MAC, and after sevoflurane (control 2; C_2). [a] Significantly ($P < 0.05$) different from C_1 ; [b] significantly ($P < 0.05$) different from 0.9 MAC sevoflurane; [c] significantly ($P < 0.05$) different from 1.2 MAC sevoflurane. *(Adapted from Hettrick et al [41])*

including volatile anesthetics, or cardiovascular disease. [134] Aortic input impedance [Z_{in} (omega)] obtained from power spectral or Fourier series analysis of aortic pressure and blood flow waveforms provides a comprehensive description of LV afterload because Z_{in} (omega) incorporates arterial viscoelasticity, frequency dependence, and wave reflection. However, because analysis of Z_{in} (omega) is conducted in the frequency domain and not as a function of time, Z_{in} (omega) is most often interpreted using an electrical three-element Windkessel model of the arterial circulation that describes characteristic aortic impedance (Z_c), total arterial compliance (C), and total arterial resistance (R). Z_c represents aortic resistance to LV ejection; C is determined primarily by the compliance of the aorta and represents the energy storage component of the arterial circulation; and R equals the combined resistances of the remaining arterial vasculature (Fig. 5-10) (Figure Not Available) . The three-element Windkessel model has been shown to closely approximate Z_{in} (omega) in a variety of physiologic conditions. [135] [136]

Volatile anesthetics alter Z_{in} (omega) by affecting the mechanical properties of the arterial vascular tree. [137] [138] [139] [140] Isoflurane produced dose-related decreases in R in chronically instrumented

Figure 5A-10 (Figure Not Available) Schematic diagram depicting the three-element Windkessel model of the arterial circulation. Diode A represents the aortic valve. Time-dependent blood flow [F(t)] and blood pressure [P(t)] entering the arterial system first encounters the resistance of the ascending aorta (characteristic aortic impedance; Z_c). Further flow is dictated by total arterial resistance (R) and total arterial compliance (C), the energy storage component of the arterial vasculature. *(From Hettrick et al [139])*

dogs consistent with the known effects of this drug on systemic vascular resistance, in contrast to the results obtained with halothane. [139] Isoflurane and halothane also caused similar increases in C and Z_c concomitant with reductions in mean arterial pressure. Thus, the major difference between the effects of isoflurane and halothane on LV afterload derived from the Windkessel model of Z_{in} (omega) was related to R, a property of arteriolar resistance vessels, and not to C or Z_c, the mechanical characteristics of the aorta (Fig. 5-11) (Figure Not Available) . A subsequent investigation demonstrated that desflurane, but not sevoflurane, also reduces R in dogs. [140] In contrast to the findings with isoflurane, however, desflurane did not affect C and Z_c, suggesting that this agent does not alter the mechanical properties of the aorta. Importantly, the inverse relationship between C and mean arterial pressure remains unchanged by volatile anesthetics, [139] [140] unlike the findings with the arterial vasodilator sodium nitroprusside [139] [141] or the intravenous anesthetic propofol. [142]

Isoflurane and halothane produce alterations in Z_{in} (omega) in cardiomyopathic dogs that are substantially different than those observed in normal dogs. [143] These volatile anesthetics decreased arterial pressure but did not affect C and Z_c in the presence of LV dysfunction. Halothane increased R and isoflurane did not reduce R in dogs with dilated cardiomyopathy. Thus, neither isoflurane nor halothane reduces arterial hydraulic resistance or favorably improves the rectifying properties of the aorta in dogs with pacing-induced cardiomyopathy (Fig. 5-12) (Figure Not Available) . The findings suggest that volatile agents do not exert beneficial actions on LV afterload in the presence of failing myocardium.

Right Ventricular Function

The crescent-shaped right ventricle (RV) is composed of embryologically distinct inflow and outflow tracts [144] [145] that differ in their structure and response to those of autonomic nervous system activity. [146] The sequential contraction of the RV inflow and outflow tracts establish regional pressure gradients within the RV during systole [147] [148] [149] and account for the peristaltic mechanical action of this pump. True isovolumic relaxation does not occur in the RV. [150] Instead, ejection

Figure 5A-11 (Figure Not Available) Histograms depicting the effects of sodium nitroprusside (SNP), halothane, and isoflurane on total arterial compliance (C; top), total arterial resistance (R; middle), and characteristic aortic impedance (Z_c; bottom). The low, medium, and high doses of volatile anesthetics are 1.25, 1.5, and 1.75 MAC, respectively. SNP doses produce comparable changes in mean arterial pressure. *Significantly ($P < 0.05$) different from control;
significantly ($P < 0.05$) different from low dose; § significantly ($P < 0.05$) different from middle dose;

of blood from the outflow tract into the pulmonary artery continues after the inflow tract has begun to relax. [148] [150]

The effects of volatile anesthetics on the function and contraction sequence of the RV inflow and outflow tracts have been studied incompletely. By using a uniform definition of end-systole and end-diastole for both regions of the RV, [151] halothane was shown to produce similar depression of contractile function in RV inflow and outflow tracts in dogs. More recently, another investigation conducted in anesthetized pigs [152] demonstrated that halothane caused dose-related decreases in RV contractility evaluated using regional preload recruitable stroke work derived from RV pressure-segment length diagrams in the RV inflow and outflow tracts in the presence and absence of autonomic nervous system reflexes. Importantly, halothane also abolished the normal RV sequential contraction pattern without exerting differential negative inotropic effects in different regions of the RV. [152] These data suggest that volatile anesthetics

may alter RV contraction dynamics by adversely affecting cardiac autonomic nervous system activity.

Systemic Hemodynamics

Volatile anesthetics cause direct negative chronotropic actions *in vitro* by depressing sinoatrial node activity. [153] However, alterations in heart rate *in vivo* are primarily determined by the interaction of volatile agents and baroreceptor reflex activity. [154] [155] Halothane does not appreciably change heart rate in humans [6] because this agent attenuates baroreceptor reflex responses. [156] [157] [158] Heart rate increases to variable degrees with enflurane; however, these increases in heart rate may be insufficient to preserve cardiac output. [11] [159] Isoflurane increases heart rate in response to simultaneous decreases in arterial pressure. [12] These findings occur with this volatile agent because baroreceptor reflexes are relatively preserved when compared with those of equi-MAC concentrations of halothane and enflurane. [155] Desflurane also causes dose-related increases in heart rate in humans. [37] [38] [160] Desflurane- and isoflurane-induced tachycardia may be more ronounced in pediatric patients or in the presence of vagolytic agents and, conversely, may be attenuated in neonates [161] and geriatric patients or by the concomitant administration of opioids. [62] [163] Rapid increases in the inspired desflurane concentration above 1 MAC may be associated with further transient increases in heart rate and arterial pressure resulting from sympathetic nervous system activation. [42] [44] fsInterestingly, similar increases in heart rate are also observed when the inspired isoflurane concentration is rapidly increased. [44] The cardiovascular stimulation induced by rapid increases in desflurane or isoflurane concentration in humans results from activation of tracheopulmonary and systemic receptors [45] and is attenuated by pretreatment with $beta_1$ -adrenoceptor antagonists, $alpha_2$ -adrenoceptor agonists, or opioids. [43] In contrast to the findings with isoflurane and desflurane, sevoflurane neither alters heart rate [164] [165] [166] [167] nor causes cardiovascular stimulation during rapid increases in anesthetic concentration in humans. [168]

All modern volatile anesthetics cause concentration-related decreases in arterial pressure. [6] [11] [12] [37] [160] [164] fsfsThe mechanism by which these agents reduce arterial pressure differs among anesthetics. Decreases in arterial pressure produced by halothane and enflurane can be primarily attributed to reductions in myocardial contractility and cardiac output. [1] In contrast, decreases in arterial pressure associated with isoflurane, desflurane, and sevoflurane anesthesia occur as a result of reductions in LV afterload, [139] [140] whereas myocardial contractility is relatively preserved. [1] Thus, isoflurane, desflurane, and sevoflurane maintain cardiac output because these agents produce less pronounced reductions in myocardial contractility and greater decreases in systemic vascular resistance than does halothane or enflurane in humans. [34] [166] [169] Isoflurane and desflurane may also preserve autonomic nervous system regulation of the circulation to a greater degree than do other volatile anesthetics. [42] [155] [168] The baroreceptor reflex-mediated tachycardia that occurs during isoflurane and desflurane anesthesia serves to maintain cardiac output despite simultaneous declines in myocardial contractility and stroke volume. Declines in arterial pressure produced by volatile anesthetics may be attenuated by surgical stimulation or concomitant administration of nitrous oxide. [38] [170] Volatile anesthetics also cause modest, dose-related increases in right atrial pressure in humans. [34] [169] These effects probably occur as a result of direct negative inotropic actions. The vasodilating effects of isoflurane, desflurane, and sevoflurane cause less pronounced increases in right atrial pressure than those observed during halothane or enflurane anesthesia.

The cardiovascular effects of volatile anesthetics are altered by the duration of anesthesia. Increases in myocardial contractility and cardiac output and decreases in LV preload and afterload occur after several hours of constant MAC anesthesia. [6] [12] [37] [159] [171] Heart rate may also increase during prolonged halothane [6] [171] or enflurane [159] anesthesia; however, arterial pressure remains constant. Recovery from circulatory depression is greatest during halothane anesthesia [171] and less pronounced during prolonged administration of isoflurane [12] and desflurane. [37] The time-dependent improvements in hemodynamics observed with volatile anesthetics are antagonized by propranolol and may result from enhanced sympathetic nervous system activity. [172]

The systemic hemodynamic effects of volatile agents in the presence of LV dysfunction are similar but not identical to those observed in the normal heart. Volatile

anesthetics, including isoflurane, modestly increase or do not affect heart rate in experimental animals with pacing- or doxorubicin-induced dilated cardiomyopathy [65] [173] and in patients

with coronary artery disease and LV dysfunction. [62] [64] [174] [175] These findings may be attributed to altered baroreceptor reflex activity, beta $_1$ -adrenoceptor down regulation, and increases in central sympathetic and withdrawal of parasympathetic nervous system tone associated with heart failure. [176] Isoflurane and halothane cause pronounced reductions in LV end-diastolic pressure and chamber dimension in cardiomyopathic dogs concomitant with decreases in mean arterial pressure. [65] These findings support previously observed declines in pulmonary artery pressures during isoflurane, enflurane, and halothane anesthesia in patients with coronary artery disease and heart failure [62] [64] [174] [175] and indicate that venodilation represents a major hemodynamic consequence of these anesthetics in experimental and clinical heart failure. In contrast to the findings in normal dogs, isoflurane did not beneficially influence, and halothane detrimentally affected, the determinants of LV afterload in cardiomyopathic dogs. [143] As a result of these actions and the simultaneous declines in LV preload and myocardial contractility, cardiac output may be more profoundly reduced during isoflurane or halothane anesthesia in the presence of preexisting LV dysfunction. [143]

VOLATILE ANESTHETICS AND CARDIAC ELECTROPHYSIOLOGY

Cardiac Conduction

Volatile anesthetics slow the rate of sinoatrial node discharge by direct and indirect effects on sinoatrial node automaticity. [153] [177] These actions may be altered *in vivo* by vasoactive drugs or autonomic nervous system activity. [178] Halothane, enflurane and, to some extent, isoflurane shorten cardiac action potential and effective refractory period duration in normal Purkinje fibers [177] [179] [180] however, these agents prolong His-Purkinje and ventricular conduction times. [177] [180] [181] Halothane, enflurane, and isoflurane also prolong atrioventricular conduction time and refractoriness. [180] [182] [183] When combined with the direct actions of volatile anesthetics on sinoatrial node discharge, these data suggest that volatile anesthetics have the potential to produce bradycardia and atrioventricular conduction abnormalities. However, primary disturbances in atrioventricular conduction leading to second or third degree atrioventricular block in humans probably do not occur with volatile anesthetics in the absence of conduction disease or drugs that directly prolong the atrioventricular conduction time. [184] [185]

Volatile agents may have pro- or antiarrhythmogenic actions against abnormal cardiac electrophysiologic mechanisms produced by myocardial ischemia or infarction. Halothane, enflurane, and isoflurane have been shown to be cardioprotective against ventricular fibrillation produced by coronary artery occlusion [186] [187] and reperfusion. [188] Protective effects against ouabain-induced arrhythmias have also been demonstrated during halothane anesthesia. [189] Volatile anesthetics may also exert antiarrhythmic effects by opposing subsidiary pacemaker activity in infarcted myocardium. [179] Conversely, halothane and, to a lesser extent, isoflurane may be arrhythmogenic in Purkinje fibers in experimental myocardial infarction by facilitating reentrant activity or by increasing temporal dispersion of refractory-period recovery. [179] [190] These actions may be related to inhibition of slow Na^+ current in false tendon fibers and induction of reentry of premature impulses into more refractory Purkinje fibers in the border zone of an ischemic area. [191] Halothane, enflurane, and isoflurane have been shown to prolong the QT_c interval in humans. [192] These data suggest that patients with idiopathic or acquired long QT syndrome may be at greater risk of developing *torsades de pointes* tachycardia [193] during anesthesia with these drugs.

Epinephrine-Induced Arrhythmias

Halothane and, to a lesser extent, other volatile anesthetics sensitize myocardium to the arrhythmogenic effects of epinephrine. [194] [195] [196] Sensitization is the interaction between volatile anesthetics and catecholamines that leads to reductions in the threshold for both atrial and ventricular arrhythmias. Sequentially escalating doses of epinephrine produce premature ventricular contractions and sustained ventricular tachyarrhythmias during halothane anesthesia. [194] Halothane-epinephrine-induced arrhythmias are attenuated by pretreatment with thiopental, [194] presumably via effects on the atrioventricular node or the upper His bundle. [197] A synergistic interaction between $alpha_1$ - and beta-adrenoceptors has been strongly implicated in the pathogenesis of halothane-epinephrine-induced ventricular arrhythmias. [198] Stimulation of the $alpha_{1A}$ -adrenoceptor in the His-Purkinje system by epinephrine during halothane anesthesia transiently slows Purkinje fiber conduction. [199] [200] This proarrhythmogenic effect is mediated by phospholipase C and the intracellular second messenger, inositol triphosphate. [200] Recent evidence indicates that enhanced conduction in the Purkinje-ventricular muscle junction accompanied by simultaneous $alpha_1$ -adrenoceptor-mediated depression of Purkinje conduction also plays an important role in halothane-epinephrine-induced arrhythmias. [201] The doses of epinephrine required to produce ventricular arrhythmias during desflurane or sevoflurane anesthesia [198] [202] fsare similar to but significantly less than those observed during administration of isoflurane and halothane, respectively. Halothane-catecholamine sensitization also promotes abnormal automaticity of dominant and latent atrial pacemakers. [203] [204] [205] [206] These effects may produce premature ventricular contractions and arrhythmias originating from the His bundle. [203] Intact sinoatrial node function reduces the incidence of epinephrine-induced ventricular escape during halothane anesthesia and is protective against His bundle arrhythmias. [206]

VOLATILE ANESTHETICS AND THE CORONARY CIRCULATION

Coronary Vascular Effects In Vitro

Volatile anesthetics have been shown to cause direct coronary artery vasodilation *in vitro*; however, simultaneous reductions in the determinants of myocardial oxygen consumption (MVO_2), including heart rate, preload, afterload,

and inotropic state, produced by these agents cause coronary vasoconstriction *in vivo* via metabolic autoregulation. Volatile anesthetic-induced alterations in coronary blood flow are also affected by reductions in coronary perfusion pressure produced by these agents. Thus, the combination of direct and indirect actions ultimately determines the net effect of volatile anesthetics on coronary vascular tone. Halothane, isoflurane, and enflurane cause vasodilation of isolated coronary arteries. [207] [208] [209] [210] [211] [212] [213] [214] Halothane produces greater coronary artery dilation than does isoflurane at equivalent MAC [208] [209] [210] [212] [213] in isolated coronary arteries larger than 2000 mum. [208] [210] [211] [212] [213] In contrast, isoflurane causes vasodilation of predominantly small (<900 mum) canine epicardial coronary arteries. [211] Halothane may produce greater vasodilator effects in large coronary arteries than does isoflurane because halothane causes more pronounced suppression of voltage-dependent Ca^{2+} current. [215]

The direct negative inotropic effects of volatile anesthetics cause a reduction in coronary blood flow in isolated, contracting hearts during precise control of ventricular loading conditions via flow-metabolism coupling. [216] In these conditions, a decrease in myocardial O_2 demand is accompanied by an increase in coronary vascular resistance, findings that may be incorrectly interpreted suggesting that volatile agents produce coronary vasoconstriction. However, examination of the actions of volatile anesthetics on myocardial O_2 extraction and the ratio of myocardial O_2 delivery to MVO_2 reveals that inhalational anesthetics are coronary vasodilators. Halothane and isoflurane decrease myocardial O_2 extraction and increase the ratio of O_2 delivery to consumption in isolated, beating hearts. [217] [218] [219] [220] These findings indicate that volatile anesthetics produce direct coronary vasodilation in isolated hearts because myocardial O_2 delivery exceeds MVO_2 and coronary sinus O_2 tension increases. Halothane, isoflurane, and sevoflurane also cause similar reductions in adenosine-induced coronary flow reserve [221] in tetrodotoxin-arrested, isolated hearts. Because mechanical work is not performed in this preparation, these findings support the hypothesis that volatile agents cause direct coronary vasodilation of similar magnitude.

Coronary Vascular Effects In Vivo

Halothane has variable effects on coronary blood flow and coronary vascular resistance *in vivo* that occur concomitant with changes in MVO_2. [222] [223] [224] [225] Decreases in MVO_2 cause declines in coronary blood flow with relative maintenance or modest increases in coronary vascular resistance during halothane anesthesia. [14] [226] [227] Despite the decreases in coronary blood flow, halothane increases coronary sinus O_2 tension and decreases O_2 extraction, [223] [225] indicating that halothane is a relatively weak coronary vasodilator. Like halothane, isoflurane variably alters coronary blood flow *in vivo*. [19] [228] [229] [230] [231] Isoflurane reduces MVO_2 and simultaneously decreases O_2 extraction, indicating direct coronary vasodilation. [229] Isoflurane has also been shown to produce mild and transient increases in blood flow independent of changes in MVO_2 and autonomic nervous system activity during inhalational induction of anesthesia. [232] Perfusion of the left anterior descending coronary artery with blood previously equilibrated with isoflurane dramatically increases coronary blood flow [233]; however, only mild coronary vasodilation occurs after a period of anesthetic equilibration in a similar experimental model. [230] Isoflurane-induced increases in coronary blood flow are not accompanied by epicardial coronary artery dilation, indicating that isoflurane dilates predominantly small coronary arteries. [234] However, adenosine, a potent coronary vasodilator, causes considerably greater vasodilation in coronary microvessels than does isoflurane. [235] The effects of enflurane on the coronary circulation *in vivo* are somewhat controversial. [212] [218] [219] [220] Enflurane produces greater reductions in MVO_2 than does isoflurane, concomitant with metabolically determined declines in coronary blood flow. [236] [237] However, isoflurane produces more profound decreases in myocardial O_2 extraction than does enflurane, indicating that isoflurane is a more potent coronary vasodilator than its structural isomer. [237]

The influence of the new volatile anesthetics on coronary blood flow in the intact cardiovascular system has been examined incompletely. Desflurane and isoflurane caused similar increases in the ratio of O_2 delivery to consumption and decreases in O_2 extraction, consistent with those of coronary vasodilation. [238] However, the increases in coronary blood flow produced by desflurane, but not isoflurane, are attenuated by pharmacologic blockade of the autonomic nervous system, suggesting that isoflurane causes greater direct coronary vasodilation *in vivo* than does desflurane. [16] Sevoflurane does not appear to produce any significant degree of coronary vasodilation, [46] [221] [239] [240] [241] in contrast to the findings with other volatile agents.

Coronary Vasodilator Reserve and Autoregulation

Coronary vasodilator reserve, defined as the ratio of peak coronary blood flow after brief coronary artery occlusion (e.g., reactive hyperemia) and baseline flow, has been shown to be affected by halothane and isoflurane. [242] Coronary vasodilator reserve is greater during isoflurane as compared with halothane anesthesia. [242] This observation suggested that halothane may be a more potent coronary vasodilator than isoflurane because greater baseline coronary vasodilation should be accompanied by a reduced ability to further increase coronary blood flow in response to a brief ischemic episode. However, halothane also reduces the determinants of MVO_2 to a greater degree than does isoflurane *in vivo*. Peak coronary blood flow during reactive hyperemia and percent flow debt repayment are directly related to the intensity of the ischemic stimulus and the magnitude of O_2 debt accrued during coronary artery occlusion. Thus, differences in coronary vasodilator reserve produced by isoflurane and halothane may reflect differences in the intensity of ischemia during coronary occlusion and not the relative vasodilator efficacy of these volatile anesthetics. [216]

Dilation of coronary arteriolar resistance vessels by volatile anesthetics alters pressure autoregulation in the coronary vasculature. [243] Changes in autoregulation produced by vasoactive drugs, including volatile agents, are typically determined by the slope of the pressure-flow curve generated by progressive constriction of a coronary artery.

Figure 5A-13 (Figure Not Available) A qualitative description of the effects of volatile anesthetics on the coronary blood flow (CBF)-pressure relationship demonstrating the effect of adenosine-induced maximal coronary vasodilation in awake and anesthetized dogs. Solid lines are drawn from mean slopes determined by linear regression analysis. Dashed lines represent the nonlinear portion of the curve and are estimates. When compared with the findings obtained in awake dogs, the anesthetics affect absolute CBF variably but do not increase the slope of the

CBF-pressure plots. *(From Hickey et al [235])*

Changes in these pressure-flow curves demonstrate that autoregulation is disrupted during anesthesia when compared with that of the conscious state (Fig. 5-13) (Figure Not Available) . Isoflurane produces more profound alterations in autoregulation than does halothane or enflurane as indicated by greater increases in the slope of the pressure-flow relation. Coronary perfusion pressure also plays a more important role in the determination of coronary blood flow during anesthesia. Although volatile anesthetics impair coronary autoregulation to some degree, these agents do not produce the profound degree of coronary vasodilation and inhibition of autoregulation caused by adenosine or dipyridamole. [230] [237] [243] In contrast to volatile agents, these drugs cause maximal coronary vasodilation and inhibit pressure autoregulation to such a degree that coronary blood flow becomes directly dependent on coronary perfusion pressure. Volatile anesthetics are only weak coronary vasodilators.

Mechanisms of Volatile Anesthetic - *Induced Coronary Vasodilation*

Volatile anesthetics produce direct coronary artery relaxation by affecting intracellular Ca^{2+} regulation at several locations in the vascular smooth muscle cell. [216] Volatile agents inhibit Ca^{2+} influx through voltage- [215] and receptoroperated [207] [208] [212] [213] [244] Ca^{2+} channels in coronary vascular smooth muscle. Volatile anesthetics also reduce Ca^{2+} accumulation in and release by the coronary vascular smooth muscle sarcoplasmic reticulum (SR), [245] inhibit G proteins linked to phospholipase C, [244] and decrease formation of the second messenger inositol triphosphate. [246]

The coronary vasodilating actions of volatile agents are probably not related to the production or release of nitric oxide (endothelium-dependent relaxing factor). Investigations conducted in isolated coronary [214] and aortic [245] [247] [248] [249] vascular preparations and in the intact canine coronary circulation [233] demonstrated that volatile anesthetic-induced coronary vasodilation occurs independently of nitric oxide. However, some experimental evidence suggests that the direct coronary vasodilator effects of isoflurane may be mediated by the vascular endothelium. [207] [250] Conversely, other data indicate that halothane, enflurane, and isoflurane may adversely affect the release or action of nitric oxide. [247] [248] [249] [251] [252] Although nitric oxide-induced formation of cyclic guanosine monophosphate (cGMP) may be attenuated to some degree by halothane, [253] several studies indicate that volatile anesthetics do not affect vasodilation produced by the nitric oxide donors sodium nitroprusside and nitroglycerin. [248] [252] [254] [255] Volatile anesthetics may also reduce the stability of nitric oxide by generating oxygen-derived free radicals [255] while leaving nitric oxide release and its action on vascular smooth muscle unaffected. [251] Whether the results of these later studies conducted in isolated aortic preparations are applicable to the coronary circulation requires further evaluation, but these investigations provide important information about the potential effects of volatile agents on the coronary vasculature.

Halothane and isoflurane have recently been shown to cause coronary vasodilation by activation of adenosine triphosphate (ATP)-sensitive potassium (K_{ATP}) channels. [256] [257] Increases in coronary blood flow in response to halothane and isoflurane were attenuated by the K_{ATP} channel antagonist glyburide in isolated rat hearts and anesthetized pigs, respectively. [256] [257] Glyburide also partially blocked increases in coronary blood flow during intracoronary administration of volatile anesthetic-equilibrated blood in canine hearts *in situ.*[258] Isoflurane-induced reductions in coronary vascular resistance were attenuated by the selective adenosine $_1$ (A_1) receptor antagonist 8-cyclopentyl-1,3,dipropylxanthine (DPCPX). [259] These data suggest that coronary vasodilation produced by isoflurane may partially occur as a result of stimulation of A_1 receptors coupled to K_{ATP} channels. [259] [260]

Volatile Anesthetics and Ischemic Myocardium

Halothane and isoflurane decrease subendocardial blood flow and myocardial lactate extraction, produce contractile dysfunction, and cause electrocardiographic changes in the presence of a coronary stenosis concomitant with declines in coronary perfusion pressure. [51] [261] [262] Regional ischemia during isoflurane- or halothane-induced reductions in perfusion pressure is functionally indicated by the appearance of paradoxical systolic lengthening and postsystolic shortening. [51] [263] Contractile dysfunction in the region distal to a critical coronary stenosis is more severe during isoflurane as compared with halothane anesthesia coincident with higher flows in the normal zone and lower flows in the ischemic zone. [262] [264] These findings suggest that coronary vasodilation produced by isoflurane may cause a detrimental redistribution

of coronary blood flow away from ischemic myocardium if hypotension is allowed to occur.

The adverse effects of volatile anesthetics on ischemic myocardium are avoided if coronary perfusion pressure is restored. Subendocardial blood flow in the perfusion bed distal to a critical coronary stenosis is reduced during isoflurane-induced declines in arterial pressure; however, treatment of hypotension with phenylephrine restores subendocardial blood flow to values observed before administration of isoflurane. [265] [266] The transmural distribution of coronary blood flow between the subendocardium and subepicardium (endo/epi ratio) decreases during isoflurane anesthesia despite control of arterial pressure. Administration of phenylephrine to maintain arterial pressure constant increases subepicardial blood flow more than subendocardial flow. This increase in subepicardial perfusion accounts for the decline in the endo/epi ratio in the absence of an absolute reduction in subendocardial flow. Restoration of coronary perfusion pressure to baseline levels during isoflurane anesthesia also increases coronary collateral blood flow and normalizes myocardial O_2 tension in the ischemic zone. [236]

Investigations in dogs with steal-prone anatomy (complete occlusion of a coronary artery with collateral flow from an adjacent vessel having a critical stenosis) have repeatedly demonstrated that isoflurane and halothane do not alter collateral-dependent or ischemic zone myocardial blood flow, [267] [268] [269] [270] [271] endo/epi distribution, [267] [268] or electrocardiogram [267] when diastolic arterial pressure is held constant. Coronary collateral perfusion is unchanged during isoflurane or halothane anesthesia in dogs at a mean arterial pressure of 50 mm Hg. [272] Coronary steal does not occur in a chronically instrumented canine model of coronary artery disease with isoflurane, [269] [271] halothane, [270] desflurane, [273] or sevoflurane [274] independent of coronary stenosis severity or coronary collateral development. [268] [269] [270] [271] The findings also refute earlier evidence in dogs with ameroid constrictor- induced augmentation of the coronary collateral circulation, suggesting that isoflurane reduces collateral blood flow and causes coronary steal *in vivo*. [275] These effects of volatile anesthetics are in marked contrast to those obtained with adenosine, a potent coronary vasodilator that produces coronary steal when arterial pressure is maintained at control levels in models of multivessel coronary artery disease (Fig. 5-14) (Figure Not Available) . [269] [271] [276]

Volatile Anesthetic - *Induced Myocardial Protection*

The relatively academic controversy about volatile anesthetic-induced coronary vasodilation and coronary steal has detracted from substantial experimental evidence indicating that volatile agents exert important cardioprotective effects during myocardial ischemia and reperfusion injury. Halothane attenuates ST segment changes caused by brief coronary artery occlusion [277] [278] and decreases ST segment elevation to a greater extent than do propranolol and sodium nitroprusside despite producing similar hemodynamic effects. [278] Halothane and isoflurane reduce myocardial infarct

Figure 5A-14 (Figure Not Available) Occluded-to-normal- and occluded-to-stenotic-zone myocardial blood flow in dogs with steal-prone coronary artery anatomy in the conscious state (C), during 1.1 and 1.9 MAC isoflurane (I) anesthesia, during adenosine (A) infusions (0.54 and 1.08 mg/min), and during maintenance of heart rate and arterial pressure at conscious values during the highest doses (BP). Isoflurane does not cause coronary steal, in contrast to significant (* $P < 0.05$) reductions in blood flow to collateral-dependent myocardium produced by adenosine. *(From Hartman et al [271])*

size after coronary artery ligation. [55] [56] [279] [280] [281] Enflurane decreases cardiac lactate production in the presence of a critical coronary artery stenosis during artificial control of perfusion pressure. [57] Isoflurane and desflurane have been shown to produce beneficial actions on LV diastolic mechanics during acute regional myocardial ischemia. [61] Halothane, enflurane, and isoflurane decrease myocardial reperfusion injury and improve functional recovery after global ischemia in isolated hearts. [282] [283] [284] [285] Volatile agents also enhance systolic functional recovery of stunned myocardium when these agents are administered before and during, [58] [60] but not after, [286] [287] brief periods of myocardial ischemia *in vivo* (Fig. 5-15) (Figure Not Available) . These effects are accompanied by preservation of high-energy phosphate levels. [58] Volatile anesthetics have been shown to attenuate the effect of oxygen-derived free radicals on LV pressure development in isolated hearts. [288] Halothane also preserves contractile function and ultrastructural integrity during reperfusion after normothermic cardioplegic arrest. [59]

Volatile anesthetics may also produce beneficial effects on blood flow to ischemic myocardium. Decreases in collateral blood flow after coronary artery occlusion have

been shown to be less pronounced than declines in flow to normal myocardium in the presence of halothane. [289] The ratio of myocardial O_2 delivery to MVO_2 is also increased in collateral-dependent myocardium during halothane anesthesia. [289] Recent evidence indicates that sevoflurane actually increases blood flow to collateral-dependent myocardium when arterial pressure is maintained at conscious values. [274] Halothane may inhibit platelet thrombi formation via increases in platelet cyclic adenosine monophosphate concentration and decrease cyclical variations in coronary blood flow associated with a critical coronary artery stenosis. [290] Most recently, volatile anesthetics have been shown to attenuate adhesion of neutrophils and platelets in the coronary vasculature after ischemia and reperfusion. [291]

The mechanisms responsible for volatile anesthetic-induced cardioprotection during myocardial ischemia and reperfusion are understood incompletely. The beneficial effects of volatile anesthetics may be attributed to a favorable reduction in myocardial oxygen demand required for active contraction with concomitant preservation of energy-dependent vital cellular processes because these agents cause direct negative inotropic, lusitropic, and chronotropic effects and decrease LV afterload. However, halothane also exerts protective effects during complete functional arrest induced by cardioplegia, [59] indicating that preferential alterations in myocardial oxygen supply-demand relations are not solely responsible for the antiischemic actions of this anesthetic. Halothane, enflurane, and isoflurane may significantly lower excessive intracellular Ca^{2+} during reperfusion via a direct decline in the net transsarcolemmal Ca^{2+} transient resulting from partially inhibited Ca^{2+} channel activity [69] [71] [72] [73] or an indirect reduction of oxygen-derived free radical formation. [288]

Recent evidence indicates that the cardioprotective effects of isoflurane during postischemic, reperfusion injury are partially mediated by activation of K_{ATP} channels. [260] The K_{ATP} channel antagonist glyburide completely abolished the protective effects of isoflurane in stunned myocardium but did not alter the time course of recovery of contractile function when administered alone (Fig. 5-16) (Figure Not Available) [259] [292] These results *in vivo* suggest that isoflurane activates K_{ATP} channels. This hypothesis is supported by preliminary data using patch clamp techniques demonstrating that isoflurane stimulates outward K^+ current through K_{ATP} channels in isolated ventricular myocytes. [293] Isoflurane may also reduce the sensitivity of K_{ATP} channels to inhibition by ATP, thereby increasing the open state probability of the channel. [294] The role of the A_1 receptor in the enhanced functional recovery of stunned myocardium produced by isoflurane has been recently examined. [295] The selective A_1 receptor antagonist DPCPX partially attenuated but did not completely abolish the beneficial effects of isoflurane in stunned myocardium produced by multiple brief episodes of ischemia and reperfusion. [295] However, isoflurane eliminated increases in interstitial adenosine measured with a myocardial microdialysis technique during repetitive periods of coronary artery occlusion and reperfusion in this study. The attenuation of ATP breakdown and subsequent reduction in interstitial adenosine observed during isoflurane anesthesia were similar to those observed after ischemic preconditioning [296] or

Figure 5A-15 (Figure Not Available) Segment-shortening data (expressed as a percent of control) during a 15-minute coronary artery occlusion (O) and at various times after reperfusion in the conscious (C) and halothane-anesthetized (H) states. Comparisons are made at various times with those animals anesthetized with halothane for 2.25 hours and allowed to emerge from anesthesia over a 5-hour period but not undergoing coronary artery occlusion and reperfusion. *(From Warltier et al [60])*

Figure 5A-16 (Figure Not Available) Percent segment shortening (%SS) in the intermittently ischemic and reperfused left anterior descending (LAD) coronary artery region. %SS decreases significantly ($P < 0.05$) from baseline during each 5-minute LAD occlusion and reperfusion in all groups. Significant decreases in %SS during each 5-minute reperfusion and throughout 180 minutes of final reperfusion are observed in dogs pretreated with glyburide, a K_{ATP} channel antagonist, in the presence or absence of isoflurane. %SS recovers to baseline values after reperfusion in dogs receiving isoflurane alone.

administration of the K_{ATP} channel agonist bimakalim. [297] These findings suggest that isoflurane either directly activates A_1 receptors or indirectly enhances sensitivity of A_1 receptors to reduced quantities of endogenously released adenosine. [295] These results also support the hypothesis that K_{ATP} channel activation represents the end effector of the cardioprotective signal transduction pathway activated during isoflurane anesthesia. [260]

Experimental evidence suggests that isoflurane reduces myocardial infarct size *in vivo* by activating K_{ATP} channels in a manner that bears striking similarity to those observed during ischemic preconditioning. Isoflurane has been previously shown to decrease the extent of myocardial infarction [279] ; however, the mechanisms responsible for this beneficial action have only recently been elucidated. Halothane, enflurane, and isoflurane decreased infarct size in isolated and *in situ* rabbit hearts to an extent similar to that of ischemic preconditioning. [280] The protective effects of halothane were completely abolished by pretreatment with selective antagonists to either the A_1 receptor or protein kinase C. Isoflurane also markedly reduced the extent of myocardial infarction in barbiturate-anesthetized, acutely instrumented dogs. [56] The protective effect of isoflurane was equivalent to that caused by ischemic preconditioning, occurred despite discontinuation of isoflurane 30 minutes before prolonged coronary artery occlusion, could not be explained by beneficial alterations in hemodynamics, and was abolished by pretreatment with glyburide (Fig. 5-17) (Figure Not Available) [56] This "anesthetic-induced preconditioning" has also been described in rabbits. [281] These data indicate that isoflurane-induced reductions in myocardial infarct size are characterized by a short-term memory phase similar to that of ischemic preconditioning and are consistent with previous findings that pharmacologic stimulation of both A_1 receptors and K_{ATP} channels mimics the conditions present during ischemic preconditioning. [298]

Coronary Vascular Effects of Volatile Anesthetics in Humans

Evaluation of the actions of volatile anesthetics on the human coronary circulation is difficult not only because the methods used to determine coronary blood flow in humans are limited but also because the interpretation of clinical findings during anesthesia is complicated by the changes in hemodynamics, the impact of surgery, and the use of adjuvant anesthetics or vasoactive drugs. Halothane decreases MVO_2 [62] [299] and variably alters coronary blood flow in patients with coronary artery disease; however, metabolic or electrocardiographic evidence of ischemia has not been observed during halothane anesthesia. [62] [299] [300] [301] Coronary blood flow may be reduced by halothane or enflurane [302] in

Figure 5A-17 (Figure Not Available) Schematic illustration of canine myocardium subjected to a 60-minute coronary artery occlusion and reperfusion and then stained to identify the region of myocardial infarction (black area) within the area of myocardium at risk for infarction (light-gray area). Isoflurane decreased the extent of myocardial infarction. The protective effect of isoflurane was equivalent to that produced by ischemic preconditioning and was abolished by pretreatment with glyburide. *Significantly ($P < 0.05$) different from control. *(Modified from Kersten et al [56])*

some patients concomitant with decreases in MVO_2 , but simultaneous declines in O_2 extraction [62] [302] reflect relative coronary vasodilation.

A report published in 1983 by Reiz et al [63] described the occurrence of myocardial ischemia as indicated by new electrocardiographic changes and abnormal myocardial lactate extraction in 10 of 21 patients anesthetized with isoflurane undergoing major vascular surgery. Five patients were treated with phenylephrine and pacing to return arterial pressure and heart rate to control values, and after these interventions, electrocardiographic and metabolic derangements resolved in 2 of 5 patients. Despite the apparent dependence of these new episodes of myocardial ischemia on alterations in systemic hemodynamics, the authors [63] proposed that isoflurane had caused coronary steal in these patients, even though no specific evidence of blood flow redistribution between normal and collateral-dependent zones was presented. The data of Reiz et al [63] have not been uniformly supported by subsequent studies. Coronary blood flow has been shown to remain unchanged during isoflurane anesthesia in patients undergoing coronary artery bypass graft surgery; however, coronary sinus O_2 content increases consistent with modest coronary vasodilation. [303] [304] [305] Isoflurane alone does not produce electrocardiographic or metabolic evidence of ischemia. [304] Instead, myocardial ischemia occurring during isoflurane anesthesia is most often associated with tachycardia or hypotension. [64] [300] [303] [305] In addition, isoflurane actually increases the tolerance to pacing-induced ischemia in patients with coronary artery disease. [306] Comparisons of studies examining the effects of isoflurane on the incidence of intraoperative myocardial ischemia are also complicated by differences in patient age, surgical procedure, operative time, and preoperative LV ejection fraction. [307] [308] Importantly, compelling evidence demonstrating redistribution of coronary blood flow away from ischemic to normal myocardium in humans anesthetized with isoflurane has yet to appear.

The incidence of intraoperative myocardial ischemia in susceptible patients has been difficult to define. Less than 50 percent of intraoperative ischemic episodes have been linked to alterations in systemic hemodynamics. [309] [310] [311] [312] The strongest predictor of intraoperative ischemia remains preexisting ischemia on arrival to the operating room and not anesthetic technique. [309] [311] The only hemodynamic event definitively related to intraoperative ischemia in patients undergoing coronary artery bypass graft surgery is tachycardia. [311] Recent evidence [313] [314] advocating the perioperative use of beta $_1$ -adrenoceptor antagonists to prevent myocardial ischemia strongly supports this contention. Sternotomy causes greater increases in calculated indices of MVO_2 , [315] myocardial lactate production, [316] and the

incidence of hypertension requiring treatment with vasoactive drugs [316] during morphine as compared with halothane anesthesia. In contrast, induction of anesthesia with desflurane in patients undergoing coronary artery bypass surgery may be associated with tachycardia, hypertension, and a greater incidence of ischemia than that occurring during induction with sufentanil. [317] Steal-prone anatomy has been identified in 23 percent of patients with coronary artery disease enrolled in the Coronary Artery Surgery Study. [318] However, patients with steal-prone coronary anatomy do not have a greater incidence of ischemia during desflurane anesthesia as compared with other forms of coronary artery disease. [317] The incidence of myocardial ischemia and adverse cardiac outcomes has been shown to be similar in cardiac patients undergoing noncardiac surgery during sevoflurane as compared with isoflurane anesthesia. [319] New electrocardiographic changes, incidence of postoperative myocardial infarction, and mortality are similar in patients undergoing coronary artery bypass graft surgery independent of anesthetic technique [310] [311] [312] [315] [316] [317] [320] [321] [322] or the presence of steal-prone anatomy. [322] In summary, despite the findings that volatile anesthetics are mild coronary vasodilators, these agents do not cause abnormal redistribution of myocardial perfusion resulting in ischemia when tachycardia and hypotension are avoided.

VOLATILE ANESTHETICS AND NEURAL CONTROL OF THE CIRCULATION

Volatile anesthetics have been shown to depress baroreceptor reflex control of arterial pressure in experimental animals to varying degrees. [178] [323] [324] [325] [326] [327] [328] [329] [330] This inhibition of baroreceptor reflex activity occurs as a result of depression of central nervous system integration of afferent baroreceptor input, attenuation of efferent autonomic nervous system activity,

and reductions in ganglionic transmission and endorgan response. [178] [326] [331] [332] Volatile anesthetics increase resting afferent nerve traffic and enhance the sensitivity of arterial baroreceptors by a Ca^{2+}-dependent mechanism. [326] [331] [333] These anesthetic-induced increases in baroreceptor sensitivity and discharge frequency tonically reduce overall sympathetic nervous system activity and attenuate sympathetic responses to declines in arterial pressure. [334]

Halothane, enflurane, and isoflurane (Fig. 5-18) (Figure Not Available) inhibit preganglionic sympathetic efferent activity at clinically relevant concentrations *in vivo*. [326] [328] [329] [330] [331] Volatile agents reduce postganglionic sympathetic nerve activity. [326] [331] Postsynaptic nicotinic receptors in the stellate ganglion are also blocked by halothane. [335] [336] These findings indicate that attenuation of ganglionic transmission represents a major mechanism by which volatile agents depress sympathetic nerve traffic. [337] Depression of sympathetic outflow caused by volatile anesthetics has also been suggested by examination of endogenous plasma norepinephrine kinetics. [338] [339] Halothane, isoflurane, and enflurane decrease plasma concentrations of norepinephrine to varying degrees by causing a more pronounced reduction in norepinephrine spillover than in clearance. [338] [339] In fact, halothane-induced reductions in norepinephrine release from postganglionic sympathetic nerves [340] may also contribute to depression of reflex vasoconstriction in peripheral blood vessels observed with this agent. [341] Volatile anesthetics attenuate parasympathetic nervous system function as well. Halothane has been shown to depress vagal nerve efferent activity by direct measurement of parasympathetic nerve activity. [330] These findings are supported by the results of several other studies demonstrating that volatile anesthetics inhibit reflex bradycardia in response to increases in arterial pressure. [323] [326] [331] [342] Parasympathetic and sympathetic nervous system outflows appear to be depressed to equivalent degrees during halothane [331] [342] [343] or isoflurane anesthesia. [326]

The effects of volatile anesthetics on neural control of the cardiovascular system have been examined incompletely in healthy humans and have not been described in patients with autonomic nervous system dysfunction. Halothane [154] and enflurane [344] produce greater attenuation of baroreceptor reflex regulation of heart rate than do equi-MAC concentrations of isoflurane. [155] Depression of baroreceptor function by these volatile agents may be more profound when compared with that of fentanyl, diazepam, and nitrous oxide anesthesia. [345] Baroreceptor-mediated control of peripheral vascular resistance is also attenuated in young volunteers during halothane anesthesia. [158] Steady-state anesthetic concentrations of sevoflurane have recently been shown to cause greater depression of sympathetic nerve activity measured directly with microneurography than desflurane at equivalent levels of hypotension. [168] These findings parallel results demonstrating pronounced sympathetic hyperactivity during rapid increases in inspired desflurane concentration in humans (Fig. 5-19) (Figure Not Available) [42] [44] Importantly, the actions of volatile anesthetics on baroreceptor reflex control of the circulation may be profoundly altered during autonomic dysfunction in elderly patients [346] or those with essential hypertension, diabetes mellitus, or heart failure. [347] Further investigation will be required to test these hypotheses, however.

NITROUS OXIDE AND CARDIOVASCULAR FUNCTION

Myocardial Contractility and Left Ventricular Diastolic Function

Experiments in papillary muscle [348] [349] [350] and isolated heart preparations [220] have consistently demonstrated that nitrous oxide produces a direct negative inotropic effect. Conflicting results about the influence of nitrous oxide on contractility have been observed in experimental animals and healthy volunteers. Several problems have contributed to apparently contradictory results *in vivo*. Observed changes in contractile

Figure 5A-18 (Figure Not Available) Baseline renal sympathetic efferent nerve activity (NA) and arterial blood pressure (BP) recorded in a conscious and isoflurane (I)-anesthetized dog (1.5 and 2.5% inspired concentration). function may be influenced by the actions of nitrous oxide on the systemic circulation or by autonomic nervous system reflex effects [351] [352] because nitrous oxide may increase sympathetic nervous system tone. [353] [354] [355] Studies using nitrous oxide alone are difficult to perform and interpret because this gas does not produce total anesthesia at partial pressures less than 1 atm. [356] [357] [358] [359] [360] [361] The effects of nitrous oxide on contractile function may be influenced by different baseline anesthetics. [362] [363] [364] [365] [366] [367] [368] Lastly, lack of use of load-insensitive measures of myocardial contractility has allowed only qualitative assessment of the effects of nitrous oxide on intrinsic inotropic state in the intact heart.

The regional preload recruitable stroke work relationship demonstrated that nitrous oxide depresses myocardial contractility in dogs anesthetized with isoflurane or sufentanil in the absence of autonomic nervous system activity (Fig. 5-20) (Figure Not Available) [369] Seventy percent nitrous oxide decreased M_w by 28 percent and 41 percent during sufentanil and isoflurane anesthesia, respectively. These results indicate that 70 percent nitrous oxide decreased contractility to approximately the same extent as 1 MAC isoflurane. Similar findings have been reported using LV end-systolic pressure-dimension relations in acutely instrumented dogs. [368] These nitrous oxide-induced myocardial depressant effects may be offset by concomitant increases in sympathetic nervous system tone. [354] The negative inotropic actions of nitrous oxide may be more pronounced in the presence of preexisting LV dysfunction. [370] In addition, nitrous oxide-induced depression of contractile function appears to overcome the mild sympathomimetic effect of this anesthetic gas in patients with coronary artery [360] [365] [366] [371] [372] [373] or valvular heart disease [360] [374] because increases in baseline sympathetic nervous system activity cannot be further augmented by nitrous oxide in these clinical conditions.

The actions of nitrous oxide on LV diastolic function have been studied incompletely. Modest increases in maximal

Figure 5A-20 (Figure Not Available) Effects of nitrous oxide on preload recruitable stroke work (PRSW) slope in the presence of isoflurane (top panel) and sufentanil (bottom panel) as presented as a percent of control (I or S only, respectively). *Significantly ($P < 0.05$) different from I or S only;
significantly ($P < 0.05$) different from I or S plus 30 percent nitrous oxide. *(From Pagel et al [369])*

lengthening velocity and maximal rate of decline of force have been observed in ferret papillary muscle concomitant with decreases in contractile state. [350] No changes in the rate of isometric or isotonic relaxation were observed, indicating that nitrous oxide does not substantially modify myocardial relaxation. [350] Nitrous oxide has recently been shown to modestly increase segmental indices of LV chamber compliance and reduce early LV filling in acutely instrumented dogs. [375] These findings are supported by evidence indicating that nitrous oxide may produce LV diastolic dysfunction after cardiopulmonary bypass in patients undergoing coronary artery bypass graft surgery. [373]

Nitrous oxide causes dose-related reductions in the intracellular Ca^{2+} transient *in vitro*. [350] [376] This finding indicates that nitrous oxide-induced depression of myocardial contractility is related to decreases in Ca^{2+} availability for contractile activation. Nitrous oxide does not affect myofibrillar sensitivity to Ca^{2+} [350] [377] or Ca^{2+} uptake and release from the SR. [377] In addition, the diastolic Ca^{2+} transient is unaffected by nitrous oxide, suggesting that this anesthetic gas does not alter myocardial relaxation kinetics. [376]

Hemodynamics

Assessment of the hemodynamic effects of nitrous oxide in humans is often complicated by concomitant administration of volatile anesthetics, opioids, or other anesthetic adjuvants in the presence or absence of cardiovascular disease. Typical clinical concentrations of nitrous oxide (e.g., 40-70%) cause modest increases in heart rate in healthy volunteers. [356] [378] Small increases in heart rate also occur when hyperbaric concentrations of nitrous oxide are administered [379] or when this anesthetic gas is added to volatile anesthetics. [380] Declines in heart rate have been observed with nitrous oxide in patients with coronary artery disease anesthetized with isoflurane [174] or halothane. [381] Modest reductions in heart rate have been also reported in patients anesthetized with morphine or fentanyl undergoing cardiac surgery. [360] [365] [366] Sixty percent nitrous oxide causes small increases in arterial pressure in humans. [378] Increases in arterial pressure also occur in hyperbaric conditions [379] or during halothane anesthesia in volunteers, [352] [362] consistent with a mild sympathomimetic effect. Other studies have also indicated that partial substitution of nitrous oxide for a volatile anesthetic either does not affect or modestly increases arterial pressure during enflurane, [367] isoflurane, [364] or desflurane [160] anesthesia in experiments conducted at constant MAC. In contrast, reductions in arterial pressure have been observed in patients with coronary artery disease receiving nitrous oxide in the presence and absence of opioids. [365] [371] [382]

Small increases in cardiac output and stroke volume have been observed during administration of 60 percent nitrous oxide in oxygen in volunteers. [378] Cardiac output remains unchanged in the presence of hyperbaric nitrous oxide, [379] however. Cardiac output has been shown to be greater in volunteers anesthetized with halothane and nitrous oxide than in those receiving halothane alone, [362] concomitant with increases in sympathetic nervous system tone. The addition of nitrous oxide to enflurane, isoflurane, or desflurane anesthesia also modestly increased cardiac output. [37] [38] [364] [367] In contrast, nitrous oxide reduces cardiac output and stroke volume in healthy volunteers [383] and patients with cardiac disease receiving opioids [360] [365] [366] [381] [382] Hyperbaric nitrous oxide (1.5 MAC) caused a modest reduction in systemic vascular resistance. [379] In contrast, systemic vascular resistance is higher during volatile anesthesia in the presence of as compared with the absence of

nitrous oxide. [37] [38] [362] [364] [376] Pretreatment with the ganglionic blocker hexamethonium attenuated the relative increase in systemic vascular resistance observed during administration of halothane and nitrous oxide, [352] findings that may be consistent with a reduction in sympathetic nervous system tone. Nitrous oxide-induced increases in systemic vascular resistance have also been reported in volunteers and patients with cardiac disease anesthetized with opioids. [360] [383] [384]

Nitrous oxide increases venous tone and decreases venous capacitance in conscious volunteers. [356] This anesthetic gas has also been shown to modestly increase pulmonary artery pressures and pulmonary vascular resistance in patients with coronary artery disease anesthetized with morphine and diazepam [365] or halothane. [385] Thus, the combined effects of enhanced venous return, elevated pulmonary vascular

resistance, and depressed contractile function probably contribute to the increases in central venous pressure observed with nitrous oxide in humans. Hyperbaric nitrous oxide also enhances central venous pressure in association with increases in pulmonary vascular resistance. [379] Nitrous oxide inhibits norepinephrine uptake by the lung, and subsequent increases in plasma norepinephrine levels detected in the pulmonary vasculature may be partially responsible for the characteristic increases in pulmonary vascular resistance observed during administration of this agent. [386] Nitrous oxide-induced increases in pulmonary vascular resistance may be more pronounced in adults with pulmonary hypertension [385] [387] and in children with increased pulmonary blood flow. [388] Elevations in pulmonary artery pressures and vascular resistance have also been described during administration of nitrous oxide in neonatal lambs. [389] Such increases in pulmonary vascular resistance may adversely enhance right-to-left atrial or ventricular shunts and compromise arterial oxygenation in patients with congenital heart disease. [390]

NITROUS OXIDE AND CARDIAC ELECTROPHYSIOLOGY

Reversible atrioventricular dissociation has been reported in humans anesthetized with nitrous oxide and volatile or opioid-based anesthetics. [391] Addition of nitrous oxide to halothane anesthesia lowers the threshold at which arrhythmias occur. [392] This observation may result from a combination of sympathetic nervous system stimulation by nitrous oxide and myocardial sensitization by halothane. [393] The incidence of arrhythmias has been shown to be reduced during combined nitrous oxide-opioid anesthesia when compared with halothane anesthesia alone. [394]

NITROUS OXIDE AND THE CORONARY CIRCULATION

Nitrous oxide does not produce direct effects on the coronary vasculature *in vitro*. [291] [395] [396] FSThis anesthetic gas alters coronary blood flow concomitant with changes in MVO_2 in dogs. [397] [398] Nitrous oxide decreases myocardial segment shortening, [399] [400] increases postsystolic shortening, [401] and redistributes transmural coronary blood flow preferentially to the subepicardium (decreased endo/epi ratio) [400] in experimental models of coronary artery disease. Nitrous oxide also decreases the recovery of contractile function of stunned myocardium. [402] Nitrous oxide-induced sympathetic nervous system activation and imbalances of myocardial O_2 supply and MVO_2 represent potential mechanisms by which this anesthetic gas further delays contractile recovery of stunned myocardium. [403] In the presence of a volatile anesthetic, nitrous oxide decreases MVO_2 and myocardial O_2 extraction [175] [381] and may exacerbate myocardial ischemia during concomitant reductions in arterial pressure in patients with coronary artery disease. [174] However, more recent studies demonstrate that the addition of nitrous oxide to volatile or opioid anesthetics does not increase the incidence of new regional wall motion abnormalities as assessed by transesophageal echocardiography. [175] [404]

NITROUS OXIDE AND NEURAL CONTROL OF THE CIRCULATION

Nitrous oxide causes pupillary dilation, diaphoresis, and increases in systemic vascular resistance, central blood volume, and forearm vascular resistance in volunteers during halothane anesthesia, [352] suggesting that nitrous oxide activates the sympathetic nervous system. A subsequent study demonstrated that nitrous oxide does indeed increase sympathetic nerve traffic measured using sympathetic microneurography in human volunteers, [354] especially during the first 15 to 30 minutes of exposure to this anesthetic gas. Although baroreceptor reflex-mediated control of heart rate is impaired during administration of nitrous oxide, regulation of sympathetic outflow to peripheral blood vessels is preserved. [353] This finding suggests nitrous oxide does not alter sympathetic vasoconstrictor-induced maintenance of arterial pressure and may be partially responsible for the relative stability of hemodynamics during nitrous oxide anesthesia.

XENON

The anesthetic properties of the noble gas xenon were first described more than 50 years ago. [405] Xenon has a blood gas partition coefficient less than that of nitrous oxide, [406] does not undergo biotransformation, [407] provides rapid induction and emergence from anesthesia, [408] [409] [410] and exerts analgesic effects [411] independent of alpha$_2$ -adrenergic and opioid receptors. [412] Despite these advantageous properties, xenon has not been routinely used for clinical anesthesia in the United States because it is more expensive than nitrous oxide and volatile anesthetics. In recent years, more efficient manufacturing techniques and development of low-flow administration and recycling systems have reduced the cost of xenon and rekindled interest in its clinical use. [409] [413] [414]

Xenon has been shown to cause minimal systemic and pulmonary hemodynamic effects *in vivo*, [408] [409] [415] [416] [417] preserve myocardial contractility in humans, [408] and attenuate increases in plasma epinephrine and cortisol concentrations associated with surgical stimulation. [415] The effects of xenon on systemic hemodynamics, LV systolic and diastolic function, and the determinants of LV afterload have recently been examined in chronically instrumented dogs before and after the development of rapid LV pacing-induced cardiomyopathy. [418] Xenon was remarkably devoid of hemodynamic effects in normal and cardiomyopathic dogs anesthetized with isoflurane. Xenon did not alter isofluraneinduced reductions in preload recruitable stroke work slope (M $_w$) in the presence and absence of pacing-induced LV dysfunction (Fig. 5-21) (Figure Not Available) . Xenon caused greater increases in tau in isoflurane-anesthetized, cardiomyopathic dogs as compared with normal dogs; however, indices of early LV filling and chamber compliance remained unchanged, suggesting that xenon does not appreciably influence LV diastolic function

Figure 5A-21 (Figure Not Available) Histograms illustrating the effects of isoflurane (ISO) and xenon on preload recruitable stroke work slope (M $_w$; top panel), the peak rate of increase of left ventricular pressure (+dP/dt$_{max}$; middle panel), and percent segment shortening (%SS; bottom panel) in normal (hatched bars) and cardiomyopathic dogs (solid bars) receiving 1.5 MAC isoflurane in the presence and absence of 30, 50, and 65% xenon. *Significantly ($P < 0.05$) different from conscious;
significantly ($P < 0.05$) different from ISO alone;
significantly ($P < 0.05$) different from ISO and 30 percent xenon; ¶ significantly ($P < 0.05$) different from corresponding value in normal dogs. *(From Hettrick et al [418])*

during isoflurane anesthesia. Xenon also produced relatively minor alterations in the determinants of LV afterload in dogs before and after pacing. Taken together, these recent data indicate that xenon produces very subtle cardiovascular effects during isoflurane anesthesia in dogs with and without experimental dilated cardiomyopathy. [418]

SUMMARY

Volatile anesthetics exert profound effects on the cardiovascular system by altering the inotropic, chronotropic, dromotropic, and lusitropic state of the heart. These agents also have significant actions on both the preload and afterload systems. These pharmacologic effects cause dramatic changes in hemodynamics that may be accentuated in patients with underlying cardiovascular disease. Less profound but equally important effects are observed with nitrous oxide and xenon. Recently, some of the volatile anesthetics have been shown to be cardioprotective, directly reducing the sequelae of ischemia and reperfusion injury. The use of inhaled anesthetics requires clear understanding of their complex cardiovascular pharmacology.

Chapter 5B - Pulmonary Pharmacology

Neil E. Farber
Paul S. Pagel
David C. Warltier

INTRODUCTION

This chapter describes the physiologic control mechanisms involved in modulating various anatomic components of the pulmonary system and the direct effects of inhaled anesthetics on this system. Specific sections of the chapter focus on airway and pulmonary vascular resistance, mucociliary function, and ventilatory control.

EFFECTS OF INHALED ANESTHETICS ON BRONCHOMOTOR TONE

Transient increases in airway resistance may be caused in part by an increase in bronchiolar smooth muscle tone. A retrospective review [1] found that patients without recent symptoms of asthma had a very low frequency of perioperative respiratory complications, but other retrospective studies [2] [3] have reported that intraoperative bronchospasm developed in approximately 6 percent of patients with asthma. Prospective studies have demonstrated that 1.7 percent of patients with asthma experienced a severe respiratory outcome [4] and that 25 percent wheezed after the induction of anesthesia. [5] Of 40 cases of bronchospasm resulting in settled malpractice claims (from the American Society of Anesthesiologists Closed Claims Project), 88 percent involved brain damage or death, and only half of these 40 patients had a history of asthma or chronic obstructive pulmonary disease. Significant bronchospasm can occur in normal subjects with no underlying lung disease secondary to a noxious stimulus, and the bronchial smooth muscle pharmacology of inhaled agents is of great clinical importance.

Pharmacology of Bronchial Smooth Muscle

Mougdil [6] and Pinto-Pereira [7] have summarized the mechanisms by which increases in airway resistance may occur. Airway smooth muscle, which extends as far distally as the terminal bronchioles, is under the influence of both parasympathetic and sympathetic nerves as well as non-adrenergic noncholinergic mechanisms. The parasympathetic nerves located in the vagi mediate baseline airway tone and reflex bronchoconstriction. Changes in intracellular calcium (Ca^{2+}) levels and Ca^{2+} influx can be caused by alterations in cyclic nucleotides. Agonist-induced contraction may be mediated by an increase in myosin light chain kinase activity, a phosphorylation of the 20-kd regulatory myosin light chain, and an increase in calcium sensitivity. Acetylcholine, or stimulation of the vagus nerve, is believed to provide an increase in the amounts of cyclic guanosine

---

monophosphate (cGMP) relative to cyclic adenosine monophosphate (cAMP), resulting in smooth muscle contraction. Release of histamine in the airway or various forms of mechanical or chemical stimulation can result in an increase in afferent vagal activity, with subsequent reflex bronchoconstriction. This increase in bronchomotor tone can be attenuated by atropine. In addition to M3 muscarinic receptors on airway smooth muscle that mediate bronchoconstriction, presynaptic M2 muscarinic receptors inhibit acetylcholine release, causing bronchodilation. Thus, low doses of pharmacologic agents such as ipratropium, which preferentially inhibit M2 receptors, may paradoxically result in bronchoconstriction. [8]

Adrenergic receptors in bronchial smooth muscle are classified into alpha and beta $_2$ types. alpha-Receptors are found in the bronchial tree in humans, but their activity seems to be low and clinically of undefined significance. beta $_2$ -Receptor subtypes play an important role in bronchiolar muscle responsiveness. Stimulation of $beta_2$ -receptors in bronchial smooth muscle causes relaxation, which is mediated by a relative increase in the intracellular concentration of cAMP.

The respiratory epithelium releases substances that can modulate bronchial smooth muscle tone. Removal of epithelium enhances contractile responses to acetylcholine, histamine, or serotonin in large airways and decreases relaxation responses to isoproterenol in small airways, [9] [10] analogous to the effect of damage of endothelium on vascular smooth muscle tone. Endogenous epithelial factors have not yet been identified, but the endothelial-derived relaxing factor, nitric oxide, may play a similar role in respiratory epithelium.

Inhaled Anesthetics

Volatile anesthetics have classically been considered to be potent bronchodilators, and there exists an overwhelming body of evidence in support of this contention. In a retrospective study, Shnider and Papper [2] found that in 49 patients with preanesthetic symptoms of bronchospasm, halothane was superior to ether, cyclopropane, and ethylene in decreasing wheezing. Colgan [11] noted an increase in "bronchial distensibility" in dogs anesthetized with halothane, ether, or methoxyflurane, with halothane having the most pronounced effect. Increasing concentrations of halothane caused a dose-dependent decrease in resting airway resistance in spontaneously breathing dogs. [12] However, the possibility of bronchodilation secondary to an increased resting arterial carbon dioxide tension ($PaCO_2$) with deeper planes of anesthesia was not excluded in either study. Halothane and diethyl ether caused relaxation of resting tone in isolated guinea pig tracheal strips. [13] These anesthetics also attenuated tracheal muscle constriction produced by acetylcholine, but only halothane accomplished this in clinically relevant doses.

Hickey et al [14] demonstrated the importance of controlled levels of $PaCO_2$ in evaluating the effects of drugs on bronchial smooth muscle tone. Halothane and cyclopropane produced no change in resistance of the resting unstimulated airway in anesthetized, mechanically ventilated, normocapnic dogs. When either administration of histamine or vagal stimulation induced a state of increased bronchial tone, 1.5 minimum alveolar concentration (MAC) halothane produced significant dilation compared with cyclopropane. Halothane, enflurane, and methoxyflurane were found to reverse the bronchoconstricting effects of hypocapnia *in vivo* in the isolated left lower lobe of the dog, [15] with halothane being most efficacious. Halothane also was shown to attenuate the bronchoconstricting effects of hypocarbia without significant actions on the resistive work of breathing in the unstimulated state in humans undergoing cardiopulmonary bypass. [16]

A series of studies using dogs sensitized to aerosolized ascaris antigen, a bronchospasm model developed by Hirshman and Bergman [17] has greatly contributed to our understanding of the effect of anesthetics on airway smooth muscle. Halothane and enflurane (1 MAC) similarly attenuate antigen-induced bronchospasm. However, unlike an asthmatic attack during anesthesia, the stimulus to incite bronchospasm was not continued throughout the study. Isoflurane and halothane (1.5 MAC) were found to produce a similar decrease in airway resistance using the same experimental preparation. [18] Similar results were obtained with methacholine-induced (direct-acting stimulus) airway constriction. These data suggest that isoflurane and halothane act both by depressing airway reflexes and by direct bronchodilation. Furthermore, whereas isoflurane appears to share significant bronchodilating properties with halothane and enflurane, halothane more effectively increased dynamic compliance (a measure of small airway resistance) than did isoflurane. This finding is made more interesting in light of data that showed that, *in vitro,* isoflurane preferentially relaxes the bronchiole in comparison with the bronchus. [19] The structure of the respiratory epithelium changes from pseudostratified columnar cells of the large airways to thinner, cuboidal cells of the bronchioles, and therefore it is not surprising that topographic heterogeneity exists. Park and colleagues have demonstrated that isoflurane and halothane equipotently dilate fourth-order bronchi at equivalent MAC multiples. [20]

Ascaris antigen-induced asthma was associated with increased plasma histamine levels, which were not prevented by halothane anesthesia. [21] In another study of histamine-induced bronchospasm, halothane and topical atropine both decreased bronchoconstriction, but halothane did not add to the bronchodilating effects of atropine. [22]

Brown and colleagues, [23] using computed tomography (CT), have shown that, at low concentrations, halothane is a better bronchodilator than is isoflurane (Fig. 5-22) (Figure Not Available) . Halothane has also been demonstrated to have a greater relaxing effect than isoflurane at similar MAC in intact airway smooth muscle as measured by high resolution CT. [24] All volatile anesthetic agents including the newer anesthetics sevoflurane [25] [26] and desflurane [27] have been shown to relax airway smooth muscle. Both halothane and desflurane, as with isoflurane and the intravenous anesthetics ketamine, midazolam, and propofol, [28] appear to relax

distal airways (bronchioles) more than they do proximal airways (bronchi). The relative potency of sevoflurane on relaxing distal versus proximal airways is unknown. Also, the efficacy of desflurane on methacholine or histamine-induced bronchoconstriction has not been investigated. Neither halothane, enflurane, sevoflurane, nor isoflurane (1 or 2 MAC) altered baseline pulmonary resistance and dynamic pulmonary compliance.

Figure 5B-22 (Figure Not Available) High-resolution computed tomography scan from one dog. Upper left = control; upper right = during 0.5 percent halothane; lower left = during 1.0 percent halothane; lower right = during 1.5 percent halothane. Note the progressive dilation of the airways as indicated by the arrows. *(From Brown et al [37])*

However, these four anesthetics significantly attenuated increases in pulmonary resistance and decreases in dynamic pulmonary compliance due to intravenous histamine. Halothane was most effective in altering indices of bronchodilation, whereas responses to isoflurane, enflurane, and sevoflurane were similar. [26] In contrast, halothane, enflurane, and sevoflurane were found to be equipotent at dilating third- or fourth-generation bronchi as measured directly *in vivo* with a fiberoptic bronchoscope. [29]

Mechanisms of Action

Volatile anesthetics relax airway smooth muscle by directly depressing smooth muscle contractility and affecting bronchial epithelium and indirectly by inhibiting reflex neural pathways.

The mechanism of the direct depression is unclear. Halothane was initially believed to have beta-agonist activity in airway smooth muscle as the reduction of airway resistance produced by halothane in dogs was blocked by the beta-adre-nergic receptor antagonist sotalol. [12] These effects may have been drug-specific rather than attributable to the drug class, or sotalol may have had smooth muscle contracting properties because propranolol does not antagonize the relaxing properties of halothane on acetylcholine-mediated bronchoconstriction. [13] The concentration of intracellular $Ca^{2+}{}_i$ is an important regulator of smooth muscle reactivity. There are several intracellular mediators responsible for Ca^{2+} mobilization, which are potential sites of action for volatile anesthetics. Halothane causes small increases in cAMP concentrations, which can lead to decreases in intracellular Ca^{2+} in airway smooth muscle. [30]

Halothane also suppressed the contraction of dog tracheal smooth muscle initiated by both direct and indirect electrical stimulation. [31] Halothane may inactivate or reduce free Ca^{2+} in the cytoplasm and/or suppress influx of Ca^{2+} across the cell membrane. Volatile anesthetics affect the function of G proteins (membrane-bound proteins that couple receptors to cellular effectors) in a variety of tissues. However, halothane does not depress airway contractility by an effect on pertussis toxin-sensitive inhibitory G proteins that attenuate beta -adrenoceptor-induced relaxation. [32] Halothane decreases the intracellular concentration of Ca^{2+} and Ca^{2+} influx during submaximal, but not maximal, muscarinic stimulation. [33] This anesthetic also decreases Ca^{2+} sensitivity, resulting in reduced force of contraction even in the presence of constant Ca^{2+} concentrations. [33] Recently, Warner and coworkers [34] demonstrated that halothane attenuates ACh-induced Ca^{2+} sensitization in canine tracheal smooth muscle to a greater extent than does isoflurane or sevoflurane (analogous to the differential effects of volatile anesthetics on relaxing airway smooth muscle). Warner also suggested that whereas halothane depletes sarcoplasmic reticular Ca^{2+} stores, this is not the mechanism by which a reduction in airway contractility occurs. [35]

The bronchoconstricting effects of low inhaled CO_2 mixtures were attenuated by inhaled but not by intravenous halothane. [16] This finding suggests that halothane acts directly on the airway musculature and/or local reflex arcs rather than via centrally controlled reflex pathways. Both halothane- and isoflurane-induced bronchodilation partially depend on the presence of bronchial epithelium. [20] A prostanoid (such as prostaglandin E_2 or I_2) and/or nitric oxide may mediate the bronchodilatory effects of the volatile anesthetics. Isoflurane-mediated bronchodilation is more dependent on nitric oxide than on prostanoids whereas the opposite is true for halothane. Focal epithelial damage or inflammation may occur in distal/small airways in those with asthma or allergen exposure, and as a consequence, the bronchodilatory response to volatile anesthetics may be reduced. [6] Thus, the greatest bronchodilatory action of the anesthetics in patients with chronic reactive airway disease may occur in the proximal airways.

Neural stimulation of intrinsic airway nerves *in vitro* produces a cholinergic contractile response that is inhibited by atropine. Volatile anesthetics bronchodilate, at least in part by modulating cholinergic neural transmission in the airways. [31] [36] The combination of atropine and halothane together did not increase airway caliber over that attained with each treatment alone, suggesting that halothane dilates baseline airways by blocking vagal tone. [37] There also exists a bronchodilatory neural reflex that is nonadrenergic and noncholinergic in nature and believed to be mediated by nitric oxide. [38] Halothane, at concentrations <1%, does not significantly affect the activity of the nonadrenergic, noncholinergic neural system or the formation or release of nitric oxide by this neural system. [39] Finally, the direct antagonism of histamine is not the mechanism of volatile anesthetic-induced bronchodilation. Antigen-induced increases in plasma histamine concentrations are not prevented by previously anesthetizing animals with halothane. [21]

Clinical Effects

Appropriate anesthetic management of the patient with reactive airways disease has been reviewed. [6] [7] [40] Volatile anesthetics may be an effective method of treating status asthmaticus when other more conventional treatments have failed. Gold and Helrich [41] evaluated the effect of halothane and tracheal intubation on six patients treated unsuccessfully for status asthmaticus for at least 72 hours with bronchodilators, steroids, and antibiotics. No significant change in airway resistance was recorded in either the anesthetic or immediate postanesthetic period. Patients improved within 3 days after treatment, but the lack of a control group precludes interpretation. Several studies, however, have demonstrated that in refractory patients with status asthmaticus, the use of inhalational anesthetics may be beneficial. [42] [43] [44] [45] [46] [47] Halothane treatment may be associated with an increased risk of cardiac arrhythmias and cardiovascular depression such that isoflurane has been suggested to be the inhaled anesthetic of choice in status asthmaticus. [47] However, use of 1 percent halothane in 12 patients in status asthmaticus who required mechanical ventilation was associated with a rapid reduction in bronchospasm and barotrauma injury, improvement in arterial blood gas tensions, and a lack of adverse hemodynamic effects, including cardiac arrhythmias. [46]

Rooke et al [48] recently compared the bronchodilating effects of halothane, isoflurane, sevoflurane, and thiopental/ nitrous oxide in 66 nonasthmatic patients undergoing induction of anesthesia and tracheal intubation (Fig. 5-23) (Figure Not Available) . All volatile anesthetics significantly reduced respiratory system resistance (thiopental/nitrous oxide did not change resistance), and equi-MAC sevoflurane decreased resistance as much as halothane and more so than isoflurane. Thus, the previously described animal studies demonstrating equipotency of sevoflurane and isoflurane and greater potency of halothane for bronchodilation must be extrapolated with caution to humans as ascaris- or histamine-mediated experimental bronchospasm may not precisely mimic tracheal intubation-induced bronchospasm in humans.

The effect of the addition of albuterol to halothane anesthesia on airway reactivity was examined in dogs. [49] Halothane attenuated histamine-induced bronchoconstriction,

Figure 5B-23 (Figure Not Available) The percentage change in respiratory system resistance in patients after 5 and 10 minutes of maintenance anesthesia with either 0.25 mg/kg/min thiopental + 50% nitrous oxide; or 1.1 MAC sevoflurane, halothane, or isoflurane. All volatile anesthetics decreased resistance. Sevoflurane decreased resistance more than did isoflurane. *(From Rooke et al [46])*

and the beta-adrenoceptor agonist albuterol further dilated the airways, indicating an additive or synergistic effect. There was also no negative interaction between the dilatory effects of halothane and isoproterenol on canine tracheal smooth muscle. [32] Neither halothane nor isoproterenol affected the ability of the alternative treatment to relax acetylcholine-contracted tracheal strips. These findings support the use of beta-adrenoceptor agonists in the treatment of bronchospasm in patients already receiving halothane. Results may differ somewhat with other volatile anesthetics or beta agonists. An example is the beta $_2$ -adrenergic agonist fenoterol: while lowering respiratory system resistance following endotracheal intubation, it did not further decrease resistance as that observed with 1.3 percent isoflurane alone. [50] The results of the latter study may be due in part to the methodology of measurement of respiratory system resistance, which also reflected alterations in lung and chest-wall resistance as well as tissue viscosity.

The actions of volatile anesthetics on bronchomotor tone, at least *in vitro,* are dependent on the agent eliciting contraction. [24] Relaxation of tracheal smooth muscle by halothane and isoflurane is greatest in the presence of the endogenous mediator serotonin (potentially representing anaphylactoid or immunologic reactions) in comparison to the contraction produced by acetylcholine (representing the neurally derived mediator of reflex bronchospasm). In contrast to the relaxing effects of isoproterenol, the absolute amount of airway smooth muscle relaxation by halothane is not dependent on the degree of contraction, suggesting that volatile anesthetics remain effective even during severe bronchospasm.

The actions of volatile anesthetics in decreasing bronchomotor tone and neurally mediated airway reflexes may be opposed in the anesthetized patient in part by a decrease in functional residual capacity, which results in increasing airway resistance. [51] Patients with asthma are at increased risk for morbidity and mortality in the perioperative period. Future investigations in humans with newer volatile anesthetics will benefit from advances in knowledge of mechanisms of anesthetic action on airway smooth muscle and contractile responses to pathophysiologic alterations.

Clinical Implications

Bronchospasm may occur in diseases other than asthma, and indeed even normal, healthy patients undergoing surgical stimulation of pulmonary parenchyma or airways are known to be at risk of developing bronchospasm. [52] Clinically discernible bronchospasm is not an unusual event following stimulation or irritation of the trachea by an endotracheal tube in lightly anesthetized patients. In anticipating such events in patients with known reactive airway disease, the choices of preoperative medication, induction agent, muscle relaxant, and type of inhalational anesthetic drug are important factors in minimizing clinical symptoms.

Halothane may be a more potent bronchodilator than other inhaled anesthetics. Studies in humans have not closely examined the effects of desflurane on airway resistance. However, the often-profound upper airway effects of desflurane as a respiratory irritant (coughing, respiratory secretions, breath-holding, and laryngospasm, especially in the pediatric population) may outweigh the benefit of any

direct bronchodilatory actions. Differences in bronchodilating effects between volatile anesthetics may exist, but of greater clinical importance is avoiding or minimizing airway irritation and maintaining adequate depth of anesthesia with the agent that is chosen.

EFFECTS OF INHALED ANESTHETICS ON MUCOCILIARY FUNCTION

Normal Mucociliary Function

Foreign particulate matter, microorganisms, and dead cells are removed by the upward clearance of mucus from the tracheobronchial tree as a primary pulmonary defense mechanism. Ciliated respiratory epithelium extends throughout the respiratory tract as far as the terminal bronchioles and decreases in density (as do mucus-producing goblet cells and submucous glands) from trachea to alveoli. [53] Ciliary motion consists of a rapid stroke in a cephalad direction, followed by a slower recovery stroke in the opposite direction. Movements of proximal cilia are coordinated to closely follow movements of cilia that are immediately distal. The resulting wave of motion is referred to as metachronism. The bending of individual cilia appears to be the result of an adenosine triphosphate (ATP)-dependent sliding of two parallel fibers within the ciliary filament and does not appear to involve the autonomic nervous system in mammals.

Mucus represents a mixture of water, electrolytes, and macromolecules (lipids, mucins, and enzymes) secreted by goblet cells and mucosal glands. The rheologic properties of mucus influence the rate and efficiency of ciliary function in that thicker layers of mucus appear to slow the removal of surface particles from the airway whereas high elasticity and low viscosity appear to promote the most rapid ciliary transport. The presence and characteristics of the mucus layer may also promote the coordination of ciliary beats. The physical and chemical characteristics of mucus in expectorated specimens have been studied extensively by Reid. [54] Characteristics may differ from those present *in vivo* because of contamination by salivary secretions and desiccation of expectorated secretions. [55]

Mucociliary function in single cilia or respiratory epithelial tissue cultures may be assessed by use of high-speed videomicroscopy to examine the ciliary beat frequency. *In vivo* techniques in animals have made use of a tracheal window, whereas in humans the velocity of mucus movement has been measured with radioactive markers or with a fiberoptic bronchoscope. The deposition of radiopaque or radioactive particles throughout the lung fields followed by radiographic examinations of clearance of these inhaled particles allows examination of mucociliary function in both peripheral and central airways.

Specific Effects of Anesthetics

Postoperative hypoxemia and atelectasis are common causes of perioperative morbidity. Many factors other than anesthesia may affect and diminish mucociliary function, particularly in the mechanically ventilated patient. Poorly humidified inspired gases may decrease ciliary movement and dry out mucus. In dogs, mucus flow rates were normally maintained for a 40-minute period if inspired air temperature was higher than 32°C and included an inspired water vapor content of 33 mg/L. [56] However, 3 hours of inhalation of dry air results in a complete cessation of tracheal mucus flow, which may be restored by use of inspired gases with 100 percent relative humidity at 38 C. [57] Other factors diminishing the rate of mucus movement are high inspired oxygen concentration, inflation of the endotracheal tube cuff, and positive-pressure ventilation. [58]

The effect of various anesthetic agents on mucociliary flow has been determined with scintillation counters measuring radioactive droplet progression in the trachea of dogs (Fig. 5-24) (Figure Not Available) . [58] [59] [60] Halothane, enflurane, nitrous oxide with halothane, and nitrous oxide with morphine--all dose-dependently and in a similar fashion--decreased mucociliary movement. [59] [60] Clearance of mucus from both central (trachea and mainstem bronchi) and peripheral airways following 6 hours of halothane (1.2 MAC) was delayed by at least 3 hours. [61]

Inhaled anesthetics may diminish rates of mucus clearance by decreasing ciliary beat frequency or disrupting metachronism or by altering the characteristics or quantity of mucus produced. Exposure to any of six inhaled anesthetics caused dose-related decreases in ciliary activity and cellular mobility of the ciliated protozoan *Tetrahymena pyriformis.*[62] The dose that effectively terminated organism and ciliary movement in 50 percent of the protozoans closely corresponded to MAC values of the various anesthetics. The mechanism by which cilia were affected was not delineated, but the rapidity and reversibility of the depression suggested that metabolic depression of ATP stores was not involved. Extrapolation from the protozoan to mammalian airway epithelia must be performed with caution, however; the results suggest a direct inhibitory effect on mucus clearance. Halothane (at doses greater than 3%) depressed ciliary movement in cultures of canine ciliated epithelium. [63] The sensitivity of cilia to halothane was less than that found in *T. pyriformis.* The effects of anesthetics on ciliary beat frequency in humans have yet to be elucidated.

Pulmonary surfactant decreases the work of breathing by reducing surface tension at the fluid-gas interface; like mucus, it plays a role in removing foreign particles from airways and enhances the bactericidal capacity of alveolar macrophages. The effects of halothane on cultured alveolar type II cells, which secrete surfactant, and on the metabolism of phosphatidylcholine, the main lipid component of surfactant, have been investigated. [64] Halothane dose-dependently reduced phosphatidylcholine synthesis (but not secretion) by alveolar cells during a 4-hour exposure (Fig. 5-25). (Figure Not Available) The reduction in phosphatidylcholine was progressive with longer durations of halothane exposure and reversible within 2 hours following termination of halothane. Also, high concentrations of halothane disrupted the energy metabolism of cultured alveolar cells, decreasing ATP content and increasing glycolytic metabolism (measured as lactate production).

Clinical Effects

Gamsu et al [65] compared the rate of tantalum clearance from the lungs of postoperative patients who had received general anesthesia for either intra-abdominal or lower extremity

Figure 5B-24 (Figure Not Available) Mucociliary clearance measured as tantalum clearance in patients undergoing surgery with either general or local anesthesia (awake). Note the decrease in mucociliary clearance in both peripheral and central airways during halothane and thiopental anesthesia. *(Modified from Forbes and Gamsu [61])*

orthopedic procedures. Patients who underwent orthopedic procedures showed no significant differences from a control group undergoing tracheography. These patients also did not develop atelectasis. In contrast, retention of tantalum was demonstrated for as long as 6 days following intra-abdominal surgery, with an average retention time three times that of the control group. Retention of tantalum was gravity-dependent and correlated with the retention of mucus demonstrated in areas of atelectasis. Disappearance of tantalum from these atelectatic areas occurred only after reexpansion of collapsed lung segments. In a study of tracheal mucus velocity, Teflon discs were placed on the tracheal mucosa and observed through a fiberoptic bronchoscope in young anesthetized women undergoing gynecologic surgery. [66] Control values of mucus velocity in awake volunteers were 20 mm/min. Anesthesia with 1 to 2 percent halothane and 60 percent nitrous oxide rapidly decreased the rate of mucus travel to 7.7 mm/min, with little or no motion observed after 90 minutes of anesthesia. Inspired gases were humidified, but the use of high inspired concentrations of oxygen, a cuffed endotracheal tube, and positive pressure ventilation were confounding factors. Thus, assessment of the direct effects of halothane is difficult. Bronchial mucosal transport velocity was also determined using radiolabeled albumin microspheres deposited distally in the mainstem bronchi by a fiberoptic bronchoscope in patients without lung disease undergoing general anesthesia. [67] There were no significant changes in mucus velocity following administration of isoflurane (1.5 MAC). Whether the lack of effect of isoflurane on mucus transport was related to the use of isoflurane rather than halothane or

species, i.e., the use of humans rather than animals, is unknown. Mucus pooling in animals occurs during and after anesthesia, suggesting a need in the immediate postoperative period for vigorous pulmonary therapy directed at enhancing clearance of secretions from the airways.

Konrad and coworkers [68] have shown in patients undergoing abdominal or thoracic surgery that smokers have significantly slower bronchial mucus transport velocities than do nonsmokers and postulated that this may be related to an increased incidence of postoperative pulmonary complications in smokers. Some evidence exists that patients with chronic obstructive pulmonary disease anesthetized by regional techniques show a lower incidence of respiratory failure than those having general anesthesia, [69] but other studies have failed to confirm this advantage. Possibly of greater importance

Figure 5B-25 (Figure Not Available) Effect of halothane on phosphatidylcholine (PC) synthesis by alveolar type II cells. PC synthesis measured as the incorporation of [^{3} H-methyl]-choline into PC and expressed as disintegrations per minute per microgram intracellular protein. * $P < 0.05$, ** $P < 0.01$ versus respective control. (A) Effect of increasing halothane concentration with 4-hour exposure. (B) Effect of increasing exposure time to 2 percent halothane. *(Modified from Molliex et al [64])*

are the consequences of the specific procedure, with intrathoracic and intra-abdominal surgery having greater morbidity related to compromised respiratory function as compared with peripheral procedures.

Clinical Implications

Many factors contribute to postoperative pulmonary complications. The specific roles of depressed mucociliary function and alterations in type II alveolar cells in such complications are unknown. Prolonged anesthesia may lead to pooling of mucus and changes in alveolar cell surfactant metabolism, resulting in deleterious effects on pulmonary function such as atelectasis and respiratory infections. Those at greatest risk would include patients with excessive or abnormal mucus or surfactant production (chronic bronchitis, asthma, respiratory tract infection, cystic fibrosis, and chronic mechanical ventilation).

Controlled studies of the effects of inhaled anesthetics on mucociliary function and surfactant metabolism in patients with pulmonary compromise have not been performed, nor has the precise effect of volatile anesthetics on the rate of pulmonary complications been clearly delineated. The actions of the newer volatile anesthetics desflurane and sevoflurane on mucociliary function have not been adequately studied, although there are no compelling reasons to suspect a clinically significant difference should exist among various anesthetics.

EFFECTS OF INHALED ANESTHETICS ON PULMONARY VASCULAR RESISTANCE

Determinants of Pulmonary Vascular Resistance

Determining the actions of pharmacologic agents on pulmonary vascular pressures and pulmonary vascular resistance (PVR) is a complicated task because many vasoactive

agents have direct effects on the pulmonary circulation as well as indirect effects mediated via alterations of cardiac output, preload, and afterload. Increased vascular distending pressure may cause an increase in cross-sectional diameter of the pulmonary vascular bed and a compensatory reduction in PVR. Similarly, changes in lung volume may alter the dimensions of the vasculature and, hence, affect resistance. Both increases in lung volume above functional residual capacity caused by increased airway pressure and decreases in lung volumes below normal functional residual capacity are associated with passive increases in PVR. High lung volumes compress pulmonary vessels; at low lung volumes, vessels are shorter, narrower, and more tortuous, apparently because of loss of supportive tethering of surrounding lung tissue. Resistance in the pulmonary circuit appears to be lowest at a lung volume equivalent to the functional residual capacity. Changes in PVR and pressure may have significant effects on gas or fluid exchange in the lung. Increased PVR gives rise to an increase in pulmonary artery pressure if cardiac output is maintained constant and thereby promotes increased transudation of fluid into the interstitium of the lung. PVR may be increased by alterations in positive end-expiratory pressure, lung volume, alveolar hypoxia and hypercarbia, and critical closing pressure (parallel shift in pressure-flow curves). Many anesthetic drugs tend to reduce lung volume and therefore may have indirect effects on PVR through this mechanism.

Direct changes in pulmonary vascular tone alter PVR (changes in slope of pressure-flow relationship). Such direct changes may be induced by alterations in sympathetic tone, by local changes in PO_2 and PCO_2, or by changes in concentrations of catecholamines and other vasoactive substances released locally or in blood perfusing the lung. Regional changes in PVR are particularly important in that they may alter the relative distribution of blood flow within the lung, leading to altered ventilation-perfusion relationships and accompanying changes in gas exchange. Thus, an increase in PVR in an area of atelectasis and localized tissue hypoxia optimizes gas exchange, including a decreased alveolar-arterial oxygen tension gradient [$P(A\text{-}a)O_2$], by shifting blood flow away from the atelectatic segment to better ventilated regions of the lung. This phenomenon, termed hypoxic pulmonary vasoconstriction (HPV), is unique to the pulmonary circulation as other vascular beds (e.g., coronary and cerebral) dilate in response to hypoxia. Hypoxic vasoconstriction appears to have protective value, and drugs that interfere with this protective mechanism may adversely affect gas exchange. Infusion of a pulmonary vasodilator such as nitroprusside attenuates HPV, decreases PaO_2, and increases pulmonary shunting in dogs with oleic acid-induced pulmonary edema. [70]

The pulmonary vasodilator action of inhaled anesthetics including halothane, isoflurane, enflurane, sevoflurane, and desflurane in normal lungs is minimal. [71] [72] [73] Mild decreases in PVR by volatile anesthetics are offset *in vivo* by a concurrent decrease in cardiac output. The net effect is usually little or no change in pulmonary artery pressure and a small decrease in pulmonary blood flow. Nitrous oxide has little effect on cardiac output and pulmonary blood flow. Overall, changes in PVR are small, tending to increase slightly during administration of nitrous oxide.

Hypoxic Pulmonary Vasoconstriction

HPV (Ch. 15) . is locally mediated; it occurs in isolated perfused lungs, and a similar response may be elicited in animals following autonomic nervous system blockade or catecholamine depletion. The sympathetic nervous system may, however, play a role in augmenting the response in certain circumstances, particularly in the presence of systemic hypoxemia. HPV in normal lungs appears when alveolar PO_2 is less than 100 mm Hg and is maximal when PO_2 is approximately 30 mm Hg. [74] [75] Recently, HPV has been investigated in humans with healthy lungs. [76] Unilateral graded hypoxia and unilateral single-step hypoxia produced similar reductions in the perfusion of the hypoxic lung to approximately 30 percent (at an inspired O_2 concentration of 0.05). Mixed venous PO_2 (PvO_2) may influence HPV in the atelectatic lung because PO_2 in the collapsed segment approaches that of PvO_2. [77] [78] Acidosis is also a pulmonary vasoconstrictor both in intact animals and in isolated perfused lungs. Changes in PVR in response to acidosis are small at normal alveolar oxygen tensions, but in the presence of alveolar hypoxia they are dramatically enhanced. Thus, elevations in arterial hydrogen ion concentration, alveolar PCO_2, or both may augment pulmonary vasoconstriction.

Inhaled Anesthetics and Hypoxic Pulmonary Vasoconstriction

Many mechanisms exist, such as pulmonary atelectasis and diminished functional residual capacity relative to closing capacity of the lung, that cause a decrease in oxygenation and an increase in $P(A\text{-}a)O_2$ during anesthesia. The effects of numerous inhaled anesthetics on HPV have been examined in a variety of animal and experimental models, with conflicting results. Experiments and results are summarized in Table 5-1 .

The effect of inhalational anesthetics on HPV is multifactorial, involving direct pulmonary vascular actions and indirect cardiovascular, autonomic, and humoral actions. In general, most *in vitro* studies have demonstrated some degree of attenuation of HPV with all inhalational anesthetics (Fig. 5-26) (Figure Not Available) . Inhibition of HPV has been demonstrated with halothane, [71] [79] [80] [81] [82] [83] isoflurane [71] [72] enflurane, [71] [84] sevoflurane, [72] desflurane, [73] and nitrous oxide, using isolated perfused lungs or an in situ preparation with constant perfusion. [85] [86] [87] Marshall et al [71] examined the effects of halothane, enflurane, and isoflurane on the HPV response to global hypoxia. All three drugs dose-dependently depressed HPV, and similar MAC values (approximately 0.6 MAC) depressed HPV by 50 percent in an *in vitro* preparation allowing for control of lung perfusion and eliminating any effect of the sympathetic nervous system. A more recent study in isolated rat lungs confirmed depression of HPV by both isoflurane and halothane, but the addition of verapamil reduced HPV by an additional 35 to 40 percent, implying an additive effect and different sites of action. [88] Furthermore, halothane reduced the resistance of the middle vascular segment in atelectatic and hypoxic lung, suggesting a direct action on small vessels and capillaries. [82] [89]

Modified from Pavlin EG, Yu JY: Cardiopulmonary pharmacology. In Miller RD (ed): Anesthesia, Churchill Livingstone, New York, 1994.

With the left lower lobe of a dog lung selectively ventilated with an hypoxic gas mixture and the remainder of the lung ventilated with 100 percent oxygen, the effect of hypoxia on PVR was assessed by measuring blood flow to the isolated lobe and comparing it with total pulmonary blood flow. [90] [91] A significant decrease in flow to the isolated lobe occurred in the presence of localized alveolar hypoxia during constant pulmonary blood flow (cardiac output), pulmonary artery pressure, and left atrial pressure. Neither halothane nor nitrous oxide administered to the isolated lobe diminished the magnitude of HPV, although a dose-related inhibition could be demonstrated in the presence of isoflurane. These experiments were also performed with the anesthetic agent administered to the whole animal and to the isolated lung segment. Whereas halothane, isoflurane, and enflurane diminished cardiac output, the effects on blood flow to the isolated segment were almost identical to those obtained when administration of anesthetic gas was confined to the isolated lobe alone.

The mechanism of the direct inhibitory action of volatile anesthetics on HPV is unclear but may be related to enhancement of arachidonic acid metabolism [83] [92] or other endothelial-derived vasodilating factors. [93] However, volatile anesthetic-induced inhibition of HPV is not dependent on the presence of pulmonary vascular endothelium, nitric oxide, or guanylate cyclase. [94] [95] [96] Volatile anesthetics may also disrupt Ca^{2+} homeostasis, which is intimately involved in pulmonary vasoconstriction. Interestingly, halothane and isoflurane, in isolated canine pulmonary artery rings, attenuated endothelium-dependent vasodilation by inhibiting accumulation of cGMP [96] and an ATP-sensitive potassium channel-mediated interaction between nitric oxide and prostacyclin. [97] Halothane and enflurane also attenuate ATP-sensitive potassium channel-mediated pulmonary vasodilation in chronically instrumented dogs. [98] In contrast, isoflurane enhanced isoproterenol-mediated vasodilation. [99]

Findings from *in vitro* studies suggest that volatile anesthetics exert inhibitory actions on HPV, but results from *in vivo* investigations have been surprisingly inconclusive. Sykes et al [100] examined the effects of one-lung hypoxia on relative pulmonary blood flow distribution in dogs, as measured using xenon. [133] One lung was ventilated with nitrogen,

Figure 5B-26 (Figure Not Available) Concentration-dependent inhibition of hypoxic pulmonary vasoconstriction (HPV) in rabbit lungs by desflurane (closed circles) and halothane (open circles). Values are mean ± SEM and expressed as a percentage of control. * $P < 0.05$ versus control HPV. The half-maximum inhibiting effect (ED_{50}) values were within the range of 1 and 2 MAC (for rabbits) for both agents. *(From Loer et al [73])*

and the other was ventilated with 100 percent oxygen. A redistribution of flow to the well-oxygenated lung was found, indicating active HPV, which was preserved in the presence of halothane at inspired concentrations of up to 3 percent. In contrast, using the same experimental preparation, ether and nitrous oxide profoundly affected the redistribution of pulmonary blood flow in response to hypoxia. [101] [102] Other *in vivo* investigations have also determined that nitrous oxide markedly attenuates HPV. [90] [91] [103] Halothane, isoflurane, and enflurane may have minimal or no effects on HPV *in vivo*.[90] [91] [104] [105] [106] [107] Recently, Lennon and Murray [92] have shown that isoflurane anesthesia attenuates HPV in chronically instrumented dogs as compared with the response measured in the same animal in the conscious state. Pulmonary vascular pressure (pulmonary arterial pressure-left atrial pressure) versus pulmonary blood flow relationships were generated in the absence of baseline anesthesia and acute surgical trauma to demonstrate flow dependency of the HPV. Unlike the case of isoflurane, inhibition of HPV was not observed using the same preparation in the presence of sevoflurane or desflurane. [108]

Clinical Effects

One obvious explanation for differences in results between *in vitro* and *in vivo* studies is the influence of cardiac output. The effect of anesthetics on HPV versus the effect on cardiac output was compared using data from a variety of studies. [109] The efficacy of HPV varies inversely with cardiac output (as pulmonary blood flow), and a direct inhibition of HPV by anesthetics might be opposed by a decreased cardiac output such that HPV may appear to be unaffected. The net HPV response is unchanged when the cardiac output is reduced by potent inhalational anesthetics and attenuated when cardiac output is maintained (e.g., during nitrous oxide). Thus, whereas the HPV response may be directly inhibited by the volatile anesthetic, the effectiveness of the HPV response is indirectly enhanced by the depression of cardiac output.

Isoflurane does not affect pulmonary shunt in patients without pulmonary disease, even at concentrations that cause systemic hypotension. [110] The effects of diethyl ether and halothane on pulmonary blood flow distribution during nitrogen ventilation of one lung in humans were examined. [104] HPV occurred in the nitrogen-ventilated lung during intravenous anesthesia with barbiturates but disappeared with the inhalation of either halothane or diethyl ether in the ventilated lung. Abolition of HPV was accompanied in most patients by a decrease in PaO_2. In contrast to this study, clinical observations in patients undergoing one-lung ventilation during thoracic surgery have failed to demonstrate changes consistent with attenuation of HPV by halothane. No significant differences in shunt fraction or PaO_2 were found when pulmonary gas exchange during intravenous anesthesia (ketamine) was compared with that during enflurane anesthesia. [111] Ketamine does not inhibit HPV, and this suggests that enflurane also does not affect HPV. In clinical practice, thoracic surgery is typically carried out in patients in the lateral position with an open chest, altering relative distribution of perfusion pressures. The diseased nondependent lung would alter pulmonary vascular responsiveness to hypoxia, as might surgical manipulation of the lung. [112]

Benumof et al [113] have provided convincing evidence that inhalational anesthetics are safe to use in patients undergoing thoracotomy with one-lung ventilation and that halothane and isoflurane only minimally impair arterial oxygenation (Fig. 5-27) (Figure Not Available) . The increase in shunt and decrease in oxygenation caused by halothane or isoflurane was consistent with approximately a 20 percent inhibition of HPV at 1 MAC. Instead of a single lung being able to decrease its blood flow by 50 percent, 1 MAC halothane or isoflurane would result in a hypoxic lung being able to decrease its blood flow by 40 percent. This change in flow corresponds to an increase in the pulmonary shunt by 4 percent of the cardiac output. Isoflurane appears to preserve HPV to a greater extent than does halothane, which may be related to a greater maintenance of cardiac output. [113] Recently, minimal and similar changes were shown to occur with isoflurane and desflurane in patients undergoing thoracotomy and single lung ventilation. [114] Increases in shunt fraction and the alveolar-to-arterial oxygen tension gradient were attributed to the onset of one-lung ventilation rather than to a specific action of the volatile anesthetics.

An important factor involved in modulating the effects of HPV may be the overall effect of pulmonary artery pressure.

Figure 5B-27 (Figure Not Available) Arterial oxygenation (PaO_2) and intrapulmonary shunt (Qs/Qt) in patients ventilated with both lungs (2-LV) or with one lung (1-LV). Patients received either an inhalational (IH) agent halothane or isoflurane or an intravenous (IV) anesthetic thiopental. Note the minimal effect on PaO_2 and shunt that occurs in changing from a volatile anesthetic to an IV agent. *(Modified from Benumof et al [113])*

High pulmonary artery pressures may tend to cause passive distension of constricted vascular beds and thereby reverse HPV. Alternatively, reflex pulmonary and systemic vasoconstriction in response to stimuli such as hypotension may increase PVR in healthy lung segments, leading to a shift of blood flow to the diseased (hypoxic) areas of lung.

Remarkable and reversible increases in pulmonary shunting have been demonstrated by administration of pulmonary vasodilators such as nitroprusside and nitroglycerin in dogs with oleic acid-induced pulmonary edema. [70] Some anesthetics probably produce a similar response in patients with adult respiratory distress syndrome or with other types of pulmonary pathology associated with large right-to-left intrapulmonary shunts. Finally, although Lennon and Murray have demonstrated an inhibitory effect of isoflurane on HPV in chronically instrumented dogs, [92] these investigators have also shown that isoflurane did not influence pulmonary vascular tone in the presence of increased pulmonary vascular resistance following single-lung transplantation in chronically instrumented dogs. [115]

Clinical Implications

The precise effects of various anesthetics in patients with preexisting pulmonary disease remain to be defined; however, the action of anesthetic gases on the pulmonary vasculature must be taken into account as one possible factor when considering the causes of hypoxemia during general anesthesia. Additional investigations need to be performed, particularly in humans, before the actions of a particular anesthetic can be predicted.

The clinical findings appear to indicate that potent inhalational anesthetics exert only mild inhibitory effects on HPV and subsequent oxygenation. Furthermore, given the efficacy of nondependent lung continuous positive pressure in improving oxygenation, the inhibition of HPV by volatile anesthetics should not significantly influence clinical decisions. The net effect of anesthetics on HPV is multifactorial, depending on a number of other factors that commonly occur intraoperatively.

EFFECTS OF INHALED ANESTHETICS ON CONTROL OF VENTILATION

Alterations of minute ventilation are the most obvious effects of anesthetics. Many different stimuli interact in a complex manner to determine the level of ventilation in humans. The traditional approach to studying effects of anesthetics on ventilation has been to measure ventilatory responsiveness (expired minute volume, respiratory frequency, or $PaCO_2$) before and after drug administration. A complete description of ventilatory control is beyond the scope of this chapter; excellent reviews of this subject already exist. [116] [117] However, an understanding of normal ventilatory responses and control mechanisms is necessary to appreciate the actions of anesthetics and the methods by which these effects are measured.

Control of Breathing

A control system that modulates ventilation is necessary to maintain stability of blood gas tensions and acid-base status and to integrate frequency and tidal volume in such a manner as to minimize the work of breathing in response to variations in the total ventilatory requirements (Fig. 5-28) . The system responsible for receiving and integrating the many input signals and ultimately producing movement of air in and out of the lungs is composed of the following:

Sensors, which may be chemical (peripheral and central chemoreceptors) or mechanical (distortion receptors located in airways, alveoli, and respiratory muscles).

Respiratory control system, which integrates the signal inputs from the receptor sites, centers of consciousness, and

Figure 5B-28 Some aspects of the reflex control of ventilation. Sensors include central and peripheral chemoreceptors as well as a variety of mechanoreceptors. Inputs from these many sources interact to alter ventilatory controller output from pontomedullary sites to muscles of respiration, thus altering ventilation and ultimately gas exchange.

other influences (e.g., pain) and culminates in a level and pattern of nerve traffic to the muscles of respiration.

Motor system, composed of the chest wall and intercostal, diaphragmatic, and abdominal muscles, all of which respond to signals from the control center via the phrenic and spinal nerves.

The respiratory rhythm generator resides within the brain stem, where two main groups of respiratory neurons are found: the dorsal respiratory group, composed of cells active during inspiration; and the ventral respiratory group, containing both inspiratory and expiratory neurons. The isolated medulla oblongata is capable of generating a rhythmic, although abnormal, respiratory pattern. [118] However, the precise mechanism of rhythm generation is still unknown. An exciting *in vitro* neonatal brain slice model was developed by Smith [119] that demonstrates that at least in the immature animal, a group of pacemaker (self-oscillating) respiratory neurons in the rostral ventral respiratory group exists that might be the elusive rhythm generator. No analogous group of cells has been demonstrated to date in adult animal models. The rostral pons contains the pneumotaxic center, which involves inspiratory and expiratory neurons and plays a modulating role, integrating vagal and chemoreceptive inputs. The inspiratory controller output, independent of mechanical factors, may be measured in the human as the pressure developed in the first 0.1 second of inspiration at functional residual capacity by acute airway occlusion. [120]

General Ventilatory Effects of Anesthetics

In general, all volatile anesthetics decrease tidal volume. However, the resultant depression of minute ventilation may be partially offset by a concomitant increase in respiratory rate (Fig. 5-29) . [121] [122] Early studies demonstrated that isoflurane produced more profound respiratory depression than did halothane. In contrast to halothane, isoflurane did not progressively increase respiratory frequency (Fig. 5-30) (Figure Not Available) . [123] [124] Enflurane, like halothane, dosedependently reduces tidal volume and minute ventilation with a dose-related tachypnea. [125] The degree of respiratory depression, as shown by increased resting $PaCO_2$, lessened with prolonged administration (3-7 hours) of halothane or enflurane. [125] [126]

Figure 5B-29 Comparison of mean changes in resting $PaCO_2$, tidal volume, respiratory rate, and minute ventilation in patients anesthetized with either halothane (H), isoflurane (I), enflurane (E), sevoflurane (S), desflurane (D), or nitrous oxide (N). Anesthetic-induced tachypnea compensates in part for the ventilatory depression caused by all volatile anesthetics (decrease minute ventilation and tidal volume and concomitant increase in $PaCO_2$). Desflurane results in the greatest increase in $PaCO_2$ with corresponding reductions in tidal volume and minute ventilation. Isoflurane, like all other inhaled agents, increases respiratory rate; however, isoflurane does not result in dose-dependent tachypnea. *(Data from Eger [124] ; Hickey [122] ; Lockhart [127] ; Doi [126] ; Fourcade [123] ; Caverley [125])*

Figure 5B-30 (Figure Not Available) The effect of surgical stimulation on the ventilatory depression of inhaled anesthesia with isoflurane in the presence and absence of nitrous oxide. Surgical stimulation increased alveolar ventilation and decreased $PaCO_2$ at all depths of anesthesia examined. *(Modified from Eger et al [131])*

The newer inhalational anesthetics--desflurane and sevoflurane--also exhibit dose-related ventilatory depression, primarily by reducing tidal volume. [127] [128] [129] [130] Unlike isoflurane, sevoflurane and desflurane both cause dose-related increases in respiratory frequency. Thus, desflurane does not significantly reduce minute ventilation until concentrations greater than 1.6 MAC have been achieved. However, at higher concentrations, the reduction of respiratory rate was less than that which occurred with halothane. The relative increases in $PaCO_2$ as an index of respiratory depression with volatile anesthetics (<1.24 MAC) are:

Enflurane > desflurane = isoflurane > sevoflurane = halothane

At higher concentrations, the ventilatory depression produced by desflurane is similar to enflurane, and sevoflurane is similar to isoflurane. [122] [123] [127] [128] [129] [130] Eger et al [131] have demonstrated that isoflurane-induced respiratory depression is reduced by surgical stimulation (see Fig. 5-30) (Figure Not Available) . In addition, the resting $PaCO_2$ during desflurane or sevoflurane anesthesia is significantly decreased in the presence of nitrous oxide at equi-MAC.

Mechanoreceptors and Breathing

Central respiratory control mechanisms regulate tidal volume and inspiratory and expiratory times to achieve adequate ventilation and gas exchange. Input signals emanate not only from chemoreceptors but also from mechanoreceptors in the upper airways, lungs, and chest wall, mediated by the vagus nerve and spinal nerves. Respiratory muscle function may be assessed via measurements of neural activation or directly by an electromyogram and by mechanical responses (tidal volume, minute ventilation, and analysis of motion and pressures generated by specific muscles). It should be recognized that upper airway musculature, including pharyngeal, laryngeal, and those of the soft palate, may also be affected by inhaled anesthetics.

Lung and Airway Receptors

Airway receptors (Ch. 15) . that may have some relevance to the effect of anesthetics include laryngeal and pulmonary irritant receptors and pulmonary stretch receptors. These receptors play an important role in the regulation of breathing patterns, laryngeal and pulmonary defense mechanisms, and bronchomotor tone. Irritant receptors are situated between airway epithelial cells and may mediate rapid reflex responses such as coughing, laryngospasm, bronchoconstriction, and mucus secretion following the induction of general anesthesia, abrupt increases in the inspired concentration of volatile anesthetics, and sudden mechanical deformation of the laryngotracheobronchial system.

Slow-adapting pulmonary stretch receptors, located within small airway smooth muscle (high concentration near the carina), respond to stretching or changes in lung volume. Increases in lung volume increase afferent nerve traffic via the vagus nerve to the respiratory control center, thereby inhibiting further inspiration (the Hering-Breuer reflex). This limitation of inspiration elicited by pulmonary stretch receptors may determine the relationship between tidal volume and respiratory frequency, but unlike in animals, the Hering-Breuer reflex cannot be demonstrated in the awake resting human during normal tidal volume breathing. The alteration in ventilatory pattern by anesthetics has been attributed to sensitization of pulmonary stretch receptors, leading to lower tidal volumes and tachypnea. The presence of volatile anesthetics increased vagal afferent discharge at varying lung volumes in decerebrate cats (i.e., sensitization of pulmonary stretch receptors), [132] but little evidence exists of such a mechanism in humans. [133] There is evidence in the cat that halothane-induced tachypnea is primarily a suprapontine effect, but the mechanism of production of tachypnea with decreased tidal volume in anesthetized humans remains unclear.

The direct effects of halothane, isoflurane, and enflurane on pulmonary and laryngeal irritant receptors and on tracheobronchial slow-adapting stretch receptors have been investigated in spontaneously breathing and vagotomized, paralyzed dogs. [134] [135] All three volatile anesthetics increase the activity of laryngeal irritant receptors [134] and inhibit pulmonary irritant receptors. [135] In addition, the volatile anesthetics elevate the excitation threshold and increase the sensitivity of low-threshold stretch receptors. The inspiratory activity was augmented while the end-expiratory activity was greatly attenuated. [135] The clinical implications of these findings have yet to be determined, but these anesthetic-induced changes may in part relate to effects on reducing bronchomotor tone.

It has been suggested that general anesthesia may result in posterior tongue displacement, producing upper airway obstruction; however, several recent studies do not confirm this. [136] [137] Anteroposterior displacement of upper airway structures occurs with changes in head position that are in

the same direction as that of the mandible. In addition, general anesthesia and paralysis may widen the dimensions of the larynx, [136] but the nasopharyngeal airway decreases in size. Volatile anesthetics produce a greater depression of the upper airway electromyogram [138] or nerve activity [139] as compared to that of the diaphragm in intact anesthetized, spontaneously breathing cats [138] (Fig. 5-31) (Figure Not Available) and in paralyzed, ventilated, vagotomized cats. [139] The extent to which this depression of upper airway motoneuron activity is a result of an anesthetic-induced inhibition of the reticular activating system is unknown.

Ventilatory Mechanics and Mechanoreceptors in the Chest Wall

Induction of general anesthesia reduces the functional residual capacity. Possible mechanisms involve a loss of tonic parasternal intercostal muscle activity [140] [141] [142] and development of phasic expiratory activity of respiratory muscles (Fig. 5-32) (Figure Not Available) , [142] alteration in diaphragm position, [141] or changes in thoracic blood volume. [142] There is a sparing of diaphragmatic activity relative to that of intercostal muscle function during halothane anesthesia. [140] [141] A change in diaphragmatic shape occurs whereby dependent regions shift cephalad, and non-dependent regions tend to shift caudad during anesthesia (Fig. 5-33) . [143] [144] Anesthesia-enhanced expiratory muscle activity results in inward displacement of the rib cage, thereby contributing to the reduction in functional residual capacity. In contrast, despite attenuation of parasternal intercostal muscle activity, inspiratory rib cage expansion may remain relatively well preserved due to phasic

Figure 5B-32 (Figure Not Available) Representative record from one subject while awake and during halothane anesthesia. Upper three tracings are electromyograms. Lower tracings represent rib cage and abdominal dimensions measured by respiratory impedance plethysmography. Open and closed circles denote the beginning and end of inspiration, respectively. Note that the amplitude of rib cage and abdominal excursions diminish during halothane, but the relationship between their amplitudes is preserved. *(From Warner et al [142])*

inspiratory activity of scalene muscles. [141] There is no direct correlation between changes in functional residual capacity and anesthesia-induced atelectasis. Areas of atelectasis in dependent lung regions frequently occur in anesthetized, spontaneously ventilating humans. Atelectatic densities may be related to alterations in respiratory muscle tone and not specifically to any single chest-wall structure. [143] They may be decreased by the application of positive end-expiratory pressure or by phrenic nerve stimulation of the diaphragm. [145]

The reason(s) for the differential anesthetic effects on inspiratory and expiratory respiratory muscles is unknown but may be related to direct actions on brain-stem control mechanisms or differential sensitivities of premotor neurons and motoneurons. Stuth et al [146] [147] have shown in vagotomized dogs that bulbospinal respiratory neurons are more resistant to the depressant effects of volatile anesthetics than is phrenic nerve activity. Increases in CO_2 drive can

Figure 5B-33 Diagram of a midsagittal section of the thorax while awake (solid lines) and while anesthetized (dashed lines) with 1.2 MAC halothane. Chest-wall configuration was determined using images of the thorax obtained by three-dimensional fast computed tomography. *(From Warner et al [143])*

---

only partially compensate for the anesthetic-induced depressant actions. There also exists a trend toward lesser depression of expiratory versus inspiratory bulbospinal premotor neurons to halothane. These findings suggest that the effects of inhalational agents on respiratory muscle func-tion may be a result of a more profound influence on the motor efferent pathways, including spinal respiratory motoneurons, rather than brain-stem mechanisms (Fig. 5-34) (Figure Not Available) . [147] Volatile anesthetics also depress neuromuscular transmission and skeletal muscle contractility. Isoflurane, enflurane, and sevoflurane depress the tension of the diaphragm in response to phrenic nerve stimulation. [148] [149] Note that whereas these results may help explain clinically observed phenomena in humans, species differences do exist. For example, volatile anesthetics decrease expiratory muscle activity in dogs and maintain parasternal intercostal activity, effects that are opposite of those in observed humans. [141] [142] [143]

Alterations in chest-wall positions change efferent impulses from stretch receptors in intercostal muscle spindles to maintain tidal volume during variations in inspiratory resistance. Increases in spindle discharge enhance motor activity to muscle fibers until muscle shortening relieves tension in the spindles. With increased inspiratory resistance, the muscle spindles detect a failure of shortening by the appropriate amount, and afferent signals are subsequently increased to the motor neuron pool. Accessory muscles of inspiration may be brought into use as well. This reflex increase in inspiratory effort results in sustained tidal volume and minute ventilation with increasing inspiratory resistive loads. These and other forces explain the ability of the body to maintain normal ventilation with different body positions

and inspiratory resistances and changes in compliance.

During halothane anesthesia, ventilation is maintained in spite of increases in resistance, such as during partial occlusion of an endotracheal tube or decrease in lung compliance, until a threshold is reached. [150] At that point, minute ventilation is diminished, with retention of CO_2. Minute ventilation is maintained by increasing the work of breathing, even during 2 MAC halothane anesthesia at modest inspiratory resistances as caused by small-diameter endotracheal tubes or humidifiers. [151]

Expiration is passively affected by the recoil characteristics of the lung during normal quiet breathing. In anesthetized patients, the ventilatory response to expiratory resistance is diminished more than that to inspiratory resistance. Both conscious and anesthetized humans exhibit decreases in respiratory rate during expiratory resistive loads, but only anesthetized subjects have rib cage-abdominal wall motion asynchrony. [152] Anesthetized subjects also have increased but less effective ventilation. This may have clinical relevance for spontaneously breathing anesthetized patients who have obstruction to exhalation either extrinsically such as in a breathing circuit or intrinsically as by asthma or emphysema. Consistent with this finding, patients with chronic obstructive pulmonary disease not retaining CO_2 while awake hypoventilated to a greater degree than did normal patients during halothane anesthesia (Fig. 5-35) (Figure Not Available) . [153]

Figure 5B-34 (Figure Not Available) Effect of increasing halothane on phrenic nerve and neuron activity. With increasing anesthetic depth, both peak phrenic nerve (PPA) and peak neuron activities are depressed. PPA shows the greatest sensitivity to halothane. (A) Phrenic nerve activity and the discharge frequency of an inspiratory bulbospinal neuron. Inspiratory (phrenic burst) duration decreases with increasing anesthetic depth. (B) Peak expiratory neuron (E), peak inspiratory neuron (I) activity, and PPA. Expiratory neuronal activity was most resistant to the effects of halothane. Bars = normalized mean ± SEM, numbers within bars = numbers of neurons studied for each condition. *(Modified from Stuth et al [147])*

Figure 5B-35 (Figure Not Available) Comparison of $PaCO_2$ in anesthetized, spontaneously breathing patients, relative to preoperative forced expiratory volume in 1 second (FEV_1). Patients with chronic obstructive pulmonary disease (COPD) did not exhibit CO_2 retention prior to anesthesia, yet the degree of alveolar hypoventilation is much greater in the more severely obstructed patients. *(From Pietak et al [153])*

EFFECTS OF ANESTHETICS ON VENTILATORY RESPONSE TO CHEMICAL STIMULI

Effects of anesthetics on respiratory drive are typically characterized by the ventilatory responsiveness to alterations in $PaCO_2$ or to a hypoxic insult. A complete discussion of chemical ventilatory control may be found in other reviews. [116] [117] In brief, chemoreceptors are both central and peripheral. Central chemoreceptors, located near the ventrolateral medulla and possibly more widespread in the brain stem, respond to changes in hydrogen ion concentration in the adjacent cerebrospinal fluid rather than to alterations in arterial PCO_2 or pH. Carbon dioxide, unlike the hydrogen ion, rapidly diffuses through the blood-brain barrier, and, thus, central chemoreceptors are more affected by respiratory than by metabolic alterations in blood gases. In contrast, peripheral chemoreceptors, located in the carotid bodies, are sensitive to changes in arterial $PaCO_2$, pH, and most importantly PaO_2. The mechanisms by which peripheral chemoreceptive cells respond to hypoxia and hypercapnia appear to be separate and synergistic in that hypoxemia potentiates the chemical drive to a CO_2 challenge. The peripheral chemoreceptors contribute about one-third to resting minute ventilation at normocapnia and normoxia. This contribution diminishes to about 15 percent during hyperoxic normocapnia, suggesting that the 85 percent of the CO_2 drive under hyperoxia is under central chemoreceptor control. Both stimuli cause membrane depolarization and activation of afferent nerve transmission. [154]

Responses to Carbon Dioxide

As described earlier, changes in ventilation secondary to alterations in $PaCO_2$ are mediated principally at the level of the medulla. Patients whose peripheral chemoreceptors have been denervated by bilateral carotid endarterectomy demonstrate approximately 85 percent of the increase in ventilation observed prior to denervation secondary to inhaled CO_2.

Apneic Thresholds

Apneic threshold is defined as the highest $PaCO_2$ at which a subject will remain apneic. The apneic threshold is approximately 4 or 5 mm Hg below resting $PaCO_2$ achieved during spontaneous ventilation. In humans, there are no significant agent-specific or depth-related effects of ether, halothane, or isoflurane on the relationship between apneic thresholds and resting $PaCO_2$ (Fig. 5-36) (Figure Not Available) . [155] The difference between resting $PaCO_2$ and apneic threshold is not related to the slope of the CO_2 response curves or to the level of resting $PaCO_2$. This suggests that assisted ventilation to lower $PaCO_2$ below the apneic threshold during anesthesia would ultimately become controlled ventilation.

Another clinically important aspect of this observation relates to reestablishment of spontaneous ventilation in the mechanically hyperventilated patient. Carbon dioxide stores in the body must accumulate to return the $PaCO_2$ level toward the apneic threshold on cessation of mechanical ventilation. The deeper the level of anesthesia, the longer the period of apnea necessary before the patient will commence spontaneous ventilation. Alternative methods of management might be to continue mechanical ventilation with the anesthetic gases progressively decreased or to maintain higher $PaCO_2$ during mechanical ventilation. These maneuvers will either decrease the apneic threshold or increase the resting $PaCO_2$, diminishing the time of apnea required to initiate spontaneous ventilation.

Carbon Dioxide Response Curves

Inspiration of CO_2 in normal subjects increases minute ventilation by approximately 3 L/min per mm Hg of $PaCO_2$, demonstrating a high gain from a central chemoreceptor in response to variations in $PaCO_2$. The slope of the plot of minute ventilation versus $PaCO_2$ is an index of ventilatory drive. Hypoxic conditions should be avoided to minimize peripheral chemoreceptor stimulation during such experiments. All inhaled anesthetics, including the newer agents desflurane and sevoflurane, dose-dependently depress the ventilatory response to hypercarbia. [122] [123] [124] [127] [128] [156] High concentrations of volatile anesthetics may virtually obliterate the hypercarbia-induced increase in ventilatory drive. Even nitrous oxide at 1.5 MAC under hyperbaric conditions lowers the response slope to 15 percent of control. [156] The slope of the ventilatory response curve during halothane

Figure 5B-36 (Figure Not Available) Ventilatory responses to increased CO_2 and apneic thresholds during ether, isoflurane, and halothane anesthesia in patients. The apneic threshold had a relatively fixed relationship to the resting $PaCO_2$. With an increase in ventilatory depression at increasing depth of anesthesia, resting $PaCO_2$ and apneic threshold increase by approximately the same amount. *(Modified from Hickey et al [155])*

anesthesia (like the resting $PaCO_2$) returns toward normal after 6 hours of anesthesia, although ventilatory responsiveness to CO_2 is still profoundly depressed. Studies by Hornbein et al [157] showed that addition of nitrous oxide to halothane depressed ventilation less than an equi-MAC dose of halothane alone. This does not appear, however, to alter the CO_2 ventilatory response slope of desflurane. [127] In contrast to the controversial effects of subanesthetic concentrations of inhalational agents on the hypoxic response (discussed below), low doses of volatile anesthetics (except enflurane [158]) do not significantly attenuate the ventilatory response to hypercarbia. [159]

Depression of ventilatory responsiveness to inhaled CO_2 has considerable clinical relevance. Carbon dioxide accumulation and concomitant acidemia may cause dysfunction in several organs, including the heart, where this condition may produce potentially dangerous arrhythmias. The attenuation of the normal ventilatory responses to elevated $PaCO_2$ makes clinical diagnosis of hypercarbia difficult and necessitates measurement of either arterial or end-tidal CO_2 tensions. During anesthesia, the ventilatory system will be less likely to compensate for CO_2 elevations secondary to rebreathing of CO_2 from malfunctioning anesthetic circuits or to increased metabolic production of CO_2. Pietak et al [153] have demonstrated the decreased ability of patients with chronic obstructive pulmonary disease to respond to increased $PaCO_2$ during anesthesia.

Experimental studies have shown that CO_2 rebreathing activates expiratory respiratory muscles such as the internal intercostals but does not reverse the profound depression of parasternal intercostal muscle activity produced by halothane. [160] There is a prolongation of expiration that leads to a decrease in breathing frequency during the course of rebreathing. That control of individual respiratory muscles is different in the halothane-anesthetized dog and human during rebreathing [161] does not necessarily indicate that other systems are dissimilar between species. Halothane dose-dependently depressed the peripheral chemoreceptor transduction (phrenic nerve response) to an acute, severe CO_2 stimulation of the peripheral chemoreceptors in paralyzed, vagotomized dogs. [162] The CO_2 sensitivity was diminished, but it was not abolished by surgical doses of halothane. It appears that halothane similarly depresses peripheral and central CO_2 sensitivities, [163] although the peripheral chemoreceptors only contribute to approximately 15 percent of the total CO_2 sensitivity. The response of peripheral chemoreceptors may not seem to be of great clinical import. However, if the peripheral chemoreceptor response to hypoxia is abolished at low doses of inhalational anesthetics, this may

contribute to a ventilatory impairment during concomitant episodes of hypercarbia and hypoxia, as may occur perioperatively.

Ventilatory Responses to Hypoxemia

Inhaled anesthetics, including nitrous oxide, dose-dependently attenuate the ventilatory response to hypoxia in both animals and humans. [158] [159] [164] [165] [166] The peripheral chemoreceptors appear to be the major site of the inhibitory action of anesthetics. This is evidenced by the rapidity of inhibition of the hypoxic response (30 seconds) [167] and that 0.5 to 1.0 percent halothane administered to decerebrate cats reduced carotid sinus nerve discharge when the peripheral chemoreceptors were stimulated by a variety of methods. [168] Alternatively, Stuth et al [169] demonstrated that in vagotomized dogs the phrenic nerve response to hypoxia is dose-dependently attenuated but not abolished by surgical doses of halothane. The results also did not indicate a selective depression of peripheral versus central effects of chemoreflexes. The etiology for these differences may be attributed to the profound degree of hypoxia induced in the animal studies (PO_2 <40 mm Hg), a more potent respiratory stimulus compared with that used in human studies (PO_2 approximately 50 mm Hg).

Figure 5B-37 (Figure Not Available) The ventilatory responses to acute isocapnic hypoxia (to approximately 44 mm Hg) in one subject during control (awake) and at 0.1 and 0.2 MAC isoflurane. Solid bars = period A (2-minute period before induction of hypoxia) and period B (minutes 3 and 4 of hypoxia); V_E = minute ventilation. *(From van den Elsen et al [177])*

A significant depression of hypoxia-induced ventilatory responsiveness was observed at 1 MAC halothane, and the usual synergistic effect of hypoxia and hypercarbia on ventilation was profoundly attenuated.

There is a biphasic response to hypoxia. Both adults and neonates display a similar initial hypoxia-induced increase in ventilation, but newborn animals and humans exhibit a more pronounced ventilatory decline to the prehypoxic level or less. This biphasic reaction may represent a balance between active inhibition of brain-stem neuronal activities and augmentation of peripheral chemoreceptor function. [170] Interestingly, halothane induces a biphasic ventilatory response (similar to that in the newborn) in kittens that have previously attained an adult-like hyperventilatory hypoxic response. [171] Whether the cause of this altered response is mediated solely via peripheral chemoreceptors or also at the level of the brainstem is unknown.

Knill and Gelb [159] demonstrated that peripheral chemoreceptor function was more sensitive to the effects of anesthetic agents in humans than in dogs, with significant attenuation of the response at 0.1 MAC halothane. The hypoxic ventilatory response was proposed to be more sensitive to the effects of inhaled anesthetics versus the response to hypercapnia. [158] [159] [172] Recently, there has been considerable controversy about subanesthetic concentrations of inhalational agents on hypoxic ventilatory drive. Temp and coworkers [173] [174] showed no effect of 0.1 MAC isoflurane on hypoxic drive in humans, whereas Dahan and coworkers [175] [176] [177] and others [178] have confirmed the original findings of Knill and Gelb (Fig. 5-37) (Figure Not Available) . The reason(s) for these discrepancies may be related to differences in techniques and study conditions, including differences in the state of arousal achieved in each study and the variability that may occur by studying subjects on different days. [174] Subanesthetic concentrations of most volatile anesthetics depress the ventilatory response to hypoxia in normocapnic, quiet, resting subjects, but desflurane does appear to be an exception (Fig. 5-38) (Figure Not Available) . However, subanesthetic concentrations of desflurane do decrease hypoxic sensitivity during concomitant hypercapnia, suggesting an effect at the peripheral chemoreceptors. [179] Robotham [180] has suggested, as discussed below, that the discrepant results of these hypoxia studies reinforce the clinical importance of volatile anesthetic effects on postoperative responses to hypoxia.

Clinical Implications

The profound depression of hypoxic responsiveness suggests that patients will manifest a diminished ventilatory response to hypoxemia for some time after cessation of an anesthetic and at concentrations of halothane that one would expect in a patient in the recovery room. The postoperative patient with residual anesthetic is at greater risk of hypoventilation in the absence of any significant stimuli such as pain or stimulation from recovery room personnel. Auxiliary modalities of stimulation that at least prevent eye-closing may, in part, attenuate the effects of low levels of anesthetics on hypoxic drive. Whereas surgical stimulation

Figure 5B-38 (Figure Not Available) Influence of 0.1 MAC of five volatile anesthetic agents on the ventilatory response to a step decrease in end-tidal oxygen concentration. Values are mean ± SD. Subanesthetic concentrations of the volatile anesthetics, except desflurane, profoundly depress the response to hypoxia. *(From Sarton et al [181])*

intraoperatively somewhat decreases anesthetic-induced ventilatory depression, this same amount of stimulation will not prevent impairment of chemoreflexes, including those of hypoxia and hypercarbia. [181] [182]

The importance of this depressive phenomenon may be more profound in patients who depend to some degree on a hypoxic drive to set their level of ventilation (such as those with chronic respiratory failure). Thus, the ability of these patients to maintain adequate ventilation while spontaneously breathing an inhaled anesthetic may be severely impaired. There are few clinical differences between the currently available volatile anesthetics, in terms of the hypoxia-induced ventilatory response. An exception appears to be the lack of effect of sedative doses of desflurane in normocapnic patients.

SUMMARY

Inhalational anesthetics have potent and clinically significant effects on respiratory function. Anesthetics reduce the tone of bronchial smooth muscle, mucociliary function, and pulmonary vasculature. In addition, they alter the activity of respiratory sensors, the central nervous system, and respiratory muscles. These actions are mediated via a variety of mechanisms including indirect actions on afferent, central, and efferent neural pathways and direct actions on peripheral end-organs and tissues. The depressant effects of these drugs are further enhanced in patients with pulmonary disorders. An understanding of the multifactorial actions of inhalational anesthetics on the respiratory system is critical to the safe delivery of anesthesia.

Chapter 6 - Metabolism and Toxicity of Inhaled Anesthetics

Jeffrey M. Baden
Susan A. Rice

INTRODUCTION

The inhaled anesthetics are not biochemically inert. They are metabolized *in vivo*, and their metabolites can cause both acute and chronic toxicities. In this chapter, we present the metabolism and toxicity of the inhaled anesthetics and discuss their known and hypothesized associations.

METABOLISM

Biotransformation may produce profound effects on the actions of a drug. Metabolism may result in pharmacologic and toxicologic actions that may be equal to, greater than, or less than anticipated. Furthermore, the actions of a drug metabolite may be entirely different from those of its parent. Many factors, such as the extent of drug absorption, excretion, secretion, and metabolism, affect drug efficacy and toxicity. These factors themselves are affected by chemical and physical properties of the drug. In the following sections, we discuss the properties of drugs and cellular membranes that influence drug availability at the cellular sites of metabolism.

PHYSICOCHEMICAL CONSIDERATIONS

Properties of Drug Molecules

Three physicochemical properties primarily determine the distribution of a drug molecule and its availability for metabolism: ionization, lipid solubility, and molecular size and shape. The degree to which a drug is ionized depends on the negative log of the acid ionization constant (pK_a) of the drug and the pH of the solution in which it is dissolved. Most drugs are weak bases or weak acids and have one or more functional groups that can be ionized. The pK_a for weak acids is high, whereas that for weak bases is low. The relationships among the degree of ionization, the pK_a, and the pH of a drug is described by the Henderson-Hasselbach equation:

Lipid solubility of a drug is determined by the presence or absence of lipophilic (hydrophobic) or nonpolar groups. Alkyl groups (C_nH_{2n+1}), such as the methyl group (CH_3), are nonpolar. The lipophilic properties of a molecule increase as the length of the alkyl group increases. For example, the presence of an *n*-propyl group ($CH_3CH_2CH_2$) makes the compound more lipophilic than the presence of a methyl group. Lipophilic properties of molecules increase when an alkyl group is inserted, whether the substitution occurs on a carbon, nitrogen, oxygen, or sulfur atom. Substitution of oxygen by sulfur often markedly increases the lipophilic properties of a drug. The hydrophilic or polar properties are increased, and simultaneously the lipophilic properties are decreased, when a molecule contains structural elements that allow hydrogen bonding of water (e.g.,
OH,
O
,
CHO,
COOH,
COOR,
Cl, and
Br). The presence of unsaturated bonds (e.g.,
CH=CH
) further promotes the hydrophilic properties of a molecule. Molecular size and shape also determine drug distribution. Various types of

membranes have different pore sizes that allow the passage of different sized molecules. For example, molecules larger than 4 A in radius are excluded from the erythrocyte, and molecules up to about the size of albumin (molecular weight 69,000; major axis 150 A; minor axis 35 A) can appear in the glomerular filtrate. All three physicochemical factors
ionization, lipid solubility, and molecular size and shape
influence the distribution of a drug and its ability to penetrate cellular membranes.

Properties of Cellular Membranes

Cellular and subcellular membranes are lipid in nature. They contain large quantities of phospholipids, cholesterol, and neutral lipids in association with proteins. Membrane phospholipids have distinct polar and nonpolar regions. They form a bilayer in which nonpolar hydrocarbon chains are directed toward the center, whereas polar head groups remain in contact with the aqueous phase on the bilayer surface. This lipid structure is either completely or partially penetrated by membrane proteins that bind to interior and exterior surfaces of the bilayer. The proteins are necessary both for the maintenance of membrane integrity and for the specialized transport of endogenous and exogenous molecules. In concert with drug properties, membrane properties determine the ability of a drug to enter cells.

Very small molecules and ions (e.g., Cl^-) apparently diffuse through aqueous membrane channels, whereas lipid-soluble molecules may diffuse freely through the membrane. Water-soluble molecules and ions of moderate size, including the ionic form of most drugs, cannot passively diffuse through the membrane but enter the cell by specialized transport. The overall lipid solubility (i.e., the relative lipophilic and hydrophilic properties) of a drug molecule determines whether the drug will readily cross biologic membranes by a passive process. Membranes are generally permeable to the nonionized forms of lipid-soluble drugs. Ionized groups on a molecule (e.g.,
COO^- from
COOH, which is almost completely ionized at pH 7.4) interact strongly with water dipoles and, as a result, penetrate the lipoidal cell membrane poorly, if at all. The diffusion rate of a drug roughly parallels the concentration gradient for the nonionized drug form. In general, the greater the lipid solubility, the greater the rate at which a drug moves through membranes.

Function of the Liver in Drug Metabolism

Inhaled anesthetics are primarily metabolized by the liver and, to a lesser extent, by other tissues (e.g., gastrointestinal tract, kidneys, lungs, skin). The following discussion of drug metabolism is limited to the liver because most anesthetic biotransformation occurs in this organ, and the principles of drug metabolism are similar from tissue to tissue.

Hepatic physiology is fully discussed in Chapter 17 ; however, a brief description is included in this discussion to aid in understanding the relationship between drug metabolism and toxicity. The liver is the largest organ in the body and weighs about 1,500 g in adult humans. It is unique from the standpoint that it has a double blood supply: 70 percent of the flow from the portal vein and 30 percent from the hepatic artery. Blood in the portal vein comes from the alimentary canal, pancreas, and spleen. Thus, any toxic material absorbed from the alimentary canal is processed by the liver before it enters the systemic circulation. Blood flows through the hepatic sinusoids from the periphery of the hepatic lobule, fed by portal veins and hepatic arteries, to the centrally located hepatic venule (central vein).

The hepatocyte contains several structures that are involved in intermediary and drug metabolism, most notably the endoplasmic reticulum. This membranous matrix of lipoprotein is the major site of protein synthesis, electron transfer, lipid metabolism, and hormone and drug metabolism. It is also the main site for the synthesis of

the lipoid and protein structural components for the cell and its organelles. The rough endoplasmic reticulum (RER) is the site of protein synthesis and is identified by the presence of adjacent ribosomes. The RER is extensively developed in protein-secreting cells. The smooth endoplasmic reticulum (SER) is identified by its lack of ribosomes. It is the site of drug metabolism, bilirubin conjugation, steroid synthesis, and some enzyme synthesis. The SER is extensively developed in steroid-secreting cells. In hepatocytes, both RER and SER participate in drug metabolism. Many *in vitro* studies of the liver and its drug-metabolizing capability are performed with hepatocytes and microsomes. The latter organelles are not naturally occurring, but they are formed from the breakage and reformation of the RER and SER during cell fractionation.

DRUG METABOLISM

Discussion of xenobiotic metabolism for the purposes of this chapter is limited to the reactions that are most relevant to the inhaled anesthetics. Metabolism requires the interaction of drug (substrate) with an enzyme. These enzyme-catalyzed reactions proceed at a rate approximately 10^9 times faster than that of a noncatalyzed reaction. Enzymes enable the clearance of drugs at rates much faster than would otherwise occur. Under appropriate conditions, the enzyme and the parent drug molecule form a complex resulting from intermolecular forces (e.g., ionic, Van der Waals). The complex then decomposes, by one of many mechanisms, and the enzyme is regenerated and a product (metabolite), different from the parent drug, is liberated. The simple equation that follows serves to emphasize the point that metabolism is a multistep process.

Enzyme + drug
enzyme-drug complex
enzyme + metabolite (2)

Metabolism can be an important determinant of the therapeutic activity and the toxicity of a drug. Unlike most drugs, the inhaled anesthetics are administered in great excess of the amount metabolized. Biotransformation therefore has little effect on the pharmacologic activity of anesthetics,

but it may have a significant effect on the toxicity of anesthetics.

The major enzymatic reactions of drug metabolism are oxidation, reduction, hydrolysis, and conjugation. These reactions are biotransformation reactions. Conjugation is a synthesis reaction. A drug may have a chemical structure suitable for biotransformation via one or more of these reactions. When several reactions are possible, the result may be "competition" of several enzymes for the drug. Each enzymatic reaction results in a metabolite that itself may be further metabolized. The ratios of various metabolites depend on enzymatic reaction rates, drug concentration near the enzymes, physicochemical reactions between metabolites and enzymes, competition of multiple drugs or endogenous substrates for the same enzyme, and many other factors.

The pattern of drug metabolism is common to all animal species; it is biphasic and consists of stepwise biotransformation and synthesis reactions. Figure 6-1 shows the general scheme of drug metabolism. Phase 1 (biotransformation) consists of the oxidation (hydroxylation), hydrolysis, or reduction of a lipid-soluble or nonpolar drug. Phase 2 (synthesis) consists of the conjugation of a drug or its metabolite with an endogenous compound (predominantly glycine, sulfate, or glucuronic acid). The result of either phase of metabolism is the production of metabolites that are generally more polar than the parent drug and are more readily excreted in the bile or urine. Both phases of biotransformation are the result of drug interaction with enzymes present in plasma, cytoplasm, mitochondria, and endoplasmic reticulum. The quantitative and qualitative differences in metabolism that are seen among species reside mainly in the nature and the occurrence of these enzymes.

Phase 1 metabolism occurs primarily in the environment of the endoplasmic reticulum, whereas phase 2 metabolism occurs primarily in the more aqueous environment of the cytoplasm. Substrates of phase 1 reactions are seldom substrates of phase 2 reactions, but products of phase 1 metabolism are often substrates of phase 2 metabolism.

Phase 1 Reactions

Microsomal Drug-Metabolizing Enzymes

The phase 1 enzymes most relevant to metabolism of the inhaled anesthetics are the mixed-function oxidases. This large collection of phase 1 enzymes is also known as the cytochrome P-450. The cytochrome P-450-mediated reactions, along with other phase 1 enzyme reactions, provide important pathways whereby the cell makes xenobiotics into more polar and thus more easily eliminated compounds. These enzymes are capable of participating in several different types of reactions, but the oxidation reactions are the most common. Monooxygenase is another name that is descriptive of metabolism during which one atom of molecular oxygen (O_2) is inserted at the carbon-hydrogen bond of a substrate, while the other atom of oxygen is incorporated into cellular water (H_2O). The key enzymes of this membrane-bound multicomponent system are the hemoproteins, the cytochrome P-450 isozymes, and the flavoprotein, reduced nicotinamide adenine dinucleotide phosphate (NADPH)-cytochrome P-450 reductase. The cytochrome P-450 superfamily includes many isozymes, more than 150 of which have thus far been characterized in animals. [1] Thirty of an estimated 50 to 200 cytochrome P-450s have been characterized in humans. [2]

This system requires O_2 and NADPH for the overall hydroxylation reaction, which is represented as follows:

$RH + O_2 + NADPH + H^+$
$ROH + NADP^+ + H_2O$ (3)

RH is the substrate, ROH is the oxidized (i.e., hydroxylated) product, and NADPH is the reduced form of nicotinamide adenine dinucleotide phosphate. Electrons flow from NADPH to the flavoprotein, NADPH-cytochrome P-450 reductase, to the heme group of cytochrome P-450, and ultimately

Figure 6-1 Two phases of drug metabolism, biotransformation and synthesis, generally result in the formation of more water-soluble metabolites, which are readily excreted in the urine and bile.

to molecular oxygen. Under some circumstances, the reduced form of nicotinamide adenine dinucleotide (NADH) can contribute an electron instead of NADPH. The intermediate electron carrier for NADH is another microsomal hemoprotein, cytochrome b_5.

A scheme of cytochrome P-450-mediated drug hydroxylation is shown in Figure 6-2. In the figure, the heme iron of cytochrome P-450 is shown in its ferric (Fe^{3+}) state in the endoplasmic reticulum. The first step in biotransformation is the reaction of substrate (RH) with oxidized cytochrome P-450 (Fe^{3+}) to form a complex [$(RH)Fe^{3+}$]. This complex rapidly accepts one electron (e^-) from NADPH- cytochrome P-450 reductase that reduces the heme iron to its ferrous state [$(RH)Fe^{2+}$]. The

relative absence of oxygen at this point determines whether compounds that are capable of reductive metabolism will be reductively metabolized. One such anesthetic, halothane, is discussed later in the chapter. In the presence of O_2, the oxidative reaction occurs, and the reduced complex rapidly combines with O_2 to yield an oxygenated complex [$(RH)Fe^{2+}(O_2)$]. A second electron from NADPH-cytochrome P-450 reductase, or in some cases from NADH-cytochrome b_5 reductase, reduces the oxyferrous complex [$(RH)Fe^{3+}(O_2-)$]. Subsequently, the oxygen-oxygen bond is ruptured, and one atom of oxygen remains associated with the heme iron to produce an activated complex $(RH)(FeO)^{3+}$. This complex abstracts a hydrogen from the substrate, thus producing a free radical (R·). An internal electronic rearrangement occurs, resulting in the addition of a hydroxyl group to the substrate. The resultant complex [$(ROH)Fe^{3+}$] dissociates and liberates the hydroxylated substrate (ROH) and regenerates the oxidized form of cytochrome P-450 (Fe^{3+}).

As previously mentioned, cytochrome P-450 is not a single entity, but rather it is what is referred to as a superfamily of many isozymes having different substrate specificities.

Figure 6-2 A drug (RH), which is a substrate for the hepatic mixed-function oxidase system, interacts with cytochrome P-450 and is biotransformed to a hydroxylated product (ROH).

Along with differences in the hepatic content of cytochrome P-450 among mammalian species and individuals, the differences in cytochrome isozymes may be responsible for the variations in rates and pathways of anesthetic metabolism *in vivo* and *in vitro* that are observed between humans and laboratory animals. [3] [4] [5] Such variation has been observed for cytochrome P-450-mediated dehalogenation and dealkylation of the inhaled anesthetics. [6] [7] [8] [9] [10] [11] [12] [13] [14] [15] [16] [17] Differences in metabolism must be carefully considered when estimating human risk for drug toxicity from animal data.

The older literature is very confusing, but recently, a uniform nomenclature was adopted to identify the cytochrome P-450. The following brief discussion should clear up any confusion about the various enzymes known to metabolize the inhaled anesthetics. The cytochrome P-450 nomenclature makes use of a combination of Arabic numerals and letters following P-450. The first numeral identifies the cytochrome P-450 family. The following letter designates the subfamily, and the subsequent number represents the gene within the subfamily. Cytochrome P-450 2E1, for example, is a member of the cytochrome P-450 2 family, which is a large family of isozymes that metabolizes many diverse drugs and endogenous compounds. [18] The isozymes of the cytochrome P-450 2E subfamily metabolize small, rather polar molecules, which include many inhaled anesthetics (e.g., halothane, enflurane, sevoflurane, and methoxyflurane) and halogenated hydrocarbons (e.g., chloroform, vinyl chloride, and trichloroethylene). Other cytochromes P-450 may also metabolize these molecules, but cytochrome P-450 2E is the predominant subfamily across animal species. The isozyme cytochrome P-450 2E1 is particularly important with regard to anesthetic metabolism. The highest concentration of cytochrome P-450 2E1 is found in the liver in perivenular hepatocytes of both humans and animals. This isozyme is also known to be present in extrahepatic tissues of rat (e.g., kidney, lung, and epithelial cells of the colon).

Globular molecules (e.g., phenobarbital) are the primary substrates of the cytochrome P-450 2B subfamily, but these isozymes also specifically metabolize methoxyflurane and halothane. Phenobarbital induces many members of the 2B subfamily in animals, but not in humans. The concentration of the 2B subfamily in human liver is very low and is not known to be induced. In human liver, the cytochrome P-450 3A subfamily may account for as much as 60 percent of the total cytochrome P-450 present. Large, nonplanar substrates (e.g., alfentanil, lidocaine, and midazolam) are preferred by these isozymes. Cytochrome P-450 3A metabolizes isoflurane in rats, but it is unclear whether this same isozyme is responsible for metabolism in humans. These cytochromes are induced by phenytoin, phenobarbital, and rifampin, to name a few agents.

Reactions Relevant to Inhaled Anesthetic Biotransformation

The most common drug biotransformation reactions are oxidation, reduction, and hydrolysis. Reactions within these categories are numerous and varied and are catalyzed by two classes of enzymes. The first primarily metabolizes endogenous (naturally occurring) substrates, but it can also

metabolize exogenous (foreign) substrates. The second class consists of the so-called drug-metabolizing enzymes, which reside in the endoplasmic reticulum of the hepatocyte and other cells throughout the body. The drug-metabolizing enzymes include the cytochrome P-450-mediated reactions, which are the primary means for xenobiotic biotransformation. The inhaled anesthetics are metabolized by these enzymes predominantly by oxidation reactions. Dehalogenation and O-dealkylation oxidation reactions are responsible for most anesthetic metabolism. Although an additional oxidation reaction, epoxidation, accounts for the biotransformation of only a few anesthetics, it is important because of the toxic potential of epoxides. Reductive reactions result in substrate reduction by transferring electrons to the substrate rather than to O_2. Examples of the biotransformation reactions relevant to the inhaled anesthetics are shown in the following sections.

O-Dealkylation

O-Dealkylation results from hydroxylation of an alkyl group (
CH_2R
) adjacent to the oxygen of an ether bond. The hemiacetal thus formed is a relatively unstable intermediate that rapidly decomposes to an alcohol (ROH) and an aldehyde (R
CHO). The aldehyde may then either be reduced by alcohol dehydrogenase to an alcohol or oxidized by aldehyde oxidase to form a carboxylic acid. The rate of the O-dealkylation reaction decreases as the length of the alkyl chain increases.

Dehalogenation

Dehalogenation is the result of hydroxylation of the halogen-containing carbon (
CHX_2). The resultant alcohol is chemically unstable and decomposes to a carboxylic acid and thus liberates halogen. Two halogens on the terminal carbon represent the optimal condition for dehalogenation, whereas a terminal carbon with three halogens is oxidized to a very limited extent.

Epoxidation

An epoxide is formed when oxygen is attached to adjacent unsaturated carbons of an olefin (
CH = CH
). Most epoxides are highly strained molecules and are extremely reactive because of the ease with which the epoxide ring can be opened. Some epoxides may be hydrated by the microsomal enzyme, epoxide hydrase.

Reduction

The reductively catalyzed reactions by cytochrome P-450 are very different from the oxidatively catalyzed reactions. Because oxygen inhibits the reductive reaction, at least one electron is presumably accepted directly by the substrate from cytochrome P-450. The reductive reactions relevant to the inhaled anesthetics are those in which a halogen (X) is replaced by a hydrogen. Reductive metabolism via cytochrome P-450 has been confirmed for only one anesthetic, halothane.

Phase 2 Reactions

Phase 2 reactions are conjugations. They occur when the drug contains a group suitable for combination with an endogenous compound (e.g., glycine, sulfate, glucuronic acid). The chemical groups on the drug molecule usually associated with these reactions are
OH,
COOH,
NH_2 , and
SH. The product is generally a polar, water-soluble metabolite that is readily excreted. A typical conjugation reaction is illustrated in the following equation:

Conjugation of a drug containing a hydroxyl (
OH) group with UDPGA (uridine diphosphate glucuronic acid; D-glucuronic acid in its "active" form) is catalyzed by glucuronyl

transferase, which is located in the hepatic RER. The resulting glucuronide is more water soluble than the parent drug because of the polar sugar moiety. The free carboxyl (
COOH) group of the glucuronide, which is almost completely ionized at body pH, further enhances water solubility. Although a drug initially may not contain a chemical group suitable for a conjugation reaction, one may be attained through a phase 1 reaction (i.e., by oxidation, reduction, or hydrolysis). Urochloralic acid is an example of an anesthetic metabolite that results from multiple consecutive biotransformations. [19] It is the glucuronic acid conjugate of trichloroethanol, a metabolite from the phase 1 metabolism of trichloroethylene.

Influences on Drug Metabolism

Although cytochrome P-450 is most often thought of as being responsible for the deactivation of toxic compounds, they are in fact also responsible for the activation of drugs and chemicals to toxic forms. Any factor that can influence metabolism has the potential to affect toxicity. Biotransformation is affected by many factors, including route of administration, species, strain, sex, age, diet, season, temperature, time of day, frequency of administration, and the previous or concurrent administration of other drugs or exposure to chemicals. Species generally has the greatest influence on both the therapeutic activity and the toxicity of a drug. The basis for species differences in drug action is ultimately genetic. Genetics ultimately determines absorption, distribution, metabolism, and excretion of all xenobiotics.

In humans, genetic factors that are otherwise undetected may be revealed in the expression of therapeutic activity or toxicity of a drug. For example, physiologic disposition of a drug may be unusual if there is structural variation in the serum protein that binds the drug. Even small changes in binding proteins may greatly affect a drug's disposition and, ultimately, its biologic activity. Genetic factors appear to be more important than environmental factors (e.g., diet and pollutant exposure) in determining the overall rate of drug metabolism and elimination in humans, although enzyme induction and inhibition may account for some unusual responses to drugs. Studies of halothane metabolism and elimination in twins lend support to the importance of genetic factors in metabolism. These studies demonstrated far less variation in identical twins than in fraternal twins or in the general population, even when environmental factors were quite dissimilar. [20]

Genetic differences also contribute to both qualitative and quantitative differences in drug metabolism among species. Differences may be observed in the ratios or types of metabolites that are formed. Qualitative differences among species generally result from the presence or absence of specific enzymes in those species. Quantitative differences result from variations in the amount and localization of enzymes, the amount of natural inhibitors, and the competition of enzymes for specific substrates. The amount of enzyme present in organs of different species can have a great effect on therapeutic activity and toxicity. Human liver contains less cytochrome P-450 per gram of tissue than do the livers of other species. For example, rat liver contains approximately 30 to 50 nmol/g of liver, whereas human liver contains 10 to 20 nmol/g. Furthermore, human liver is 2 percent of body weight, whereas rat liver is approximately 4 percent. These differences explain in part why humans metabolize drugs *in vivo* at rates that may be 10 to 20 times slower than the rate in rats. [2] [3] [4] [5]

Numerous genetic factors and environmental factors (including chemicals, drugs, and diet) affect the drug-metabolizing enzymes. The phenomena of enzyme induction and inhibition are the most obvious examples. Treatment of humans and animals with certain agents results in enzyme induction, the enhanced metabolism of a variety of drugs and chemicals. This phenomenon is due to an increased *de novo* rate of enzyme synthesis and, in some instances, a decreased rate of enzyme degradation. Cytochrome P-450 is the system best studied in this regard. It is known to be induced by numerous agents in humans and by literally hundreds of agents in experimental animals. [5] [21] [22] [23] Generally, enzyme inducers are highly lipophilic drugs and chemicals that are metabolized by the cytochrome P-450 isozymes they induce. Induction is thought to be determined largely by the extent and duration of the interaction of the inducing agent with the enzyme concerned. The inducing properties of a drug are unrelated to the nature of its pharmacologic or toxicologic activity and may differ markedly from those of other drugs in the same class.

Induction by drugs such as phenobarbital results in proliferation of the SER and an increase in liver weight. With this type of inducer, NADPH-cytochrome P-450 reductase and specific cytochrome P-450 isozymes are preferentially increased. Although other inducers increase the synthesis of specific cytochrome P-450 isozymes, they do not affect cytochrome P-450 reductase or liver weight. Many chemical and drug classes, including anesthetics, anticonvulsants, insecticides, sedatives, steroids, and tranquilizers, contain one or more compounds considered to be enzyme inducers. [5] [22] [23] Even the inhaled anesthetics can induce drug-metabolizing enzymes in experimental animals [7] [24] [25] and in humans [26] if exposure is sufficiently prolonged. In many case reports of drug toxicity, enzyme induction has been suggested to be a causative factor, although the claims are not often supported by good evidence. If the parent compound is toxic, enhanced metabolism decreases toxicity. If the metabolites are more toxic than the parent compound, metabolism increases toxicity. Enzyme-inducing agents have the potential to modify both acute and chronic toxicities of anesthetics. In view of the current practice of polypharmacy, enzyme induction may be common in patients undergoing surgery. Enzyme induction does not necessarily increase the metabolism of all drugs from the same class. For example, unlike methoxyflurane metabolism, enflurane metabolism is not significantly increased *in vivo* following phenobarbital or phenytoin treatment in humans [9] and in animals [8] [27] [28] or *in vitro* following treatment in animals. [8] [28] Even when anesthetics that are metabolized to toxic metabolites are administered to surgical patients taking enzyme-inducing drugs, significant amounts of toxic metabolites are not necessarily produced. [9] [13] [29]

The consequences of enzyme inhibition for therapeutic activity and toxicity can be just as great as those of enzyme induction. Many compounds inhibit the activity of the drug-metabolizing enzymes and thereby alter the duration and intensity of pharmacologic action and the severity of toxic effects.

There are several mechanisms of inhibition. [30] Protein synthesis inhibitors such as cycloheximide decrease enzyme synthesis and thus reduce enzyme concentrations. Other agents are reversible inhibitors that compete for the active site of the same enzyme responsible for metabolism of the drug of interest. Still others are irreversible inhibitors that degrade the heme in cytochrome P-450. It has been recognized for many years that millimolar concentrations of methoxyflurane (5.8 mmol/L), enflurane (13.3 mmol/L), and halothane (18.8 mmol/L) destroy cytochrome P-450 in microsomal preparations. [31]

METABOLISM OF SPECIFIC ANESTHETICS

Nonhalogenated Inhaled Anesthetics

Nonhalogenated agents have been used as anesthetics, but only nitrous oxide (N_2O) is currently in use. The metabolism of several of these previously used agents was discussed in an earlier edition of this book. The interested reader will find information on diethyl ether and ethylene. [32] There is still no evidence to suggest mammalian metabolism of cyclopropane.

Nitrous Oxide

Nitrous oxide (N_2O) is not metabolized by enzymatic action in human tissue. There is, however, a physicochemical reaction of N_2O with vitamin B_{12} [33] in which N_2O is reductively metabolized by rat and human intestinal bacteria to molecular nitrogen (N_2). [34] N_2O reduction in bacteria may occur via a single electron transfer process that results in the formation of nitrogen gas (N_2) and free radicals. The reaction between vitamin B_{12} and N_2O was first reported in 1968, [33] but its clinical relevance was not realized for 10 years. [35] The clinical effects are discussed in the section on toxicity. The *in vivo* physicochemical reaction between N_2O and the cob(I)alamin [Cob(I)] of vitamin B_{12} and the mechanism of methionine synthase inactivation is not known. Experimental evidence in *Escherichia coli* implicates cob(I)alamin as the reactive intermediate that reductively degrades N_2O with the concomitant oxidation of the cobalamin. [36] Methionine synthase is inactivated when the highly reduced cob(I)alamin is oxidized by N_2O. N_2 and an oxidant are thus produced via a single-electron transfer. This concomitant formation of a damaging oxidant species implies that cobalamin is not the primary site of damage in the short term, but rather that the protein structure proximal to cobalamin is initially modified.

Evidence for induction of drug metabolism by N_2O is contradictory. Hepatic enzyme induction in experimental animals has been reported following prolonged exposure to unspecified concentrations of N_2O. [37] Conversely, rats continuously exposed to 20 percent N_2O for 14 to 35 days exhibited inhibition of hepatic drug metabolism and induction of pulmonary and testicular metabolism. [38] Mice exposed to as much as 50 percent N_2O for 4 hours per day for 14 weeks exhibited no increase in hepatic content of cytochrome P-450 or in defluorination of enflurane or methoxyflurane. [39] In another study, hexobarbital sleeping time in rats, used as an indicator of drug metabolism, was unchanged following exposure to 50 percent N_2O for 7 hours per day for 5 days. [24]

Halogenated Inhaled Anesthetics

This section addresses the metabolism of the halogenated inhaled anesthetics in use in the United States. Three older anesthetics that are not currently in use, chloroform, trichloroethylene, and fluroxene, have been extensively studied and have greatly contributed to our current understanding of halogenated hydrocarbon metabolism. These three anesthetics are discussed in a previous edition of this chapter. [32]

Halothane

Halothane (CF_3
$CHBrCl$) is extensively metabolized (i.e.,
25-45% of the absorbed halothane). Its major metabolite in humans and animals is trifluoroacetic acid, which is formed from oxidative metabolism via the cytochrome P-450 system. The end products of the oxidative pathways that are detected in the urine are the sodium salt

of trifluoroacetic acid, chloride (Cl^-), and bromide (Br^-). Two cytochrome P-450 isozymes (i.e., 2E1 and 2B4) are primarily responsible for oxidative metabolism of halothane to trifluoroacetic acid. [17] [18] [40] The rate-limiting step in oxidative metabolism is breakage of the carbon-hydrogen bond. [41] The first metabolite formed is 1,1,1-trifluoro-2-chloro-2-bromoethanol (not shown in Eq. 6-11), which rapidly decomposes to produce hydrogen Br^- and a reactive trifluoro-acetylchloride. This latter metabolite is also a reactive compound; it decomposes in the presence of water to produce trifluoroacetic acid. The trifluoroacetylchloride intermediate is also known to react with phosphatidyl ethanalomine, a membrane lipid [42] ; *N*-trifluoroacetyl-2-aminoethanol has been identified in urine. [43] Other potential reactions and products related to this intermediate are discussed in the section on hepatotoxicity. Although significant amounts of trifluoroethanol have been identified in the urine of experimental animals, neither trifluoroethanol nor its glucuronide conjugate has been found in human urine. Likewise, trifluoroacetaldehyde, another possible metabolite, has not been isolated from human urine.

An alternative and minor route of halothane metabolism (i.e., <1% of absorbed halothane) is via a reductive pathway that requires the relative absence of oxygen and the presence of an electron donor. Both Br^- and F^- are end products of this pathway. [44] [45] [46] Two volatile metabolites (1,1-difluoro-2-chloroethylene [CDE] and 1,1,1-trifluoro-2-chloroethane [CTE]) and a volatile metabolite-decomposition product (1,1-difluoro-2-bromo-2-chloroethylene [DBE]) were first identified in the exhaled gases of patients anesthetized with halothane. [47] The formation of CDE and the release of F^- probably results from a cytochrome P-450-mediated two-electron reduction of halothane, whereas CTE formation and the production of free radicals result from a cytochrome P-450-mediated one-electron reduction. [18] [48] [49] The suicidal inactivation of cytochrome P-450 observed under hypoxic conditions (<40 torr O_2) [50] is presumably the result of cytochrome P-450 binding covalently to a reactive intermediate of CTE metabolism. The release of F^-, CDE, and DBE from halothane under anaerobic conditions can be catalyzed by reduced cytochrome P-450, hemoglobin, or hemin. [45] This finding suggests that the reaction is nonenzymatic and may only require reduced heme. DBE can also be produced nonenzymatically through the base-catalyzed decomposition of halothane as a result of interaction with soda lime. [47]

The human cytochrome P-450 responsible for halothane metabolism has not been isolated, but in rabbits, cytochromes P-450 2B4 and P-450 2E1, the phenobarbital-and ethanol-inducible forms, respectively, metabolize halothane. [40] Cytochrome P-450 2E1 metabolized halothane more than twice as rapidly as did cytochrome P-450 2B4. The human equivalent of P-450 2E1 is inducible by both ethanol and isoniazid. In experimental animals, increased halothane metabolism

follows administration of inducing agents such as phenobarbital, [50] [51] [52] Aroclor 1254, [46] and isoniazid. [53] Prolonged exposure to subanesthetic concentrations of halothane results in increased drug metabolism in experimental animals [7] [24] and humans. [26]

Methoxyflurane

Metabolism of methoxyflurane (CH_3
O
CF_2
$CHCl_2$) has been studied extensively, both *in vivo* and *in vitro.* It is estimated that as much as 75 percent of absorbed methoxyflurane is metabolized by humans. The molecule can be oxygenated either at the methyl carbon or at the dichloroethyl carbon. [54] [55] The major metabolites are methoxydifluoroacetic acid, F^-, and dichloroacetic acid. [37] [54] [56] It is not known whether methoxydifluoroacetic acid is further metabolized in humans, although it would be expected to decompose in the acid environment of the kidneys and consequently to release oxalic acid and additional F^-. Cytochrome P-450 2B4 and 2E1 are the principal isozymes responsible for the hepatic metabolism of methoxyflurane. [57] Defluorination of methoxyflurane occurs more rapidly than its *O*-demethylation. [10] [54] [58] The carbon-hydrogen bond at the dichloroethyl carbon of methoxyflurane is broken approximately seven times more rapidly by

rabbit hepatic cytochrome P-450 2B4 than is the bond at the methyl carbon. [17] [57] Both these reactions require cytochrome b_5 to provide the second electron. [17] [58] [59] In the kidneys, cytochrome P-450 2E1 is also the primary isozyme for metabolism, followed by 2A6 and 3A4. [60] Metabolism of methoxyflurane is increased *in vivo* and *in vitro* following treatment with enzyme-inducing drugs such as phenobarbital, [6] phenytoin, [8] ethanol, [14] [15] diazepam, [16] and isoniazid. [11] [12] Its metabolism is subject to inhibition *in vivo* and *in vitro* by SKF-525A and *in vitro* by metyrapone. [10]

In addition to cytochrome P-450-dependent metabolism, methoxyflurane can be defluorinated by both an enzymatic, non-cytochrome P-450-dependent reaction [61] and a nonenzymatic [62] reaction. The enzymatic defluorination was confirmed and was suggested to be catalyzed by glutathione-S-transferase. [63] The nonenzymatic defluorination of meth-oxyflurane may not be significant *in vivo;* the reaction requires both glutathione and coenzyme B_{12} and shows an *in vitro* pH optimum of 10. [62]

Enflurane

Enflurane (CHF_2
O
CF_2
CHClF) is essentially no longer used in the United States, but examination of its metabolism serves to illustrate how relatively minor changes in chemical structure can dramatically affect the extent of metabolism. Enflurane is slowly metabolized (i.e.,
2-8% of absorbed enflurane). This low rate of reaction made metabolism studies difficult because of the limits of detection released by oxidative dehalogenation. Initial oxidation and breaking of the carbon-hydrogen bond may occur at either the chlorofluoromethyl carbon or at the difluoromethyl carbon. Studies of the metabolism of enflurane with rat [64] and human hepatic microsomes, [65] and the isolation of difluoro-methoxy-difluoroacetic acid from rat liver, [66] human urine, [66] [67] human hepatic microsomes, and c2 DNA-expressed P-450 2E1 [65] suggest that primary metabolism occurs at the chlorofluoromethyl carbon. Detection of insignificant amounts of chlorofluoroacetic acid further suggests that there is very little metabolism at the difluoromethyl carbon. [66] The reactive intermediate formed from oxidation at the chlorofluoromethyl carbon can either hydrolyze to produce difluoromethoxydifluoroacetic acid or acetylate tissue protein to produce an adduct with immunogenic potential. [68]

Surgical patients treated on a long-term basis with phenobarbital, phenytoin, or diazepam or who consumed ethanol prior to anesthesia did not have elevated serum F^- concentrations compared with untreated patients. [9] In contrast, about 50 percent of surgical patients on chronic isoniazid therapy demonstrated significantly elevated serum F^- concentrations. [13] It is unclear why 50 percent of patients did not significantly defluorinate enflurane. Purified cytochrome P-450 2E1 from rabbits [69] and humans [65] [70] demonstrates that this cytochrome is predominantly, if not exclusively, responsible for enflurane defluorination in human liver. Isoniazid alone seems to significantly enhance *in vitro* enflurane metabolism in rats, [11] [12] rabbits, [65] and humans. [71] Treatment of rats with phenobarbital, [8] [10] [28] phenytoin, [8] or ethanol [14] [15] only slightly increases enflurane metabolism. As with methoxyflurane, defluorination of enflurane in rats decreases following treatment with either SKF-525A or metyrapone. [10] Continuous exposure of rats to subanesthetic concentrations of enflurane significantly decreases hexobarbital sleeping time, an indication of enhanced metabolism, which, in turn, indicates enzyme induction. [24] Exposure of mice to 0.5 percent enflurane for 5 days per week up to 73 days did not alter hepatic microsomal cytochrome P-450 concentrations or defluorination rates of methoxyflurane, enflurane, or isoflurane. [72] Sevoflurane defluorination, however, was increased.

Isoflurane

Isoflurane (CHF_2
O
CHCl
CF_3), an isomer of enflurane, was the most slowly metabolized of the fluorinated inhaled anesthetics [3] [73] [74] [75] until the introduction of desflurane. The lipid and blood solubilities of isoflurane are limited (blood/gas partition coefficient of 1.41). [76] The metabolism of isoflurane, estimated to be approximately 0.2 percent of the absorbed anesthetic, results from oxidation of the alpha-carbon, presumably by hepatic cytochrome P-450 2E1. [77] As with enflurane, the difluoromethyl carbon of isoflurane is resistant to, but not without, oxidation [66] [78] as evidenced by traces of trifluoroacetic acid recovered from the urine of rats and humans. Trifluoroacetaldehyde and trifluoroacetylchloride, expected intermediates between isoflurane and trifluoroacetic acid, may also be produced. Cytochrome P-450 2E1 and 3A are thought to be responsible for the majority of isoflurane metabolism. [17] [77] [79]

Although phenobarbital, [6] [73] phenytoin, [8] ethanol, [14] and isoniazid [11] [12] pretreatments increase the defluorination of isoflurane, enzyme induction has not produced serum F^-

concentrations of clinical significance. [73] [75] Prolonged exposure to subanesthetic concentrations of isoflurane enhances the hexobarbital sleeping time of rats. [24] Mice exposed to as much as 0.5 percent isoflurane for 4 hours per day, 5 days per week for 9 weeks did not result in significant changes in hepatic microsomal cytochromes P-450 or b_5 or in defluorination rates of methoxyflurane, enflurane, or isoflurane. [80]

Desflurane

Desflurane (CHF_2
O
CHF
CF_3), previously known as I-653, is the newest volatile anesthetic. It is expected to be metabolized in a manner similar to isoflurane. It has low solubility in lipid and blood (blood/gas partition coefficient of 0.42). [76] [78] The substitution of a F in desflurane for the chlorine at the alpha-carbon in isoflurane decreases the metabolism at this site, such that there is significantly less metabolism of desflurane to F^- and nonvolatile organic F^- compounds compared with isoflurane. Peak serum F^- concentrations in rats are seen immediately after exposure to desflurane. No increases in serum F^- above baseline concentrations were measured after volunteers received 7.4 minimum alveolar concentration (MAC)-hours of desflurane. [81] Significant increases in serum trifluoroacetic acid concentrations, however, were measured; peak concentrations were attained 24 hours postexposure. Urinary trifluoroacetic acid excretion was also significantly increased. The same cytochrome P-450 that metabolizes isoflurane is expected to metabolize desflurane. Pretreatment of rats with phenobarbital or ethanol only slightly enhances serum F^- concentrations for a brief period. [78] [82]

Sevoflurane

Sevoflurane (CH_2 F
O
CH
$(CF_3)_2$) was investigated experimentally for over a decade before the first clinical trials were initiated in the United States. It is currently used in Japan. The *in vitro* rate of sevoflurane defluorination is approximately the same as that of methoxyflurane. [83] [84] *In vivo,* however, serum F^- concentrations following sevoflurane administration are significantly less than those following methoxyflurane, [83] [84] [85] presumably the result of great differences in blood/gas partition coefficients of the two agents (0.69 versus 10.2). [76] Approximately 1 to 5 percent of absorbed sevoflurane is biotransformed. [85] [86] The alpha-carbon is the most likely site of oxidation of sevoflurane rather than the trifluoromethyl carbons. Experiments using cytochrome P-450 2E1 purified from rabbits [69] and humans [77] [78] confirm the results of *in vitro* studies with liver microsomes and show that this isozyme is the predominant, if not the only, enzyme participating in sevoflurane defluorination. As with methoxyflurane, the addition of cytochrome b_5 to the reaction mixture significantly enhances metabolism.

In a study of human volunteers, nonvolatile organic fluoride, 80 percent of which was in the form of hexafluoroisopropanol, was detected in the blood and urine of volunteers

anesthetized with sevoflurane. [85] Hexafluoroisopropanol is not subject to further degradation, but it is conjugated to glucuronide. [85] [88] Studies in patients and volunteers have shown that much of the metabolism of sevoflurane to F^- occurs during anesthetic exposure, presumably because of the low tissue solubility of sevoflurane and the stability of its metabolites. [85] [88] [89] Peak serum F^- concentrations are reached within a few hours of the end of anesthesia. *In vivo* studies show increased sevoflurane defluorination in rats following phenobarbital treatment. [84] *In vitro,* sevoflurane defluorination is increased in rat hepatic microsomes by pretreatment with phenytoin, [8] isoniazid, [11] [12] ethanol, [15] and phenobarbital. [8] [84]

Several decomposition products are formed during the *in* vitro interaction of sevoflurane with soda lime. [90] Two products are found in the closed anesthesia circuit. Pentafluoroisopropenyl fluoromethyl ether [CF_2 =C(CF_3)OCH_2 F; compound A] is the major degradation product detected. A proton presumably is abstracted from hydrogen on the isopropyl group of sevoflurane by soda lime in a manner that is similar to the base-catalyzed deprotonation of halothane by soda lime to yield difluorobromochloroethylene (CF_2 =CClBr). [47] Compound B [CH_3 OCF_2 CH(CF_3)OCH_2 F] is the minor degradation product detected in the anesthesia circuit and presumably results from the addition of methoxide ion (CH_3 O^-) produced from the interaction of methanol with soda lime to compound A.

TOXICITY

Mechanisms of Toxicity

Expression of drug toxicity is influenced by many factors. In this section, we focus on mechanisms of tissue injury that are most relevant to the inhaled anesthetics. Toxicity is a dose-dependent response, and there is a threshold that must be surpassed before toxicity is produced. Toxicity may be induced by any of a number of mechanisms, including the intracellular accumulation of metabolites in toxic amounts, the formation of haptens that can initiate systemic hypersensitivity or immune responses, the production of reactive intermediates that either adduct (form covalent bonds) to tissue macromolecules or initiate destructive free radical chain reactions, and the depletion of endogenous compounds that act as intracellular and extracellular antioxidants.

The threshold dose for toxicity may change, but what can be called the molecular threshold dose generally would be constant. Thus, it is the molecular dose at the target site that determines toxicity. This dose may be achieved because of increased metabolite production, altered tissue sequestration, or decreased excretion. Other drugs or chemicals, altered physiologic states, or pathologic states may also have an effect. When the concentration of a metabolite surpasses the intracellular threshold for toxicity (i.e., molecular threshold dose), tissue injury results from the direct or indirect actions of the metabolite. Direct toxicity may result from the inhibition or modification of enzymatic and structural systems necessary for maintaining cellular integrity (e.g., membrane transport systems). Indirect toxicity may result from interaction with an endogenous compound that elicits an immune response.

Possibly the most important drug-mediated mechanism of toxicity is the production of reactive intermediates during metabolism. [91] Reactive intermediates may initiate toxicity by covalently binding with tissue macromolecules to form adducts or by initiating free radical chain reactions. Although few drugs themselves are sufficiently reactive to form covalent bonds with cell macromolecules (e.g., intracellular proteins, enzymes, nucleic acids), some drugs, including several inhaled anesthetics, produce reactive intermediates during phase 1 metabolism. Binding of a reactive intermediate with tissue protein to produce a hapten-protein conjugate is one example of a potentially toxic covalent interaction. The conjugate may, in turn, induce the synthesis of drug-or metabolite-specific antibodies and may initiate hypersensitivity or immune responses. [92] The binding of reactive intermediates to tissue macromolecules may adversely affect cellular metabolism, protein synthesis, replication, or transport mechanisms by covalently binding to proteins, nucleic acids, and other cellular components. The chemically stable adducts formed may produce a variety of injuries such as necrosis, mutagenesis, teratogenesis, carcinogenesis, and drug allergies.

In addition to producing nucleophilic intermediates, metabolism may produce intermediates with single unpaired electrons in their outer molecular orbital shells, known as free radicals. These are short-lived but highly reactive intermediates that can initiate chain reactions and produce pathologic damage. [93] Once generated, free radicals react with cellular components producing polymerization or cross-linking of enzymes and proteins, auto-oxidation of lipids within the membranes, and damage to nucleic acids (e.g., main chain breaks in the nucleic acid strands or degradation of purine and pyrimidine rings). [94] Free radicals are generated during the normal course of cell metabolism (e.g., cytochrome P-450-mediated reactions, which continue to function in the absence of intracellular substrate by transferring electrons to cell lipids). The concentration of these radicals is stringently maintained, however, at less than 10^{-9} mol/L. [93] Tissue injury ensues in the presence of free radical reactions when the endogenous antioxidants responsible for scavenging free radicals are depleted. Thus, the depletion of glutathione and other sulfhydryl-containing compounds promotes tissue injury that may progress to cell death.

Reactions of free radical intermediates are generally assumed to be so rapid that no radicals escape the tissue in

which they are formed. Because inhaled anesthetics are strongly lipophilic, damage from their reactive intermediates would occur mainly in lipid membranes that are especially rich in unsaturated fatty acids. These unsaturated compounds are highly susceptible to damage because the presence of a double bond weakens the carbon-hydrogen bond of the alpha-methylene carbon atom (i.e., the carbon atom adjacent to the carbon with an unsaturated bond). Free radicals initiate peroxidation by abstracting hydrogen from the alpha-methylene carbon. [94] This results in rearrangement of double bonds and subsequent attack by oxygen. Unless terminated, oxidative damage will be transferred to adjacent fatty acids. Halothane and chloroform at anesthetizing concentrations *in vivo* stimulate lipoperoxidation in phenobarbital-pretreated rats and may initiate tissue damage by this mechanism. [95]

The detrimental effects of reactive intermediates on cellular integrity depend on the extent of free radical reactions, subsequent covalent binding, and the cellular functions that are impaired. The precise mechanism by which specific reactive intermediates initiate cellular injury is seldom clear because total binding of a reactive intermediate does not correlate well with the degree of toxicity. For example, although the metabolites of certain chemical carcinogens bind covalently to liver microsomes, there is no strict correlation between total adduction and cell damage. New investigative tools have helped to determine experimentally which specific cellular macromolecule is adducted. The difficulty still lies in determining which interaction is responsible for which tissue damage.

Organs and Organ Systems

Effects on the Liver

Drug-mediated hepatotoxicity ranges in severity from slight dysfunction to massive hepatic necrosis. The cause may be hepatocellular damage, cholestasis, interference with bilirubin metabolism, or immunologically mediated [91] tissue injury. Direct hepatotoxins, such as carbon tetrachloride and chloroform, cause dose-related, consistent, and reproducible hepatic cellular damage. Indirect hepatotoxins, such as erythromycin and cloxacillin, cause dose-independent and inconsistent hepatic injury resulting from hypersensitivity and humoral or cellular immunoreactions. [92]

The incidence and extent of hepatotoxicity directly attributable to inhaled anesthetics are difficult to determine. All anesthetic techniques reduce liver blood flow to some degree and may contribute to postoperative liver dysfunction. [96] Although studies of healthy volunteers find no evidence of hypoxia or anaerobic metabolism in the liver, this may not be the case for patients with preexisting liver damage or other illnesses. In general, surgical manipulation and the surgical site appear to be more important factors in decreasing liver blood flow than is the anesthetic agent or technique. [96] The liver may be predisposed to postoperative dysfunction and necrosis by chronic liver disease, viral infection (e.g., viral hepatitis and cytomegalovirus), septicemia, severe burns, nutritional deficiency, and previous or concomitant drug treatment. Traditional measures of liver function, serum enzymes, proteins, and bilirubin, and the alkaline phosphatase and the aminotransferases (i.e., aspartate aminotransferase and alanine aminotransferase) have stood the test of time for characterizing hepatic damage. Unfortunately, clinical tests available to assess liver function are for the most part crude, not tissue specific, and only reflect abnormalities in the presence of severe disorders.

The inhaled anesthetics may act as both direct and indirect hepatotoxins. Chloroform and fluroxene have direct hepatotoxic effects, and both have been discontinued for clinical use because of their hepatotoxicity. The hepatotoxic effects of these anesthetics, along with those of diethyl ether and cyclopropane, are discussed in an earlier edition of this chapter. Halothane was introduced into clinical practice in 1956, but it was not until 1963 that several clinical reports of postoperative jaundice

and liver necrosis were published. [97] [98] [99] The clinical and pathologic findings resembled those of the classic hepatotoxin, chloroform. These reports prompted a number of retrospective studies from which it was generally concluded that halothane was associated with the same incidence of postoperative hepatic damage as other anesthetics. Because some fault could be found in all the retrospective studies (e.g., lack of proper control groups or inadequate numbers), the National Halothane Study was conducted. [100] A committee reviewed retrospectively the incidence of fatal massive hepatic necrosis occurring in approximately 850,000 surgical patients. The incidence of massive hepatic necrosis associated with halothane was 7 of 250,000 halothane anesthetics or about 1 in 35,000, and not 1 in 10,000, as is sometimes reported. The committee concluded that "unexplained fever and jaundice in a specific patient following halothane might reasonably be considered a contraindication to subsequent use." Dykes and Bunker [101] commented that massive or intermediate hepatic necrosis was not documented for any patient in the study who was jaundiced after halothane administration and who died following subsequent halothane administration.

It is now clear that halothane is associated occasionally with liver damage in adults, especially after repeated administration. [102] [103] [104] Even children, once thought immune to "halothane hepatitis," are now known to be susceptible. [105] [106] The lack of a suitable animal model hampered early efforts to elucidate the mechanism of halothanemediated hepatotoxicity. Unlike chloroform and fluroxene, which produce fatty infiltration, centrilobular necrosis, and elevated transaminase values in experimental animals, halothane did not produce hepatotoxicity in early animal models. Even prolonged exposure to halothane did not consistently result in hepatic lesions. Animal models of halothane-mediated hepatotoxicity eventually were developed that proved useful in determining the role of biotransformation in hepatic injury. Centrilobular necrosis following halothane exposure under various conditions occurs in rats pretreated with Aroclor 1254 (a mixture of polychlorinated biphenyls), [46] isoniazid, [53] phenobarbital, [52] and triiodothyronine. [107] These early models are discussed in a previous edition of this chapter [32] and in a published review. [108] Localized hypoxia, disturbed calcium homeostasis, altered cellular metabolism and depletion of energy stores, and immune-mediated injury are all mechanisms that have been proposed to explain halothane hepatotoxicity.

Because halothane hepatitis is both rare and unpredictable, it was speculated that some patients are predisposed to the condition because they produce unusual

amounts of hepatotoxic metabolites or they experience an immunologic response that initiates hepatotoxicity. The latter mechanism was proposed to explain the increased frequency and the overall reduced latency of hepatitis following repeated halothane exposure. The clinical features often associated with halothane hepatitis, such as fever, rash, peripheral eosinophilia, and increased incidence and severity with multiple administrations, are also observed with allergic reactions. It now appears that there are two separate clinical entities: one is a mild hepatotoxicity occurring shortly following halothane exposure, and the other is a rare, severe, often fatal hepatotoxicity with delayed onset. The mild form of hepatotoxicity that may be experienced by as many as 20 percent of anesthetized patients is possibly the result of some form of direct toxicity that has been demonstrated by one or more of the animal models. The fulminant form, halothane hepatitis, currently is thought to be an immune-mediated toxicity.

Halothane is oxidatively metabolized by cytochrome P-450 to trifluoroacetyl chloride (CF_3COCl), an unstable and reactive intermediate that can covalently trifluoroacetylate several proteins of the endoplasmic reticulum. The trifluoroacetylated hepatic proteins are believed to be involved in the immune response leading to halothane hepatitis. The immunologic basis for halothane hepatitis has been discussed in several articles. [92] [108] [109] [110] The first human data suggestive of an immune-mediated mechanism came in 1980 when an antibody from the sera from 7 of 11 patients with fulminant hepatic necrosis following halothane exposure reacted with the surface of hepatocytes isolated from halothane-exposed rabbits. [111] Patients had circulating antibodies that recognize halothane-altered hepatic microsomal proteins (neoantigens). Some of these neoantigens have since been identified as trifluoroacetylated endoplasmic reticulum proteins. At least 8 halothane-induced hepatic antigens have been identified in halothane-exposed rabbits, rats, and humans. [109] [110] [111] [112] [113] [114] [115]

Trifluoroacetylated proteins (i.e., antigens) are expressed in all halothane-exposed patients, but only a small portion of this population mounts an immune response to the antigens leading to hepatotoxicity. In patients who develop halothane hepatitis, antibody responses are elicited to a variety of trifluoroacetylated and normal liver antigens. [115] The antigens can become translocated from the endoplasmic reticulum to the surface membrane. One intriguing possibility is that the trifluoroacetylated epitope can be mimicked by an endogenous substance. Two such proteins have been identified that cross-react with antibodies from halothane-exposed animals and patients. [109] It is suggested that altered self-tolerance may be related to halothane hepatitis.

Enflurane was first used in North America in 1966. Of the millions of enflurane anesthetics administered since that time, there are relatively few case reports of liver damage that have been associated with its use. In 1986, Eger et al [116] published reviews of ten published reports and several unpublished reports of liver damage after enflurane. Many of the cases were missing critical information on the duration of anesthetic exposure, histologic confirmation of hepatic lesions, and previous exposure to hepatic disease and hepatotoxic agents. In addition, several patients were hypotensive and in shock and underwent operations with known potential for hepatic dysfunction. These investigators concluded that the evidence did not support the existence of enflurane-induced hepatic dysfunction similar to that seen with halothane.

Several case reports suggested that enflurane anesthesia of halothane-sensitized patients resulted in hepatotoxicity. [117] [118] Covalently bound, acetylated protein adducts from halothane and enflurane-exposed rats were recognized by specific anti-trifluoroacetylated protein antibodies isolated from the sera of patients with halothane hepatitis. [119] This cross-reactivity suggests that enflurane has the potential to produce an immune-mediated hepatotoxic response. The protein adducts formed from enflurane would be similar to those of halothane and thus could act as antigens and cross-react with halothane antibodies, or vice versa. Because the metabolism of enflurane is significantly less than that of halothane, presumably fewer antigenic tissue adducts are formed with enflurane, with a correspondingly smaller likelihood of toxicity.

Stoelting et al [120] reported the assessment of the contribution of isoflurane to 45 cases of hepatic dysfunction following anesthesia that had been reported to the Food and Drug Administration of the United States. They concluded that current evidence did not support an association between isoflurane and postoperative hepatic dysfunction. In 1993, a case was reported in which a patient with an uneventful initial exposure to isoflurane anesthetic for cecopexy had repeated episodes of hepatitis after subsequent exposures to isoflurane. [121] The second isoflurane anesthetic for pyloroplasty was for a 2-hour period, and the third anesthetic for gastrojejunostomy was 30 minutes of isoflurane, followed by 150 minutes of enflurane. This patient had a far greater serum transaminase and alkaline phosphatase concentration after the second anesthetic than after the third. Unfortunately, as with many other cases, the evidence is suggestive but insufficient to draw firm conclusions.

The potential for hepatotoxicity caused by halothane, enflurane, and isoflurane is directly related to their relative degree of oxidative metabolism to acetylated protein adducts. Twenty percent of absorbed halothane is oxidatively metabolized *in vivo* to a reactive acetylated halide metabolite, whereas only 2 percent of enflurane and 0.2 percent of isoflurane are metabolized to reactive metabolites.

Methoxyflurane was introduced into clinical practice in the United States in 1960. Although none of the metabolites of methoxyflurane is known to be hepatotoxic, there have been a number of reports of hepatic dysfunction and death from hepatic coma following methoxyflurane exposure. In a review of 24 cases of methoxyflurane-associated hepatitis, Joshi and Conn [122] presented evidence for a syndrome similar to that described earlier for unexplained hepatitis following halothane administration. They concluded that a rare and indirect immunologic hepatic injury may occur that may have a direct effect on the liver by interfering with splanchnic circulation. In humans, the adverse minor changes in liver function appear to be reversible and may be related to dose. It is still unclear whether hepatic dysfunction, as measured by bromsulphalein retention and serum hepatic enzyme elevation, was the result of the depth and duration of the anesthetic exposure, the type of operation, the extent of preexisting hepatic disease, or methoxyflurane itself.

Studies of patients and volunteers do not suggest that desflurane is associated with hepatic toxicity in humans. [123] [124]

There is, however, one report of a patient who developed fulminant hepatitis 12 days after receiving a desflurane anesthetic. [125] This patient had been exposed to halothane, 10 and 18 years previously, for periods of less than an hour. There is a suggestion that this patient experienced desflurane-induced fulminant hepatitis, because desflurane is metabolized to a trifluoroacetyl chloride metabolite, as is halothane, and the serum antibodies from this patient reacted with trifluoroacetylated liver microsomal proteins. Not unexpectedly, because of the limited metabolism of desflurane, animal studies have produced little evidence for hepatotoxicity with desflurane under the same conditions that produce hepatotoxicity in 20 percent of isoflurane-exposed and 100 percent of halothane-exposed rats. [82]

There are no reports of sevoflurane and hepatic dysfunction. A clinical study of 50 surgical patients showed no significant changes in transaminases and hepatic function following 1 to 7 MAC-hours of sevoflurane anesthesia. [89] Sevoflurane exposure of untreated, phenobarbital-treated, and Aroclor 1254-treated rats likewise showed no significant changes in serum transaminases, liver triglycerides, or glutathione concentrations. [126] There are no case reports of hepatic necrosis following N_2O administration when hypoxia has been ruled out as a possible contributing factor. Several cases of hepatic necrosis have been reported, however, when N_2O was combined with intravenous barbiturate administration. [127] [128] Evidence suggests that N_2O has little potential for producing hepatotoxicity. Continuous exposure of rats to 20 percent N_2O for as long as 35 days produced no significant changes in liver serum enzymes or in glutathione content. [38]

Effects on the Kidney

Inhaled anesthetics depress renal function; they decrease urine flow, glomerular filtration rate, renal blood flow, and electrolyte excretion. These changes are usually secondary to effects on the cardiovascular, sympathetic, and endocrine systems and almost always return to normal shortly after anesthesia and surgery. If they persist for any length of time into the postanesthetic period, the cause is often a combination of factors such as prior existence of renal or cardiovascular disease, severe fluid and electrolyte imbalance, and the administration of mismatched blood; the choice of anesthetic is seldom an important factor. Such physiochemical responses should be recognized, but they are not true toxic reactions and are not considered further. Occasionally, however, the inorganic F^- that is released during metabolism of fluorinated anesthetics may be directly nephrotoxic. Methoxyflurane is the classic example, and although this agent is seldom used in clinical practice, its nephrotoxicity is discussed briefly as a basis for understanding the nephrotoxic potential of all current and future fluorinated anesthetics.

Methoxyflurane

Vasopressin-resistant polyuric renal insufficiency was first reported in 1966 in patients receiving prolonged methoxyflurane anesthesia for abdominal surgery. [129] Subsequently, evidence indicated that the causative agent was F^-. The evidence was based on three observations. First, serum F^- concentrations following methoxyflurane administration in humans show positive correlation with the degree of renal dysfunction. [130] Second, vasopressin-resistant polyuric renal insufficiency similar to that seen in humans after prolonged methoxyflurane anesthesia can be consistently elicited in male Fischer 344 rats injected with sodium F^-. [131] Finally, F^- is a potent inhibitor of many enzyme systems including those involving antidiuretic hormone. [132] Fischer 344 rats are excellent models for studying F^--induced nephropathy because they demonstrate renal changes following F^- administration similar to those seen in humans, including polyuria, hypernatremia, serum hyperosmolality, increased blood urea nitrogen and creatinine, and decreased blood urea nitrogen and creatinine clearances. Furthermore, they have about the same serum F^- threshold for renal dysfunction as do humans.

The extent of nephrotoxicity in general surgical patients has been correlated with peak serum F^- concentrations and methoxyflurane dose (in MAC-hours, that is, end-tidal concentration as a fraction of MAC times the duration of anesthesia, in hours). [133] After 2.5 to 3.0 MAC-hours of methoxyflurane, which corresponds to peak serum F^- concentrations of 50 to 80 mumol/L, patients had subclinical toxicity characterized by a delayed return to maximum preoperative urinary osmolality, elevated serum urate concentration, and decreased urate clearance. If a test of vasopressin resistance had been performed on these surgical patients, the threshold methoxyflurane dose and serum F^- concentration to produce subclinical toxicity undoubtedly would have been lower. After 5 MAC-hours of methoxyflurane, serum F^- concentrations were 90 to 120 mumol/L, and patients had well-established but mild nephrotoxicity manifested by serum hyperosmolality, hypernatremia, polyuria, and urinary hypo-osmolality. Seven to 9 MAC-hours of methoxyflurane led to serum F^- concentrations up to 175 mumol/L and marked nephrotoxicity.

Despite the overall correlation between nephrotoxicity and peak serum F^- concentrations, individual patients given the same methoxyflurane dose vary in their nephrotoxic susceptibility. Genetic heterogeneity, drug interaction, preexisting renal disease, and a host of other factors could account for differences observed among patients. For example, enzyme induction is clearly important; both Fischer 344 rats [134] and human volunteers [133] pretreated on a long-term basis with the classic enzyme inducer phenobarbital, show increased defluorination and nephrotoxicity. Other enzyme inducers such as phenytoin, [8] ethanol, [14] [15] and diazepam [16] also increase methoxyflurane defluorination in rats. One example of a drug interaction is the additive nephrotoxic effect seen in patients receiving both methoxyflurane and the aminoglycoside antibiotic, gentamicin. [135] The same effect is seen in Fischer 344 rats in which concurrent administration of methoxyflurane and gentamicin produces greater nephrotoxicity than expected from either drug alone. [136]

Enflurane

Enflurane defluorination may occasionally result in serum F^- concentrations high enough to produce mild renal impairment. In a study with Fischer 344 rats, 6 to 10 hours of 2.5 percent enflurane anesthesia produced a mild vasopressin-resistant polyuric renal dysfunction. [27] Peak serum

F^- concentrations were 40 to 57 mumol/L, just reaching the threshold for renal toxicity. Surgical patients rarely show renal dysfunction following enflurane anesthesia. [13] Although postoperative serum F^- concentrations are significantly higher than background concentrations, they seldom reach the threshold for nephrotoxicity. In comparison with methoxyflurane, serum F^- concentrations following enflurane anesthesia peak earlier and fall more rapidly, emphasizing the important role that lipid solubility has in determining total F^- production (Fig. 6-3) . In one study, peak serum F^- concentrations from nine surgical patients averaged 22.2 mumol/L following enflurane exposures averaging 2.7 MAC-hours. [137] The only controlled human study to show mild renal dysfunction following enflurane anesthesia involved 11 healthy volunteers. [138] After 9.6 MAC-hours of enflurane, maximum urinary osmolality following antidiuretic hormone administration was reduced from approximately 1,050 to 800 mOsm; mean serum F^- concentration was 33.6 mumol/L. The mild impairment of renal concentrating ability was not associated with hypernatremia, serum hyperosmolality, or increased serum creatinine or urea nitrogen and therefore was not regarded as clinically significant.

Some clinicians have speculated that enflurane administered to patients with significant preexisting renal disease could produce additional renal dysfunction. Such fears have not been borne out in studies of Fischer 344 rats with surgically induced chronic renal insufficiency. [139] [140] Furthermore, results of a study of patients with mild to moderate renal

Figure 6-3 Serum inorganic fluoride (F^-) concentrations before and after administration of methoxyflurane, sevoflurane, enflurane, isoflurane, and desflurane anesthesia. Following 2 to 3 MAC-hours of methoxyflurane, mean peak serum F^- concentration was 61 ± 8 mumol/L, which slowly declined. Sevoflurane anesthesia of 3.7 MAC-hours resulted in a mean peak F^- concentration of 30.6 ± 2.2 mumol/L, which declined more rapidly than methoxyflurane but remained elevated for several days. After 2.7 MAC-hours of enflurane, mean peak F^- concentrations were 22.2 ± 2.8 mumol/L, which also declined over several days. There was no increase and almost no increase in F^- concentrations following desflurane and isoflurane administrations, respectively.

insufficiency showed no clinically significant difference between preoperative and postoperative renal function following either enflurane or halothane administration. [141] Another concern with enflurane is that F^- concentrations, and hence the risk of nephrotoxicity, may be higher in obese patients. In one study, the peak serum F^- concentration in an obese patient weighing 130 kg was 52 mmol/L after 5 hours of exposure to enflurane. [137] In another study, peak serum F^- concentrations averaged 28 mmol/L in morbidly obese patients compared with 17 mmol/L in nonobese patients. [142] Studies have not been performed in humans to determine whether nephrotoxicity is more common in obese patients receiving enflurane, but such has been shown to be the case in obese Fischer 344 rats. [143]

Enzyme induction does not significantly increase enflurane defluorination measured *in vitro* [28] or in surgical patients [9] receiving common enzyme-inducing drugs such as ethanol, phenobarbital, and phenytoin. In contrast, prior long-term treatment with isoniazid may result in higher than expected serum concentrations of F^- and a transient urinary concentrating defect following enflurane anesthesia. Work with Fischer 344 rats has shown that, unlike phenobarbital and phenytoin, isoniazid significantly increases enflurane defluorination. [11] [12] In addition, a study of surgical patients has shown that approximately one-half of those patients treated with isoniazid on a long-term basis prior to enflurane anesthesia had significantly higher serum F^- concentrations than predicted, [13] but these were not sufficiently high or sufficiently sustained to produce clinically significant renal impairment. An unsubstantiated theory is that fast acetylators metabolize isoniazid and induce the cytochrome P-450 isozyme responsible for enflurane metabolism.

Isoflurane

Isoflurane, an isomer of enflurane, is defluorinated much less than enflurane. In nine surgical patients receiving, on average, 3 MAC-hours of isoflurane, mean peak serum F^- concentration measured 6 hours after anesthesia was only 4.4 mumol/L. [74] Thus, isoflurane should not be associated with F^- nephrotoxicity in most clinical situations. For patients having prolonged anesthesia with isoflurane, however, caution is warranted. In patients who received about 19 MAC-hours of isoflurane, peak plasma F^- levels were much higher in the isoflurane group compared with the halothane group. [144] In fact, 40 percent of patients administered isoflurane had peak plasma F^- levels greater than 50 mmol/L. Caution may also be warranted in obese patients, because in a rat model, peak serum F^- concentrations averaged 27 mmol/L after 4 hours' exposure. [143] Enzyme induction does not appear to be a problem with isoflurane because phenobarbital pretreatment of rats only slightly enhances isoflurane defluorination and does not produce clinically significant increases in F^- concentration. [28] Prolonged isoflurane administration has been investigated for uses outside the operating room. Isoflurane was investigated for its ef-fectiveness in long-term sedation of patients on mechanical ventilation. [145] [146] In the first study, the highest serum F^- concentration was measured for a 2-year-old child who received 73 MAC-hours of isoflurane and had a serum F^- of 37 mumol/L. [145] In the second study, pediatric patients on mechanical ventilation received isoflurane for 13 to

497 MAC-hours. The highest serum F^- concentration was 26.1 mumol/L, with no alterations in serum creatinine or osmolality. [146] Although it appears that isoflurane can be administered for very long periods without producing clinically significant serum F^- concentrations, there are influences on metabolism, and renal and hepatic functions should be carefully followed.

Sevoflurane

Sevoflurane is moderately defluorinated to approximately the same extent as that of enflurane. Results of clinical studies show that serum F^- concentrations often peak above 50 mmol/L even when sevoflurane is administered during surgery of average duration. [89] [147] Because of sevoflurane's low blood/gas solubility (0.69) and its rapid elimination, F^- concentrations fall very quickly after surgery, and renal toxicities are not expected from sevoflurane administration. Defluorination of sevoflurane is induced with phenobarbital, [8] [84] [148] isoniazid, [11] [12] and ethanol [15] in rats. *In vivo* studies have shown that although peak F^- levels are comparable to those with enflurane, sevoflurane has less nephrotoxic potential, as measured by maximum urine concentrating ability and the production of *N*-acetyl-beta-glucosaminidase, an indicator of renal tubular damage. [149] Numerous clinical studies of F^- production and nephrotoxic potential of sevoflurane have been performed and have been reviewed elsewhere. [150] Many of the same issues were addressed with sevoflurane as with enflurane, including serum and urinary F^- levels after prolonged exposure, [147] [149] [151] urine concentrating ability, [149] [151] [152] [153] effect of obesity, [152] and the effect of preexisting renal impairment. [154] The consensus from these studies is that sevoflurane has little potential for nephrotoxicity, a conclusion supported by its apparently safe administration to many millions of patients worldwide. There is, however, concern because a decomposition product of sevoflurane, compound A, is nephrotoxic in rats at ppm concentrations that could potentially be achieved in a low-flow system. [155] [156] The lesion has been described as corticomedullary tubular necrosis.

Desflurane

Clinical studies thus far performed with desflurane show no evidence of nephrotoxicity. Desflurane is extremely resistant to defluorination and serum F^- concentrations in surgical patients after exposure to desflurane are not increased above background concentrations. [82] [157] As expected from these findings, desflurane does not appear to be nephrotoxic. [123] [158]

Halothane

Halothane is not significantly defluorinated under normal clinical conditions and is not nephrotoxic. In patients who received about 19 MAC-hours of halothane, peak plasma F^- levels were much higher in the isoflurane group compared with the halothane group. [144] Defluorination is enhanced slightly in rats under conditions of hypoxia and enzyme induction, but not to an extent that would be associated with renal damage.

There is no doubt that F^- is the causative agent in anesthetic-induced nephropathy; however, the lack of correlation between peak serum F^- levels and nephrotoxicity following administration of newer anesthetics such as sevoflurane has led one investigator to suggest that intrarenal production of F^- is more important in the etiology of nephrotoxicity than the total body production of F^-. [60] This question is open to debate at this point in time, but one hopes that it will be resolved. If the intrarenal production of F^- has a significant influence on toxicity, then the renal cytochrome P-450 isozymes become very important in any design considerations for new fluorinated anesthetics.

Effects on Hematopoietic and Neurologic Systems

N_2O is the only anesthetic reported to produce hematologic toxicity and neurotoxicity with long-term administration. Both these toxicities are the result of the interaction of N_2O with vitamin B_{12} and the disruption of several pathways involved in one-carbon chemistry. The biochemical basis of this effect is the oxidation of the cobalt in vitamin B_{12} by a physicochemical reaction with N_2O that was previously discussed (see Eq. 6-9).

The time required to produce megaloblastic hematopoiesis with N_2O exposure varies among patients and perhaps depends on their general state of health. In healthy patients undergoing routine surgery, mild megaloblastic bone marrow changes are not seen after 6 hours, but they are seen after about 12 hours of exposure to 50 percent N_2O; after 24 hours of exposure, changes are marked. [159] Complete bone marrow failure can be expected after several days of continuous exposure. [160] Limited evidence suggests that N_2O produces bone marrow changes earlier in seriously ill patients. [161] Evidence also suggests that the bone marrow changes are preventable by pretreating patients with large doses of folinic acid. [159] This drug is converted to the 5,10-methylene tetrahydrofolate needed for thymidine synthesis (Fig. 6-4) .

The neurologic disease, subacute combined degeneration of the spinal cord, develops only after several months of daily exposure to N_2O. The symptoms and signs include numbness and paresthesia in the extremities, loss of balance and unsteady gait, impairment of touch, and muscle weakness. In the late 1970s, the disease was recognized to be similar to vitamin B_{12} deficiency, but treatment with vitamin B_{12} did not alleviate the symptoms or enhance recovery. [162] Thus, it occurs in those who abuse N_2O on a long-term basis and in those rare individuals who work for many months in an environment grossly contaminated with the gas. Dental personnel who are occasionally exposed to greater than 1,000 ppm waste N_2O in poorly ventilated dental operatories for long periods are particularly at risk. In one study, 3 of 20 dentists exposed to mean concentrations up to 4,600 ppm had abnormal bone marrow. [163] Personnel in modern scavenged operating suites, however, are rarely exposed to such conditions and would not be expected to have problems. Epidemiologic surveys confirm that dental, but not operating room, personnel have a higher incidence of neurologic

Figure 6-4 Conversion of methyltetrahydrofolate and homocysteine to tetrahydrofolate and methionine.

disease, although exposure to waste N_2O has not definitely been shown to be the cause. [164]

In humans and animals, there is an irreversible inactivation of the enzyme methionine synthase, which requires vitamin B_{12} in the completely reduced form to act as its coenzyme. Methionine synthase catalyzes the conversion of methyltetrahydrofolate and homocysteine to tetrahydrofolate and methionine (see Fig. 6-4) . Failure to produce these products has a number of biochemical consequences including reduced synthesis of thymidine, which is an essential DNA base. The clinical syndrome associated with oxidation of vitamin B_{12} is essentially the same as that seen in pernicious anemia: megaloblastic hematopoiesis and subacute combined degeneration of the spinal cord. The time required for inactivation of methionine synthase depends on the species. In rats exposed to 50 percent N_2O, the half-time of inactivation

is about 5 minutes. [165] Recovery of activity takes 3 to 4 days because of oxidation of the vitamin B_{12}, which is irreversible and covalently bound to the enzyme. Thus, new enzyme must be synthesized to restore activity. In humans, the half-life of inactivation is much longer than in rats, about 45 minutes. [165] Nevertheless, after several hours of routine anesthesia with N_2O, methionine synthase activity is very low. The decrease of thymidine synthesis takes somewhat longer to develop but also lasts several days. Experimental data suggest that there is a threshold concentration of about 1,000 ppm (0.1%) below which N_2O has no biochemical effect. [166]

Reproduction and Development

The inhaled anesthetics present potential for adverse reproductive and developmental effects for both patients administered inhaled anesthetics and health care personnel exposed to waste anesthetics. In the United States, at least 50,000 pregnant women (
1.6%) undergo anesthesia and surgery during gestation for indications unrelated to pregnancy. [167] Operations for ovarian cysts, acute appendicitis, mammary tumors, and repair of incompetent cervix are most common. The risk of unexpected abortion or premature labor clearly is higher following anesthesia. What is not immediately obvious is whether the patient's disease, surgery, anesthesia, or a combination of these is the precipitating cause. Perhaps an even greater concern is that anesthesia during pregnancy may lead to an increased incidence of congenital abnormalities in the offspring of the patient. To assess the incidence of various anesthesia-and surgery-related hazards occurring during pregnancy, at least five major and several minor studies have been performed. [168] [169] [170] [171] [172] [173] [174]

The most extensive and thorough study links and analyzes data from three Swedish health care registries, the Medical Birth Registry, the Registry of Congenital Malformations, and the Hospital Discharge Registry for the years 1973 to 1981. [174] Among the 720,000 pregnant patients whose records were examined, there were 5,405 operations performed. The adverse reproductive and developmental outcomes examined were stillbirths, early postnatal deaths, low birth weight, and congenital anomalies. Women who had an operation did not have an increased incidence of stillbirths or of congenital anomalies among offspring. In contrast, the incidence of postnatal death within 7 days of delivery was increased when an operation occurred during the second or third trimester but not during the first trimester. The incidence of low birth weight and premature delivery was increased regardless of the trimester in which an operation occurred. The cause of these hazards was not determined, although the finding that no particular type of operation or anesthesia was associated with a higher incidence of adverse

outcome suggests that the patient's disease played the major role in determining the outcome.

In recent years, the increasing popularity of *in vitro* fertilization has afforded some opportunity to study the effects of anesthetics on ova. Various anesthetic regimens have been examined for their effects on rates of fertilization and cleavage of oocytes, pregnancy, and carriage to term. Results for general anesthesia have been variable, although there is some consensus that regimens that include inhaled anesthetics produce adverse effects. [175] [176] In a well-controlled study of *in vitro* fertilization, no difference in fertilization or pregnancy rates was found between patients having isoflurane anesthesia with or without N_2O, a finding implying that short exposures to N_2O are not harmful. [177] A publication on transvaginal oocyte retrieval and reproductive outcome [178] reported that general anesthesia with N_2O in combination with opiates, barbiturates, and halothane resulted in significantly lower clinical pregnancy rates (14.5%) compared with patients receiving local anesthesia (23.7%) or epidural block (25.8%). There were no adverse effects reported for oocyte collection, embryo yield, or embryo transfer. *In vitro* test systems of *Drosophila* larvae, sea urchin eggs, and mice embryos have shown significant adverse effects on development. [179] The relevance of these findings to the human situation is unknown at this time; however, the amount of anesthetic encountered by these test systems would be significantly greater than would be encountered in scavenged operating rooms.

Several studies have examined the effects of the inhaled anesthetics on sperm. In the only study of human sperm, semen was collected from 46 anesthesiologists who had worked for a minimum of 1 year in a scavenged operating suite. [180] Semen from 26 residents beginning an anesthesia training program were used as controls. The concentration of sperm and the percentage of abnormally shaped sperm were not different between the two groups. Furthermore, sperm collected from 13 of the 26 residents after they had been working for 1 year was not different from the first sample. Studies of mice and rats under various experimental conditions have provided both positive and negative results, but insufficient information is available to permit extrapolation to humans. Thus, despite some suggestive animal data, inhaled anesthetics have not been shown to have significant effects on sperm in humans. However, the scope of both animal and human studies so far performed has been limited, and only moderate assurance of no effect has been achieved.

Twenty reports have been published of epidemiologic surveys that have examined the reproductive performance of operating room and dental personnel exposed to waste gases. [181] [182] [183] [184] [185] [186] [187] [188] [189] [190] [191] [192] [193] [194] [195] [196] [197] [198] [199] [200] Table 6-1 . lists the overall outcome of these surveys. An evaluation of the merits of each of these studies is beyond the scope of this chapter, which summarizes the outcomes. The interested reader is referred to a review of these studies. [201] In a review of many of the studies prior to 1978, an estimate was made of the relative risks for particular adverse health effects. [202] The magnitude of the relative risk for spontaneous abortion among exposed women was approximately 1.3. The increase was reported to be both consistent and statistically significant. For congenital abnormalities among offspring of anesthetic-exposed women, the relative risk was approximately 1.2. The overall data for wives of exposed males and for congenital abnormalities among their offspring were less consistent than the data for spontaneous abortion. For both spontaneous abortion and congenital abnormalities, the increases observed were small and could not be attributed to a specific cause. Exposure to waste anesthetic gases, viruses, roentgenograms, a variety of chemicals other than anesthetics, or a combination of these factors could have accounted for the positive results. Furthermore, most surveys had serious methodologic faults, including failure to verify the medical data supplied by respondents.

To resolve whether there were adverse effects that had not been appropriately acknowledged, in 1985 Buring et al [203] performed a meta-analysis of five studies [182] [183] [184] [186] [195] in which these investigators analyzed spontaneous abortion and congenital abnormalities among female physicians and nurses potentially exposed to waste anesthetics. Risk ratios were 1.3 (95% confidence interval [CI], 1.2-1.4) for spontaneous abortion and 1.2 (95% CI, 1.0-1.4) for congenital abnormalities, both of which were statistically significant. Response or recall bias or both, however, could explain these significant associations because most of the studies relied on voluntary responses and self-reported outcomes. One of the

acknowledged shortcomings of these studies (i.e., the lack of a quantitative measure of exposure) was addressed in two more recent retrospective studies [199] [200] that

attempted to quantitate N_2O exposure among female dental assistants. These investigators reported that in unscavenged dental suites, exposure to more than 5 and 3 hours of N_2O per day, respectively, was associated with reduced fertility and increased spontaneous abortion rates.

A retrospective cohort study design, which is subject to both selection and recall bias, was used for the majority of epidemiologic studies listed in Table 6-1 . One of the weakest links in the epidemiologic studies of adverse reproductive and developmental outcomes following occupational anesthetic exposure is the lack of quantification of the extent and duration of anesthetic exposure. Data generally were collected by self-administered questionnaire without verification of either exposure or outcome. In addition, the extent and duration of exposure to waste anesthetics has decreased in recent years, so it is difficult to draw conclusions on the likely adverse effects of current anesthetic exposure based on these earlier studies at conditions of higher exposure. In the only three studies in which medical records were used to confirm medical data, negative results were obtained for a number of adverse reproductive effects including spontaneous abortion. [191] [195] [196]

In addition to problems in quantification of exposure, there is also a problem of identifying the cause of any congenital malformation that is observed. Although human development is remarkably consistent, it is not always perfect, and congenital malformations, both severe and trivial, are found in 2 to 4 percent of all births in countries in which records are kept. [204] There are many mechanisms involved in abnormal development (Table 6-2) . Some, such as mutations that result in specific biochemical abnormalities and chromosomal nondisjunction, are well established. (See the section on genotoxicity later in this chapter for a brief discussion of mutations.) Others, such as interference with abnormal cell membrane states, are less certain mechanisms of teratogenicity. Although the cause of most defects remains unknown, chemical teratogenesis in humans is well established (Table 6-3) . Because of the difficulty in identifying causes and investigating mechanisms in humans, sophisticated animal studies have been developed over the last 30 years for examining the teratogenicity of chemicals. The complete assessment of a chemical now involves examining its effect on mating behavior, fertility, embryonic and fetal wastage, congenital anomalies, and postnatal survival and behavior. Animal studies provide useful information, but they are limited because of the difficulty of extrapolating animal data to humans and the relatively low statistical power to detect the presence of a weak teratogen.

Alteration of nucleic acid function
Removal of cell precursors and substrates
Lack of energy source
Enzyme inhibition
Change in cell membrane characteristics

The developmental effects of the inhaled anesthetics have also been extensively studied in animals in an attempt to control conditions that cannot be controlled in epidemiologic studies. These studies tried to control for the many factors (e.g., genetic variability, environment, diet) that could contribute to the background incidence of congenital malformations in humans. Studies of the inhaled anesthetics on reproductive processes of experimental animals have been conducted at both trace and subanesthetic concentrations to simulate occupational exposure and at anesthetic concentrations to simulate surgical exposure. The large number of such studies precludes a complete discussion in this chapter. The interested reader is referred to several reviews. [201] [205] [206] In general, N_2O is the only inhaled anesthetic that has been convincingly shown to be directly teratogenic to experimental animals, but only under experimental conditions that are considered extreme. High concentrations (50-75%) delivered to rats for 24-hour periods during organogenesis and low concentrations (0.1%) delivered to rats continuously throughout pregnancy result in an increased incidence of fetal resorptions and visceral and skeletal abnormalities. [207] [208] A particularly interesting abnormality produced by high N_2O exposure is situs inversus, in which there is a disturbance of the left/right body axis so that organs such as the heart are on the wrong side of the body. [209] Although effects in rodents are seen only after extended periods of continuous exposure, it is not known whether humans are more sensitive than rodents and would show effects after shorter periods of exposure.

The mechanisms that produce teratogenic effects with N_2O are slowly being revealed. The former leading theory was that inhibition of methionine synthase causes critical shortages of intracellular thymidine and, hence, DNA, which is needed by the rapidly growing embryo. Certainly, both decreased DNA synthesis and decreased total DNA content have been observed in embryos immediately after N_2O exposure. [210] [211] It now appears that lack of methionine rather than the lack of thymidine plays the critical role in all the adverse reproductive effects other than situs inversus. [212] Furthermore, an entirely different mechanism accounts for the situs inversus, namely, stimulation of alpha $_1$ -adrenergic receptors by N_2O. [213] The effect is mediated by activation of calmodulin kinase II but not phosphokinase C (PKC). [214] N_2O teratogenesis is being actively investigated, not only because of its relevance to patient and occupational safety, but also because N_2O can be used to determine the importance of vitamin B_{12} , folates, one-carbon chemistry, and the adrenergic system in developmental processes.

Halothane, enflurane, and isoflurane are also teratogenic to rodents, but only when they are administered at anesthetizing

concentrations for many hours on several days during pregnancy. Desflurane and sevoflurane have not been tested, but they are expected to have the same effects. The consensus is that the teratogenic effects observed in animals exposed to the inhaled anesthetics are caused by physiologic changes associated with anesthesia, rather than by inherent terotologic properties of the anesthetics themselves. Nonetheless, all findings emphasize the potential for anesthetics to interfere with developmental processes regardless of the mechanism.

Developmental toxicity also encompasses the cognitive and functional deficits that may occur in the absence of observable morphologic changes. Organ systems are most sensitive to chemical teratogens during periods of development (organogenesis). The central nervous system may be particularly vulnerable during the period of myelination. In humans, this period is from the fourth intrauterine month through the second postnatal year. Thus, a chemical or drug may produce behavioral teratogenesis if administered late in gestation or even after birth. Anesthetics have not escaped scrutiny as possible behavioral teratogens. A study of 1-day-old rats exposed to 0.75 or 1.0 percent halothane with or without 50 or 75 percent N_2O for 6 hours demonstrated dose-dependent decrements in PKC activity in growth cone particles isolated from the forebrains. [215] There were no effects at 0.5 percent halothane or 25 percent N_2O. Although the anesthetic concentrations causing effects were high, the importance of PKC in signal transductions in developing brain and the potential disruption by anesthetics cannot be ignored. To date, although some rodent studies have shown behavioral deficits following exposure to the inhaled anesthetics, [216] [217] [218] the mechanism for these changes is unknown, and the applicability to humans is unclear. In general, the anesthetic exposure conditions can be considered extreme relative to any reasonably expected human exposure.

Human studies have generally focused on long-term behavioral effects of maternal obstetric medication, including epidural anesthesia. Claims have been made that the medication given at delivery to the mother produces depressed motor skills and impaired language ability in the infant and child for several years. Such claims,

however, are controversial. Behavioral abnormalities of offspring whose mothers received inhaled anesthetics at any time during delivery have not been well studied. Furthermore, studies have not been done to assess neurobehavioral function of children of operating room personnel who have been exposed to waste anesthetic gases. Firm conclusions about the risk of the occurrence of behavioral teratogenesis among the offspring of exposed personnel or in exposed patients therefore await further investigation. If the number of scientific articles published can be regarded as a measure of scientific concern, the behavioral effects following *in utero* and perinatal exposure to the inhaled anesthetics do not appear to be a significant problem.

DNA, Genetics, and Neoplasia

The potential long-term adverse health effects from occupational exposure to trace concentrations of waste anesthetic gases have been recognized for more than 20 years. Even if inhaled anesthetics have a low potential for causing long-term toxicity, exposure of a large population may represent a considerable public health hazard. In the United States, about 50,000 hospital operating room personnel, including anesthesiologists, nurse anesthetists, and operating room technicians, are exposed daily to waste anesthetic gases. [167] In addition, surgeons, dental personnel, and veterinarians and their technical assistants have a variable but sometimes heavy exposure to waste anesthetics. The total number of exposed or potentially exposed personnel in the United States each year is about 225,000. [167] Of particular concern have been the reports that inhaled anesthetics possess mutagenic and carcinogenic potentials.

Genotoxicity

Investigators have been interested in the mutagenic potential of inhaled anesthetics for several reasons. First, many chemical carcinogens are also mutagens, although the reverse is not necessarily true. Thus, finding that a particular anesthetic is a mutagen also implies a potential for carcinogenesis that should be evaluated. Second, mutagens may pose a threat to the integrity of the human genome (the totality of genes and chromosomes).

Mutations are heritable changes in genetic information. Unrepaired mutations in germ cells can be passed from generation to generation. Unrepaired mutations in somatic cells can result in diseases including cancer. The four types of mutations traditionally recognized are base-pair mutations, frame-shift mutations, deletions or rearrangements of chromosomal segments, and nondisjunction of chromosomes between daughter cells. In addition, a fifth and novel type of mutation has been recognized that involves continuous repeats of three nucleotides at a specific site in a gene. [219] *In vitro* assays for mutagenicity require much less time and expense than *in vivo* tests for carcinogenicity, and these assays have become popular screening methods for detecting carcinogens. A wide variety of test systems has been used to examine the mutagenicity of inhaled anesthetics including assays with bacteria, yeast, mammalian cells in culture, and intact mammals. Most studies of the anesthetic agents have been reviewed elsewhere [206] and are only summarized here.

Extensive work has been done with the Ames *Salmonella*/mammalian hepatic microsome system, which uses several strains of histidine-dependent *S. typhimurium* as tester organisms. This system is a well-validated assay for mutagenicity and often is regarded as the standard against which other systems are compared. It has been used to test most currently and formerly used anesthetics. Only divinyl ether and fluroxene give unequivocally positive mutagenic responses, whereas trichloroethylene gives a weak mutagenic response. Other anesthetics including N_2O, halothane, and enflurane are not mutagenic when tested under a wide variety of experimental conditions and anesthetic concentrations. The finding that some mutagenic anesthetic metabolites have a chemical structure reminiscent of vinyl chloride (CH_2 =CHCl) is consistent with the known high reactivity and mutagenicity of this class of chemicals. Of the many inhaled anesthetic metabolites that have been tested in the *Salmonella* assay, only 1,1-difluoro-2-bromo-2-chloroethylene (CF_2 =CBrCl) and 1,1-difluoro-2-chloroethylene (CF_2 =CHCl) have been found to be

even weakly mutagenic. In general, results from numerous studies with other test systems have confirmed those from studies with *Salmonella.* [206] [220] Although there are some anomalous results, the overwhelming evidence from *in vitro* tests indicates that all currently used and most previously used anesthetics are not mutagens.

Genotoxicity studies of humans exposed to inhaled anesthetics have generally been negative. In an early study from 1977, [221] no significant difference in the number of chromosomal aberrations could be detected between the lymphocytes obtained from operating room nurses and those obtained from surgical outpatient nurses. Mutagenic activity was not detected in the *Salmonella* assay either for urine of personnel working in scavenged or unscavenged operating rooms or for urine of anesthesiology residents during the first 15 months of training. [222] Finally, lymphocytes from personnel exposed to waste anesthetic gases for durations up to 312 months had no higher incidence of chromosomal aberrations or sister chromatid exchange compared with lymphocytes from unexposed individuals. [223] This later study was an extension of previous negative studies by the same authors of sister chromatid exchanges in lymphocytes of operating room personnel exposed to waste anesthetic gases and of patients anesthetized with halothane, enflurane, or fluroxene. In contrast to these negative results, studies in 1990 [224] and 1992 [225] showed cytogenic damage in operating room personnel exposed to waste anesthetic gases. Another study, in 1993, [226] showed DNA single-strand breaks in lymphocytes of patients immediately after anesthesia with isoflurane/nitrous oxide. Why these differences in results exist among the studies is at present unknown, although positive results could be explained by multiple factors unassociated with the anesthetics. As with the teratogenicity and carcinogenicity studies described elsewhere in this chapter, genotoxicity studies of operating room personnel are more realistically studies of the work environment, which is composed of many chemical and physical agents as well as anesthetic gases.

Carcinogenicity

Chemical carcinogenesis is a multistage, multistep process leading to the formation of malignant tumors. There are two general classes of carcinogens: genotoxic and nongenotoxic. The former directly interacts with DNA, and the latter does not. Chemical carcinogenesis consists of three operationally defined stages: initiation, promotion, and progression (Fig. 6-5) . Genotoxic carcinogens are often referred to as *initiators* because, in interacting with DNA, they initiate the process in normal cells. Initiation is most often accomplished in several steps, the first of which is the metabolic activation of the chemical to a reactive intermediate. The second step consists of the covalent binding of the reactive intermediate to DNA. One or more cell divisions are required to "set" or "fix" the mutation. Before the mutation is fixed, the DNA may still be repaired. Initiation is accomplished only when the mutation is fixed. Once initiation has occurred, there is still no guarantee that a cell with defective DNA will survive a sufficiently long period to proceed in the process of carcinogenesis because initiated cells are also subject to apoptosis (natural cell death).

Figure 6-5 Multistage, multistep chemical carcinogenesis.

Nongenotoxic carcinogens, unlike genotoxic carcinogens, do not initiate cells. Nongenotoxic agents act through other mechanisms to promote the growth of initiated cells; thus, the term *promoter* is often applied to these carcinogens. These agents may interact with other cellular components to promote the growth of these cells. A common mechanism is increased rate of cellular proliferation preventing the normal repair process. One thing in common with these agents is that the promotion of initiated cells into tumors requires the continued presence of the promoter. Without its presence, apoptosis results in the elimination of single initiated cells and natural regression of the preneoplastic tumors. The terms initiator and promoter are used to indicate the state of carcinogenesis in which a chemical is first active. An initiator may also have activity as a promoter. The phase of progression that results in the appearance of clinically apparent tumors involves additional phenotypic and genotypic changes to cells resulting in karyotypic instability. These mechanisms are not understood, and many cancers appear to occur over a prolonged period.

Covalent binding of reactive intermediates to tissue macromolecules is presumed to be a necessary requirement for initiation of chemical carcinogenesis. Covalent binding, however, is not sufficient for initiation because the binding must be specific to a DNA site that would result in miscoding of a necessary gene product or a regulatory gene. As previously discussed, the mutation caused by covalent binding must also be "fixed" in the DNA by cell division. Current techniques can distinguish specific binding sites, but the older literature did not, thus giving the impression that any covalent binding was paramount to carcinogenesis.

Structural evaluation of chemicals for similarities to known carcinogens is useful to identify potential mutagens, but often minor changes in structure have profound effects on mutagenic and carcinogenic activity. Methoxyflurane, enflurane, and isoflurane are alpha-haloethers, as are the nonanesthetic but carcinogenic chemicals bis(chloromethyl)ether,

chloromethyl methyl ether, and bis(alpha-chloroethyl)ether. The anesthetics, however, are not mutagenic. Halothane is an alkyl halide, as are the animal carcinogens methyl iodide, butyl bromide, and butyl chloride. Halothane, however, is not mutagenic. Fluroxene and divinyl ether also contain the vinyl moiety similar to the human and animal carcinogen, vinyl chloride. Although the structural similarity between the anesthetics and several chemical carcinogens provides suggestive evidence for an association between anesthetics and carcinogenicity, there are no epidemiologic or other data to support that suggestion. Despite the obvious advantage of surveying human populations to determine the carcinogenic risk of exposure to anesthetics, such surveys have provided little information on the carcinogenicity of specific anesthetics. The primary reason is that the doses of anesthetics to which surveyed individuals have been exposed have not been measured and at best have been estimated. Nonetheless, the studies thus far performed should indicate whether waste anesthetics are associated with a higher incidence of cancer.

There have been several surveys of cancer incidence among operating room and dental workers (Table 6-4) . [186] [192] [198] [227] [228] [229] [230] [231] In the largest, the American Society of Anesthesiologists conducted a retrospective survey of 49,595 operating room personnel working throughout the United States. [186] A 1.3- to 1.9-fold increase in cancer incidence was noted among female members of the American Society of Anesthesiologists and the American Association of Nurse Anesthetists compared with unexposed control female groups. No increase in cancer incidence was seen among surveyed males. In an earlier study, the incidence of cancer among 525 female nurse anesthetists in Michigan was compared with that of women participating in the Connecticut Tumor Registry. [228] The nurse anesthetists had a higher incidence of malignancies diagnosed during 1971 than did all the women of Connecticut during 1966 to 1969. In another large study, a national survey of health among dental personnel was reported. [193] The study population consisted of 30,650 dentists and 30,547 chairside assistants and was readily divided into those who used or did not use inhaled anesthetics to provide pain relief and sedation of patients. Otherwise, both groups did similar work under similar conditions. An estimate of anesthetic exposure was made by noting the number of hours per week spent by each respondent in the dental operatory. About 80 percent of inhaled anesthetics users were exposed to N_2O alone, whereas the remainder were also exposed to potent volatile anesthetics. The cancer incidence among female chairside assistants exposed to waste anesthetics for more than 8 hours per week was 50 percent greater than among those not exposed, although the increase was not statistically significant ($P = .056$). Analysis of various types of cancer showed that only cancer of the cervix occurred more frequently ($P = .06$) in exposed women than in unexposed women. However, a more recent study (1990) of health effects associated with waste anesthetic exposure in Ontario hospital personnel did not show an increased cancer incidence for either men or women compared with unexposed controls. [198] Collectively, the foregoing studies of cancer incidence appear to suggest a small risk to women directly exposed to waste anesthetic gases. However, because of problems with study design and the small increase in cancer incidence observed, reviewers have generally been unconvinced of the existence of a hazard to humans. [202] [205] [206] This lack of conviction is strengthened by the uniformly negative results from surveys of deaths from cancer [192] [227] [229] [230] [231] (see Table 6-4) .

Problems in interpreting epidemiologic surveys led many investigators to turn to animal studies to provide information on the carcinogenic potential of specific anesthetics. In early studies, chloroform was found to be a rodent carcinogen when the drug was administered in very high doses by oral gavage, but this route of administration is not relevant to inhaled exposure of patients or operating room personnel. It is now recognized that hepatic tumorigenesis in rodents with chloroform is related to high-dose cytotoxicity and the subsequent increased rate of reparative proliferation. At lower doses, at which cytotoxicity is not present, tumor formation is absent. Indeed, when halothane, methoxyflurane, enflurane, isoflurane, and N_2O have been administered by inhalation and assessed in adequate studies, results for carcinogenicity have been uniformly negative. [232] [233] [234] [235] [236] [237] Parenthetically, in none of these studies was there evidence of other types of organ toxicity on histologic examination. The conclusion from both animal and human studies is that there is no carcinogenic risk from exposure to the currently used inhaled anesthetics.

TABLE 6-4 -- Epidemiologic Surveys for Cancer Incidence or Deaths Among Personnel Exposed to Waste Anesthetic Gases

STUDIED RESULT	POPULATION	RESULTS	INVESTIGATORS (YEAR)
Deaths	ASA Members	Negative	Bruce et al [227] (1968)
Incidence	Nurse anesthetists	3.3-fold increase for 1971	Corbett et al [228] (1973)
Incidence	ASA members	1.3 to 1.9-fold increase for women; negative for men	American Society of Anesthesiologists [186] (1974)
Deaths	ASA members	Negative	Bruce et al [229] (1974)
Deaths	Anesthetists	Negative	Doll and Peto [230] (1977)
Deaths	Anesthetists and offspring	Negative	Tomlin [192] (1979)
Incidence	Dental personnel	1.5-fold increase for women; negative for men	Cohen et al [193] (1980)
Deaths	Anesthetists	Negative	Neil et al [231] (1987)
Incidence	Operating room personnel	Negative	Guirguis et al [198] (1990)

ASA, American Society of Anesthesiologists

SUMMARY

In summary, the inhaled anesthetics are not chemically inert or innocuous. As is the case with all drugs, there are risks that accompany their use. Historically, there have been significant toxicities associated with anesthetics that were for the most part first observed in humans. As more has been learned about how chemicals act in biologic systems, anesthetics have been designed that are more chemically stable and more resistant to biodegradation. The result has been inhaled anesthetics that are less toxic. Overall, the current-day inhaled anesthetics are not very toxic. The identification of both acute and chronic toxicities in humans associated with the use of the inhaled anesthetics is difficult because of myriad confounding factors. As in any field of study, it is essential that no one study, whether positive or negative, is taken as the definitive answer, but rather that all available information is evaluated for merit. In evaluating studies and data related to the toxicity of the inhaled anesthetics, it is helpful to remember that certain widely accepted formal criteria need to be met before the association between any agent and any adverse health outcome can be accepted as likely to be causal. These criteria evaluate the strength of the association, the dose-response relationship, the specificity of the association, the appropriate temporal association, the consistency of the association across multiple studies, the biologic plausibility of the association, and the coherence of the evidence.

Chapter 7 - Inhaled Anesthetic Delivery Systems

J. Jeff Andrews

INTRODUCTION

An anesthesia system consists of the various components that communicate with each other during the administration of inhalation anesthesia. [1] System components include the anesthesia machine, the vaporizers, the anesthetic circuit, the ventilator, and the scavenging system. A thorough understanding of these parts is essential to the safe practice of anesthesia. Malpractice claims associated with gas delivery equipment are infrequent but severe and continue to occur in the 1990s. [2] This chapter discusses the normal operation, function, and integration of major system components. More importantly, it illustrates some problems and hazards associated with each and describes appropriate preoperative checks.

ANESTHESIA MACHINES

Anesthesia machines have evolved from simple, pneumatic devices to sophisticated, computer-based, fully integrated anesthesia systems (Figs. 7-1 (Figure Not Available) , 7-2) (Figure Not Available) . A few years ago, a rudimentary background in pneumatics sufficed, but today, an understanding of pneumatics, electronics, and even computer science is useful. Even though it is difficult for the anesthesiologist to achieve a thorough understanding of modern anesthesia machines, it is essential to the safe practice of anesthesia. The anesthesiologist must be aware of design differences between manufacturers so that appropriate preoperative checks can be performed. The only two major anesthesia machine manufacturers in the United States are Ohmeda and North American Drager.

Anesthesia Machine Standards

Anesthesia machine standards provide guidelines to manufacturers regarding minimum performance, design characteristics, and safety requirements for anesthesia machines. During the past 2 decades, the progression of anesthesia machine standards has been as follows:

1979: American National Standards Institute Z79.8-1979 [3]

1988: American Society for Testing and Materials (ASTM) F1161-88 [4]

1994: ASTM 1161-94 [5]

1998: ASTM F29.01.09 [6]

To comply with the new 1998 ASTM F29.01.09 standard, newly manufactured workstations must have monitors that have the following parameters: continuous breathing system pressure, exhaled tidal volume, ventilatory carbon dioxide (CO_2) concentration, anesthetic vapor concentration, inspired oxygen concentration, oxygen supply pressure, arterial hemoglobin oxygen saturation, arterial blood pressure, and continuous electrocardiogram. These monitors must be

Figure 7-1 (Figure Not Available) Ohmeda CD anesthesia system. *(Courtesy of Ohmeda, A Division of BOC Health Care, Madison, Wisconsin.)*

enabled and functioning automatically when the machine is in use. The anesthesia workstation must have a prioritized alarm system that groups the alarms into three categories: high, medium, and low priority. [6]

Generic Anesthesia Machine

A diagram of a generic two-gas anesthesia machine is shown in Figure 7-3 (Figure Not Available) . Both oxygen and nitrous oxide have two supply sources: a pipeline supply source and a cylinder supply source. The pipeline supply source is the primary gas source for the anesthesia machine. The hospital piping system provides gases to the machine at approximately 50 pounds per square inch gauge (psig), which is the normal working pressure of most machines. The cylinder supply source serves as a back-up if the pipeline fails. The oxygen cylinder source is regulated from 2,200 to approximately 45 psig, and the nitrous oxide cylinder source is regulated from 745 to approximately 45 psig. [7] [8] [9] [10] [11] [12] [13] [14] [15] [16] [17] [18] [19] [20] [21] [22] [23]

A safety device traditionally referred to as the fail-safe valve is located downstream from the nitrous oxide supply source. It serves as an interface between the oxygen and nitrous oxide supply sources. This valve shuts off or proportionally

Figure 7-2 (Figure Not Available) North American Drager Narkomed 4 anesthesia system. *(Courtesy of North American Drager, Telford, Pennsylvania.)*

decreases the supply of nitrous oxide (and other gases) if the oxygen supply pressure decreases. Contemporary machines have an alarm device to monitor the oxygen supply pressure. An alarm is actuated at a predetermined oxygen pressure, such as 30 psig. [7] [8] [18] [23]

Most Ohmeda machines have a second-stage oxygen regulator located downstream from the oxygen supply source. It is adjusted to a precise pressure level, such as 14 psig. [8] [11] [12] [13] [14] [15] [16] [17] This regulator supplies a constant pressure to the oxygen flow control valve, regardless of fluctuating oxygen pipeline pressures. For example, the flow from the oxygen flow control valve is constant if the oxygen supply pressure is greater than 14 psig.

The flow control valves are an important anatomic landmark because they divide the anesthesia machine into two parts. The high-pressure circuit is the part of the machine that is upstream from the flow control valves, and the low-pressure circuit is the part of the machine that is downstream from the flow control valves. The operator regulates flow entering the low-pressure circuit by adjusting the flow control valves. The oxygen and nitrous oxide flow control valves are linked mechanically or pneumatically by a proportioning system to help prevent delivery of a hypoxic mixture. The flow travels through a common manifold and may be directed to a calibrated vaporizer. Precise amounts of inhaled anesthetic can be added, depending on the vaporizer setting.

Figure 7-3 (Figure Not Available) Diagram of a generic two-gas anesthesia machine. *(Modified from Check-Out, A Guide for Preoperative Inspection of an Anesthesia Machine. American Society of Anesthesiologists, Park Ridge, Illinois, 1987.)*

The total fresh gas flow travels toward the common gas outlet. [7] [8]

Many Ohmeda machines have a machine outlet check valve between the vaporizers and the common gas outlet. [8] [9] [10] [11] [12] [13] [14] [15] Its purpose is to prevent backflow into the vaporizer, thereby minimizing the effects of downstream intermittent pressure fluctuations on inhaled anesthetic concentration (see Intermittent Back Pressure). The presence or absence of a check valve profoundly influences the decision regarding the preoperative leak test that is indicated (see Checking Anesthesia Machines). The oxygen flush connection joins the mixed-gas pipeline between the one-way check valve and the machine outlet. Thus, the oxygen flush,

when activated, has a "straight shot" to the common gas outlet. [7] [8]

Pipeline Supply Source

The pipeline supply source is the primary gas source for the anesthesia machine. Most hospitals have a central piping system to deliver medical gases such as oxygen, nitrous oxide, and air to the operating room. The central piping system must supply the anesthesia machine with the appropriate gas at the appropriate pressure for the machine to function properly. Unfortunately, this does not always occur.

In a survey of approximately 200 hospitals in 1976, 31 percent reported difficulties with pipeline systems. [24] The most common problem was inadequate oxygen pressure, followed by excessive pipeline pressures. The most devastating reported hazard, however, was accidental crossing of oxygen and nitrous oxide pipelines, which caused several deaths. This problem caused 23 deaths in a newly constructed wing of a general hospital in Sudbury, Ontario, during a 5-month period. [24] [25]

The operator must take two actions if a pipeline crossover is suspected. First, the back-up oxygen cylinder must be turned on. Then, the pipeline supply must be disconnected. This second step is mandatory because the machine preferentially uses the inappropriate 50-psig pipeline supply source instead of the lower pressure (45-psig) oxygen cylinder source.

Gas enters the anesthesia machine through the pipeline inlet connections (Fig. 7-3 (Figure Not Available) ; see arrows). The pipeline inlet fittings are gas-specific Diameter Index Safety System threaded body fittings. The Diameter Index Safety System provides threaded noninterchangeable connections for medical gas lines, which minimizes the risk of misconnection. A check valve is located downstream from the inlet. It prevents reverse flow of gases from the machine to the pipeline or to the atmosphere. [6]

Cylinder Supply Source

Anesthesia machines have reserve E cylinders if a pipeline supply source is not available or if the pipeline fails. Color-coded cylinders are attached to the anesthesia machine through the hanger yoke assembly. The hanger yoke assembly orients and supports the cylinder, provides a gas-tight seal, and ensures a unidirectional flow of gases into the

machine. [7] Each hanger yoke is equipped with the Pin Index Safety System. The Pin Index Safety System is a safeguard introduced to eliminate cylinder interchanging and the possibility of accidentally placing the incorrect gas on a yoke designed to accommodate another gas. Two pins on the yoke are arranged so that they project into the cylinder valve. Each gas or combination of gases has a specific pin arrangement. [26]

Gas travels from the high-pressure cylinder source to the anesthesia machine when the cylinder is turned on (see Fig. 7-3 (Figure Not Available)). A check valve is located downstream from each cylinder if a double-yoke assembly is used. The check valve has several functions. First, it minimizes gas transfer from a cylinder at high pressure to one with lower pressure. Second, it allows an empty cylinder to be exchanged for a full one while gas flow continues from the other cylinder into the machine with minimal loss of gas. Third, it minimizes leakage from an open cylinder to the atmosphere if one cylinder is absent. [7] [8] A cylinder supply pressure gauge is located downstream from the check valves. The gauge indicates the pressure in the cylinder having the higher pressure when two reserve cylinders of the same gas are opened at the same time. [20]

Each cylinder supply source has a pressure-reducing valve known as the cylinder pressure regulator. It reduces the high and variable storage pressure present in a cylinder to a lower, more constant, pressure suitable for use in the anesthesia machine. The oxygen cylinder pressure regulator reduces the oxygen cylinder pressure from a high of 2,200 psig to approximately 45 psig. The nitrous oxide cylinder pressure regulator receives pressure of up to 745 psig and reduces it to approximately 45 psig. [7] [8]

The cylinders should be turned off except during the preoperative machine checking period or when a pipeline source is unavailable. If left on, the reserve cylinder supply can be silently depleted whenever the pressure inside the machine decreases to a value lower than the regulated cylinder pressure. Oxygen pressure within the machine can decrease below 45 psig with oxygen flushing or with ventilator use, particularly at high peak flow rates. The pipeline supply pressures of all gases can be less than 45 psig if problems exist in the central piping system. If the cylinders are left on, they eventually become depleted. Then, no reserve supply would be available if a pipeline failure occurs. [8] [27]

Oxygen Supply Pressure Failure Safety Devices

Oxygen and nitrous oxide supply sources existed as independent entities in older models of anesthesia machines, and they were not pneumatically or mechanically interfaced. Therefore, abrupt or insidious oxygen pressure failure had the potential to lead to the delivery of a hypoxic mixture. The ASTM F29.01.09-1998 standard states that "The anesthesia gas supply device shall be designed so that whenever oxygen supply pressure is reduced to below the manufacturer-specified minimum, the delivered oxygen concentration shall not decrease below 19 percent at the common gas outlet." [6] Contemporary anesthesia machines have a number of safety devices that act together to minimize the risk of hypoxia as oxygen pressure decreases. Several of these devices are described in the following sections.

Pneumatic and Electronic Alarm Devices

Many older anesthesia machines have a pneumatic alarm device that sounds a warning when the oxygen supply pressure decreases to a predetermined threshold value, such as 30 psig. The ASTM F29.01.09-1998 standard mandates that a medium-priority alarm shall be activated within 5 seconds when the oxygen pressure decreases below a manufacturer-specific pressure threshold. [6] Electronic alarm devices are now used to meet this guideline.

Fail-Safe Valves

A fail-safe valve is present in the gas line supplying each of the flowmeters except that for oxygen. Controlled by oxygen supply pressure, the valve shuts off or proportionally decreases the supply pressure of all other gases (nitrous oxide, air, CO_2 , helium, nitrogen) as the oxygen supply pressure decreases. Unfortunately, the misnomer "fail-safe" has led to the misconception that the device prevents administration of a hypoxic mixture. This is not the case. Machines that are not equipped with a flow proportioning system (see Proportioning Systems) can deliver a hypoxic mixture under normal working conditions. The oxygen flow control valve can be closed intentionally or accidentally. Normal oxygen pressure keeps other gas lines open so that a hypoxic mixture can result. [7] [8]

Ohmeda machines are equipped with a fail-safe valve known as the pressure-sensor shut-off valve (Fig. 7-4) (Figure Not Available) . The valve is threshold in nature, and it is either open or closed. Oxygen supply pressure opens the valve, and the valve return spring closes the valve. Figure 7-4 (Figure Not Available) shows a nitrous oxide pressure-sensor shut-off valve with a threshold pressure of 20 psig. [12] [13] [15] [16] [17] Figure 7-4 (Figure Not Available) A, an oxygen supply pressure greater than 20 psig is exerted on the mobile diaphragm. This pressure moves the piston and pin upward, and the valve opens. Nitrous oxide flows freely to the nitrous oxide flow control valve. In Figure 7-4 (Figure Not Available) B, the oxygen supply pressure is less than 20 psig, and the force of the valve return spring completely closes the valve. [8] Nitrous oxide flow stops at the closed fail-safe valve, and it does not advance to the nitrous oxide flow control valve.

North American Drager uses a fail-safe valve known as the oxygen failure protection device (OFPD) that interfaces the oxygen pressure with that of other gases, such as nitrous oxide, air, CO_2 , helium, and nitrogen. [18] [19] [20] [21] [22] [23] It differs from Ohmeda's oxygen pressure-sensor shut-off valve because the OFPD is based on a proportioning principle rather than a threshold principle. The pressures of all gases controlled by the OFPD decrease proportionally with the oxygen pressure. The OFPD consists of a seat-nozzle assembly connected to a spring-loaded piston (Fig. 7-5) (Figure Not Available) . The oxygen supply pressure in the left panel is 50 psig. This pressure pushes the piston upward, forcing the nozzle away from the valve seat. Nitrous oxide (or other gases) advance toward

Figure 7-4 (Figure Not Available) Pressure-sensor shut-off valve. The valve is open in A because the oxygen supply pressure is greater than the threshold value of 20 psig. The valve is closed in B because of inadequate oxygen pressure. *(Modified from Bowie and Huffman [6])*

the flow control valve at 50 psig. The oxygen pressure in the right panel is zero psig. The spring is expanded and forces the nozzle against the seat, preventing flow through the device. Finally, the center panel shows an intermediate oxygen pressure of 25 psig. The force of the spring partially closes the valve. The nitrous oxide pressure delivered to the flow control valve is 25 psig. There is a continuum of intermediate configurations between the extremes (0-50 psig) of oxygen supply pressure. These intermediate valve configurations are responsible for the proportional nature of the OFPD. [18]

Second-Stage Oxygen Pressure Regulator

Most contemporary Ohmeda machines have a second-stage oxygen pressure regulator set at a specific value ranging from 12 to 19 psig. [12] [13] [14] [15] [16] [17] Oxygen flowmeter output is constant when the oxygen supply pressure exceeds the set value. Ohmeda pressure-sensor shut-off valves are set at a higher threshold value (20-30 psig). This ensures that oxygen is the last gas flow to decrease if oxygen pressure fails.

Flowmeter Assembly

The flowmeter assembly (Fig. 7-6) (Figure Not Available) precisely controls and measures gas flow to the common gas outlet. The flow control valve regulates the amount of flow that enters a tapered, transparent flowtube known as a Thorpe tube. A mobile indicator float inside the flowtube indicates the amount of flow passing through the flow control valve. The quantity of flow is indicated on a scale associated with the flowtube. [7] [8]

Physical Principles of Flowmeters

Opening the flow control valve allows gas to travel through the space between the float and the flowtube. This space is known as the annular space (Fig. 7-7) (Figure Not Available) . The indicator float hovers freely in an equilibrium position where the upward force resulting from gas flow equals the downward force on the float resulting from gravity at a given flow rate. The float moves to a new equilibrium position in the tube when flow is changed. These flowmeters are commonly referred to as *constant pressure* flowmeters because the pressure

Figure 7-5 (Figure Not Available) Oxygen failure protection device, which responds proportionally to changes in oxygen supply pressure (see text for details). *(Modified from Narkomed 2A Anesthesia System [18])*

Figure 7-6 (Figure Not Available) Oxygen flowmeter assembly. The oxygen flowmeter assembly is composed of the flow control valve assembly plus the flowmeter subassembly. *(Modified from Bowie and Huffman [6])*

decrease across the float remains constant for all positions in the tube. [7] [26] [28]

Flowtubes are tapered, with the smallest diameter at the bottom of the tube and the largest diameter at the top. The term *variable orifice* designates this type of unit because the annular space between the float and the inner wall of the flowtube varies with the position of the float. Flow through the constriction created by the float can be laminar or turbulent, depending on the flow rate (Fig. 7-8) (Figure Not Available) . The characteristics

Figure 7-7 (Figure Not Available) The annular space. The clearance between the head of the float and the flowtube is known as the annular space. It can be considered an equivalent to a circular channel of the same cross-sectional area. *(Modified from Macintosh et al [26])*

of a gas that influence its flow rate through a given constriction are viscosity (laminar flow) and density (turbulent flow). Because the annular space is tubular at low flow rates, laminar flow is present, and *viscosity* determines the gas flow rate. The annular space simulates an orifice at high flow rates, and turbulent gas flow then depends predominantly on the *density* of the gas. [7] [28]

Components of Flowmeter Assembly

Flow Control Valve Assembly.

The flow control valve assembly (see Fig. 7-6 (Figure Not Available)) is composed of a flow control knob, a needle valve, a valve seat, and a pair of valve stops. [7] The assembly can receive its pneumatic input either directly from the pipeline source (50 psig) or from a second-stage pressure regulator. The location of the needle valve in the valve seat changes to establish different orifices when the flow control valve is adjusted. Gas flow increases when the flow control valve is turned counterclockwise, and it decreases when the valve is turned clockwise. Extreme clockwise rotation results in damage to the needle valve and

Figure 7-8 (Figure Not Available) Flowtube constriction. The lower pair of illustrations represents the lower portion of a flowtube. The clearance between the head of the float and the flowtube is narrow. The equivalent channel is tubular because its diameter is less than its length. Viscosity is dominant in determining gas flow rate through this tubular constriction. The upper pair of illustrations represents the upper portion of a flowtube. The equivalent channel is orificial because its length is less than its width. Density is dominant in determining gas flow rate through this orificial constriction. *(Modified from Macintosh et al [26])*

---

the valve seat. Therefore, flow control valves are equipped with valve "stops" to prevent this occurrence. [8]

Safety Features.

Contemporary flow control valve assemblies have numerous safety features. The oxygen flow control knob is physically distinguishable from other gas knobs. It is distinctively fluted, projects beyond the control knobs of the other gases, and is larger in diameter than the flow control knobs of other gases. All knobs are color coded for the appropriate gas, and the chemical formula or the name of the gas is permanently marked on each. Flow control knobs are recessed or protected with a shield or barrier to minimize inadvertent change from a preset position. If a single gas has two flowtubes, the tubes are arranged in series and are controlled by a single flow control valve. [6]

Flowmeter Subassembly.

The flowmeter subassembly (see Fig. 7-6 (Figure Not Available)) consists of the flowtube, the indicator float with float stops, and the indicator scale. [7]

Flowtubes.

Contemporary flowtubes are made of glass. Most have a single taper in which the inner diameter of the flowtube increases uniformly from bottom to top. Manufacturers provide double flowtubes for oxygen and nitrous oxide to provide better visual discrimination at low flow rates. A fine flowtube indicates flow from approximately 200 mL/min to 1 L/min, and a coarse flowtube indicates flow from approximately 1 L/min to 10 to 12 L/min. The two tubes are connected in series and

are supplied by a single flow control valve. The total gas flow is that shown on the higher flowmeter.

Indicator Floats and Float Stops.

Contemporary anesthesia machines use several different types of bobbins or floats, including plumb-bob floats, [11] [12] [13] [16] [17] rotating skirted floats, [14] [15] and ball floats. [18] [19] [20] [21] [22] Flow is read at the top of plumb-bob and skirted floats and at the center of the ball on the ball-type floats. [7] Flowtubes are equipped with float stops at the top and bottom of the tube. The upper stop prevents the float from ascending to the top of the tube and plugging the outlet. It also ensures that the float will be visible at maximum flows instead of being hidden in the manifold. The bottom float stop provides a central foundation for the indicator when the flow control valve is turned off. [7] [8]

Scale.

The flowmeter scale can be marked directly on the flowtube or located to the right of the tube. [6] Gradations corresponding to equal increments in flow rate are closer together at the top of the scale because the annular space increases more rapidly than does the internal diameter from bottom to top of the tube. Rib guides are used in some flowtubes with ball-type indicators to minimize this compression effect. They are tapered glass ridges that run the length of the tube. There are usually three rib guides that are equally spaced around the inner circumference of the tube. In the presence of rib guides, the annular space from the bottom to the top of the tube increases almost proportionally with the internal diameter. This results in a nearly linear scale. [7] Rib guides are employed on North American Drager flowtubes. [18] [19] [20] [22]

Safety Features.

The flowmeter subassembly for each gas on the Ohmeda Modulus I, Modulus II, Modulus II Plus, and CD is housed in an independent, color-coded, pin-specific module. The flowtubes are adjacent to a gas-specific, color-coded backing. The flow scale and the chemical formula or the name of the gas is permanently etched on the backing to the right of the flowtube. [11] [12] [13] [16] [17] Flowmeter scales are individually hand calibrated by use of the specific float to provide a high degree of accuracy. The tube, float, and scale make an inseparable unit. The entire set must be replaced if any component is damaged. [11] [12] [13] [16] [17]

North American Drager does not use a modular system for the flowmeter subassembly. The flow scale, the chemical symbol, and the gas-specific color codes are etched directly onto the flowtube. [18] [19] [20] [21] [22] The scale in use is obvious when two flowtubes for the same gas are used.

Problems with Flowmeters

Leaks.

Flowmeter leaks are a substantial hazard because the flowmeters are located downstream from all machine safety devices except the oxygen analyzer. [1] Leaks can occur at the O-rings between the glass flowtube and the metal manifold and in the glass flowtubes, the most fragile pneumatic component of the anesthesia machine. Gross damage to glass flowtubes is usually apparent, but subtle cracks and chips may be overlooked, resulting in errors of delivered flows. [29]

In 1963, Eger et al [30] demonstrated that in the presence of a flowmeter leak, a hypoxic mixture is less likely to occur if the oxygen flowmeter is located downstream from all other flowmeters. Figure 7-9 (Figure Not Available) is a contemporary version of the figure in Eger's original publication. The unused air flowtube has a large leak. Nitrous oxide and oxygen flow rates are set at a ratio of 3:1. A potentially dangerous arrangement is shown in Figures 7-9 (Figure Not Available) A and B because the nitrous oxide flowmeter is located in the downstream position. A hypoxic mixture can result because a substantial portion of oxygen flow passes through the leak, and all nitrous oxide is directed to the common gas outlet. A safer configuration that complies with the ASTM F29.01.09-1998 machine standard [6] is shown in Figures 7-9 (Figure Not Available) C and D. The oxygen flowmeter is located in the downstream position. A portion of the nitrous oxide flow escapes through the leak, and the remainder goes toward the common gas outlet. A hypoxic mixture is less likely because all the oxygen flow is advanced by the nitrous oxide. [30] North American Drager flowmeters are arranged as in Figure 7-9 (Figure Not Available) . C, and Ohmeda flowmeters are as in Figure 7-9 (Figure Not Available) D.

A leak in the oxygen flowtube can produce a hypoxic mixture even when oxygen is located in the downstream position (Fig. 7-10) . [1] [29] Oxygen escapes through the leak, and nitrous oxide flows toward the common outlet, particularly at high ratios of nitrous oxide to oxygen flow.

Inaccuracy.

Flow error can occur even when flowmeters are assembled properly with appropriate components. Dirt or static electricity can cause a float to stick, and the actual flow may be higher or lower than that indicated. Sticking

---

Figure 7-9 (Figure Not Available) Flowmeter sequence--a potential cause of hypoxia. In the event of a flowmeter leak, a potentially dangerous arrangement exists when nitrous oxide is located in the downstream position (A and B). The safest configuration exists when oxygen is located in the downstream position (C and D) (see text for details). *(Modified from Eger et al [30])*

is more common in the low flow range because the annular space is smaller. A damaged float can cause inaccurate readings because the precise relationship between the float and the flowtube is altered. Back pressure from the breathing circuit can cause a float to drop so that it reads less than the actual flow. Finally, if flowmeters are not aligned properly in the vertical position, readings can be inaccurate because tilting distorts the annular space. [7] [29] [31]

Ambiguous Scale.

Before the standardization of flowmeter scales and the widespread use of oxygen analyzers, at least two deaths resulted from confusion created by ambiguous scales. [29] [31] [32] The operator read the float position beside an adjacent but erroneous scale in both cases. Today, this error is less likely to occur because contemporary flowmeter scales are marked either directly onto, or to the right of, the appropriate flowtube. [6] Confusion is minimized when the scale is etched directly onto the tube.

Proportioning Systems

Manufacturers have equipped newer machines with proportioning systems in an attempt to prevent delivery of a hypoxic mixture. Nitrous oxide and oxygen are interfaced either mechanically or pneumatically so that the minimum oxygen concentration at the common outlet is 25 percent.

Figure 7-10 Oxygen flowtube leak. An oxygen flowtube leak can produce a hypoxic mixture regardless of the flowtube arrangement.

Ohmeda Link-25 Proportion Limiting Control System

Contemporary Ohmeda machines use the Link-25 System. The heart of the system is the mechanical integration of the nitrous oxide and oxygen flow control valves. It allows independent adjustment of either valve, yet automatically intercedes to maintain a minimum 25 percent oxygen concentration with a maximum nitrous oxide-oxygen flow ratio of 3:1. The Link-25 automatically increases oxygen flow to prevent delivery of a hypoxic mixture. [11] [12] [13] [14] [15] [16] [17]

Figure 7-11 (Figure Not Available) shows the Ohmeda Modulus II Link-25 System. The nitrous oxide and oxygen flow control valves are identical. A 14-tooth sprocket

is attached to the nitrous oxide flow control valve, and a 28-tooth sprocket is attached to the oxygen flow control valve. A chain physically links the sprockets. When the nitrous oxide flow control valve is turned through two revolutions, or 28 teeth, the oxygen flow control valve revolves once because of the 2:1 gear ratio. The final 3:1 flow ratio results because the nitrous oxide flow control valve is supplied by approximately 26 psig, whereas the oxygen flow control valve is supplied by 14 psig. Thus, the combination of the mechanical and pneumatic aspects of the system yields the final oxygen concentration. [12] [13]

Figure 7-11 (Figure Not Available) Ohmeda Link-25 proportion limiting control system (see text for details). *(Modified from Andrews JJ: Delivery systems for inhaled anesthetics. In Barash PG, Cullen BF, Stoelting RK [eds]: Clinical Anesthesia, 3rd ed. Philadelphia, New York, Lippincott-Raven, 1997, pp 535-572.)*

North American Dr a ger Oxygen Ratio Monitor Controller

North American Drager's proportioning system, the oxygen ratio monitor controller (ORMC), is used on the North American Drager Narkomed 2A, 2B, 3, and 4. [18] [19] [20] [21] [22] [23] It is a pneumatic oxygen-nitrous oxide interlock system designed to maintain a fresh gas oxygen concentration of at least 25 ± 3 percent. The device controls the fresh gas oxygen concentration to levels substantially higher than 25 percent at oxygen flow rates of less than 1 L/min. The ORMC limits nitrous oxide flow to prevent delivery of a hypoxic mixture. [18] [19] [20] [21] [22] This is unlike the Ohmeda Link-25, which actively increases oxygen flow.

A schematic of the ORMC is shown in Figure 7-12 (Figure Not Available) . It is composed of an oxygen chamber, a nitrous oxide chamber, and a nitrous oxide slave control valve; all are interconnected by a mobile horizontal shaft. The pneumatic input into the device is from the oxygen and the nitrous oxide flowmeters. These flowmeters are unique because they have specific resistors located downstream from the flow control valves. These resistors create back pressures directed to the oxygen and nitrous oxide chambers. The value of the oxygen flowtube resistor is three to four times that of the nitrous oxide flowtube resistor, and the relative value of these resistors determines the value of the controlled fresh gas oxygen concentration. The back pressure in the oxygen and nitrous oxide chambers pushes against rubber diaphragms attached to the mobile horizontal shaft. Movement of the shaft regulates the nitrous oxide slave control valve, which feeds the nitrous oxide flow control valve. [1] [19] [23]

If the oxygen pressure is proportionally higher than the nitrous oxide pressure, the nitrous oxide slave control valve opens more widely, allowing more nitrous oxide to flow. As the nitrous oxide flow is increased manually, the nitrous oxide pressure forces the shaft toward the oxygen chamber. The valve opening becomes more restrictive and limits the nitrous oxide flow to the flowmeter.

Figure 7-12 (Figure Not Available) illustrates the action of a single ORMC under different sets of circumstances. The back pressure exerted on the oxygen diaphragm, in the upper configuration, is greater than that exerted on the nitrous oxide diaphragm. This causes the horizontal shaft to move to the left, opening the nitrous oxide slave control valve. Nitrous oxide is then able to proceed to its flow control valve and out through the flowmeter. In the bottom configuration, the nitrous oxide slave control valve is closed because of inadequate oxygen back pressure. [1] [18] [23]

Limitations

Proportioning systems are not foolproof. Machines equipped with proportioning systems can still deliver a hypoxic mixture under the following conditions.

Wrong Supply Gas.

Both the Link-25 and the ORMC are fooled if a gas other than oxygen is present in the oxygen pipeline. In the Link-25 System, the nitrous oxide and oxygen flow control valves continue to be mechanically linked, and a hypoxic mixture proceeds to the common outlet. The oxygen rubber diaphragm of the ORMC recognizes adequate

Figure 7-12 (Figure Not Available) North American Drager oxygen ratio monitor controller (see text for details). *(Modified from Schreiber P: Safety Guidelines for Anesthesia Systems. Telford, Pennsylvania, North American Drager, 1984.)*

"oxygen" pressure, and flow of both the wrong gas plus nitrous oxide results. The oxygen analyzer is the only machine monitor that detects this condition in both systems.

Defective Pneumatics or Mechanics.

Normal operation of the Ohmeda Link-25 and the North American Drager ORMC is contingent on pneumatic and mechanical integrity. [33] Pneumatic integrity in the Ohmeda System depends on properly functioning second-stage regulators. A nitrous oxide-oxygen ratio other than 3:1 results if the regulators are not precise. The chain connecting the two sprockets must be intact. A 97-percent nitrous oxide concentration can occur if the chain is cut or broken. [34] In the North American Drager System, a functional OFPD is necessary to supply appropriate pressure to the ORMC. The mechanical aspects of the ORMC, such as the rubber diaphragms, the flowtube resistors, and the nitrous oxide slave control valve, must likewise be intact.

Leaks Downstream.

The ORMC and the Link-25 function at the level of the flow control valves. A leak down-stream from these devices, such as from a broken oxygen flowtube (see Fig. 7-10), can cause delivery of a hypoxic mixture. Oxygen escapes through the leak, and the predominant gas delivered at the common outlet is nitrous oxide. The oxygen analyzer is the only machine safety device that can detect the problem. [1] North American Drager recommends a preoperative positive-pressure leak test to detect such a leak. [18] [19] [20] [21] [22] Ohmeda recommends a preoperative negative-pressure leak test because of the check valve located at the common outlet (see Checking Anesthesia Machines). [9] [10] [11] [12] [13] [15]

Inert Gas Administration.

Administration of a third inert gas, such as helium, nitrogen, and CO_2 , can cause a hypoxic mixture because contemporary proportioning systems link only nitrous oxide and oxygen. [11] [12] [13] [14] [15] [16] [17] [18] [19] [20] [21] [22] [35] Use of an oxygen analyzer is mandatory if the operator uses a third inert gas.

Oxygen Flush Valve

The oxygen flush valve allows direct communication between the oxygen high-pressure circuit and the low-pressure circuit (see Fig. 7-3 (Figure Not Available)). Flow from the oxygen flush valve enters the low-pressure circuit downstream from the vaporizers and downstream from the Ohmeda machine outlet check valve. The spring-loaded valve stays closed until the operator opens it by depressing the oxygen flush button. Actuation of the valve delivers 35 to 75 L/min to the breathing circuit. [8]

The oxygen flush valve can provide effective jet ventilation if the anesthesia machine is equipped with a one-way check valve positioned between the vaporizer and the oxygen flush valve. Because the Ohmeda Modulus II has such a valve, the entire oxygen flow of 45 to 75 L/min is delivered to the common gas outlet at a high pressure of 50 psig. On the other hand, the Ohmeda Modulus II Plus, which does not have the check valve, provides only 7 psig at the common gas outlet because some oxygen flow travels retrograde through an internal relief valve located upstream from the oxygen flush valve. The North American Drager Narkomed 2A, which also does not have the check valve, provides an intermediate pressure of 18 psig to the common gas outlet because some oxygen flow travels retrograde through a pop-off valve located in the vaporizers. [36]

The oxygen flush valve is associated with several hazards. A defective or damaged valve can stick in the fully open position, causing barotrauma. [37] A valve sticking

in a partially open position can result in patient awareness because the oxygen flow from the incompetent valve dilutes the inhaled anesthetic. [38] Improper use of normally functioning oxygen flush valves also can result in problems. Overzealous intraoperative oxygen flushing can dilute inhaled anesthetics. Oxygen flushing during the inspiratory phase of positive-pressure ventilation can cause barotrauma. Excess volume cannot be vented from the breathing circuit because the ventilator relief valve is closed and the adjustable pressure-limiting (APL) valve is either out of circuit or closed. [39] If a machine is equipped with a freestanding vaporizer downstream from the common gas outlet, oxygen flushing can deliver large quantities of inhaled anesthetic to the patient. Finally, inappropriate preoperative use of the oxygen flush to evaluate the low-pressure circuit for leaks can be misleading, particularly on Ohmeda machines with a check valve at the common outlet. [40] Back pressure from the breathing circuit closes the check valve airtight, and major low-pressure circuit leaks can go undetected (see Checking Anesthesia Machines).

VAPORIZERS

Through the years, vaporizers have evolved from rudimentary ether inhalers to copper kettles to the present temperature-compensated, variable-bypass vaporizers. With the introduction of the new inhaled anesthetic desflurane, an even more sophisticated, electrically heated, pressurized, electronically controlled vaporizer has been introduced. Before variable-bypass vaporizers and the new Tec 6 desflurane vaporizer are discussed, certain physical principles are reviewed briefly to facilitate understanding of the operating principles, construction, and design of contemporary vaporizers.

Physics

Vapor Pressure

Contemporary inhaled volatile anesthetics exist in the liquid state below 20°C. When a volatile liquid is in a closed container, molecules escape from the liquid phase to the vapor phase until the number of molecules in the vapor phase is constant. These molecules bombard the wall of the container and create a pressure known as the saturated vapor pressure. As the temperature increases, more molecules enter the vapor phase, and the vapor pressure increases (Fig. 7-13) (Figure Not Available) . Vapor pressure is independent of atmospheric pressure and is contingent only on the temperature and the physical characteristics of the liquid. The boiling point of a liquid is that temperature at which the vapor pressure equals atmospheric pressure. [41] [42] [43] At 760 mm Hg, the boiling points for desflurane, isoflurane, halothane, enflurane,

Figure 7-13 (Figure Not Available) Vapor pressure versus temperature curves for desflurane, isoflurane, halothane, enflurane, and sevoflurane. The vapor pressure curve for desflurane is both steeper and shifted to higher vapor pressures when compared with the curves for other contemporary inhaled anesthetics. *(From inhaled anesthetic package insert equations and from Susay et al [74])*

and sevoflurane are approximately 22.8, 48.5, 50.2, 56.5, and 58.5°C, respectively. Unlike other contemporary inhaled anesthetics, desflurane boils at temperatures commonly encountered in clinical settings, such as pediatric and burn operating rooms. This unique physical characteristic mandates a special vaporizer design for the delivery of desflurane.

Latent Heat of Vaporization

Energy must be expended to convert a molecule from the liquid to the gaseous state because the molecules of a liquid tend to cohere. The latent heat of vaporization is defined as the number of calories required to change 1 g of liquid into vapor without a temperature change. The energy for vaporization must come from the liquid itself or from an outside source. The temperature of the liquid decreases during vaporization in the absence of an outside energy source. Energy loss can lead to significant decreases in temperature of the remaining liquid. This temperature drop greatly decreases vaporization. [41] [43] [44]

Specific Heat

The specific heat of a substance is the number of calories required to increase the temperature of 1 g of a substance by 1°C. [41] [43] [44] The substance can be solid, liquid, or gas. The concept of specific heat is important to the design, operation, and construction of vaporizers because it is applicable in two ways. First, the specific heat value for an inhaled anesthetic is important because it indicates how much heat must be supplied to the liquid to maintain a constant temperature when heat is lost during vaporization. Second, manufacturers select vaporizer metals that have a high specific heat to minimize temperature changes associated with vaporization.

Thermal Conductivity

Thermal conductivity is a measure of the speed with which heat flows through a substance. The higher the thermal conductivity, the better the substance conducts heat. [41] Vaporizers are constructed of metals that have relatively high thermal conductivity, a characteristic that helps maintain a uniform temperature.

Variable-Bypass Vaporizers

The Ohmeda Tec 4, the Ohmeda Tec 5, and the North American Drager Vapor 19.1 are classified as variable-bypass, flowover, temperature-compensated, agent-specific,

out-of-circuit vaporizers. [41] *Variable-bypass* refers to the method for regulating output concentration. As gas flow enters the vaporizer's inlet, the setting of the concentration control dial determines the ratio of flow that goes through the bypass chamber and through the vaporizing chamber. The gas channeled to the vaporizing chamber flows over the liquid anesthetic and becomes saturated with vapor. Thus, *flowover* refers to the method of vaporization. The Tec 4, the Tec 5, and the Vapor 19.1 are classified as *temperature-compensated* because they are equipped with an automatic temperature-compensating device that helps maintain a constant vaporizer output over a wide range of temperatures. These vaporizers are *agent specific* and *out of circuit* because they are designed to accommodate a single agent and to be located outside the breathing circuit. Variablebypass vaporizers are used to deliver halothane, enflurane, isoflurane, and sevoflurane, but not desflurane (see Electrically Heated, Pressurized Vaporizers).

Basic Operating Principles

A diagram of a generic, variable-bypass vaporizer is shown in Figure 7-14 (Figure Not Available) . Vaporizer components include the concentration control dial, the bypass chamber, the vaporizing chamber, the filler port, and the filler cap. Using the filler port, the operator fills the vaporizing chamber with liquid anesthetic. The maximum safe level is predetermined by the position of the filler port, which is positioned to minimize the chance of overfilling. If a vaporizer is overfilled or tilted, liquid anesthetic can spill into the bypass chamber, causing an overdose. The concentration control dial is a variable restrictor, and it can be located either in the bypass chamber or in the outlet of the vaporizing chamber. The function of the concentration control dial is to regulate the relative flow rates through the bypass and vaporizing chambers.

Flow from the flowmeters enters the inlet of the vaporizer. More than 80 percent of the flow passes straight through the bypass chamber to the vaporizer outlet, and

this accounts for the name "bypass chamber." Less than 20 percent of the flow from the flowmeters is diverted through the vaporizing chamber. Depending on the temperature and the vapor pressure of the particular inhaled anesthetic, the flow through the vaporizing chamber entrains a specific flow of inhaled anesthetic. All three flows, that is, flow through the bypass chamber, flow through the vaporizing chamber, and flow of entrained anesthetic, exit the vaporizer at the outlet. The final concentration of inhaled anesthetic is the ratio of the flow of the inhaled anesthetic to the total gas flow. [41] [46]

The vapor pressure of an inhaled anesthetic depends on the ambient temperature (see Fig. 7-13 (Figure Not Available) .). For example, at 20°C, the vapor pressure of isoflurane is 238 mm Hg, whereas at 35°C, the vapor pressure almost doubles (450 mm Hg). Variable-bypass vaporizers have an internal mechanism to compensate for different ambient temperatures. The temperature-compensating valve of the Ohmeda Tec 4 is shown in Figure 7-15 (Figure Not Available) [47] At high temperatures, such as those commonly used in pediatric or burn operating rooms, the vapor pressure inside the vaporizing chamber is high. To compensate for this increased vapor pressure, the bimetallic strip of the temperature-compensating valve leans to the right. This allows more flow to pass through the bypass chamber and less flow to pass through the vaporizing chamber. The net effect is a constant vaporizer output. In a cold operating room environment, the vapor pressure inside the vaporizing chamber decreases. To compensate for this decrease in vapor pressure, the bimetallic strip swings to the left, causing more flow to pass through the vaporizing chamber and less to pass through the bypass chamber. The net effect is a constant vaporizer output.

Factors That Influence Vaporizer Output

The output of an ideal vaporizer with a fixed dial setting would be constant, regardless of varied flow rates, temperatures, back pressures, and carrier gases. Designing such a

Figure 7-14 (Figure Not Available) Generic variable bypass vaporizer (see text for details). *(Modified from Andrews JJ: Delivery systems for inhaled anesthetics. In Barash PG, Cullen BF, Stoelting RK [eds]: Clinical Anesthesia, 3rd ed. Philadelphia, New York, Lippincott-Raven, 1997, pp 535-572.)*

Figure 7-15 (Figure Not Available) Simplified schematic of the Ohmeda Tec 4 vaporizer (see text for details). *(Modified from Andrews JJ: Delivery systems for inhaled anesthetics. In Barash PG, Cullen BF, Stoelting RK [eds]: Clinical Anesthesia, 3rd ed. Philadelphia, New York, Lippincott-Raven, 1997, pp 535-572.)*

vaporizer is difficult because as ambient conditions change, the physical properties of gases and of vaporizers themselves can change. [46] Contemporary vaporizers approach ideal but still have some limitations. Several factors listed below can influence vaporizer output.

Flow Rate.

With a fixed dial setting, vaporizer output varies with the rate of gas flowing through the vaporizer. This variation is particularly notable at extremes of flow rates. The output of all variable-bypass vaporizers is less than the dial setting at low flow rates (<250 mL/min). This results from the relatively high density of volatile inhaled anesthetics. The turbulence generated at low flow rates in the vaporizing chamber is insufficient to upwardly advance the vapor molecules. At extremely high flow rates, such as 15 L/min, the output of most variable-bypass vaporizers is less than the dial setting. This discrepancy is attributed to incomplete mixing and saturation in the vaporizing chamber. Also, the resistance characteristics of the bypass chamber and the vaporizing chamber can vary as flow increases. These changes can result in decreased output concentration. [46]

Temperature.

Because of improvements in design, the output of contemporary temperature-compensated vaporizers is almost linear over a wide range of temperatures. Automatic temperature-compensating mechanisms in bypass chambers maintain a constant vaporizer output with varying temperatures. [8] [47] [48] A bimetallic strip (see Fig. 7-15 (Figure Not Available)) or an expansion element (Fig. 7-16) (Figure Not Available) directs a greater proportion of gas flow through the bypass chamber as temperature increases. [46] Wicks are placed in direct contact with the metal wall of the vaporizer to help replace heat used for vaporization. Vaporizers are constructed with metals having relatively

Figure 7-16 (Figure Not Available) Simplified schematic of the North American Drager Vapor 19.1 vaporizer (see text for details). *(Modified from Andrews JJ: Delivery systems for inhaled anesthetics. In Barash PG, Cullen BF, Stoelting RK [eds]: Clinical Anesthesia, 3rd ed. Philadelphia, New York, Lippincott-Raven, 1997, pp 535-572.)*

high specific heat and high thermal conductivity in order to minimize heat loss.

Intermittent Back Pressure.

Intermittent back pressure associated with positive-pressure ventilation or with oxygen flushing can cause higher vaporizer output concentration than the dialed setting. This phenomenon, known as the pumping effect, [41] [46] [49] [50] [51] is more pronounced at low flow rates, low dial settings, and low levels of liquid anesthetic in the vaporizing chamber. Additionally, the pumping effect is increased by rapid respiratory rates, high peak inspired pressures, and rapid drops in pressure during expiration. [47] [48] [49] [50] [51] The Ohmeda Tec 4 and the North American Drager Vapor 19.1 are relatively immune from the pumping effect. [47] [48] One proposed mechanism for the pumping effect is dependent on retrograde pressure transmission from the patient circuit to the vaporizer during the inspiratory phase of positive-pressure ventilation. Gas molecules are compressed in both the bypass and the vaporizing chambers. When the back pressure is suddenly released during the expiratory phase of positive-pressure ventilation, vapor exits the vaporizing chamber via the vaporizing chamber outlet and retrograde through the vaporizing chamber inlet. This occurs because the output resistance of the bypass chamber is lower than that of the vaporizing chamber, particularly at low dial settings. The enhanced output concentration results from the increment of vapor that travels in the retrograde direction to the bypass chamber. [46] [49] [50] [51]

To decrease the pumping effect, the vaporizing chambers of the Tec 4 and the Vapor 19.1 are smaller than those of older variable-bypass vaporizers, such as the Fluotec Mark II (750 mL). [47] [48] [50] Therefore, no substantial volumes of vapor can be discharged from the vaporizing chamber into the bypass chamber during the expiratory phase. The North American Drager Vapor 19.1 (see Fig. 7-16 (Figure Not Available)) has a patented long spiral tube that serves as the inlet to the vaporizing chamber. [48] [50] When the pressure in the vaporizing chamber is released, some of the vapor enters this tube but does not enter the bypass chamber because of tube length. [50] The Tec 4 (see Fig. 7-15 (Figure Not Available)) has an extensive baffle system in the vaporizing chamber, and a one-way check valve has been inserted at the common outlet to minimize the pumping effect. This check valve attenuates but does not eliminate the pressure increase, because gas still flows from the flowmeters to the vaporizer during the inspiratory phase of positive-pressure ventilation. [41] [52]

Carrier Gas Composition.

Vaporizer output is influenced by the composition of the carrier gas that flows through the vaporizer. [47] [48] [53] [54] [55] [56] [57] [58] [59] [60] When the carrier gas is quickly switched from 100 percent oxygen to 100 percent nitrous oxide, there is a rapid transient decrease in vaporizer output followed by a slow increase to a new steady-state value (Fig. 7-17 (Figure Not Available) .B) [58] [59] The transient decrease in vaporizer output is attributed to nitrous oxide's being more soluble than oxygen in halogenated liquid. [58] Therefore, the quantity of gas leaving the vaporizing chamber is transiently diminished until the anesthetic liquid is totally saturated with nitrous oxide.

The explanation for the new steady-state output value is less well understood. [60] With contemporary vaporizers, such as the North American Drager Vapor 19.1 and the Ohmeda Tec 4, the steady-state output value is less when nitrous oxide rather than oxygen is the carrier gas (Fig. 7-17 (Figure Not Available) .B) [47] [48] Conversely,

Figure 7-17 (Figure Not Available) Halothane output of a North American Drager Vapor 19.1 vaporizer with different carrier gases. The initial output concentration is approximately 4% halothane when oxygen is the carrier gas at flows of 6 $L \cdot min^{-1}$ (A). When the carrier gas is quickly switched to 100% nitrous oxide (B), the halothane concentration decreases to 3% within 8-10 seconds. Then, a new

steady-state concentration of approximately 3.5% is attained within 1 minute (see text for details). *(Modified from Gould et al [55])*

the output of some older vaporizers is enhanced when nitrous oxide is the carrier gas instead of oxygen. [53] [55] The steady-state plateau is achieved more rapidly with increased flow rates, regardless of the ultimate output value. [59] Factors that contribute to the characteristic steady-state response resulting when various carrier gases are used include the viscosity and density of the carrier gas, the relative solubilities of the carrier gas in the liquid anesthetic, the flow splitting characteristics of the specific vaporizer, and the dial setting. [55] [58] [59] [60]

Safety Features

The North American Drager 19.1, the Ohmeda Tec 4, and the Ohmeda Tec 5 have many safety features that have minimized or eliminated many hazards that were once associated with variable-bypass vaporizers. Agent-specific, keyed filling devices help prevent a vaporizer from being filled with the wrong agent. Overfilling of these vaporizers is minimized because the filler port is located at the maximum safe liquid level. Today's vaporizers are firmly secured to the vaporizer manifold, and there is little need to move them. Thus, problems associated with tipping are minimized. Contemporary interlock systems prevent administration of more than one inhaled anesthetic. [47] [48] [61]

Hazards

Despite many safety features, some hazards are still associated with contemporary variable-bypass vaporizers.

Misfilling.

Vaporizers not equipped with keyed fillers have been occasionally misfilled with the wrong anesthetic liquid. [62] A potential for misfilling exists even on contemporary vaporizers equipped with keyed fillers. [63] [64]

Contamination.

Contamination of anesthetic vaporizer contents occurred when an isoflurane vaporizer was filled with a contaminated bottle of isoflurane. A potentially serious incident was avoided because the operator did not use the contaminated vaporizer after detecting an abnormal acrid odor. [65]

Tipping.

Tipping can occur when vaporizers are incorrectly "switched out" or moved. However, tipping is unlikely when a vaporizer is attached to a manifold in the upright position. Excessive tipping can cause the liquid agent to enter the bypass chamber and can cause a high output concentration. [66] The Tec 4 is slightly more immune to tipping than the Vapor 19.1 because of its extensive baffle system. However, if either vaporizer is tipped, it should not be used until it has been flushed for 20 to 30 minutes at high flow rates with the vaporizer set at a low concentration. [41]

Overfilling.

Improper filling procedures combined with failure of the vaporizer sight glass can cause overfilling and overdose. Liquid anesthetic enters the bypass chamber, and up to 10 times the intended vapor concentration can be delivered. [67]

Simultaneous Inhaled Anesthetic Administration.

Two inhaled anesthetics can be administered simultaneously when the center Tec 4 vaporizer is removed from Ohmeda machines equipped with the older style Selectatec vaporizer manifold. The left or right vaporizer should be moved to the central position if the central vaporizer is removed as indicated by the manifold label. The interlock system then functions properly because the two remaining vaporizers are adjacent. [12] [13] [14]

Leaks.

Leaks occur often with vaporizers, and vaporizer leaks can cause patient awareness. [41] [68] [69] A loose filler cap is the most common source of vaporizer leaks. Leaks can occur at the O-ring junction between the vaporizer and its manifold. A vaporizer must be in the on position to detect a leak within it. Vaporizer leaks in the North American Drager System can be detected with a conventional positive-pressure leak test because of the absence of check valves. Ohmeda recommends using a negative-pressure leak testing device (suction bulb) to detect vaporizer leaks in the Modulus I, Modulus II, and Excel models because of the check valve at the machine outlet [11] [12] [13] [15] (see Checking Anesthesia Machines).

Electrically Heated, Pressurized Vaporizers

Controlled vaporization of desflurane requires an electrically heated, pressurized vaporizer because of desflurane's unique physical properties. [70] [71] The vapor pressure of desflurane is three to four times that of contemporary inhaled anesthetics, and it boils at 22.8°C, [72] which is near room temperature (see Fig. 7-13 (Figure Not Available)). Desflurane has a minimum alveolar anesthetic concentration value of 6 to 7 percent. [72] Desflurane is valuable because it has a low blood gas solubility coefficient of 0.45 at 37°C, and recovery from anesthesia is more rapid than with other potent inhaled anesthetics. [72]

Unsuitability of Contemporary Variable-Bypass Vaporizers for Controlled Vaporization of Desflurane

Desflurane's high volatility and moderate potency preclude its use with contemporary variable-bypass vaporizers, such as Ohmeda Tec 4, Tec 5, or North American Drager Vapor 19.1, for two reasons [70] :

1. The vapor pressure of desflurane is near 1 atm. The vapor pressures of enflurane, isoflurane, halothane, and desflurane at 20°C are 172, 240, 244, and 669 mm Hg, [72] respectively (see Fig. 7-13 (Figure Not Available)). Normal flow through a traditional vaporizer would vaporize many more volumes of desflurane. For example, at 1 atm and 20°C, 100 mL/min passing through the vaporizing chamber entrains 735 mL/min of desflurane versus 29, 46, and 47 mL/min of enflurane, isoflurane, and halothane, respectively. [70] Under these same conditions, the amount of bypass flow necessary to achieve sufficient distribution of anesthetic vapor to produce 1 percent desflurane output would be approximately 73 L/min, compared with 5 L/min or less for the other three anesthetics. At greater than 22.8°C at 1 atm, desflurane boils. The amount of vapor produced would be limited only by the heat energy available from the vaporizer owing to its specific heat. [70]
2. Contemporary vaporizers lack an external heat source. Although desflurane has a heat of vaporization approximately equal to that of enflurane, isoflurane, and halothane, its minimum alveolar anesthetic concentration is four to nine times higher than that of the other three inhaled anesthetics. Thus, the absolute amount of desflurane vaporized over a given time period is considerably higher than that occurring with other anesthetics. Supplying desflurane in higher concentrations would cause excessive cooling of the vaporizer. In the absence of an external heat source, temperature compensation using traditional mechanical devices would be almost impossible over a broad clinical range of temperatures because of desflurane's steep vapor pressure versus temperature curve (see Fig. 7-13 (Figure Not Available)). [70]

Operating Principles of the Tec 6

To achieve controlled vaporization of desflurane, Ohmeda has introduced the Tec 6 vaporizer, which is electrically heated and pressurized. [73] The physical appearance and operation of the Tec 6 are similar to those of contemporary vaporizers, but some aspects of the internal design and operating principles are radically different. A simplified schematic of the Tec 6 is shown in Figure 7-18 (Figure Not Available) . The vaporizer has two independent gas circuits arranged in parallel. The

fresh gas circuit is shown in red, and the vapor circuit is shown in white.

Figure 7-18 (Figure Not Available) Simplified schematic of the Tec 6 desflurane vaporizer. *(Modified from Andrews JJ: Operating Principles of the Ohmeda Tec 6 Desflurane Vaporizer: A Collection of Twelve Color Illustrations. Washington, DC, Library of Congress, 1996.)*

The fresh gas from the flowmeters enters at the fresh gas inlet, passes through a fixed restrictor (R1), and exits at the vaporizer gas outlet. The vapor circuit originates at the desflurane sump, which is electrically heated and thermostatically controlled to 39°C, a temperature well above desflurane's boiling point. The heated sump assembly serves as a reservoir of desflurane vapor. At 39°C, the vapor pressure in the sump is approximately 1,300 mm Hg absolute, [74] or approximately 2 atm absolute (see Fig. 7-13 (Figure Not Available)). Just downstream from the sump is the shut-off valve. After the vaporizer warms up, the shut-off valve fully opens when the concentration control valve is turned to the "on" position. A pressure-regulating valve downstream from the shut-off valve downregulates the pressure to approximately 1.1 atm absolute (74 mm Hg gauge) at a fresh gas flow rate of 10 L/min. The operator controls desflurane output by adjusting the concentration control valve (R2) , which is a variable restrictor. [70]

The vapor flow through R2 joins the fresh gas flow through R1 at a point downstream from the restrictors. Until this point, the two circuits are physically divorced. They are interfaced pneumatically and electronically, however, through differential pressure transducers, a control electronics system, and a pressure-regulating valve. When a constant fresh gas flow rate encounters the fixed restrictor, R1, a specific back pressure that is proportional to the fresh gas flow rate pushes against the diaphragm of the control differential pressure transducer. The differential pressure transducer conveys the pressure difference between the fresh gas circuit and the vapor circuit to the control electronics system. The control electronics system regulates the pressure-regulating valve so that the pressure in the vapor circuit equals the pressure in the fresh gas circuit. This equalized pressure supplying R1 and R2 is the working pressure, and the working pressure is constant at a fixed fresh gas flow rate. If the operator increases the fresh gas flow rate, more back pressure is exerted on the diaphragm of the control pressure transducer, and the working pressure of the vaporizer increases. [70]

Table 7-1 (Table Not Available) shows the approximate correlation between fresh gas flow rate and working pressure for a typical vaporizer. At a fresh gas flow rate of 1 L/min, the working pressure is 10 millibars, or 7.4 mm Hg gauge. At a fresh gas flow rate of 10 L/min, the working pressure is 100 millibars, or 74 mm Hg gauge. Therefore, there is a linear relationship between fresh gas flow rate and working pressure. When the fresh gas

TABLE 7-1 -- Fresh Gas Flow Rate Versus Working Pressure

(Not Available)

From Andrews JJ, Johnston RV Jr: The new Tec 6 desflurane vaporizer. Anesth Analg 76:1338, 1993.

flow rate is increased tenfold, the working pressure increases tenfold. [70]

Listed below are two specific examples to demonstrate the operating principles of the Tec 6. [70]

Example A: Constant fresh gas flow rate of 1 L/min, with an increase in the dial setting. With a fresh gas flow rate of 1 L/min, the working pressure of the vaporizer is 7.4 mm Hg. That is, the pressure supplying R1 and R2 is 7.4 mm Hg. As the operator increases the dial setting, the opening at R2 becomes larger, allowing more vapor to pass through R2. Specific vapor flow values at different dial settings are shown in Table 7-2 (Table Not Available) .

Example B: Constant dial setting with an increase in fresh gas flow from 1 to 10 L/min. At a fresh gas flow rate of 1 L/min, the working pressure is 7.4 mm Hg, and at a dial setting of 6 percent, the vapor flow rate through R2 is 64 mL/min (see Tables 7-1 (Table Not Available) and 7-2) (Table Not Available) . With a tenfold increase in the fresh gas flow rate, there is a concomitant tenfold increase in the working pressure to 74 mm Hg. The ratio of resistances of R2 to R1 is constant at a fixed dial setting of 6 percent. Because R2 is supplied by 10 times more pressure, the vapor flow rate through R2 increases tenfold to 640 mL/min. Vaporizer output is constant because both the fresh gas flow and the vapor flow increase proportionally.

Factors That Influence Vaporizer Output

Varied altitude and carrier gas composition influence Tec 6 output and are discussed in the following sections.

Varied Altitudes.

Unlike contemporary variable-bypass vaporizers, the Tec 6 vaporizer requires manual adjustments of the concentration control dial at altitudes other than sea level to maintain a constant partial pressure of anesthetic. The Tec 6 itself works at absolute pressures; therefore, altitude makes no difference to the vaporizer's performance per se. It accurately delivers the dialed volume percent of desflurane. However, when this gas is brought to ambient atmosphere at high altitudes, the volume percent represents an absolute decrease in the partial pressure of the anesthetic, unlike with the contemporary variable-bypass vaporizers, which deliver a constant partial pressure of anesthetic. To compensate for the reduction of partial pressure of vapor at altitude, the Tec 6 rotary valve must be advanced to maintain

(Not Available)

the required anesthetic partial pressure. The required dial setting may be calculated by use of the following formula [73] :

Required dial setting = Normal dial setting (vol %) × 760 mm Hg/ambient pressure (mm Hg)

For example, at an altitude of 2,000 m, or 6,564 feet, where the ambient pressure is 608 mm Hg, the operator must advance the concentration control dial from 10 to 12.5 percent to maintain the required anesthetic partial pressure. [73] In hyperbaric settings, the operator must decrease the dial setting to prevent delivery of an overdose.

Carrier Gas Composition.

Vaporizer output approximates the dial setting when oxygen is the carrier gas because the Tec 6 vaporizer is calibrated by use of 100 percent oxygen. [73] At low flow rates when a carrier gas other than 100 percent oxygen is used, however, a clear trend toward reduction in vaporizer output emerges. This reduction parallels the proportional decrease in the viscosity of the carrier gas. Nitrous oxide has a lower viscosity than oxygen, so the back pressure generated by resistor R1 (see Fig. 7-18 (Figure Not Available)) is less when nitrous oxide is the carrier gas, and the working pressure is reduced. At low flow rates with nitrous oxide as the carrier gas, vaporizer output is approximately 20 percent less than the dial setting. This result suggests that at clinically useful fresh gas flow rates, the gas flow across resistor R1 is laminar, and the working pressure is proportional to both the fresh gas flow rate and the viscosity of the carrier gas. [75]

Safety Features

Because desflurane's vapor pressure is near 1 atm, misfilling contemporary vaporizers with desflurane can theoretically cause desflurane overdose and hypoxemia. [76] Ohmeda has introduced a unique anesthetic-specific filling system to minimize the occurrence of this hazard. The agent-specific filler cap of the desflurane bottle

prevents its use with traditional vaporizers. The filling system also minimizes spillage of liquid or vapor anesthetic by maintaining a "closed system" during the filling process. Each desflurane bottle has a spring-loaded filler cap with an O-ring on the tip. The spring seals the bottle until it is engaged in the filler port of the vaporizer. Thus, this anesthetic-specific filling system interlocks the vaporizer and the dispensing bottle, preventing loss of anesthetic to the atmosphere. [73]

Major vaporizer faults cause the shut-off valve located just downstream from the desflurane sump (see Fig. 7-18 (Figure Not Available)) to close, producing a no-output situation. The valve is closed and a "no output" alarm is activated immediately if any of the following conditions occur: (1) the anesthetic level decreases to below 20 mL, (2) the vaporizer is tilted, (3) a power failure occurs, or (4) there is a disparity between the pressure in the vapor circuit versus the pressure in the fresh gas circuit exceeding a specified tolerance. [73]

Summary

The Tec 6 vaporizer is an electrically heated, thermostatically controlled, constant-temperature, pressurized, electromechanically coupled, dual-circuit, gas-vapor blender. The

---

pressure in the vapor circuit is electronically regulated to equal the pressure in the fresh gas circuit. At a constant fresh gas flow rate, the operator regulates vapor flow by use of a conventional concentration control dial. When the fresh gas flow rate increases, the working pressure increases proportionally. At a specific dial setting at different fresh gas flow rates, vaporizer output is constant because the amount of flow through each circuit is proportional. [70]

ANESTHETIC CIRCUITS

Gas exits the anesthesia machine at the common gas outlet and then enters an anesthetic circuit. The function of an anesthetic circuit is not only to deliver oxygen and anesthetic gases to the patient but also to eliminate CO_2. CO_2 can be removed either by washout with adequate fresh gas inflow or by absorption with soda lime. This discussion is limited to semiclosed rebreathing circuits and the circle system.

Mapleson Systems

In 1954 Mapleson described and analyzed five different semiclosed anesthetic systems, and they are now classically referred to as the Mapleson systems and are designated A to E. [77] Willis et al [78] added the F system to the five original systems. The Mapleson systems are shown in Figure 7-19 (Figure Not Available) . System components can include a face mask, a spring-loaded pop-off valve, reservoir tubing, fresh gas inflow tubing, and a reservoir bag. Three distinct functional groups emerge, and they include the A, the BC, and the DEF groups. The Mapleson A, also known as the Magill circuit, has a spring-loaded pop-off valve located near the face mask, and the fresh gas flow enters the opposite end of the circuit near the reservoir bag. In the B and C systems, the spring-loaded pop-off valve is located near the face mask, but the fresh gas inlet tubing is located near the patient. The reservoir tubing and breathing bag serve as a blind limb where fresh gas, dead space gas, and alveolar gas can collect. Finally, in the Mapleson D, E, and F group, or the T-piece group, the fresh gas enters near the patient, and excess gas is popped off at the opposite end of the circuit.

Even though the component arrangement and components are simple, functional analysis of the Mapleson systems can be complex. [79] [80] The amount of CO_2 rebreathing associated with each system is multifactorial, and variables dictating the ultimate CO_2 concentration include the following: (1) fresh gas inflow rate, (2) minute ventilation, (3) mode of ventilation (spontaneous or controlled), (4) tidal volume, (5) respiratory rate, (6) inspiratory to expiratory ratio, (7) duration of the expiratory pause, (8) peak inspiratory flow rate, (9) volume of the reservoir tube, (10) volume of

Figure 7-19 (Figure Not Available) Gas disposition at end-expiration during spontaneous (left) and controlled (right) ventilation in circuits A-F. FGF, fresh gas flow. *(Modified from Sykes [81])*

the breathing bag, (11) ventilation by mask, (12) ventilation through an endotracheal tube, and (13) the CO_2 sampling site.

The performance of the Mapleson systems is best understood by studying the expiratory phase of the respiratory cycle (see Fig. 7-19 (Figure Not Available)). [81] During spontaneous ventilation, the Mapleson A has the best efficiency of the six systems, requiring a fresh gas inflow rate of only one times the minute ventilation to prevent rebreathing of CO_2. However, it has the worst efficiency during controlled ventilation, requiring a minute ventilation of as much as 20 L/min to prevent rebreathing. Systems D to F are slightly more efficient than systems B and C. To prevent rebreathing of CO_2, systems D to F require a fresh gas inflow rate of approximately 2.5 times the minute ventilation, whereas the fresh gas inflow rates required for systems B and C are somewhat higher. [80]

The relative efficiency of different Mapleson systems with respect to prevention of rebreathing during spontaneous ventilation can be summarized as follows: A > DFE > CB. During controlled ventilation, DFE > BC > A. [80] [82] The Mapleson A, B, and C systems are rarely used today, but the D, E, and F systems are commonly employed. In the United States, the most popular representative from the D, E, and F group is the Bain circuit.

Bain Circuit

The Bain circuit is a modification of the Mapleson D system. It is a coaxial circuit in which the fresh gas flows through a narrow inner tube within the outer corrugated tubing. [83] The central tube originates near the reservoir bag, but the fresh gas actually enters the circuit at the patient end (Fig. 7-20) (Figure Not Available) . Exhaled gases enter the corrugated tubing and are vented through the expiratory valve near the reservoir bag. The Bain circuit may be used for both spontaneous and controlled ventilation. The fresh gas inflow rate necessary to prevent rebreathing is 2.5 times the minute ventilation.

There are many advantages to this circuit. It is lightweight, convenient, easily sterilized, and reusable. Scavenging of the gases from the expiratory valve is facilitated because the overflow valve is located away from the patient. Exhaled gases in the outer reservoir tubing add warmth to inspired fresh gases. The hazards of the Bain circuit include unrecognized disconnection or kinking of the inner fresh gas hose. These problems can cause hypercarbia from inadequate gas flow or increased respiratory resistance.

The outer tube should be transparent to allow inspection of the inner tube. The integrity of the inner tube can be assessed, as described by Pethick. [84] High-flow oxygen is fed into the circuit while the patient end is occluded until the reservoir bag is filled. The patient end is opened, and oxygen is flushed into the circuit. If the inner tube is intact, the Venturi effect occurs at the patient end. This effect causes a decrease in pressure within the circuit, and the reservoir bag deflates. Conversely, a leak in the inner tube allows the fresh gas to escape into the expiratory limb, and the reservoir bag remains inflated. This test is recommended as a part of the preanesthesia check if a Bain circuit is used.

Circle System

The circle system is the most popular breathing system in the United States. It is so named because its components are arranged in a circular manner. This system prevents rebreathing of CO_2 by soda lime absorption but allows partial rebreathing of other exhaled gases. The extent of rebreathing of the other exhaled gases depends on component arrangement and the fresh gas flow rate.

A circle system can be semiopen, semiclosed, or closed, depending on the amount of fresh gas inflow. [85] A semiopen system has no rebreathing and requires a very high flow of fresh gas. A semiclosed system is associated with rebreathing of gases and is the most commonly used system in the United States. A closed system is one in which the inflow gas exactly matches that being taken up, or consumed, by the patient. There is complete rebreathing of exhaled gases after absorption of CO_2, and the overflow (pop-off) valve is closed.

The circle system (Fig. 7-21) consists of seven components: (1) a fresh gas inflow source; (2) inspiratory and expiratory unidirectional valves; (3) inspiratory and expiratory corrugated tubes; (4) a Y-piece connector; (5) an overflow or pop-off valve, referred to as the APL valve; (6) a reservoir bag; and (7) a canister containing a CO_2 absorbent. The unidirectional valves are placed in the system to ensure unidirectional flow through the corrugated hoses.

Figure 7-20 (Figure Not Available) The Bain circuit. *(Modified from Bain and Spoerel [85])*

Figure 7-21 Components of the circle system. B, reservoir bag; V, ventilator; APL, adjustable pressure limiting.

The fresh gas inflow enters the circle by a connection from the common gas outlet of the anesthesia machine.

Numerous variations of the circle arrangement are possible, depending on the relative positions of the unidirectional valves, the pop-off valve, the reservoir bag, the CO_2 absorber, and the site of fresh gas entry. However, to prevent rebreathing of CO_2, three rules must be followed: (1) a unidirectional valve must be located between the patient and the reservoir bag on both the inspiratory and the expiratory limbs of the circuit, (2) the fresh gas inflow cannot enter the circuit between the expiratory valve and the patient, and (3) the overflow (pop-off) valve cannot be located between the patient and the inspiratory valve. If these rules are followed, any arrangement of the other components prevents rebreathing of CO_2. [86]

The most efficient circle system arrangement that allows the highest conservation of fresh gases is one with the unidirectional valves near the patient and the pop-off valve just downstream from the expiratory valve. This arrangement conserves dead space gas and preferentially eliminates alveolar gas. A more practical arrangement, used on all contemporary anesthesia machines (see Fig. 7-21), is less efficient because it allows alveolar and dead space gas to mix before venting. [86] [87]

The advantages of the circle system include relative stability of inspired concentration, conservation of respiratory moisture and heat, and prevention of operating room pollution. Additionally, it can be used for closed-system anesthesia or with low oxygen flows. The major disadvantage of the circle system stems from its complex design. The circle system has approximately 10 connections, and the multiple connection sites set the stage for misconnections, disconnections, obstructions, and leaks. In a recent closed claim analysis of adverse anesthetic outcomes arising from gas delivery equipment, a third (25/72) of malpractice claims resulted from breathing circuit misconnections or disconnections. [2] Malfunctioning valves can cause serious problems. Rebreathing can occur if the valves stick in the open position. Total occlusion of the circuit can occur if they are stuck closed. Finally, the bulk of the circle offers less convenience and portability than the Mapleson systems.

CARBON DIOXIDE ABSORPTION

Different anesthesia systems eliminate CO_2 with varying degrees of efficiency. The closed and semiclosed circle systems both require CO_2 absorption. Desirable features of CO_2 absorbents include lack of toxicity with common anesthetics, low resistance to air flow, low cost, ease of handling, and efficiency.

The Absorber Canister

On modern anesthesia machines, the absorber canister (see Fig. 7-21) is composed of two clear plastic canisters arranged in series. The canisters can be filled either with bulk absorbent or with absorbent supplied by the factory in prefilled plastic disposable cartridges called prepacks. Free granules from bulk absorbent can create a clinically significant leak if they lodge between the clear plastic canister and the O-ring gasket of the absorber. Leaks have also been caused by defective prepacks that were larger than factory specifications. [88] Prepacks can also cause total obstruction of the circle system if the clear plastic shipping wrapper is not removed before use. [89]

Chemistry of Absorbents

Two formulations of CO_2 absorbents are commonly used today: soda lime and Baralyme.

By weight, the approximate composition of "high moisture" soda lime is 80 percent calcium hydroxide, 15 percent water, 4 percent sodium hydroxide, and 1 percent potassium hydroxide (an activator). Small amounts of silica are added in order to produce calcium and sodium silicate. This addition produces a hard compound and reduces dust formation. The efficiency of the soda lime absorption varies inversely with the hardness; therefore, little silicate is used in contemporary soda lime. Sodium hydroxide is the catalyst for the CO_2 absorptive properties of soda lime. [90] [91] Baralyme is a mixture of approximately 20 percent barium hydroxide and 80 percent calcium hydroxide. It may also contain some potassium hydroxide.

The size of the absorptive granules has been determined by trial and error, which represents a compromise between resistance to air flow and absorptive efficiency. [92] The smaller the granules, the more surface area available for absorption. However, air flow resistance increases. The granular size of soda lime and Baralyme in anesthesia practice is between 4 and 8 mesh, a size at which resistance to air flow is negligible. Mesh refers to the number of openings per linear inch in a sieve through which the granular particles can pass. A 4-mesh screen means that there are four quarter-inch openings per linear inch. An 8-mesh screen has eight eighth-inch openings per linear inch. [90]

The absorption of CO_2 by soda lime is a chemical process, not a physical process. CO_2 combines with water to form carbonic acid. Carbonic acid reacts with the hydroxides to

---

form sodium (or potassium) carbonate and water. Calcium hydroxide accepts the carbonate to form calcium carbonate and sodium (or potassium) hydroxide. The equations are as follows:

1. $CO_2 + H_2O$
 H_2CO_3

2. $H_2CO_3 + 2NaOH\ (KOH)$
 $Na_2CO_3\ (K_2CO_3) + 2H_2O + Heat$

3. $Na_2CO_3\ (K_2CO_3) + Ca(OH)_2$
 $CaCO_3 + 2NaOH\ (KOH)$

Some CO_2 may react directly with $Ca(OH)_2$, but this reaction is much slower.

The reaction with Baralyme differs from that with soda lime because more water is liberated by a direct reaction of barium hydroxide and CO_2 .

1. $Ba(OH)_2 + 8H_2O + CO_2$
 $BaCO_3 + 9H_2O + Heat$

2. $9H_2O + 9CO_2$
 $9H_2CO_3$

Then, by direct reactions and by KOH and NaOH,

3. $9H_2CO_3 + 9Ca(OH)_2$
 $CaCO_3 + 18H_2O + Heat$

Absorptive Capacity

The maximum amount of CO_2 that can be absorbed is 26 L of CO_2 per 100 g of absorbent. However, channeling of gas through granules may substantially decrease this efficiency and may allow only 10 to 20 L of CO_2 to be absorbed. [93]

Indicators

Ethyl violet, the pH indicator added to both soda lime and Baralyme to help assess the functional integrity of the absorbent, is a substituted triphenylmethane dye with

a critical pH of 10.3. [91] The color of ethyl violet changes from colorless to violet when the pH of the absorbent decreases as a result of CO_2 absorption. The pH of fresh absorbent exceeds the critical pH, and the dye exists in its colorless form (Fig. 7-22 (Figure Not Available) , left). As absorbent becomes exhausted, however, the pH decreases below 10.3, and ethyl violet changes to its violet form (see Fig. 7-22 (Figure Not Available) , right) through alcohol dehydration. Ethyl violet is not always a reliable indicator of the functional status of absorbent. Fluorescent lights can deactivate the dye so that the absorbent appears white even though it is exhausted. [94]

Interactions of Inhaled Anesthetics With Absorbents

It is important and desirable to have CO_2 absorbents that are neither intrinsically toxic nor toxic when exposed to common anesthetics. Soda lime and Baralyme generally fit this description, but inhaled anesthetics do interact with absorbents to some extent. Historically speaking, an uncommon anesthetic, trichloroethylene, reacts with soda lime to produce toxic compounds. In the presence of alkali and heat, trichloroethylene degrades into the cranial neurotoxin dichloroacetylene, which can cause cranial nerve lesions and encephalitis. Phosgene, a potent pulmonary irritant, is also produced and can cause adult respiratory distress syndrome. [95]

Sevoflurane has been shown to produce degradation products on interaction with CO_2 absorbents. [96] The major degradation product produced is fluoromethyl-2, 2-difluoro-1-(trifluoromethyl) vinyl ether, or compound A. During sevoflurane anesthesia, factors apparently leading to an increase in the concentration of Compound A include (1) low flow or closed circuit anesthetic techniques; (2) the use of Baralyme rather than soda lime; (3) higher concentrations of sevoflurane in the anesthetic circuit; (4) higher absorbent temperatures; and (5) fresh absorbent. [96] [97] [98] Baralyme dehydration increases the concentration of compound A, and soda lime dehydration decreases the concentration of compound A. [99] [100] Apparently, the degradation products do not cause toxic effects in humans, even during low-flow anesthesia, [97] but further studies are needed to verify this. [101] [102] [103]

Desiccated soda lime and Baralyme can degrade contemporary inhaled anesthetics to clinically significant concentrations of carbon monoxide (CO), which in turn can produce carboxyhemoglobin concentrations reaching 30 percent or more. Higher levels of CO are more likely after prolonged contact between absorbent and anesthetics and after disuse of an absorber for at least 2 days, especially over a weekend. Thus, case reports describing CO poisoning are most common in patients anesthetized on Monday morning, presumably

Figure 7-22 (Figure Not Available) (A and B) Ethyl violet (see text for details). *(Modified from Andrews JJ et al [94])*

because continuous flow from the anesthesia machine dehydrated the absorbents over the weekend. [104] [105]

Several factors appear to increase the production of CO, including (1) the inhaled anesthetic used (for a given minimum alveolar concentration multiple, the magnitude of CO production from greatest to least is desflurane
enflurane > isoflurane >> halothane = sevoflurane); (2) the absorbent dryness (completely dry absorbent produces more CO than hydrated absorbent); (3) the type of absorbent (at a given water content, Baralyme produces more CO than does soda lime); (4) the temperature (an increased temperature increases CO production); and (5) the anesthetic concentration (more CO is produced from higher anesthetic concentrations). [106]

In a study in swine in which partially dried Baralyme was used during desflurane anesthesia, extremely high levels of CO and carboxyhemoglobin occurred. [107] Interventions have been suggested to reduce the incidence of CO exposure in humans undergoing general anesthesia. [105] The interventions include (1) educating anesthesia personnel regarding the cause of CO production, (2) turning off the anesthesia machine at the conclusion of the last case of the day to eliminate fresh gas flow, which dries the absorbent, (3) changing the CO_2 absorbent if fresh gas was found flowing during the morning machine check, (4) rehydrating desiccated absorbent by adding water to the absorbent. [104]

ANESTHESIA VENTILATORS

The anesthesia ventilator can substitute for the breathing bag of the circle system, the Bain circuit, and other breathing systems. Ten years ago, anesthesia ventilators were mere adjuncts to the anesthesia machine. Today, they have attained a prominent central role in newer anesthesia systems. This discussion focuses on the classification, operating principles, and hazards of anesthesia ventilators.

Classification

Ventilators can be classified according to their power source, drive mechanism, cycling mechanism, and bellows type. [108] [109] The following section reviews ventilator classification and terminology before the discussion of individual anesthesia machine ventilators.

Power Source

The power source required to operate a mechanical ventilator is provided by compressed gas, electricity, or both. Older pneumatic ventilators required only a pneumatic power source to function properly. Contemporary North American Drager and Ohmeda electronic ventilators require both an electronic and a pneumatic power source. [16] [18] [19] [20] [21] [22] [110] [111]

Drive Mechanism

Most anesthesia machine ventilators are classified as double-circuit, pneumatically driven ventilators. In a double-circuit system, a driving force (compressed gas) compresses a bag or bellows, which in turn delivers gas to the patient. The driving gas in the Ohmeda 7000, 7810, and 7900 is 100 percent oxygen. [16] [110] [111] In the North American Drager AV-E, a Venturi device mixes oxygen and air. [18] [19] [20] [21] [22]

Cycling Mechanism

Most anesthesia machine ventilators are time cycled and provide ventilator support in the control mode. Inspiration is initiated by a timing device. Older pneumatic ventilators use a fluidic timing device. Contemporary electronic ventilators use a solid-state timing device and are thus classified as time cycled and electronically controlled.

Bellows Classification

The direction of bellows movement during the expiratory phase determines the bellows classification. Ascending (standing) bellows ascend during the expiratory phase (Fig. 7-23 (Figure Not Available) , right), whereas descending (hanging) bellows descend during the expiratory phase. Older pneumatic ventilators use weighted descending bellows, whereas most contemporary electronic ventilators have ascending bellows. Of the two configurations, the ascending bellows is safer. An ascending bellows does not fill if a total disconnection occurs. The bellows of a descending bellows ventilator, however, continues its upward and downward movement during a disconnection. The driving gas pushes the bellows upward during the inspiratory phase. During the expiratory phase, room air is entrained into the breathing system at the site of the disconnection because gravity acts on the weighted bellows. The disconnection pressure monitor and the volume monitor may be fooled even if a disconnection is complete (see Breathing Circuit Problems). [1]

Operating Principles of Ascending Bellows Ventilators

Contemporary examples of ascending bellows, double-circuit, electronic ventilators include the North American Drager AV-E and the Ohmeda 7000, 7800, and 7900 series. A generic ascending bellows ventilator is shown in Figure 7-23 (Figure Not Available) . It may be viewed as a breathing bag (bellows) located within a clear plastic box. The bellows physically separates the driving gas circuit from the patient gas circuit. The driving gas circuit is located outside the bellows, and the patient gas circuit is inside the bellows. During the inspiratory phase (see Fig. 7-23 (Figure Not Available) , left), the driving gas enters the bellows chamber, causing the pressure within it to increase. This increase in pressure is responsible for two events. First, the ventilator relief valve closes, preventing anesthetic gas from escaping into the scavenging system. Second, the bellows is compressed, and the anesthetic gas within the bellows is delivered to the patient's lungs. This compression action is analogous to that of the hand of the anesthesiologist squeezing the breathing bag. [39]

During the expiratory phase (see Fig. 7-23 (Figure Not Available) , right), the driving gas exits the bellows chamber. The pressure within the bellows chamber and the pilot line declines to zero,

Figure 7-23 (Figure Not Available) Inspiratory (left) and expiratory (right) phase gas flows of a generic ascending bellows anesthesia ventilator (see text for details). *(From Andrews [35])*

causing the mushroom portion of the ventilator relief valve to open. Exhaled patient gas fills the bellows before any scavenging occurs, because a weighted ball similar to those used in ball-type positive end-expiratory pressure valves is incorporated into the base of the ventilator relief valve. The ball produces 2 to 3 cm H_2O of back pressure; therefore, scavenging occurs only after the bellows fills completely and the pressure inside the bellows exceeds this pressure threshold. This design causes all ascending bellows ventilators to produce 2 to 3 cm H_2O of positive end-expiratory pressure within the breathing circuit. Scavenging occurs only during the expiratory phase because the ventilator relief valve is open only during expiration. [39]

Gas flow from the anesthesia machine into the breathing circuit is continuous and independent of ventilator activity. During the inspiratory phase of mechanical ventilation, the ventilator relief valve is closed, and the breathing system's APL valve (pop-off valve) is either closed or out of circuit. Therefore, the patient receives volume from the bellows and flowmeters during the inspiratory phase. Factors that influence the correlation between set tidal volume and exhaled tidal volume include the flowmeter settings, the inspiratory time, the compliance of the breathing circuit, the external leakage, and the location of the tidal volume sensor. [16] [17] [110] [111] Usually, the volume gained from the flowmeters during inspiration is counteracted by the volume lost to the breathing circuit compliance. The set tidal volume generally approximates the exhaled tidal volume. However, oxygen flushing during the inspiratory phase can result in barotrauma because excess volume cannot be vented. [39]

Problems and Hazards

Numerous hazards are associated with anesthesia ventilators. These include problems with the breathing circuit, the bellows assembly, and the control assembly.

Breathing Circuit Problems

Breathing circuit disconnection is a leading cause of critical incidents in anesthesia. [2] [112] The most common disconnection site is at the Y-piece. Disconnections can be complete or partial (leaks). A common source of leaks with older absorbers is failure to close the APL or pop-off valve when mechanical ventilation is initiated. The bag/ventilator switch on contemporary absorbers helps minimize this problem. Preexisting undetected leaks can be found in compressed, corrugated, disposable anesthetic circuits. For such a leak to be detected preoperatively, the circuit must be fully expanded before the circuit is checked for leaks. [113] As mentioned earlier, disconnections and leaks manifest more readily with the ascending bellows because the bellows does not fill. [1]

Several disconnection monitors exist. The most important is a vigilant anesthesia care provider who monitors breath sounds, chest wall excursion, and mechanical monitors.

Pneumatic and electronic pressure monitors are helpful in diagnosing disconnections. Factors that influence monitor effectiveness include the disconnection site, the pressure sensor location, the threshold pressure alarm limit, the inspiratory flow rate, and the resistance of the disconnected breathing circuit. [114] [115] Various anesthesia machines and ventilators have different locations for the pressure sensor and different values for the threshold pressure alarm limit (Table 7-3) . The threshold pressure alarm limit may be adjustable or preset at the factory. An audible or visual alarm is actuated if the peak inspiratory pressure of the breathing circuit does not exceed the threshold pressure alarm limit. When an adjustable threshold pressure alarm limit is available, such as on the North American Drager Narkomed 2A, 2B, 3, and 4, the operator should set the pressure alarm limit to within 5 cm H_2O of the peak inspiratory pressure. [18] [19] [20] [21] [22] Figure 7-24 (Figure Not Available) illustrates how a partial disconnection (leak) may be unrecognized by the low-pressure monitor if the

threshold pressure alarm limit is set too low or if the factory preset value is relatively low.

Respiratory volume monitors are useful in detecting disconnections. Volume monitors sense exhaled tidal volume, minute volume, or both. The user should bracket the high and low threshold volumes slightly above and below the exhaled volumes. For example, if the exhaled minute volume of a patient is 10 L/min, reasonable alarm limits would be 8 to 12 L/min.

Carbon dioxide monitors are probably the best devices for revealing patient disconnections. CO_2 concentration is measured near the Y-piece either directly or by aspiration of a gas sample to the instrument. A drastic change in the differences between the inspiratory and end-tidal CO_2 concentration or the absence of CO_2 indicates a disconnection, a nonventilated patient, or other problems. [1]

Misconnections of the breathing system are common, despite efforts by standards committees to eliminate this problem by assigning different diameters to various hoses and terminals. Anesthesia machines, breathing systems, ventilators, and scavenging systems incorporate a multitude of hose terminals. Hoses have been connected to inappropriate terminals and even to various solid cylindrically shaped protrusions of the anesthesia machine. [1]

Occlusion (obstruction) of the breathing circuit may occur. Tracheal tubes can become kinked. Hoses throughout the breathing circuit are subject to occlusion by external mechanical forces that can impinge on flow. Blockage of a bacterial filter in the expiratory limb of the circle system has caused a bilateral tension pneumothorax. [116] Incorrect insertion of flow direction-sensitive components can result in a no-flow state. [1] Examples of these components include some positive end-expiratory pressure valves and cascade humidifiers. Depending on the location of the occlusion and the pressure sensor, a high-pressure alarm may alert the anesthesiologist to the problem.

Excess inflow to the breathing circuit from the anesthesia machine during the inspiratory phase can cause barotrauma. The best example of this phenomenon is oxygen flushing. Excess volume cannot be vented from the system during inspiration

Figure 7-24 (Figure Not Available) Threshold pressure alarm limit. (Top) The threshold pressure alarm limit (dotted line) has been set appropriately. An alarm is actuated when a partial disconnection occurs (arrow) because the threshold pressure alarm limit is not exceeded by the breathing circuit pressure. (Bottom) A partial disconnection is unrecognized by the pressure monitor because the threshold pressure alarm limit has been set too low. *(Modified from Baromed Breathing Pressure Monitor. Operator's Instruction Manual. Telford, Pennsylvania, North American Drager, 1986.)*

because the ventilator relief valve is closed and the APL valve is either out of circuit or closed. [39] A high-pressure alarm, if present, may be activated when the pressure becomes excessive. In the North American Drager System, both audible and visual alarms are actuated if the high-pressure threshold is exceeded. [18] [19] [20] [21] [22] In the Modulus II Plus System, the Ohmeda 7810 ventilator automatically switches from the inspiratory to the expiratory phase when the adjustable peak pressure threshold is exceeded. [16] This minimizes the possibility of barotrauma if the peak pressure threshold is set appropriately by the anesthesiologist.

Bellows Assembly Problems

Leaks can occur in the bellows assembly. Improper seating of the plastic bellows housing can result in inadequate ventilation because a portion of the driving gas is vented to the atmosphere. A hole in the bellows can lead to alveolar hyperinflation and possibly to barotrauma in some ventilators because high-pressure driving gas can enter the patient circuit. The value on the oxygen analyzer may increase if the driving gas is 100 percent oxygen, or it may decrease if the driving gas is composed of an air/oxygen mixture. [117]

The ventilator relief valve can cause problems. Hypoventilation occurs if the valve is incompetent because anesthetic gas is delivered to the scavenging system during the inspiratory phase instead of to the patient. Gas molecules preferentially exit into the scavenging system because it represents the path of least resistance, and the pressure within the scavenging system can be subatmospheric. Ventilator relief valve incompetency can result from a disconnected pilot line, a ruptured valve, or a damaged flapper valve. [118] [119] A ventilator relief valve stuck in the closed position can produce barotrauma. Excessive suction from the scavenging system can draw the ventilator relief valve to its seat and close the valve during both the inspiratory and expiratory phases. [1] Breathing circuit pressure escalates because

excess anesthetic gas cannot be vented.

Control Assembly Problems

The control assembly can be the source of both electrical and mechanical problems. Electrical failure can be total or partial; the former is the more obvious. Some mechanical problems include leaks within the system, faulty regulators, and faulty valves. An occluded muffler on the North American Drager AV-E can cause barotrauma. Obstruction of driving gas outflow closes the ventilator relief valve, and excess patient gas cannot be vented. [120]

SCAVENGING SYSTEMS

Scavenging is the collection and subsequent removal of vented gases from the operating room. [121] The amount of gas used to anesthetize a patient commonly far exceeds the patient's needs. Therefore, scavenging minimizes operating room pollution. In 1977, the National Institute for Occupational Safety and Health prepared a document entitled "Criteria for a Recommended Standard: Occupational Exposure to Waste Anesthetic Gases and Vapors." [122] Although it was maintained that a safe level of exposure could not be defined, the National Institute for Occupational Safety and Health recommendations are shown in Table 7-4 . [122] In 1991, the ASTM released the ASTM F1343-91 standard entitled "Standard Specification for Anesthetic Equipment--Scavenging Systems for Anesthetic Gases." [123] The document provided guidelines for devices that safely and effectively scavenge excess anesthetic gas to reduce contamination in anesthetizing areas. [123]

Components

Scavenging systems have five components (Fig. 7-25) (Figure Not Available) : (1) a gas collecting assembly, (2) a transfer means, (3) a scavenging interface, (4) a gas disposal assembly tubing, and (5) an active or passive gas disposal assembly. [123] An active system uses a central vacuum to eliminate waste gases. The pressure of the waste gas itself produces flow through a passive system.

Gas Collecting Assembly

The gas collecting assembly captures excess anesthetic gas and delivers it to the transfer tubing. [123] Excess gas is vented from the anesthesia system either through the APL valve or through the ventilator relief valve. All excess gas passes through these valves, accumulates in the gas collecting assembly, and is directed to the transfer means.

Transfer Means

The transfer means carries excess gas from the gas collecting assembly to the scavenging interface. The tubing must be either 19 or 30 mm, as specified by the ASTM F1343-91 standard. [123] The tubing should be sufficiently rigid to prevent kinking, and as short as possible to minimize the chance of occlusion. Some manufacturers color code the transfer tubing with yellow bands to distinguish it from 22-mm

breathing system tubing. Many machines have separate transfer tubes for the APL valve and for the ventilator relief valve. The two tubes frequently merge into a single hose before they enter the scavenging interface. Occlusion of the transfer means can be particularly problematic because it is upstream from the pressure-buffering scavenging interface. If the transfer means is occluded, breathing circuit pressure increases, and barotrauma can occur.

Scavenging Interface

The scavenging interface is the most important component of the system because it protects the breathing circuit or ventilator from excessive positive or negative pressure. [121] The interface should limit the pressures immediately downstream from the gas collecting assembly to between -0.5 and +10 cm H_2O under normal working conditions. [123] Positive-pressure relief is mandatory, irrespective of the type of disposal system used, to vent excess gas in case of occlusion downstream from the interface. If the disposal system is active, negative-pressure relief is necessary to protect the breathing circuit or the ventilator from excessive subatmospheric pressure. A reservoir is highly desirable with active systems because it stores excess waste gas until the evacuation system can eliminate it. Interfaces can be open or closed, depending on the method used to provide positive-pressure and negative-pressure relief. [121]

Open Interfaces.

An open interface contains no valves and is open to the atmosphere, allowing both positive-pressure and negative-pressure relief. Open interfaces should be used only with active disposal systems that utilize a central vacuum system. Open interfaces require a reservoir because waste gases are intermittently discharged in surges, whereas flow to the active disposal system is continuous. [121]

Many contemporary anesthesia machines are equipped with open interfaces like those in Figures 7-26A (Figure Not Available) and B. [124] An open canister provides reservoir capacity. The canister volume should be large enough to accommodate a variety of waste gas flow rates. Gas enters the system at the top of the canister and travels through a narrow inner tube to the canister base. Gases are stored in the reservoir between breaths. Positive-pressure and negative-pressure relief is provided by holes in the top of the canister. The open interface shown in Figure 7-26 (Figure Not Available) A differs somewhat from the one shown in Figure 7-26 (Figure Not Available) B. The operator can regulate the vacuum by adjusting the vacuum control valve shown in Figure 7-26 (Figure Not Available) .B [124]

The efficiency of an open interface depends on several factors. The vacuum flow rate per minute must equal or exceed the minute volume of excess gases for spillage to be prevented. The volume of the reservoir and the flow characteristics within the interface are important. Spillage occurs if the volume of a single exhaled breath exceeds the capacity of the reservoir. Leakage can occur long before the volume of waste gas delivered to the reservoir equals the reservoir volume if large-scale turbulence occurs within the interface. [125]

Closed Interfaces.

A closed interface communicates with the atmosphere through valves. All closed interfaces must have a positive-pressure relief valve to vent excess system pressure if obstruction occurs downstream from the interface. A negative-pressure relief valve is mandatory to protect the breathing system from subatmospheric pressure if an active disposal system is used. [121] Two types of closed interfaces are commercially available. One has positive-pressure relief only; the other has both positive-pressure and negative-pressure relief. Each type is discussed in the following sections.

Positive-Pressure Relief Only.

This interface (Fig. 7-27 (Figure Not Available) , left) has a single positive-pressure relief valve and is designed to be used only with passive disposal systems. Waste gas enters the interface at the waste gas inlets. Transfer of the waste gas from the interface to the disposal system relies on the pressure of the waste gas itself because a vacuum is not used. The positive-pressure relief valve opens at a preset value, such as 5 cm H_2O, if an obstruction between

---

Figure 7-26 (Figure Not Available) (A and B) Two open scavenging interfaces. Each requires an active disposal system. APL, adjustable pressure limiting valve (see text for details). *(Modified from Dorsch and Dorsch [121])*

the interface and the disposal system occurs. [126] A reservoir bag is not necessary.

Positive-Pressure and Negative-Pressure Relief.

This interface has a positive-pressure relief valve, at least one negative-pressure relief valve, and a reservoir bag. It is used with active disposal systems. Figure 7-27 (Figure Not Available) (right) is a schematic of North American Drager's closed interface for suction systems. A variable volume of waste gas intermittently enters the interface through the waste gas inlets. The reservoir stores transient excess gas until the vacuum system eliminates it. The operator should adjust the vacuum control valve so that the reservoir bag is properly inflated (A) and not overdistended (B) or completely deflated (C). Gas is vented to the atmosphere through the positive-pressure relief valve if the system pressure exceeds +5 cm H_2O. Room air is entrained through the negative-pressure relief valve if the system pressure is more negative than -0.5 cm H_2O. A back-up negative-pressure relief valve opens at 1.8 cm H_2O if the primary negative-pressure relief valve becomes occluded. [18]

The effectiveness of a closed system in preventing spillage depends on the inflow rate of excess gas, the vacuum flow rate, and the volume of the reservoir. Leakage of waste gases into the atmosphere occurs only if the reservoir bag becomes fully inflated and the pressure increases sufficiently to open the positive-pressure relief valve. In contrast, the effectiveness of an open system in preventing spillage depends not only on the volume of the reservoir but also on the flow characteristics within the interface. [125]

Gas Disposal Assembly Tubing

The gas disposal assembly tubing (see Fig. 7-25 (Figure Not Available)) conducts waste gas from the scavenging interface to the gas disposal assembly. It should be collapse proof and should run overhead, if possible, to minimize the chance of occlusion. [123]

Gas Disposal Assembly

The gas disposal assembly ultimately eliminates excess waste gas (see Fig. 7-25 (Figure Not Available)). There are two types of disposal systems: (1) active and (2) passive.

The most common method of gas disposal is the active assembly, which uses a central vacuum. The vacuum is a mechanical flow-inducing device that removes the waste gases. An interface with a negative-pressure relief valve is mandatory because the pressure within the system is negative. A reservoir is desirable, and the larger the reservoir, the lower the suction flow rate needed. [121] [125]

A passive disposal system does not use a mechanical flow-inducing device. Instead, the pressure of the waste gas itself produces flow through the system. Positive-pressure relief is mandatory, but negative-pressure relief and a reservoir are unnecessary. Excess waste gas can be eliminated in a number of ways, including venting through the wall, ceiling, or floor or to the room exhaust grill of a nonrecirculating air conditioning system. [121] [125]

Hazards

Scavenging systems minimize operating room pollution, yet they add complexity to the anesthesia system. A scavenging system extends the anesthesia circuit all the way from the anesthesia machine to the ultimate disposal site. This extension increases the potential for problems. Obstruction of scavenging pathways can cause excessive positive-pressure in the breathing circuit, and barotrauma can occur. Excessive

vacuum applied to a scavenging system can cause negative pressures in the breathing system.

CHECKING ANESTHESIA MACHINES

A complete anesthesia apparatus checkout procedure should be performed each day before the first case. An abbreviated version should be performed before each subsequent case. Several checkout procedures exist, but the 1993 Food and Drug Administration (FDA) Anesthesia Apparatus Checkout Recommendations reproduced in Appendix I is the most popular. [127] [128] [129] [130] [131] The FDA checkout procedures serve only as generic guidelines because the designs of different machines vary considerably. Also, many machines have been modified in the field. Therefore, specific checks must be performed on specific machines. The user must refer to the operator's manual for special procedures or precautions.

The three most important preoperative checks are (1) oxygen analyzer calibration, (2) low-pressure circuit leak test, and (3) circle system test. Each is discussed in the following sections.

Oxygen Analyzer Calibration

The oxygen analyzer is the most important machine monitor because it is the only machine safety device that evaluates the integrity of the low-pressure circuit. Other machine safety devices, such as the fail-safe valve, the oxygen supply failure alarm, and the proportioning system, are all upstream from the flow control valves (see Fig. 7-3 (Figure Not Available)). The only machine monitor that detects problems downstream from the flow control valves is the oxygen analyzer. Calibration of this monitor is described in Appendix I, #9.

Low-Pressure Circuit Leak Test

The low-pressure circuit leak test checks the integrity of the anesthesia machine from the flow control valves to the common outlet. It evaluates the portion of the machine that is downstream from all safety devices except the oxy-gen analyzer. The components located within this area are precisely the ones that are most subject to breakage and leaks. Leaks in the low-pressure circuit can cause hypoxia or patient awareness. [132] Flowtubes, the most delicate pneumatic component of the machine, can crack or break. A typical three-gas anesthesia machine has 16 O-rings in the low-pressure circuit. Leaks can occur at the interface between the glass flowtube and the manifold and at the O-ring junction between the vaporizer and its manifold. Loose filler caps on vaporizers are a common source of leaks, and these leaks can cause patient awareness under anesthesia. [133]

Several different methods have been used to check the low-pressure circuit for leaks. They include the oxygen flush test, the common gas outlet occlusion test, the traditional positive-pressure leak test, the North American Drager positive-pressure leak test, the Ohmeda 8000 internal positive-pressure leak test, the Ohmeda negative-pressure

Data from Ohio Medical Products, [9] [11] *Ohmeda,* [10] [12] [13] [15] [16] [17] *North American Drager* [18] [19] [20] [21] [22]

leak test, and the new 1993 FDA universal negative pressure leak test. One reason for the large number of methods is that the internal design of various machines differs considerably. The most notable example is that most Ohmeda machines have a check valve near the common gas outlet, whereas North American Drager machines do not. The presence or absence of the check valve profoundly influences which preoperative check is indicated.

Several mishaps have resulted from the application of the wrong leak test to a machine. [31] [68] [134] Therefore, it is mandatory to perform the appropriate low-pressure leak test before every case. To do this, it is essential to understand the exact location and operating principles of the Ohmeda check valve. Most Ohmeda anesthesia machines have a machine outlet check valve located in the low-pressure circuit (Table 7-5) . The check valve is located downstream from the vaporizers and upstream from the oxygen flush valve (see Fig. 7-3 (Figure Not Available)). It is open (Fig. 7-28 (Figure Not Available) , left) in the absence of back pressure. Gas flow from the manifold moves the rubber flapper valve off its seat and allows gas to proceed freely to the common outlet. The valve closes (Fig. 7-28 (Figure Not Available) , right) if back pressure is exerted on it. [8] Back pressure sufficient to close the check valve may occur with the following conditions: oxygen flushing, peak breathing circuit pressures generated during positive-pressure ventilation, or use of a positive-pressure leak test.

Generally, machines without check valves can be tested by use of a positive-pressure leak test, and machines with check valves must be tested using a negative-pressure leak test. When performing a positive-pressure leak test, the operator generates positive pressure in the low-pressure circuit by use of flow from the anesthesia machine or from a positive-pressure bulb to detect a leak. When performing a negative-pressure leak test, the operator creates negative pressure in the low-pressure circuit by use of a suction bulb to detect leaks. Two different low-pressure circuit leak tests are described in the following sections.

Figure 7-28 (Figure Not Available) Machine outlet check valve (see text for details). *(Modified from Bowie and Huffman [6])*

Oxygen Flush Positive-Pressure Leak Test

Historically, older anesthesia machines did not have check valves in the low-pressure circuit. Therefore, it was common practice to pressurize the breathing circuit and the low-pressure circuit with the oxygen flush valve to test for internal anesthesia machine leaks. Because many modern Ohmeda machines now have check valves in the lowpressure circuit, however, application of a positive-pressure leak test to these machines can be misleading or even dangerous (Fig. 7-29) (Figure Not Available) . Inappropriate use of the oxygen flush valve to evaluate the low-pressure circuit for leaks can lead to a false sense of security despite the presence of huge leaks. [31] [40] [68] [134] Positive pressure from the patient circuit closes the check valve, and the value on the airway pressure gauge does not decline. The system appears to be tight, but in actuality, only the circuitry downstream from the check valve is leak-free. [27] Thus, a vulnerable area exists from the check valve back to the flow control valves because this area is not tested by a positive-pressure leak test.

1993 FDA Universal Negative-Pressure Leak Test

In 1993, the FDA universal negative-pressure leak test [131] (Appendix I, #5) was named universal because it can be used to check all contemporary anesthesia machines, regardless of the presence or absence of check valves in the low-pressure circuit. It can be applied to Ohmeda machines, North American Drager machines, and others. The 1993 FDA check is based on the Ohmeda negative-pressure leak test (Fig. 7-30) (Figure Not Available) . It is performed by use of a negative-pressure leak testing device, which is a simple suction bulb. The machine master switch, the flow control valves, and the vaporizers are turned off. The suction bulb is attached to the common fresh gas outlet and is squeezed repeatedly until it is fully collapsed. This action creates a vacuum in the low-pressure circuitry. The machine is leak-free if the hand bulb remains collapsed for at least 10 seconds. A leak is present if the bulb reinflates during this period. The test is repeated with each vaporizer individually turned to the "on" position because internal vaporizer leaks can be detected only with the vaporizer turned on.

The FDA universal negative-pressure low-pressure circuit leak test has several advantages. [132] It helps eliminate the present confusion regarding which check should be performed on specific machines. The universal test is quick and simple to perform. It has an obvious end point, and it isolates the problem. For example, if the bulb reinflates in less than 10 seconds, a leak is present somewhere in the low-pressure circuit. Therefore, it differentiates between breathing-circuit leaks and low-pressure circuit leaks. The universal negative-pressure leak test is the most sensitive of all contemporary leak tests because it is not volume dependent, that is, it does not involve a compliant breathing bag or corrugated hoses. It can detect leaks as small as 30 mL/min. Finally, the operator does not need a detailed or in-depth

Figure 7-29 (Figure Not Available) Inappropriate use of the oxygen flush valve to check the low-pressure circuit of an Ohmeda machine equipped with a check valve. The area within the rectangle is not checked by the inappropriate use of the oxygen flush valve. The components located within this area are precisely the ones most subject to breakage and leaks. Positive pressure within the patient circuit closes the check valve, and the value on the airway pressure gauge does not decline, despite leaks in the low-pressure circuit. *(Modified from Andrews JJ: Delivery systems for inhaled anesthetics. Figure 7-30 (Figure Not Available) FDA negative pressure leak test. (Left) A negative pressure leak testing device is attached directly to the machine outlet. Squeezing the bulb creates a vacuum in the low-pressure circuit and opens the check valve. (Right) When a leak is present in the low-pressure circuit, room air is entrained through the leak and the suction bulb inflates. *(From Andrews JJ: Understanding anesthesia machines. In 1988 Review Course Lectures. Cleveland, International Anesthesia Research Society, 1988, p 78.)*

knowledge of proprietary design differences. If the operator performs the universal test correctly, the leak is detected.

Circle System Test

The circle system test (Appendix I, #11 and #12) evaluates the integrity of the circle breathing system, which extends from the common gas outlet to the Y-piece (see Fig. 7-21). It has two parts--the leak test and the flow test. To thoroughly check the circle system for leaks and for valve integrity, both tests must be performed preoperatively. The leak test is performed by closing the pop-off valve, occluding the Y-piece, and pressurizing the circuit to 30 cm H_2O by use of the oxygen flush valve. The value on the pressure gauge does not decline if the circle system is leak-free, but this does not ensure valve integrity. The value on the gauge reads 30 cm H_2O if the unidirectional valves are stuck shut or if the valves are incompetent.

The flow test checks the integrity of the unidirectional valves. It can be performed by removing the Y-piece from the circle system and breathing through the two corrugated hoses individually. The valves should be present, and they should move appropriately. The operator should be able to inhale but should not be able to exhale through the inspiratory limb. The operator should be able to exhale but not inhale through the expiratory limb. The flow test can also be performed by use of the ventilator and a breathing bag attached to the Y-piece as described in the 1993 FDA "Anesthesia Apparatus Checkout Recommendations" (Appendix 1, #12). [131]

SUMMARY

Rapid advances in the anesthesia industry make it increasingly difficult for the anesthesia care provider to keep up with anesthesia machine technology. Nevertheless, a thorough understanding of the machine is mandatory for the safe practice of anesthesia. Machines are equipped with dozens of safety features, yet none of them is foolproof. The anesthesia care provider must still check the machine preoperatively by use of appropriate checkout procedures.

Chapter 8 - Barbiturates

Robert J. Fragen
Michael J. Avram

INTRODUCTION

For more than 50 years, barbiturates have been a standard element of anesthesia practice. Their use has profoundly affected the way anesthesiologists administer drugs, because barbiturates have a rapid but short action and are safe and effective when administered properly.

Although barbituric acid was first synthesized in 1864 by von Baeyer, it was not until 1903, when Fischer and von Mering synthesized diethylbarbituric acid, that a barbiturate with hypnotic activity became available. The many hypnotic barbiturates introduced between 1903 and 1932 had little impact on intravenous anesthesia because they had slow onsets and long durations of action. [1] In 1932, Weese and Scharpff introduced the methylated oxybarbiturate hexobarbital, bringing a new era to anesthesia, because hexobarbital had a rapid onset and short duration of hypnotic effect despite its excitatory side effects. Another barbiturate, thiopental, which is fast-acting but devoid of excitatory side effects, was first administered in 1934 by Waters and Lundy. [1] Unfortunately, a lack of understanding of pharmacokinetics led to the use of hexobarbital and thiopental for induction and maintenance of general anesthesia in the manner of diethyl ether and chloroform, sometimes with disastrous results including hypotension and prolonged sleeping times. [2] Administration of hexobarbital and thiopental in this manner to the casualties at Pearl Harbor resulted in so many deaths that intravenous anesthesia was described as "an ideal method of euthanasia." [3] The negative impact of this report was perhaps moderated both by an accompanying case report by Adams and Gray [4] and by an anonymous editorial [5] suggesting that the method of drug administration rather than the drug's inherent toxicity caused the adverse outcomes. Brodie and colleagues [6] provided further insight into the use of intravenous barbiturates by demonstrating that the effects of small doses of thiopental were terminated, not by metabolism, but by redistribution from their sites of action to other body tissues. Price [7] clarified this concept in 1960 and explained that during prolonged administration, distribution becomes less effective in terminating the drug's action because redistribution sites approach equilibrium. An understanding of its pharmacokinetics [2] [5] [6] [7] and its desirable pharmacologic properties [8] made thiopental the standard hypnotic drug to induce anesthesia.

BASIC PHARMACOLOGY

Chemistry and Formulation

The barbiturates are derivatives of barbituric acid (2,4,6-trioxohexahydropyrimidine) (Fig. 8-1) , which is devoid of hypnotic activity, or of its 2-thio analogue. Although commonly called a cyclic ureide of malonic acid because of its synthesis from urea and malonic acid, barbituric acid is actually a pyrimidine nucleus. [9] Keto-enol tautomerization (see Fig. 8-1) (or its sulfur equivalent) lends acidic character to the oxygen (or sulfur) at position 2 of the barbiturate nucleus; the predominance of the enol form, or its sulfur equivalent, in alkaline solution allows the formation of water-soluble barbiturate salts. [10]

The barbiturates commonly used for induction of anesthesia are the thiobarbiturates thiopental [5-ethyl-5-(1-methylbutyl)-2-thiobarbituric acid] and thiamylal [5-allyl-5-(1-methylbutyl)-2-thiobarbituric acid] and the methylated oxybarbiturate methohexital [alpha- *dl*-1-methyl-5-allyl-5-(1-methyl-2-pentynyl) barbituric acid] (Fig. 8-2) . The sodium salts of these drugs, which are mixed with 6 percent by

Figure 8-1 The keto and enol tautomeric forms of barbituric acid with the sites of substitution in the hypnotically active barbiturates identified as 1, 2, and 5.

weight anhydrous sodium carbonate, are reconstituted with either water or 0.9 percent sodium chloride to produce 2.5 percent, 2.0 percent, or 1.0 percent solutions of thiopental, thiamylal, or methohexital, respectively. The buffering action of the sodium carbonate in the presence of atmospheric carbon dioxide maintains the moderate alkalinity (pH 10 to 11) of the barbiturate solutions. A decrease in the alkalinity of the barbiturate solutions can result in their precipitation as free acids; therefore, they should not be reconstituted with lactated Ringer's solution, nor should the reconstituted solutions be mixed with acidic solutions of other drugs. Properly reconstituted thiobarbiturate solutions are stable for 1 week if refrigerated. Sterile water solutions of methohexital can be used up to 6 weeks after reconstitution. The bactericidal and bacteriostatic properties of thiopental solution (and, presumably, those of the other barbiturates) appear to be related to its relatively high pH. [11]

Solutions of thiopental may be incompatible with drugs in more acidic solution likely to be coadministered during the induction of anesthesia, including pancuronium, vecuronium, atracurium, alfentanil, sufentanil, and midazolam. [12] A simulation of a rapid sequence induction in which thiopental was coadministered with either vecuronium or pancuronium led to the formation of 15,000 to 20,000 17- to 39-mum particles/mL which appeared to dissolve readily in plasma but had the potential to occlude the intravenous line. [13] Such precipitation can be prevented by allowing a 30-second delay between the injection of thiopental and the injection of the muscle relaxants.

Figure 8-2 Hypnotically active barbiturates with asymmetric centers indicated by an asterisk.

Structure-Activity Relationships

Modifying the structure of the hypnotically inactive barbituric acid (see Fig. 8-1) can convert it into a hypnotic barbiturate with physicochemical properties that affect its ability to gain access to its sites of action and to interact with its receptor. The structure-activity relationships of the barbiturates are well described. [9] Hypnotic activity is introduced into the barbituric acid molecule by the addition of side chains, especially if at least one of them is branched, in positions 5 (see Figs. 8-1 and 8-2) . The length of the side chains in the 5 position influences both the potency and the duration of action of the barbituric acid derivatives; secobarbital and thiamylal are slightly more potent than pentobarbital and thiopental, respectively, because the former drugs have slightly longer (three-carbon versus two-carbon) side chains in position 5 (see Fig. 8-2) . Replacing the oxygen atom with a sulfur atom at position 2 of an active barbiturate produces a barbiturate with a more rapid onset and a shorter duration of action; the thiobarbiturates, thiopental and thiamylal, have faster onsets and shorter durations of action than their oxybarbiturate analogues, pentobarbital and secobarbital (see Fig. 8-2) . Methylation of an active barbiturate in position 1 produces a drug such as methohexital (see Fig. 8-2) with not only a rapid onset and short duration of action but also an increased incidence of excitatory side effects. Therefore, any chemical modification that increases the lipophilicity of a hypnotic barbiturate generally increases both its potency and its rate of onset while shortening its duration of action.

The effect of stereoisomerism on biologic activity is another important aspect of structure-activity relationships. Many barbiturates, including pentobarbital, secobarbital, thiopental, thiamylal, and methohexital, have asymmetric carbon atoms in one of the side chains attached to carbon 5 of the barbiturate ring [14] (see Fig. 8-2) . The *l* isomers of pentobarbital, secobarbital, thiopental, and thiamylal are nearly twice as potent as the *d* isomers despite their similar access to the central nervous system (CNS) [14] and, at least in the case of thiopental, despite having no clinically significant differences in pharmacokinetics. [15] These barbiturates are marketed as racemic mixtures. Methohexital has four stereoisomers because it has an asymmetric center at carbon 5, as well as an asymmetric carbon atom on one of the side chains attached to carbon 5 (see Fig. 8-2) . The most potent hypnotic stereoisomer of methohexital is the beta- *l,* which is four to five times as potent as the least active, alpha- *l;* however, the beta-isomers produce excessive motor activity, so methohexital is marketed as a racemic mixture of alpha-isomers. [16] Differences in the potency of stereoisomers suggest interaction with the chiral active center of a receptor or enzyme rather than a nonspecific action; side effects are often due to nonspecific actions of drugs. Therefore, some consider the less active stereoisomer to be an impurity in the drug formulation. [17]

Mechanism of Action

The gamma-aminobutyric acid ($GABA_A$) receptor complex is the most likely site of barbiturate action. [18] Of the various effects of barbiturates at the cellular level, only their effects on

Figure 8-3 (Figure Not Available) The hypothetic GABA $_A$ oligomeric complex. *(Modified from Olsen et al [20])*

the $GABA_A$ receptor complex occur at clinical drug concentrations, correlate with anesthetic potency, and are stereospecific.

GABA is the principal inhibitory neurotransmitter in the mammalian CNS. The GABA $_A$ receptor is an oligomeric complex consisting of at least five protein subunits, which assemble to form a chloride ion channel with a GABA $_A$ receptor, as well as benzodiazepine, barbiturate, steroid, and picrotoxin binding sites [18] [19] [20] (Fig. 8-3) (Figure Not Available) . Activation of the GABA $_A$ receptor increases chloride conductance through the ion channel, hyperpolarizing and thereby reducing the excitability of the postsynaptic neuron. Thus, GABA $_A$ receptors are referred to as *ligand-gated chloride ion channels.*[18] [19]

Barbiturates both enhance and mimic the action of GABA. [18] [19] By binding to their receptor, barbiturates decrease the rate of dissociation of GABA from its receptor and increase the duration of GABA-activated chloride ion channel openings. At slightly higher but still clinically relevant concentrations, barbiturates directly activate chloride channels, even in the absence of GABA. Barbiturate enhancement of the action of GABA may be responsible for its sedative-hypnotic effects, whereas the GABA-mimetic effect at slightly higher concentrations may be responsible for "barbiturate anesthesia." [18]

Pharmacokinetics/Pharmacodynamics

The physiologic pharmacokinetic models of thiopental disposition developed by Price and colleagues [7] [21] and by Bischoff and Dedrick [22] provide invaluable insight into the pharmacology of fast-acting drugs such as the barbiturates. Following intravenous administration, thiopental mixes rapidly within a central blood pool and is distributed by blood flow and molecular diffusion throughout the tissues of the body according to their rate of perfusion, their affinity for the drug, and the relative concentration of thiopental in the tissues and blood (Fig. 8-4) (Figure Not Available) . The highly perfused, relatively low-volume tissues such as the brain equilibrate rapidly with the high early concentrations of thiopental in the blood, resulting in the induction of anesthesia. Thiopental concentrations in the blood and highly perfused tissue then decrease rapidly as the drug redistributes to the large reservoir of less well perfused lean tissue such as muscle, terminating the effect of an induction dose. Despite its high affinity for thiopental, adipose tissue takes up drug slowly because of its poor perfusion; the amount of thiopental taken up by adipose tissue is not significant until long after its effects wane. The irreversible removal of thiopental from the body (i.e., the elimination clearance), like uptake into adipose tissue, is so slow relative to the uptake of drug by the lean tissue that it contributes minimally to the termination of the effect of an induction dose.

Compartmental pharmacokinetic models that mathematically characterize the blood drug concentration versus time relationships (Fig. 8-5) have largely replaced physiologic models [23] because physiologic models require extensive human data. Data from compartmental models of thiopental and methohexital disposition are presented in Table 8-1 . The central volumes of distribution (V_c) of these drugs exceed intravascular space in these models; the rapid onsets of

Figure 8-4 (Figure Not Available) Percentage of thiopental dose in the central blood pool, viscera, lean tissue, and fat after rapid intravenous administration. This model assumes there is no elimination clearance. *(From Price et al [21])*

TABLE 8-1 -- Pharmacokinetics of Thiopental and Methohexital (± SD)

DRUG	V_c (L/kg)	V_{dss} (L/kg)	Cl_e (mL/min/kg)	$t_{½beta}$ (h)	ESTIMATED HEPATIC EXTRACTION RATIO
Thiopental	0.38 ± 0.10	2.5 ± 1.0	3.4 ± 0.5	11.6 ± 6.0	0.15
Methohexital	0.35 ± 0.10	2.2 ± 0.7	10.9 ± 3.0	3.9 ± 2.1	0.50

Data from Hudson et al [24]

the effects of the drugs suggest that the brain is part of their V_c . The action of an induction dose of thiopental or methohexital is terminated by redistribution from the relatively small V_c to the much larger total apparent volume of distribution (V_{dss}), suggesting extensive uptake by some body tissues. The low, restrictive elimination clearance (Cl_e) of thiopental is a reflection of its hepatic extraction ratio, which may be low because of its extensive protein binding. Methohexital has an intermediate hepatic extraction ratio and Cl_e despite extensive protein binding. Because the elimination half-life ($t_{½beta}$) is a pharmacokinetic variable that depends directly on the V_d and inversely on the Cl_e , the difference in $t_{½beta}$ between thiopental and methohexital is due to a difference in Cl_e .

Although Cl_e begins the moment a drug reaches its clearing organs, Cl_e becomes a dominant factor in the plasma drug concentration versus time relationship only after the end of the rapid decline in plasma drug concentrations during the redistribution phase (see Fig. 8-5) . Hudson et al [24] and Burch and Stanski [25] determined the relative importance of Cl_e and redistribution to the termination of the effect of an induction dose of either thiopental or methohexital. They found that despite the threefold difference in the Cl_e of the drugs (see Table 8-1) , redistribution is the primary process terminating the effect of an induction dose of either drug; this finding is consistent with the results of physiologic models. [21] [22] However, when methohexital or thiopental is administered in large doses, as multiple doses, or by continuous infusion, the capacity of the lean tissue to dilute the drugs decreases progressively as the tissue approaches equilibrium with the blood. Thus, termination of the drug action increasingly depends

Figure 8-5 Blood thiopental concentration versus time relationship after rapid intravenous drug administration. The circles represent measured thiopental concentrations, and the line represents a computer-generated fit to a quadriexponential equation. *(Data from Henthorn et al [26])*

on the slower processes of uptake into adipose tissues and Cl_e , resulting in a prolonged drug effect. [7] As an extreme example, when thiopental was administered for 2 to 4 days of cerebral resuscitation, redistribution sites reached equilibrium with the blood, drug-metabolizing enzymes approached saturation, and recovery depended entirely on nonlinear (Michaelis-Menten) drug metabolism and took nearly 4 days [26] (Fig. 8-6) (Figure Not Available) .

Pharmacokinetics is only part of the dose-response relationship. The other component of this relationship is pharmacodynamics, or the relationship between plasma drug concentrations and drug effect. An understanding of the pharmacodynamics of a drug such as thiopental ideally requires a continuous, noninvasive measure of drug effect. Such a measure can be provided by the electroencephalogram (EEG). Buhrer et al [27] studied this relationship in detail and determined that the number of waves per second, a variable obtained from aperiodic analysis of the EEG, best characterizes thiopental's activation of the EEG at low concentrations and its subsequent inhibition of the EEG at high concentrations. The same group then examined the relationship between clinical anesthetic depth assessed by noxious stimuli and the number of waves per second from aperiodic analysis of the EEG. [28] These investigators found that

Figure 8-6 (Figure Not Available) Decline in plasma thiopental concentrations with time after a 42-hour infusion of 40.2 g of the drug for cerebral resuscitation, illustrating nonlinear (Michaelis-Menten) elimination clearance. Note the difference between this postdrug administration relationship and that for a standard dose of thiopental (see Fig. 8-8) (Figure Not Available) , which has typical distributional phases followed by linear elimination clearance. *(Modified from Stanski et al [26])*

a unique relationship between all but the deepest clinical anesthetic depth and the number of waves per second could not be defined because of the biphasic nature of the EEG response (i.e., activation followed by inhibition). [28] Thus, the number of waves per second from aperiodic analysis of the EEG does not provide a useful index of anesthetic depth. It may, nonetheless, prove useful in combined pharmacokinetic-pharmacodynamic models that include a description of this biphasic response because it may still allow an estimate of the rate of equilibration between blood thiopental concentrations and those in the brain. [29] Combined pharmacokinetic-pharmacodynamic models can potentially establish the kinetic or dynamic basis of differences in the reactivity of individuals or groups of individuals (e.g., the elderly) to the barbiturates. [30]

A real-time index of the effect of thiopental may be provided by the bispectral index (BIS). [31] BIS is a measure of hypnotic effect that is computed from EEG data and is reported as a value between 0 and 100. A patient maintained at a BIS of less than 55 from the time of induction of anesthesia with thiopental until maintenance anesthetic concentrations are adequate would have a small probability of awareness. [31]

Plasma concentrations for thiopental's hypnotic effect and for its anesthetic effect have been determined by two different methods with remarkably good agreement in the results. Hung et al [26] used a computer-controlled infusion pump to maintain various constant target serum thiopental concentrations, which were verified by serum drug concentration measurement, and assessed response to verbal command, tetanic nerve stimulation, trapezius squeeze, laryngoscopy, and laryngoscopy and intubation. Shanks and colleagues [32] determined effective plasma thiopental concentrations from a combined pharmacokinetic-pharmacodynamic model that was based on both a study in which thiopental was infused until the patient first lost voluntary motor power and then had EEG burst suppression [33] and a separate study of thiopental pharmacokinetics following rapid intravenous administration. [34] The serum concentration producing a 50 percent probability of loss of voluntary motor power was predicted to be 11.3 mug/mL, [32] which is similar to that for loss of response to verbal command, 15.6 mug/mL. [28] The mean effective thiopental concentration producing EEG burst suppression in 50 percent of the population was predicted to be 33.9 mug/mL, whereas the 50 percent probability of no response to tetanic nerve stimulation and trapezius muscle squeeze was at 30.3 and 39.8 mug/mL, respectively. Much higher thiopental concentrations were needed in the study of Hung et al to produce a 50 percent probability of no response to laryngoscopy and laryngoscopy and intubation, 50.7 and 78.8 mug/mL, respectively. [28]

CLINICAL PHARMACOLOGY AND USES

Pharmacokinetic Bases of Altered Dose Requirements

Interindividual variability in response to thiopental is well known. [35] [36] Variability in response to induction doses of thiopental is not due to differences in V_{dss}, Cl_e, or $t_{½beta}$, because these minimally affect the plasma drug concentration versus time relationship when thiopental exerts its effect and when its effect is being terminated. Differences in thiopental dose requirements must be due to altered pharmacodynamics or early distribution pharmacokinetics because thiopental has a rapid onset of effect. For example, on the basis of his physiologic model, Price [7] reasoned that the dose requirement is less in patients in hemorrhagic shock because, in this condition, the fraction of the dose received by the brain is very high and its rate of removal from the brain is very low, owing to decreased blood flow to other tissues. Price's hypothesis was substantiated by a study showing changes in the physiologic kinetics of lidocaine in hypovolemic monkeys. [37]

A decrease in the initial distribution volume of thiopental could explain increased reactivity to a standard drug dose because it would lead to less dilution of the dose and higher plasma drug concentrations. While seeking the basis of the decreased thiopental dose requirements in the elderly, Homer and Stanski [38] found no change in the pharmacodynamics with age, but they reported an age-related decrease in the initial distribution volume. Although these observations could provide a pharmacokinetic rationale for the decreased dose requirements in the elderly, neither Avram et al [34] nor Stanski and Maitre [39] could reproduce them. Despite using different methods of drug administration and different pharmacokinetic models, these investigators found similar age-related differences in clearance to the rapidly equilibrating compartment. Stanski and Maitre [39] concluded this finding could account for the age-related decrease in thiopental induction dose requirement, whereas Avram et al [34] concluded it could not. This has led both groups to develop pharmacokinetic models that are able to describe drug distribution from the moment of injection; the model of Wada et al [40] is a sophisticated physiologic pharmacokinetic model based on a scale-up to humans of a model developed in rats, whereas that of Krejcie and colleagues [41] [42] is a recirculatory compartmental pharmacokinetic model based on the disposition of markers of known physiologic spaces.

Wulfsohn and Joshi [43] suggested that if the induction dose of thiopental is based on lean body mass rather than on total body mass, there is no need to adjust the dose with age because the proportion of lean body mass decreases with increasing age. Termination of the effect of an induction dose of thiopental by redistribution to muscle [21] and the increase in the slowly equilibrating volume of distribution with age [34] are consistent with this suggestion. Furthermore, the apparently increased response of the obese [35] and of females [35] may be eliminated if the induction dose of thiopental is based on lean body mass, which represents a smaller proportion of total body mass in these patients. [43]

When the hypothesis that lean body mass and cardiac output codetermine thiopental induction dose regardless of age and sex was tested, age and sex remained important variables. Avram et al [33] determined the combined effect of the patient-specific variables of age, sex, cardiac output, and either body weight or lean body mass on thiopental requirements to reach the end point of loss of voluntary motor power (syringe drop) or the end point of EEG burst suppression. They confirmed a greater thiopental potency in females and the progressive increase in thiopental potency with age (Fig. 8-7) (Figure Not Available) . However, the multiple linear regression

---

Figure 8-7 (Figure Not Available) Cumulative percentage of patients reaching each end point (loss of voluntary motor power, the clinical end point, and EEG burst suppression, the EEG end point) versus log of the thiopental dose at each end point when thiopental was infused at 150 mg/min in 30 male and 30 female patients (A) and 10 male and 10 female patients in each of three age ranges: 18 to 45 years, 46 to 65 years, and 66 to 83 years (B). *(From Avram et al [35])*

model, which accounted for 75 percent of the variability at the syringe drop end point, included not only lean body mass or body weight but also age and sex. The multiple linear regression model for the EEG burst suppression end point accounted for nearly 90 percent of the observed variability in dose requirements and included not only lean body mass or weight and cardiac output but also age. Although these relationships were determined by infusion of thiopental at 150 mg/min, a combined pharmacokinetic-pharmacodynamic model predicts that when the same dose is infused over 30 seconds, it would produce loss of consciousness at 1 minute, lasting for 4 minutes. [29]

Wada et al [40] used their physiologic pharmacokinetic model of drug disposition in humans, based on a scale-up of a model developed in rats, to simulate arterial plasma thiopental concentrations during and after administration of 250 mg of the drug over 1 minute to "patients" of different age, gender, and body habitus and to "patients" who differed only in their cardiac output. They predicted slightly higher peak concentrations in women and the elderly and a nearly 50 percent higher peak concentration in patients with a 50 percent decrease in cardiac output (Fig. 8-8) (Figure Not Available) . Patients who are 50 or 100 percent overweight or have a 50 percent increase in cardiac output were predicted to have lower peak concentrations (see Fig. 8-8) (Figure Not Available) . This study confirmed the importance of cardiac output as a determinant of early arterial thiopental concentrations. The authors went on to predict that adjusting the thiopental induction dose on the basis of either cardiac output or lean body mass will minimize interindividual differences in peak arterial thiopental concentrations in all but extremes of cardiac output (i.e., a 50% increase or a 50% decrease).

A study of the relationship of thiopental infusion rate with dose required to reach the end point of loss of voluntary motor power (syringe drop) also lends weight to the importance of cardiac output in determining induction dose requirements. Gentry et al [44] found that the relationship of the cumulative thiopental dose with the infusion rate is not a simple linear relationship; at infusion rates of 40 to 150 mg/min, thiopental doses were not different, but as the infusion rate increased to 1200 mg/min, the dose required to reach the clinical end point nearly doubled. These observations

---

Figure 8-8 (Figure Not Available) Physiologic pharmacokinetic model predictions of arterial plasma thiopental concentrations immediately after intravenous administration of 250 mg of the drug over 1 minute in patients with different cardiac outputs (A) and body habitus (B), in a male and a female (C), and in patients of different ages (D). *(From Wada et al [40])*

were best predicted by a combined pharmacokinetic-pharmacodynamic model that reflected cardiac output. [32] This model also predicts that the thiopental dose requirement will increase rapidly at infusion rates below 40 mg/min, which are lower than clinically useful rates.

There are strong suggestions in the literature that both cardiac output and its regional distribution are important determinants of thiopental induction dose requirements. A recent study by Gin and colleagues [45] found that the thiopental dose required to produce loss of consciousness and anesthesia in pregnant women of 7 to 13 weeks' gestation was 18 and 17 percent less than that in nonpregnant women, respectively. They postulated that dose requirement decreased despite a 20 percent increase in cardiac output at 13 weeks' gestation because of altered distribution of peripheral blood flow in early pregnancy. Studies of the importance of

cardiac output and its regional distribution in determining early drug concentration histories are under way. [46]

Acute Tolerance

Acute tolerance to thiopental was first described by Brodie et al [47] and subsequently by Dundee and associates [48] and by Toner et al. [49] According to these investigators, the plasma thiopental concentration at awakening is proportional to the dose used; that is, the depth of anesthesia is independent of the plasma thiopental concentration. This suggests that the higher the induction dose of thiopental, the less sensitive a patient will be to a subsequent dose. Hudson et al [50] evaluated the relationship between venous plasma thiopental concentrations and the EEG spectral edge, going from light to moderately deep anesthesia and back during and after three infusions administered over approximately 1 hour; they found no acute tolerance. The consistency of plasma thiopental concentrations on awakening after exponential infusions delivering 0.8 to 2.6 g of thiopental led Crankshaw and colleagues [51] to conclude that there was no acute tolerance to thiopental. The discrepancies among these studies were at least partially explained by Barratt et al, [52] [53] who found that shortly after rapid intravenous drug administration, peripheral venous plasma thiopental concentrations poorly reflect brain (i.e., jugular venous) thiopental concentrations. This accounts for the apparent acute tolerance reported by Toner et al. [49]

Nighttime Hypnosis and Premedication

Pentobarbital and secobarbital provided nighttime drowsiness (hypnosis) and premedication prior to surgery before benzodiazepines replaced them (Ch. 23) . Benzodiazepines cause less cardiovascular, respiratory, and CNS depression. [54] Benzodiazepines given orally or parenterally also replaced barbiturates given orally, rectally, or parenterally for premedication in children.

Induction of General Anesthesia

Drugs and Dosage

Thiopental, thiamylal, and methohexital can be injected intravenously to induce general anesthesia and can also be used to maintain unconsciousness as the hypnotic component of a balanced anesthetic technique or a total intravenous

anesthetic technique. These barbiturates continue to be commonly used anesthetic induction agents because they induce anesthesia rapidly and pleasantly and are less expensive than propofol or etomidate. When injected intravenously, these lipid-soluble drugs act in one arm-brain circulation time and have their maximum effect in about 1 minute. [7] Because barbiturates redistribute rapidly from the brain to the lean body tissue, the duration of effect from a single induction dose is about 5 to 8 minutes. Induction doses produce the highest blood concentrations and, as a result, the most profound effects on body systems and the most side effects.The usual induction dose of thiopental for healthy adults is 2.5 to 4.5 mg/kg (Fig. 8-9) (Figure Not Available) . Doses based on lean body mass, rather than actual body weight, compensate for age, gender, and body habitus differences. [33] [40] A slightly higher dose, 5 to 6 mg/kg, is recommended for children, and 7 to 8 mg/kg is used for infants [55] (Fig. 8-10) (Figure Not Available) . To identify persons who may be particularly sensitive to the barbiturates, one can inject 25 percent of the calculated dose initially and then observe the patient's level of consciousness, respiration, and cardiovascular response. If this small dose has a great effect, the calculated dose should be reduced.

Both the patient's premedication and general health (American Society of Anesthesiologists [ASA] physical status) can influence the dose of thiopental necessary to induce anesthesia [36] (Table 8-2) (Table Not Available) . Premedicated geriatric patients require a 30 to 35 percent reduction in dose as compared with younger patients. [35] [36] Unpremedicated pregnant women of 7 to 13 weeks' gestation require 18 percent less thiopental to induce anesthesia than do nonpregnant women of similar age. [45] Benzodiazepines, opioids, and, more recently, alpha $_2$ -agonists can be used for premedication before barbiturate induction of anesthesia. Midazolam given intravenously concomitantly with thiopental shifts the dose-response curve to the left in proportion to the dose of midazolam administered. [56] Fentanyl, 5 mug/kg, given intravenously to healthy adults a few minutes before induction with thiopental decreases the median effective dose (ED $_{50}$)

Figure 8-9 (Figure Not Available) This bar graph depicts the scatter of induction doses of thiopental (mg/kg) in 2,006 consecutive unselected anesthetic inductions. See the source reference for how the induction doses were determined. *(From Dundee et al [36])*

Figure 8-10 (Figure Not Available) Estimated ED $_{50}$ ± SEM of thiopental in children of different ages from a dose-response study performed with the "up and down method." The ED $_{50}$ is the dose at which anesthesia is induced in 50 percent of the children. The dashed lines do not represent data and are only added to facilitate visual observation of the actual data. *(From Jonmarker et al [57])*

for unconsciousness from 4 to 2.2 mg/kg without causing significant change in systolic blood pressure. [57] Oral clonidine, 2 or 4 mg, decreased the induction dose of thiamylal (mean ± standard deviation [SD]) in 7- to 12-year-old children from 5.4 ± 0.9 to 4.5 ± 1.1 and 3.4 ± 0.9, respectively. [58] Patients who have severe anemia or burns, malnutrition, advanced malignant disease, uremia, ulcerative colitis, or intestinal obstruction or who are in shock require lower anesthetic induction doses of any barbiturate. Hypothermia and circulatory failure slow the circulation time and prolong anesthetic induction; therefore, a much lower dose of barbiturate is necessary, and its effect is greater. The acutely inebriated patient requires less barbiturate to induce anesthesia, whereas the patient with chronic alcoholism requires a higher dose than normal.

An induction dose of 1.5 mg/kg of methohexital is equivalent to 4 mg/kg of thiopental; thus, methohexital appears to be about 2.7 times as potent. After reviewing a large number of cases with thiopental and thiamylal anesthetics, Tovall [59] concluded that there was no difference between the drugs in potency, incidence of laryngospasm and respiratory depression, cardiotoxicity, or recovery time. In the rest of this chapter, therefore, statements about thiopental also apply to thiamylal, unless stated otherwise.

TABLE 8-2 -- Mean Thiopental Dose Following Various Premedicants

(Not Available)

From Dundee et al [36]

Injection Complications

After injection of barbiturates, there may be an urticarial rash of the upper chest, neck, and face that fades after a few minutes. Anaphylactoid reactions such as hives, facial edema, bronchospasm, and shock occasionally occur after thiobarbiturate induction. [60] [61] The absence of reactions to oral barbiturates does not ensure a lack of sensitivity to intravenous barbiturates. Treatment of these reactions is symptomatic but should include 1-mL increments of 1:10,000 epinephrine and intravenous fluids. Aminophylline can be given to treat bronchospasm.

The incidence of pain on injection is 1 to 2 percent after thiopental and up to 5 percent after methohexital [62] when injected into small veins in the back of the hand or wrist and essentially none when injected into larger veins. If methohexital is injected into an artery or is extravasated in the subcutaneous tissue, there is mild discomfort and no sequelae occur. However, if the thiobarbiturates [63] are extravasated, pain, edema, and erythema ensue, and reactions ranging from slight soreness to extensive tissue necrosis can occur locally, depending on the concentration and total amount injected. [64]

If the intravenous thiobarbiturates, especially in concentrations greater than 2.5 percent, are injected intraarterially, intense arterial spasm results, and excruciating pain can be felt from the injection site to the hand and fingers. The onset of pain and burning is immediate and can persist for hours. Within the first 2 hours, anesthesia or hyperesthesia of the hand, edema, or motor weakness can occur. Depending on the dose of drug injected, its concentration, volume, rate of injection, and the patient's level of consciousness, a range of symptoms from mild discomfort to gangrene and loss of tissue in the hand can result. [64] The presence of a pulse

does not rule out later development of thrombosis. The pathologic process is a chemical endarteritis, which destroys the endothelium, subendothelial tissues, and possibly the muscle layer. To prevent permanent sequelae, treatment is necessary to dilute the barbiturate, relieve vascular spasm, and prevent thrombosis. Injection of papaverine (40 to 80 mg in 10 to 20 mL of normal saline) or 5 to 10 mL of 1 percent lidocaine or procaine into the artery may accomplish the first two objectives. Blocking the sympathetic nerves to the upper extremity with either a stellate ganglion block or a brachial plexus block can relieve spasm. Heparin can be given intravenously to prevent thrombosis.

Side Effects During Induction of Anesthesia

Approximately 40 percent of adult patients of either gender describe an onion or garlic taste between injection of thiopental and unconsciousness. This is more prevalent in younger patients. [65] Besides producing unconsciousness, the barbiturates can cause mild muscular excitatory movements such as hypertonus, tremor, or twitching and respiratory excitatory effects including cough and hiccup. The dosedependent incidence and severity of these effects are greater after methohexital than after thiopental, especially if

TABLE 8-3 -- Incidence of omplications in Unpremedicated Patients

(Not Available)

Modified from Clarke [66]

the dose of methohexital is more than 1.5 mg/kg [66] (Table 8-3) (Table Not Available) . Although these excitatory effects are not disturbing enough to limit the use of the barbiturates, atropine or opioids given just prior to anesthetic induction will minimize the excitatory effects, whereas premedication with phenothiazines or scopolamine exaggerates them. Inadequate induction doses can also evoke excitatory responses because inhibitory areas of the brain are the first to be depressed.

Specific Organ Function Effects

Central Nervous System Effects

The barbiturates may be hyperalgesic in subanesthetic concentrations, exaggerating the response to pain. [64] Clinical signs of their hyperalgesic effect include tachycardia, hypertension, diaphoresis, tearing, and tachypnea until pain becomes controlled. At a plasma concentration range of 2 to 20 mug/mL and brain and spinal cord concentrations of 1.7 ± 0.03 and 3.5 ± 1.7 mug/g, respectively (mean ± SD), antinociceptive effects were demonstrated in the rat. [67] However, in healthy patients, sedative infusions of thiopental or propofol were not associated with clinically relevant hyperalgesia to thermal pain. [68]

Thiopental produces a dose-related depression of the EEG [69] (Fig. 8-11) (Figure Not Available) . The awake alpha pattern progresses to higher-amplitude and slower-frequency delta and theta waves until there is burst suppression and finally a flat EEG. A flat EEG can be maintained with a continuous infusion of thiopental (4 mg/kg/h) [70] or a pentobarbital infusion that maintains a plasma concentration of 3 to 6 mg/dL. [71] There is a dose-dependent depression of cerebral metabolism of oxygen ($CMRO_2$), which reaches a maximum of 55 percent when the EEG becomes flat. This reflects a decrease in neuronal, but not metabolic, need for oxygen; hypothermia is the only way to decrease the metabolic requirement. In addition, there is a parallel reduction in cerebral blood flow and intracranial pressure (ICP) [72] ; this is particularly beneficial for patients with increased ICP. Cerebral perfusion pressure is uncompromised because ICP decreases more than mean arterial pressure. The direction and magnitude of these changes are appropriate for patients with intracranial lesions, making thiopental an appropriate drug to induce anesthesia for neurosurgical operations (Ch. 52) .

Figure 8-11 (Figure Not Available) EEG changes with increasing doses of thiopental from an awake state to a flat EEG. *(From Kiersey et al [69])*

Thiopental is the preferred barbiturate for high-dose administration or prolonged use for neuroanesthesia because patients have been reported to have had epileptiform seizures after very high doses of methohexital [73] and a 33 percent incidence of postoperative seizures when methohexital was given by continuous infusion. [74] Thiopental loading, to electroencephalographic burst suppression for cerebral artery aneurysms that require cardiopulmonary bypass and deep hypothermic circulatory arrest to be safely clipped, causes negligible cardiac impairment and does not impede separation from cardiopulmonary bypass if preoperative ventricular function is good. [75]

Although thiopental is a satisfactory agent for use with somatosensory evoked potential (SSEP) monitoring, it produces detrimental effects on amplitude of motor evoked potentials (MEP). The SSEP components remain even after administration of doses that cause a flat EEG. However, there is a dose-dependent change in median nerve SSEP response and brain-stem auditory evoked response associated with the use of thiopental. [76] [77] Thiopental and propofol depress MEP to a greater extent than do etomidate or methohexital. [78] A 2-mg/kg dose of thiopental decreased the MEP amplitude 42.8 percent, and subsequent doses caused a further dose-dependent decrease. [79]

Intravenous barbiturates are safe to use as anesthetic induction agents for ophthalmologic surgical procedures, including those for open eye injuries. Intraocular pressure (IOP) decreases about 40 percent after an induction dose of thiopental or methohexital is injected. If succinylcholine is

Figure 8-12 (Figure Not Available) Depression of the ventilatory response to CO_2 by pentobarbital and thiopental in the dog. The lines relate minute ventilation (V_E) to alveolar CO_2 tension (P_{ACO_2}). The slopes are normalized to the same starting point on the abscissa. STPD, standard temperature and pressure. *(Modified from Hirshman et al [81])*

given immediately after thiopental, IOP returns to preinduction values, but if as much as 2 minutes elapses, IOP exceeds preinduction values [80] (Ch. 63) .

Respiratory Effects

The barbiturate induction agents cause central respiratory depression, the nature and duration of which depend on the dose, rate of injection, and type and dose of premedication; both the rate and depth of breathing can be depressed until apnea occurs. Although respiration returns toward normal in a few minutes, the responses to hypercarbia (Fig. 8-12) (Figure Not Available) and hypoxemia (Fig. 8-13) (Figure Not Available) are depressed for a longer time. [81] Even 2 mg/kg of pentobarbital, a dose used for premedication, depresses the ventilatory response to hypoxemia. [82]

There is a low incidence of hypersalivation and rarely bronchospasm or laryngospasm after barbiturate induction of anesthesia. Usually, these side effects are due to the insertion of artificial airways, laryngeal masks, [83] or tracheal tubes in lightly anesthetized patients; unless very large doses of barbiturates are used, laryngeal and tracheal reflexes remain intact. [84] Laryngeal reflexes are, however, more active after induction with thiopental than with equivalent doses of propofol. [85] Thiopental and volatile anesthetic agents depress the mucociliary clearance of foreign material to the same degree. [86] Both methohexital [87] and thiopental are safe for asthmatic patients, but they do not cause bronchodilation, as ketamine does.

Figure 8-13 (Figure Not Available) Depression of O_2 -CO_2 interaction by barbiturates. Hypoxic ventilatory drive (HVD) is plotted as a function of the carbon dioxide tension (P_{ACO_2}) at which the studies were done. Each line represents the least-squares regression of about 40 studies. The circles represent the baseline P_{ACO_2} and HVD obtained with each agent. *(Modified from Hirshman et al [81])*

Cardiovascular Effects

The predominant cardiovascular effect of barbiturate induction is venodilation followed by pooling of blood in the periphery. [88] Myocardial contractility is depressed, but not to the extent seen after volatile anesthetics. [89] *In vitro,* using human atrial strips, thiopental inhibited contractility more than midazolam, etomidate, propofol, and ketamine. [90] Possible mechanisms for depressed myocardial contractility involve interference with calcium transport across myocardial cells and/or altering the

nitric oxide mechanism. From a study on isolated cat papillary muscle, the negative ionotropic effect may depend on the presence of an intact endocardial epithelium, a finding suggesting that it involved the nitric oxide pathway. [91] Thiopental, as well as other intravenous anesthetics, decreases neuronal nitric oxide synthase activity. [92] Other studies suggest that thiopental may interfere with the influx of transsarcolemmal calcium [93] and can decrease sarcoplasmic reticulum calcium release and inhibit the ryanodine-induced efflux of sarcoplasmic reticulum calcium. [94] Cardiac output decreases even though heart rate increases via the only slightly depressed baroreflex mechanism. Systemic vascular resistance usually remains unchanged, but in patients with preload-independent artificial hearts and a constant cardiac output, it decreased by 21 percent. In this model, thiopental also dilates pulmonary vessels and veins. [95] Heart rate increases more after methohexital than after equivalent doses of thiopental. No arrhythmias occur after induction of anesthesia by the barbiturates as long as hypoxemia and hypercarbia are avoided. The barbiturates also decrease sympathetic output from the CNS [96] and do not sensitize the heart to catecholamines.

Both thiopental and methohexital cause an increased heart rate, which results in an increased myocardial oxygen consumption. The arteriocoronary venous oxygen difference remains normal when aortic pressure is relatively unchanged because there is a proportional decrease in coronary vascular resistance and an increase in myocardial blood flow. [97] However, if systemic pressure is low enough, coronary blood flow decreases. The barbiturates, therefore, must be used cautiously if at all in conditions in which an increased heart rate or a decrease in preload could be detrimental to the patient. Such conditions include pericardial tamponade, hypovolemia, congestive heart failure, ischemic heart disease, and heart block, as well as a high resting sympathetic tone or myocardial ischemia.

Hypotension from a given dose is greater in both treated and untreated hypertensive patients than in normotensive patients. [98] An exaggerated hypotensive effect probably occurs in the presence of a blunted baroreflex or beta-adrenergic blockade.

Gastrointestinal, Renal, and Hepatic Effects

Healthy patients and those with preexisting liver disease have essentially no changes in gastrointestinal and liver function after barbiturate induction of anesthesia. [99] Hypoproteinemia in patients with hepatic or renal disease leads to a greater fraction of unbound thiopental than in healthy patients. [100] Thus, for patients with chronic renal failure, induction doses of thiopental should be injected at a slower rate, and maintenance doses should be decreased 50 to 75 percent, but these doses may have to be given more often than in healthy patients. A given dose can have a longer duration of effect in patients with hepatic failure, and recovery can be more rapid in patients in renal failure than in others. [101]

Thiopental can decrease urine output because it decreases blood flow to the kidney, causes renal artery constriction, and results in a small decrease in the glomerular filtration rate and urinary solute secretion. [8] Controversy exists about whether there is an increase in antidiuretic hormone (ADH) secretion from the pituitary. [8] [102] In dogs, methohexital impaired osmoregulation after an osmotic challenge by inhibiting ADH. [103] Correcting hypotension and administering adequate intravenous fluids prevent the renal effects of barbiturate induction from becoming a clinical problem.

Metabolic Effects

Although there is a slight, clinically insignificant increase in blood glucose levels and impairment of the glucose tolerance test after thiopental injection, serum insulin levels do not change. [104] Heat loss results from barbiturate-induced vasodilation of cutaneous and skeletal muscle vessels, which may contribute to postoperative shivering.

Endocrine Effects

Thiopental decreases plasma cortisol concentrations but does not prevent adrenocortical stimulation from the stress of surgery [105] (Fig. 8-14) . This finding contrasts with the effect

Figure 8-14 Normal cortisol and aldosterone response after thiopental during and after general anesthesia. The adrenocortical response to stress is preserved after thiopental but is depressed after etomidate. *(Data from Fragen et al [105])*

of an induction dose of etomidate, which suppresses the adrenocortical response to stress. [105] Both thiobarbiturates cause a dose-related histamine release, in contrast to methohexital and pentobarbital [106] (Fig. 8-15) (Figure Not Available) , but histamine release is rarely of clinical consequence.

Obstetric Effects

Thiopental neither depresses nor increases the tone of the gravid uterus (Ch. 57) . [64] Thiopental is not harmful to the fetus when the drug is given for anesthetic induction for

Figure 8-15 (Figure Not Available) Comparison of percent histamine release from human mast cells when in the presence of increasing concentrations of four barbiturates. Both thiobarbiturates produced significant dose-related histamine release. Histamine release by thiamylal was significantly greater than that by thiopental from 3.3×10^{-5} to 1×10^{-3} M ($P < .05$). *(From Hirshman et al [106])*

cesarean section in doses up to 6 mg/kg, but 8 mg/kg does depress the fetus. [107] Placental circulatory factors and redistribution of thiopental in the mother and fetus protect the fetal brain and spinal cord from high concentrations of barbiturates and explain why the umbilical cord blood concentration of thiopental at delivery is one-half that in maternal blood. Safe delivery of the fetus by cesarean section is possible if accomplished within 10 minutes after anesthetic induction with either thiopental or ketamine. [108] The neonatal condition is better after thiopental induction than after midazolam induction. [109] Neurobehavioral tests showed that newborns were more depressed after mothers received thiopental than after mothers received ketamine or epidural anesthesia for vaginal deliveries. [110]

Drug Interactions

Barbiturates given to patients taking other CNS-depressant drugs such as ethanol, antihistamines, isoniazid, methylphenidate, and monoamine oxidase inhibitors cause greater CNS depression than when barbiturates are given alone. Concomitant administration of 5.6 mg/kg of aminophylline reduces both the depth and the duration of sedation after thiopental administration. [111] Long-term barbiturate use induces hepatic microsomal enzymes, which accelerate the metabolism of other drugs metabolized by the P-450 system. [112]

Recovery

The time it takes for all CNS-depressant drug concentrations, not those of the intravenous hypnotic alone, to decrease below a particular threshold level determines the speed of recovery from general anesthesia. Recovery is rapid after many anesthetic regimens that include intravenous barbiturates. For example, if healthy patients have anesthesia induced with thiopental (4 mg/kg) and anesthesia maintained with 67 percent nitrous oxide, fentanyl (100 mug), and 50- to 100-mg increments of thiopental for operations lasting 30 minutes or less, they open their eyes in 3 to 4 minutes after the nitrous oxide is discontinued, and psychomotor tests recover in 15 to 75 minutes. [113] This technique is satisfactory for outpatient or inpatient anesthesia.

Clinical recovery was faster in infants less than 1 year old after equipotent doses of methohexital compared with thiopental [114] and in volunteers after single doses of methohexital (2 mg/kg) than after thiopental (6 mg/kg), but the ability to drive a motor vehicle was impaired for 8 hours after methohexital compared with 6 hours after thiopental [115] (Fig. 8-16) (Figure Not Available) . Furthermore, psychophysiologic tests were impaired for 8 hours after thiopental, and abnormal sleep patterns on the EEG occurred for 12 hours after methohexital. [115] The recommendation that patients not drive for 24 hours after general anesthesia is based on these data.

Naloxone (0.05 mg/kg) fails to antagonize the effects of thiopental. [116] At this time, there are no specific pharmacologic antagonists to treat barbiturate overdose; maintaining a patent airway, supporting ventilation, and supporting circulation are the appropriate symptomatic treatments.

Postoperative Sequelae

Venous sequelae include thrombosis and phlebitis and may not be seen until a few days postoperatively. Venous thrombosis is reported in 3 to 4 percent of patients receiving thiopental and in a slightly higher proportion of patients after methohexital. [117] An idea of the overall incidence of venous sequelae after barbiturates compared with other induction agents is shown in Table 8-4 (Table Not Available) . Venous sequelae are usually confined to an area of the vein in close proximity to the site of injection; they are treated symptomatically.

There are four reported cases of inadvertent epidural injections of up to 20 mL of 2- to 2.5-percent solutions of thiopental. The patients were successfully treated by injecting 0.5 percent bupivacaine into the epidural space to dilute thiopental and attempt to precipitate it. [118] Methohexital (1 percent) injected epidurally was treated with an epidural injection of saline plus methylprednisolone and hyaluronidase; no sequelae occurred. [119] The incidence of nausea and vomiting after barbiturate anesthesia is less than after inhaled anesthetics, ketamine, or etomidate, but the incidence is even lower after midazolam or propofol. [64]

Paralysis and death can occur if barbiturates are given to patients with acute intermittent porphyria or variegate porphyria. Barbiturates can precipitate acute and even fatal attacks of porphyria owing to the induction of

Figure 8-16 (Figure Not Available) Mean number of performance errors (neglected instructions, collisions, and driving off the road) during 30 minutes of simulated driving 2 to 8 hours after administration of 6 mg/kg of thiopental (

delta-aminolevulinic acid synthetase, which catalyzes the rate-limiting step in the biosynthesis of porphyrins. [120]

ADMINISTRATION OF BARBITURATES BY INFUSIONS

Barbiturates administered by a continuous infusion for maintenance of hypnosis are seldom used for anesthesia because they may prolong recovery. This can be explained by looking at the context-sensitive half-time (i.e., the time it takes for the plasma concentration in the central compartment to decrease by 50 percent) for thiopental relative to other intravenous hypnotics used for anesthesia [94] (Fig. 8-17) (Figure Not Available) . Crankshaw et al [122] used the same concept in their "plasma drug efflux" method to achieve and maintain a steady plasma concentration of thiopental or methohexital rapidly. They believed that a thiopental infusion can be a major component of anesthesia when given as an exponential infusion based on lean body mass to prevent overdose in heavier patients. Even if this is possible, recovery after reasonably long barbiturate infusions is slow relative to that after propofol. A successful infusion achieves a blood concentration of 15 to 20 mug/mL on induction and 10 to 20 mug/mL during maintenance. The mean plasma concentration on awakening is 5.9 ± 1.1 mug/mL. Schwilden et al [123] developed a combined pharmacokinetic-pharmacodynamic model to provide a closed-loop feedback-control method of delivering methohexital to maintain a set EEG level of 2 to 3 Hz and to maintain unconsciousness. Thiopental infusions of 2 to 3 mg/kg/h have been used to treat refractory aminophylline seizures and to control a hyperdynamic state after coronary bypass surgery. [124]

OTHER USES OF BARBITURATES

Anticonvulsants

Both thiopental and phenobarbital can stop seizures abruptly in patients refractory to other anticonvulsant drugs, [125] but benzodiazepines have largely replaced barbiturates for the acute treatment of seizures. GABA augmentors have anticonvulsant effects, and both barbiturates and benzodiazepines facilitate the action of GABA [126] in prolonging hyperpolarization of the postsynaptic membrane.

Figure 8-17 (Figure Not Available) Context-sensitive half-times as a function of infusion duration for each of the pharmacokinetic models simulated. Note the longer context-sensitive half-time for thiopental as compared with propofol and midazolam as the infusion duration increases. *(Modified from Hughes et al [121])*

TABLE 8-5 -- Dose Structure of Antiseizure Phenobarbital Therapy

(Not Available)

From Vining [127]

Other postsynaptic effects include altered membrane conductance of chloride ions and antagonism of glutaminergic and cholinergic excitation. Presynaptically, these drugs block calcium entry into nerve terminals and diminish transmitter release. [127] Barbiturates also increase the threshold of normal brain structures during electrically induced afterdischarges and inhibit the kindling process more effectively than do other antiepileptic drugs. Furthermore, small barbiturate doses can reduce seizure activity by increasing beta- activity in the EEG. [127] Table 8-5 (Table Not Available) shows a dose schedule for phenobarbital treatment of seizures in different age groups with or without concomitant phenytoin therapy. The phenobarbital dose should be reduced in patients with hepatic or renal disease because a given dose can produce significantly higher blood concentrations in those patients.

Brain Protection

A number of actions of the barbiturates on the CNS can protect the brain in some clinical situations (Chs. 19 and 52) . [64] They decrease cerebral metabolism in areas of high brain activity until the EEG becomes flat, after which no further suppression occurs even with an increased dose. This decrease is nonlinear during a thiopental infusion (Fig. 8-18) (Figure Not Available) . [128] A possible mechanism for this protective effect may be suppression of excitatory transmission by interfering with the nitric oxide (NO)-cyclic guanosine monophosphate system. Barbiturates may either inhibit the action of NO or inactivate NO in vascular smooth muscle. [129] Another mechanism is attenuation of *N*-methyl- D-aspartate- and AMPA-mediated glutamate excitatotoxicity. [130] Other barbiturate protective actions include an inverse steal in which vasoconstriction in healthy areas of the brain shunts blood to diseased areas, a reduction of ICP and an increase in cerebral perfusion pressure, stabilization of liposomal membranes, free-radical scavenging, and an anticonvulsant effect. However, arterial hypotension must be avoided to maintain adequate cerebral perfusion pressure. The depression of cerebral metabolism neither alters the concentration of lactate, pyruvate, phosphocreatine, or adenosine triphosphate nor has important effects on the pathways of cerebral glucose metabolism. [131]

In animals, doses of thiopental sufficient to suppress EEG activity are more likely to cause hypotension or ventricular fibrillation than are equivalent doses of pentobarbital. [132] High doses of methohexital cause depression of mean arterial pressure, cerebral blood flow, and cerebral metabolism; thiopental has similar effects at equivalent EEG suppression. Methohexital causes less cerebral vasoconstriction, has less effect on cerebral metabolism, and causes blood flow to return toward control values more rapidly than equivalent doses of thiopental. [133]

In primates, barbiturates decrease cerebral infarction size after focal cerebral artery occlusion, but these agents offer no benefit after stroke or cardiac arrest. [131] In humans, thiopental provides protection if a 40 mg/kg dose, sufficient to maintain a flat EEG, is given to patients undergoing cardiac valvular surgery that is likely to have neuropsychiatric complications of emboli after normothermic cardiopulmonary bypass. However, these patients awaken more slowly and need more inotropic support than untreated patients. [134] Thiopental may also protect poorly perfused areas of the brain in patients with increased ICP secondary to carotid endarterectomy, thoracic aneurysm, and profound controlled hypotension. [135] Barbiturates may provide important brain protection for young patients by reducing hyperemic response to head injury, [136] but in adults they have

Figure 8-18 (Figure Not Available) Effect of thiopental on cerebral metabolism of oxygen ($CMRO_2$). $CMRO_2$ (percent of control) is plotted versus total dose of thiopental infused over time. Regression lines from changes in $CMRO_2$ are drawn for each EEG-determined area; for example, a decrease to 77 percent of control when the EEG is shifting and a slower decrease when an anesthetic pattern appears. *(Modified from Stulken et al [126])*

TABLE 8-6 -- Summary of the Important Clinical Properties of the Intravenous Sedative-Hypnotics Used for Anesthetic Induction [a]

[a] ++ to -- is a five-point qualitative scale describing the relative positive (+, ++), neutral (0), or negative (-, --) effect of each agent in each category.

failed to protect the brain after head trauma [137] or cardiac arrest.

Wada Test

A small dose of amobarbital (Amytal Sodium) can be injected into the carotid artery to lateralize cerebral speech dominance in neurosurgical patients; this is known as

the Wada test. [138] An alternative is injection of methohexital (3 to 5 mg) after a 1-mg test dose. [139]

Electroconvulsive Therapy

Propofol resulted in a shorter seizure duration, but blood pressure was more likely to rise above control values after methohexital, when either drug was used to provide hypnosis for electroconvulsive therapy. [140] [141] Methohexital is preferable to thiopental because transient premature atrial and ventricular contractions occur less frequently after methohexital, whether or not atropine is used for premedication. [142]

SUMMARY

The actions of thiopental and other barbiturates have not changed since they were first used by anesthesiologists. However, the understanding of their pharmacokinetics and mechanisms of action has changed. Anesthesiologists also have a better understanding of how the barbiturates affect the various body systems, thus enabling clinicians to use these drugs most effectively, yet with minimum side effects. Comparison of the anesthetic barbiturates with other sedative-hypnotics used to induce general anesthesia (Table 8-6) (Table Not Available) puts in perspective their important clinical properties. [143] Although thiopental is not the ideal intravenous drug to induce general anesthesia, its long-standing position as the standard anesthetic induction agent stems from its lack of major disadvantages.

Uses

SUMMARY

/das/book/view/29494766/875/96.html

INTRODUCTION

The introduction of thiopental into clinical practice in 1934 marked the advent of modern intravenous anesthesia. Thiopental and other barbiturates, however, are not ideal intravenous anesthetics, primarily because they provide only hypnosis (Ch. 8) . The ideal intravenous anesthetic drug would provide hypnosis, amnesia, and analgesia. Because no single drug is ideal, many other drugs are used, often together, that offer some or all of the desired effects. These drugs were introduced steadily into clinical practice with varying degrees of acceptance. With an increasing number of compounds and superior methods of intravenous anesthetic drug delivery available (Ch. 11) , the use of intravenous anesthetics continues to grow.

The future of anesthetic management involves the simultaneous use of several drugs, including inhaled anesthetics together with intravenous drugs. A 1988 survey of mortality in 100,000 cases of anesthesia reveals that the practice of combined anesthetic drug use may be safer than the use of only one or two drugs [1] ; the relative odds of dying within 7 days was 2.9 times greater when one or two anesthetic drugs were used than when three or more were used. Although it is exceedingly difficult to interpret these data, the use of several drugs may be beneficial to anesthetic care. Thus, the skillful use of multiple intravenous anesthetics is not only possible but preferable in the optimal care of patients. The purpose of this chapter is to provide information on the major nonbarbiturate and nonopioid intravenous anesthetic drugs available for clinical use today.

BENZODIAZEPINES

History

Benzodiazepines were discovered accidentally to be ef-fective sedative-hypnotic drugs. [2] Sternbach synthesized chlordiazepoxide (Librium) in 1955, but it was discarded without testing because it was considered inert. However, in 1957 the drug was discovered to have entirely unexpected "hypnotic, sedative, and antistrychnine effects in mice." [3] This first benzodiazepine was released for oral use in 1960, and in that year it was clear that in sufficiently large doses, chlordiazepoxide possessed profound hypnotic and amnestic properties, although it was not available in parenteral form for use in anesthesia. However, a patient who was taking chlordiazepoxide was reported to have fallen and fractured her sacrum accidentally; [4] this accident, which was not remembered or painful, suggested the use of benzodiazepines as anesthetics during trauma (surgery). Diazepam (Valium) was synthesized by Sternbach in 1959 in a search for a new and better compound. Oxazepam (Serax), a metabolite of diazepam, was synthesized in 1961 by Bell and was marketed by a different pharmaceutical company. Lorazepam (Ativan), a 2
chloro-substitution product of oxazepam, was synthesized in 1971 in an attempt to produce a more potent benzodiazepine. The next major achievement was Fryer and Walser's 1976 synthesis of midazolam (Versed), the first clinically used water-soluble benzodiazepine. [5] It is not certain when benzodiazepines were first used to induce anesthesia, but in 1966 several groups reported the use of diazepam for anesthesia. [6] [7] [8] Midazolam was the first benzodiazepine that was produced primarily for use in anesthesia. [9]

The benzodiazepines produce many of the characteristics sought by anesthesiologists. They produce their actions by occupying the benzodiazepine receptor, which was first discussed in December of 1971 in Milan. [10] Barnett and Fiore [11] postulated a benzodiazepine receptor, and in 1977, specific benzodiazepine receptors were described when ligands were found to interact with a central receptor. [12] The discovery and understanding of the mechanism of the benzodiazepine receptor have enabled chemists to develop many agonist compounds and even to produce a specific antagonist for clinical use.

Physicochemical Characteristics

Three benzodiazepine receptor agonists are commonly used in the practice of anesthesia in the United States: midazolam, diazepam, and lorazepam (Fig. 9-1) and Table 9-1) . All these molecules are relatively small and are lipid soluble at physiologic pH. Each milliliter of diazepam solution (5 mg) contains propylene glycol 0.4 mL, alcohol 0.1 mL, benzyl alcohol 0.015 mL, and sodium benzoate/benzoic acid in water for injection (pH 6.2 to 6.9). Lorazepam solution (2 or 4 mg/mL) contains 0.18 mL polyethylene glycol, with 2 percent benzyl alcohol as a preservative. Midazolam solution contains 1 or 5 mg/mL of midazolam with 0.8 percent sodium chloride and 0.01 percent disodium edetate, with 1 percent benzyl alcohol as a preservative. The pH is adjusted to 3 with hydrochloric acid and sodium hydroxide. Midazolam is the most lipid soluble of the three drugs *in vivo*,[13] but because of its pH-dependent solubility, is water soluble as formulated in a buffered acidic medium (pH 3.5). The imidazole ring of midazolam accounts for its stability in solution and rapid metabolism. The high lipophilicity of all three accounts for the rapid central nervous system (CNS) effect, as well as for their relatively large volumes of distri-bution. [14]

Metabolism

Biotransformation of the benzodiazepines occurs in the liver. The two principal pathways involve either hepatic microsomal oxidation (*N*-dealkylation or aliphatic hydroxylation) or glucuronide conjugation. [2] [15] The difference in the two pathways is significant, because oxidation is susceptible to outside influences and can be impaired by certain population characteristics (e.g., old age), disease states (e.g., hepatic cirrhosis), or the coadministration of other drugs that can impair oxidizing capacity (e.g., cimetidine). Conjugation is less susceptible to these factors. [2] Both midazolam and diazepam undergo oxidation reduction or phase I reactions in the liver. [16] The fused imidazole ring of midazolam is oxidized rapidly by the liver, much more rapidly than the methylene group of the diazepine ring of other benzodiazepines. This accounts for the greater hepatic clearance of midazolam compared with diazepam. Lorazepam is less affected by enzyme induction and some of the other factors known to alter the cytochrome P-450 and other phase I enzymes. For example, cimetidine inhibition of oxidative enzyme function impairs the clearance of diazepam, [17] but it has no effect on lorazepam. [16] Age decreases and smoking increases the clearance of diazepam, [18] but neither has a significant effect on midazolam biotransformation. [18] [19] Habitual alcohol consumption increases the clearance of midazolam. [20] There is new evidence that race, because of differences in isoenzymes responsible for hydroxylations, has a genetic basis for differences in drug metabolism. [21] The high frequency of mutated alleles in Asians in the genes coding for *CYP2C19* may explain the reduced hepatic biotransformation of diazepam.

The metabolites of the benzodiazepines can be important. Diazepam forms two active metabolites, oxazepam and

Figure 9-1 The structures of four benzodiazepines used in clinical anesthesia practice.

TABLE 9-1 -- Physicochemical Characterization of Three Benzodiazepines

	DIAZEPAM	LORAZEPAM	MIDAZOLAM
Molecular weight (d)	284.7 [a]	321.2 [a]	362 [a]
p K_a	3.3 (20°)	11.5 (20°)	6.2 (20°) [a]
Water soluble	No [a]	Almost insoluble	Yes [b]
Lipid soluble	Yes [a]	Yes (less so, however)	Yes [b]
	Highly lipophilic	Relatively less lipophilic	Highly lipophilic

[a] *Data from Moffet* [581]
[b] pH dependent: pH >4, lipid soluble; pH < 4, water soluble

desmethyldiazepam, both of which add to and prolong the drug's effects. Midazolam is biotransformed to hydroxymidazolams, which have activity, and when given over a longer time can accumulate. [22] However, these metabolites are rapidly conjugated and excreted in the urine. The 1-hydroxymidazolam has an estimated clinical potency 20 to 30 percent of midazolam. [23] It is excreted by the kidneys largely and can cause profound sedation in patients with renal impairment. [24] The primary hydroxymetabolite is cleared more rapidly [23] than midazolam in healthy patients (Table 9-2) (Table Not Available) . Thus, the metabolites are less potent and normally more rapidly cleared than midazolam, making them of little concern in patients with normal hepatic and renal function. Lorazepam has five metabolites, but the principal one is conjugated to glucuronide. This metabolite is inactive, water soluble, and rapidly excreted via the kidney.

Pharmacokinetics

The three benzodiazepines used in anesthesia are classified as short- (midazolam), intermediate- (lorazepam), and long-lasting (diazepam), according to their metabolism and plasma clearance [18] [25] (Table 9-3) . The plasma disappearance curves of all the benzodiazepines can be fitted to a two- or three-compartment model. Protein binding and volumes of distribution are not importantly different among these three benzodiazepines, but the clearance is significantly different. The clearance rate of midazolam ranges from 6 to 11 mL/kg/min, whereas the clearance of lorazepam is 0.8 to 1.8 mL/kg/min, and that of diazepam is 0.2 to 0.5 mL/kg/min. [18] Because of these differences in clearance, the drugs have predictably different plasma disappearance curves (Figs. 9-2 , 9-3 , and 9-4) . They also have different context-sensitive half-times (Fig. 9-5) . Although the termination of action of these drugs is primarily a result of redistribution of the drug from the CNS to other tissues after use in anesthesia, after daily (long-term) repeated administration or after prolonged continuous infusion, midazolam blood levels will decrease more rapidly than blood levels of the other drugs because of its greater hepatic clearance. Thus, patients given continuous infusions of midazolam or repeated boluses over days should awaken faster than those given diazepam or lorazepam.

Factors known to influence the pharmacokinetics of benzodiazepines are age, gender, race, enzyme induction, and hepatic and renal disease. Diazepam is sensitive to some of these factors, particularly age. Increasing age tends to reduce the clearance of diazepam [26] significantly and the clearance of midazolam to a lesser degree. [27] Lorazepam is resistant to the effects of age, gender, and renal disease on pharmacokinetics. These drugs are all affected by obesity. The volume of distribution is increased as drug goes from the plasma into the adipose tissue. Although clearance is not altered, elimination half-lives are prolonged, owing to the delayed return of the drug to the plasma in obese persons. [27] On the basis of pharmacokinetics, complex and seemingly contradictory dosing recommendations are required. For example, the induction dose of midazolam (and other benzodiazepines) should take into consideration a heavy weight (increased dose) because of the increased fat depot for the drug. However, dosing for continuous infusion in obese patients should be based on lean body weight because clearance is unaffected by weight. [18] In general, sensitivity to benzodiazepines in some groups, such as the elderly, is greater despite relatively modest pharmacokinetic effects; thus, factors other than pharmacokinetics must be considered when these drugs are used.

Pharmacology

All benzodiazepines have hypnotic, sedative, anxiolytic, amnesic, anticonvulsant, and centrally produced muscle relaxant properties. The drugs differ in their potency and efficacy with regard to each of the pharmacodynamic actions.

TABLE 9-2 -- Pharmacokinetic and Pharmacodynamic Comparison of Midazolam and Active Metabolites[a]

(Not Available)

From Mandema et al [23]

[a] All values are significantly ($P < .05$) different between midazolam and alpha-hydroxymidazolam.

TABLE 9-3 -- Pharmacokinetic Variables of Commonly Used Intravenous Anesthetics

	ELIMINATION HALF-LIFE (H)	CLEARANCE (ML/KG/MIN)	VD_{SS} (L/KG)	REFERENCE
Diazepam	20-50	0.2-0.5	0.7-1.7	[18]

Vd_{SS} , apparent volume of distribution at steady state

The chemical structure of each drug dictates its particular physicochemical properties and pharmacokinetics as well as its receptor binding characteristics. The binding of benzodiazepines to their respective receptors is of high affinity and is stereospecific and saturable; the order of receptor affinity (thus potency) of the three agonists is lorazepam > midazolam > diazepam. Midazolam is approximately three to six [28] times and lorazepam five to ten times as potent as diazepam.

The mechanism of action of benzodiazepines is reasonably well understood. [29] [30] The interaction of ligands with the benzodiazepine receptor represents one of the few examples in which the complex systems of biochemistry, mo-lecular pharmacology, and clinical behavioral patterns can be explained. More is understood about the mechanism of action of benzodiazepines than about that of many other general anesthetics, although it is still not known how the different effects (amnesic, anticonvulsant, anxiolytic, and sleep) are mediated. However, it appears that different receptor subtypes mediate these different actions; for example, anxiolytic, anticonvulsant, and muscle relaxation effects are mediated at the benzodiazepine-gamma-aminobutyric acid (GABA) $_A$ receptor and the hypnotic effects are mediated elsewhere. [31] It also seems that drug effect is a function of blood level. By using plasma concentration data and pharmacokinetic

Figure 9-2 Simulated time course of plasma levels of midazolam following an induction dose of 0.2 mg/kg. Plasma levels required for hypnosis and amnesia during surgery are 100 to 200 ng/mL, with awakening usually occurring at levels lower than 50 ng/mL.

simulations, it has been estimated that a benzodiazepine receptor occupancy of less than 20 percent may be sufficient to produce the anxiolytic effect, sedation is observed with 30 to 50 percent receptor occupancy, and unconsciousness requires 60 percent or higher occupation of benzodiazepine agonist receptors. [32]

It is agreed that benzodiazepines exert their general effects by occupying the benzodiazepine receptor that modulates GABA, the major inhibitory neurotransmitter in the brain. GABA-adrenergic neurotransmission counterbalances the influence of excitatory neurotransmitters. The benzodiazepine receptors are found in highest densities in the olfactory bulb, cerebral cortex, cerebellum, hippocampus, substantia nigra, and inferior colliculus, but lower densities are found in the striatum, lower brain stem, and spinal cord. Although there are two GABA receptors, it appears that the benzodiazepine receptor is part of the GABA $_A$ receptor complex on the

subsynaptic membrane of the effector neuron. This receptor complex is made up of three protein subunits--alpha, beta, and gamma--arranged as a pentameric aerolic glycoprotein complex (Fig. 9-6) (Figure Not Available) . These proteins contain the various ligand-binding sites of the $GABA_A$ receptor, such as the benzodiazepine, GABA, and barbiturate binding sites. The benzodiazepine binding site is located on the gamma $_2$ -subunit, [31] [33]

Figure 9-3 Simulated time course of plasma levels of diazepam following an induction dose of 0.5 mg/kg. Plasma levels required for hypnosis and amnesia during surgery are 0.6 to 1.0 mug/mL, with awakening usually occurring at levels lower than 0.5 mug/mL.

Figure 9-4 Simulated time course of plasma levels of lorazepam following an induction dose of 0.1 mg/kg. Plasma levels required for hypnosis and amnesia during surgery are between 50 and 150 ng/mL, with awakening usually occurring at levels lower than 50 ng/mL.

and the beta-subunit is thought to contain the binding site for GABA. With activation of the $GABA_A$ receptor, gating of the channel for chloride ions is triggered. The cell becomes hyperpolarized and therefore resistant to neuronal excitation. It is now postulated that the hypnotic effects of benzodiazepines are mediated by alterations in a potential-dependent calcium ion flux. [31] The degree of modulation of GABA-receptor function has a built-in limitation, and this explains the relatively high degree of safety with benzodiazepines.

A fascinating and therapeutically significant discovery regarding the benzodiazepine receptor is that the pharmacologic spectrum of ligands includes three different types or classes, [29] which have been termed agonists, antagonists, and

Figure 9-5 The context-sensitive half-times for commonly used intravenous anesthetic drugs are displayed. The context-sensitive half-time is the time for the plasma level of the drug to drop 50 percent after cessation of infusion. The duration of infusion is plotted on the horizontal axis. Note that the rapidity with which the drug level drops is directly related to the time of infusion (i.e., the longer the drug is infused, the longer the half-time). Also note that etomidate, propofol, and ketamine have significantly shorter half-times than thiopental and diazepam, which makes them more suitable for prolonged infusion.

Figure 9-6 (Figure Not Available) Model of the GABA-benzodiazepine receptor complex. Current data suggest a pentameric protein composed of alpha-, beta-, and gamma-subunits; the proposed arrangement of subunits is arbitrary. There are two sites for GABA binding (on the beta-subunits) and a single site for benzodiazepine (BDZ) binding (depicted on the gamma $_2$ -subunit). Homology between the $GABA_{alpha}$ receptor and the nicotinic acetylcholine receptor suggests that the chloride ion channel is formed by contributions from each subunit. *(Modified from Zorumski and Isenberg, [578] copyright 1991, the American Psychiatric Association. Reprinted by permission.)*

inverse agonists (Fig. 9-7) (Figure Not Available) , names that connote their actions. Agonists (e.g., midazolam) alter the conformation of the $GABA_A$ receptor complex so that binding affinity for GABA is increased, with a resultant opening of the chloride channel. Agonist and antagonist bind to a common (or at least overlapping) area of the receptor by forming differing reversible bonds with the receptor. [34] The well-known effects of an agonist then occur (anxiolysis, hypnosis, and anticonvulsant action). Antagonists (e.g., flumazenil) occupy the benzodiazepine receptor, but they produce no activity and therefore block the actions of both the agonists and inverse agonists. Inverse agonists reduce the efficiency of GABA-adrenergic synaptic transmission, and because GABA is inhibitory, the result of decreased GABA is CNS stimulation. The potency of the ligand is dictated by its affinity for the benzodiazepine receptor and the duration of effect by the rate of clearance of the drug from the receptor.

Long-term administration of benzodiazepines produces tolerance, which is defined as the decrease of efficacy of the drug over time. [35] Although the mechanism of chronic tolerance is not fully understood, it appears that long-term exposure to benzodiazepines causes decreased receptor binding and function (i.e., downregulation of the benzodiazepine-$GABA_A$ receptor complex). This would explain the increased dose requirements for anesthesia of benzodiazepines in patients who take them on a long-term basis. Interestingly, it appears that after the cessation of long-term use of benzodiazepines, there is upregulation of the receptor complex, [35] which could mean an increased susceptibility to benzodiazepines during a period after recent use.

The onset and duration of action of a single bolus administration of a benzodiazepine depend on the lipid solubility of the drug, a finding that probably explains the differences in onset and duration of action of the three benzodiazepines used in clinical practice in the United States. Midazolam and diazepam have a more rapid onset (usually within 30-60 seconds) of action than lorazepam (60-120 seconds). The half-life of equilibrium between plasma concentration and electroencephalographic (EEG) effect of midazolam is approximately

Figure 9-7 (Figure Not Available) Spectrum of intrinsic activities of benzodiazepine-receptor ligands, which range from agonists to inverse agonists. Structures of agonist, partial agonist, antagonist, partial inverse agonist, and inverse agonist compounds are shown. Intrinsic activity is greatest among agonists and is least among inverse agonists. Intrinsic activities are schematically indicated as positive by a plus sign and as negative by a minus sign, with 0 indicating a lack of intrinsic activity. *(Modified from Mohler and Richards [25])*

2 to 3 minutes and is not affected by age. [36] [37] This is about two times longer than that of diazepam, but compared with diazepam midazolam has a sixfold greater intrinsic potency. [28] Similar data for other benzodiazepines are not available. Like onset, the duration of effect is also related to lipid solubility and blood level. [38] The more rapid redistribution of midazolam and diazepam compared with lorazepam (presumably because of the lower lipid solubility of lorazepam) [13] accounts for the shorter duration of their actions.

Effects on the Central Nervous System

The benzodiazepines in a dose-related manner reduce the cerebral metabolic rate of oxygen consumption ($CMRO_2$) and cerebral blood flow (CBF) (Ch. 35) .

Midazolam and diazepam maintain a relatively normal ratio of CBF to $CMRO_2$. In healthy human volunteers, midazolam, 0.15 mg/kg, induces sleep and reduces CBF by 34 percent, despite a slight increase in arterial partial pressure of carbon dioxide (Pa_{CO_2}) from 34 to 39 mm Hg. [39] Brown et al [40] studied EEG tracings following 10 mg intravenous midazolam and showed the appearance of rhythmic beta activity at 22 Hz within 15 to 30 seconds of administration in healthy volunteers. Within 60 seconds, there was a second beta rhythm at 15 Hz. Alpha rhythm started to reappear at 30 minutes; however, after 60 minutes there was resistant rhythmic beta activity at 15- to 20-muV amplitude. The EEG changes were similar to EEG effects with diazepam and were not typical of light sleep, although the patients were clinically asleep.

Midazolam, diazepam, and lorazepam all increase the seizure initiation threshold to local anesthetics and lower the mortality rate in mice exposed to lethal doses of local anesthetics. [41] Midazolam and diazepam cause a dose-related protective effect against cerebral hypoxia, demonstrated by extending mouse survival time when mice were placed in 5 percent oxygen. The protection afforded by midazolam is superior to that of diazepam but less than that of pentobarbital. [41] Antiemetic effects are not a prominent action of the benzodiazepines.

Effects on the Respiratory System

Benzodiazepines, like most intravenous anesthetics, produce dose-related central respiratory system depression (Chs. 15 and 33) . The respiratory depression may be greater with midazolam than with diazepam and lorazepam, although comparative studies of the three do not exist. Lorazepam (2.5 mg IV) produces a similar but shorterlasting decrease in tidal volume and minute ventilation than diazepam (10 mg IV) in patients with lung disease. [42] Peak decrease in minute ventilation after midazolam (0.15 mg/kg) is almost identical to that produced in healthy patients given diazepam (0.3 mg/kg), as determined by carbon dioxide response data. [43] The slopes of the ventilatory response curves to carbon dioxide are flatter than normal (control) but not shifted to the right, as with opioids. Judging from the plasma level and steepness of the dose-response effect on Pa_{CO_2} curves [44] (Fig. 9-8) (Figure Not Available) , midazolam is about five to nine times as potent as diazepam. The

peak onset of ventilatory depression with midazolam (0.13-0.2 mg/kg) is rapid (about 3 min),

Figure 9-8 (Figure Not Available) (A) The increase of Pa CO_2 from baseline versus the plasma concentration after three intravenous bolus doses of diazepam (0.15 mg/kg) given at 20-minute intervals. (B) The increase of Pa CO_2 from baseline versus the midazolam plasma concentration after three intravenous bolus doses of midazolam (0.05 mg/kg) given at 20-minute intervals. The solid line represents a best fit model of the data from the three injections. Mean values are represented plus or minus standard error of the mean; open boxes are data from injection 1, cross-hatched boxes are data from injection 2, and solid boxes are data from injection 3. *(From Sunzel et al [44])*

and significant depression remains for about 60 to 120 minutes. [46] [46] The rate of midazolam administration affects the onset time of peak ventilatory depression; the faster the drug is given, the more quickly this peak depression occurs. [47] The respiratory depression of midazolam is more pronounced and of longer duration in patients with chronic obstructive pulmonary disease, and the duration of ventilatory depression is longer with midazolam (0.19 mg/kg) than with thiopental (3.3 mg/kg). [45] Lorazepam (0.05 mg/kg) alone does not depress the carbon dioxide response, but when lorazepam is combined with meperidine, there is predictable respiratory depression. [48] It is probable that benzodiazepines and opioids produce additive or supra-additive (synergistic) respiratory depression, even though they act at different receptors.

Apnea occurs with benzodiazepines. The incidence of apnea after thiopental or midazolam when these drugs are given for induction of anesthesia is similar. Apnea occurred in 20 percent of 1,130 patients given midazolam for induction and 27 percent of 580 patients given thiopental in clinical trials with midazolam. [9] Apnea is related to dose of benzodiazepine and is more likely to occur in the presence of opioids. Old age, debilitating disease, and other respiratory depressant drugs probably also increase the incidence and degree of respiratory depression and apnea with benzodiazepines.

Effects on the Cardiovascular System

The benzodiazepines used alone have modest hemodynamic effects (Chs. 16 and 30) . The hemodynamic changes reported with anesthetic induction doses of diazepam, midazolam, and lorazepam are shown in Table 9-4 . These values represent the peak hemodynamic effect in the first 10 minutes after administration and are derived from studies of both healthy subjects and patients with ischemic and valvular heart diseases. [49] [50] [51] [52] [53] [54] [55] [56] The predominant hemodynamic change is a slight reduction in arterial blood pressure, resulting from a decrease in systemic vascular resistance. The mechanism by which benzodiazepines maintain relatively stable hemodynamics involves the preservation of homeostatic

reflex mechanisms, [57] but there is evidence that the baroreflex is impaired by both midazolam and diazepam. [58] Midazolam causes a slightly greater decrease in arterial blood pressure than do the other benzodiazepines, but the hypotensive effect is minimal and about the same as seen with thiopental. [59] Despite the hypotension, midazolam, even in doses as high as 0.2 mg/kg, is safe and effective for induction of anesthesia even in patients with severe aortic stenosis. [60] The hemodynamic effects of midazolam and diazepam are dose related: the higher the plasma level, the greater the decrease in systemic blood pressure [44] ; however, there is a plateau plasma drug effect above which little change in arterial blood pressure occurs. The plateau plasma level for midazolam is 100 ng/mL, and that for diazepam is about 900 ng/mL. [44] Heart rate, ventricular filling pressures, and cardiac output are maintained after induction of anesthesia with benzodiazepines. In patients with elevated left ventricular filling pressures, diazepam and midazolam produce a "nitroglycerin-like" effect by lowering the filling pressure and increasing cardiac output. [52] [54]

The stresses of endotracheal intubation and surgery are not blocked by midazolam. [49] Thus, adjuvant anesthetics, usually opioids, are often combined with benzodiazepines. The combination of benzodiazepines with opioids and nitrous oxide has been investigated in patients with ischemic and valvular heart diseases. [51] [56] [60] [61] [62] [63] [64] Whereas the addition of nitrous oxide to midazolam (0.2 mg/kg) and diazepam (0.5 mg/kg) has trivial hemodynamic consequences, the combination of benzodiazepines with opioids does have a supra-additive effect. [65] The combinations of diazepam with fentanyl or sufentanil, of midazolam with fentanyl [62] or sufentanil, [64] and lorazepam with fentanyl [56] or sufentanil [63] all produce greater decreases in systemic blood pressure than does each drug alone. Presumably, combinations of benzodiazepines with remifentanil will do the same. The mechanism for this synergistic hemodynamic effect is not completely understood, but it is probably related to a reduction in sympathetic tone when the drugs are given together. [61] There is evidence that diazepam and midazolam decrease catecholamines, [58] a finding consistent with this hypothesis.

Uses

Intravenous Sedation

Benzodiazepines are used for sedation as preoperative premedication, intraoperatively during regional or local anesthesia, and postoperatively (Chs. 40 , 42 , 43 , 44 , 65 , and 65) . The anxiolysis, amnesia, and elevation of the local anesthetic seizure threshold are desirable benzodiazepine actions. The drugs should be given by titration for this use; end points of titration are adequate sedation or dysarthria (Table 9-5) . The onset of action is more rapid with midazolam, usually with peak effect reached within 2 to 3 minutes of administration; time to peak effect is slightly longer with diazepam and is still longer with lorazepam. The duration of action of these drugs depends primarily on the dose used. Although the onset is more rapid with midazolam than with diazepam after bolus administration, the recovery is similar, [66] probably because both drugs have similar early plasma

[a] Incremental doses given until desired degree of sedation is obtained

decay (redistribution) patterns (see Figs. 9-2 and 9-3) . With lorazepam, sedation and particularly amnesia are slower in onset [67] and are longer lasting than with the other two benzodiazepines. [22] [68] [69] There is often a disparity in the level of sedation as compared with the presence of amnesia (patients seem conscious and reasonably coherent, yet they are amnesic for events and instructions) with all three benzodiazepines. Lorazepam is particularly unpredictable with regard to duration of amnesia, and this is undesirable in patients who wish or need to have recall in the immediate postoperative period. [67] The degree of sedation and the reliable amnesia, as well as preservation of respiratory and hemodynamic function, are better overall with benzodiazepines than with other sedative-hypnotic drugs used for conscious sedation. Despite the wide safety margin with benzodiazepines, respiratory function must be monitored when these drugs are used for sedation to prevent undesirable degrees of respiratory depression. There may be a slight synergistic action between midazolam and spinal anesthesia with respect to ventilation. [70] Thus, the use of midazolam for sedation during regional and epidural anesthesia requires vigilance with regard to respiratory function, as when these drugs are given with opioids. Sedation for longer periods, for example in the intensive care unit (ICU), is accomplished with benzodiazepines. Prolonged infusion will result in accumulation of drug and, in the case of mid-azolam, significant concentration of the active metabolite. Reviews have pointed out concerns as well as advantages of benzodiazepine sedation. [22] [71] In a relatively small study comparing an infusion of midazolam with an intermittent bolus lorazepam, both drugs were equivalent in sedation and oxygenation effects, but the overall recovery from sedation over time was not examined. [72] The superiority of one drug over the other has not been established; both agents should always be titrated downward to maintain sedation as required. Dosing should not be fixed, but it should be reduced over time to avoid accumulation of parent or metabolites during prolonged infusion.

Induction and Maintenance of Anesthesia

Midazolam is the benzodiazepine of choice for use in anesthetic induction. Although both diazepam and lorazepam have been used for induction of general anesthesia, the faster onset and lack of venous complications make midazolam better suited for this use. With midazolam, induction

of anesthesia is defined as unresponsiveness to command and loss of the eyelash reflex. When midazolam is used in appropriate doses (see Table 9-5) , induction occurs less rapidly than with thiopental, [9] but the amnesia is more reliable. Numerous factors influence the rapidity of action of midazolam and the other benzodiazepines when used for induction of general anesthesia; these factors are dose, speed of injection, degree of premedication, age, American Society of Anesthesiologists (ASA) physical status, and concurrent anesthetic drugs. [9] [73] In a well-premedicated, healthy patient, midazolam (0.2 mg/kg given in 5-15 seconds) will induce anesthesia in 28 seconds, whereas with diazepam (0.5 mg/kg given in 5-15 seconds), induction occurs in 39 seconds. [49] Elderly patients require lower doses of midazolam than younger patients [74] [75] (Fig. 9-9) (Figure Not Available) . Patients older than 55 years and those with ASA physical status higher than III require a 20 percent or greater reduction in the induction dose of midazolam. [9] The usual induction dose of midazolam in premedicated patients is between 0.05 and 0.15 mg/kg. When midazolam is used with other anesthetic drugs (coinduction), there is a synergistic interaction, [38] [76] [77] and the induction dose is less than 0.1 mg/kg (Fig. 9-10) (Figure Not Available) . The synergy is seen when midazolam is used with opioids and/or other hypnotics such as thiopental and propofol. This combination therapy (use of two or more hypnotics) may be called *coinduction.*

Awakening after benzodiazepine anesthesia is the result of the redistribution of drug from the brain to other, less well-perfused tissues. The emergence (defined as orientation to time and place) of young, healthy volunteers who have received 10 mg of intravenous midazolam occurs in about 15 minutes, [40] and after an induction dose of 0.15 mg/kg, it occurs in about 17 minutes. [78] Emergence time is related to the dose of midazolam as well as to the dose of adjuvant anesthetic drugs. [9] Emergence from midazolam (0.32 mg/kg)/fentanyl anesthesia is about 10 minutes longer than that from thiopental (4.75 mg/kg)/fentanyl anesthesia [79] and is more prolonged than with propofol. [80] This difference accounts for some anesthesiologists' preference for barbiturates as induction drugs for short operations.

Benzodiazepines lack analgesic properties and must be used with other anesthetic drugs to provide sufficient analgesia; however, as maintenance anesthetic drugs during general anesthesia, benzodiazepines provide hypnosis and amnesia. Double-blind studies comparing midazolam and thiopental as the hypnotic component for balanced anesthesia [79] [81] have shown that midazolam is superior for this use because of better amnesia and a smoother hemodynamic course. Opioid requirements are less with midazolam. Midazolam (0.6 mg/kg) lowers the minimum alveolar concentration (MAC) of halothane by 30 percent [82] and presumably has a similar effect on other inhaled anesthetics. The question of an optimal redosing scheme after induction when midazolam is used as a maintenance hypnotic component of general anesthesia has not been answered. The amnesic period after an anesthetic dose is about 1 to 2 hours. Infusions of midazolam have been used to ensure a constant and appropriate depth of anesthesia. [82] Experience indicates that a plasma level of more than 50 ng/mL when used with adjuvant opioids (e.g., fentanyl) and/or inhalation anesthetics (e.g., nitrous oxide, volatile anesthetics) is achieved with a bolus loading dose of 0.05 to 0.15 mg/kg and a continuous infusion of 0.25 to 1 mug/kg/min. [83] This is sufficient to keep the patient asleep and amnesic but arousable at the end of surgery. Lower infusion doses may be required in some patients and with certain opioids. Midazolam as well as diazepam and lorazepam will accumulate in the blood with repeated bolus administrations or with continuous infusion, just as most intravenous anesthetics do on repeated injection. If the benzodiazepines do accumulate with repeated administrations, prolonged arousal time can be anticipated. This is less of a problem with midazolam than with diazepam and lorazepam because of the shorter context-sensitive half-time and greater clearance of midazolam.

Figure 9-9 (Figure Not Available) Simulated quantal concentration-response curves generated by the parameterized pharmacodynamic model for midazolam. *(From Jacobs et al [75])*

Figure 9-10 (Figure Not Available) Vertical axes all represent drug dose in milligrams per kilogram. On the right, median effective dose (ED_{50}) isobolograms for the hypnotic interactions among midazolam, alfentanil, and propofol are shown. The dotted lines are additive effect lines; note that all combinations fall within the line representing synergism or supra-additive effect. On the left, a triple interaction is depicted. The shaded area represents an additive plane passing through three single-drug ED_{50} points (small open circles). The largest closed circle (with arrows) is the ED_{50} point for the triple combination. The smaller closed circles are ED_{50} points for the binary combinations. R ratios on all graphs represent the interaction (1.0 indicates additive effect) of the various drug combinations. Note that the combination of midazolam and alfentanil produces the greatest synergism, but the combination of all three is also synergistic. *P* values denote the significance of the additive effects. *(Modified from Vinik et al [579])*

Side Effects and Contraindications

Benzodiazepines are remarkably safe drugs. They have relatively high margins of safety, especially compared with barbiturates. They are also free of allergenic effects and do not suppress the adrenal gland. [84] The most significant problem with midazolam is respiratory depression when the drug is given for conscious sedation. The major side effects of lor-azepam and diazepam are venous irritation and thrombophlebitis, problems related to aqueous insolubility and requisite solvents. [9] When used as sedatives or for induction and maintenance of anesthesia, benzodiazepines can produce an undesirable degree or prolonged interval of postoperative amnesia, sedation, and rarely, respiratory depression. These residual effects can be reversed with flumazenil.

New Benzodiazepines

The primary limitation of midazolam, which is the best suited benzodiazepine for use in anesthesia, is the slightly slower onset and prolonged offset compared with a hypnotic such as propofol. There are two benzodiazepine agonists that have been used in clinical trials, RO 48-6791 and RO 48-8684. [19] [37] Both are promising from a pharmacokinetic analysis because they have a larger volume of distribution and clearance than midazolam. Recovery is also faster, approximately 2-fold. It is

possible that one of these two drugs will undergo development with larger clinical trials, because a shorter-lasting benzodiazepine will be welcomed in clinical practice. The most welcome new benzodiazepine would be one rapidly metabolized by esterases, as seen with remifentanil.

FLUMAZENIL

Flumazenil (Anexate, Romazicon) is the first benzodiazepine antagonist approved for clinical use. [46] The preclinical pharmacologic studies with flumazenil revealed it to be a benzodiazepine receptor ligand with high affinity, great specificity, and by definition minimal intrinsic effect. [34] Flumazenil, like the agonists it replaces at the benzodiazepine receptor, interacts with the receptor in a concentration-dependent manner. Because it is a competitive antagonist at the benzodiazepine receptor, its antagonism is reversible and surmountable. Flumazenil has minimal intrinsic activity, [34] [85] which means that its benzodiazepine receptor agonist effects are very weak, significantly less than those of clinical agonists. Flumazenil, like all competitive antagonists at receptors, does not displace the agonist but rather occupies the receptor when an agonist dissociates from the receptor. The half-time (or half-life) of a receptor-ligand bond is a few milliseconds to a few seconds, and new ligand receptor bonds are then immediately formed. This dynamic situation accounts for the ability of either an agonist or an antagonist to occupy the receptor readily. The proportion

of receptors occupied by the agonist in the presence of an antagonist obeys the law of mass action and depends on the affinities and concentrations of the two ligands. [30] [34] Equation 1 expresses this relationship [86] :

where $[R_{Ago}]$ = receptor concentration of agonist, $[R_t]$ = total number of receptors, K_{Ago} = dissociation constant for agonist, K_{Ant} = dissociation constant for antagonist, [Ago] = concentration of agonist at the receptor, and [Ant] = concentration of antagonist at the receptor.

The ratio of agonist to total receptors produces the effects of the agonist drug, but the antagonist can alter this ratio, depending on its concentration and dissociation constant (see Eq. 1). Thus, flumazenil, which is an avid (high-affinity) li-gand, will replace a relatively weak agonist such as diazepam as long as it is given in sufficient dose (i.e., high [Ant]). However, flumazenil is cleared relatively rapidly, and the net result is that the [Ant] is reduced over time as compared with [Ago]; thus, the proportion of receptors occupied by agonist will increase, and the potential for resedation exists (Fig. 9-11) . This situation is less likely to happen when flumazenil is used to reverse midazolam, which has a more rapid clearance than other benzodiazepine agonists. [87] Another important finding is that in the presence of extremely high doses of agonist (e.g., when a mistake in dosing has occurred or suicide is attempted), flumazenil in a low dose attenuates the deep CNS depression (loss of consciousness, respiratory depression) by reducing the fractional receptor occupancy by the agonist without decreasing the agonist effects that occur at low fractional receptor occupancy (drowsiness, amnesia). Conversely, high doses of flumazenil in the presence of low doses of agonist completely

Figure 9-11 Schematic representation of the interaction of a short-acting antagonist with a longer-acting agonist, resulting in resedation. The upper curve shows agonist disappearance from blood, and the lower curve shows antagonist disappearance from plasma. Four conditions are represented: I, agonist response; II, antagonist response (the antagonist reverses the agonist effect); III, agonist response (resedation or resumption of agonist response with disappearance of short-lasting antagonist); and IV, no drug effect, with disappearance of both agonist and antagonist (both drugs are below the therapeutic level).

reverse virtually all the agonist effects. Flumazenil can precipitate withdrawal symptoms in animals or in humans physically dependent on a benzodiazepine receptor agonist. [88] This is not a problem when flumazenil is used to reverse benzodiazepine receptor agonists in anesthesia.

Physicochemical Characteristics

Flumazenil, synthesized in 1979, is similar to midazolam and other classic benzodiazepines except for the absence of the phenyl group, which is replaced by a carbonyl group [89] (see Fig. 9-1) . It forms a colorless, crystalline powder, has a dissociation constant of 1.7, and has weak but sufficient water solubility to permit its preparation in aqueous solution. Its octanol/aqueous buffer partition coefficient is 14, demonstrating moderate lipid solubility at pH 7.4 [89]

Metabolism

Flumazenil, like the other benzodiazepines, is metabolized in the liver, is rapidly cleared from the plasma, and has three known metabolites, *N*-desmethylflumazenil, *N*-desmethylflumazenil acid, and flumazenil acid. [90] The activities of these metabolites and their corresponding glucuronides are not known at present. The glucuronides probably are excreted in the urine. Because flumazenil is still under investigation, many details regarding the clinical metabolism of this drug have not been studied.

Pharmacokinetics

Flumazenil is a short-lived compound. Table 9-3 includes a summary of its pharmacokinetics, which have been described in a variety of clinical settings. [90] [91] [92] Of particular note is that, compared with benzodiazepine receptor agonists, flumazenil has the highest clearance and shortest elimination half-life. The plasma half-life of flumazenil is about 1 hour--it is the shortest-lived of all benzodiazepines used in anesthetic practice. This means that the potential exists for the antagonist to be cleared, leaving sufficient concentrations of agonist at the receptor site to cause resedation. [87] To maintain a constant therapeutic blood level over a prolonged time, either repeated administration or a continuous infusion is required. An infusion rate of 30 to 60 mug/min (0.5-1 mug/kg/min) has been used for this purpose. [93] The rapid blood clearance of flumazenil approaches hepatic blood flow, a finding that indicates that liver clearance is partially dependent on hepatic blood flow. Flumazenil, compared with other benzodiazepines, has a relatively high proportion of unbound drug; its protein binding is low, with the free fraction ranging from 54 to 64 percent. [90] This property of flumazenil could contribute to its rapid onset and greater clearance, but this hypothesis is unproven.

Pharmacology

When given in the absence of a benzodiazepine receptor agonist, flumazenil has little discernible CNS effect. Although

intrinsic (agonist and inverse agonist) effects have been ascribed to flumazenil, [85] they are clinically unimportant. It has been postulated that in low doses a stimulating effect can be seen, and in high doses a central depressant effect becomes more likely. [32] When given to volunteers and patients in clinically relevant doses, flumazenil has no effect on the EEG or cerebral metabolism. [92] [94] [95] In animals, flumazenil has no anticonvulsant properties and, in fact, reverses the anticonvulsant properties of benzodiazepines in local anesthetic-induced seizures. [96] When administered to patients who have benzodiazepine-induced CNS depression, flumazenil produces rapid and dependable reversal of unconsciousness, respiratory depression, sedation, amnesia, and psychomotor dysfunction. [32] [91] [97] [98] Flumazenil can be given prior to, during, or after the agonist to block or reverse the CNS effects of the agonist. The usual clinical need is to reverse the effects of agonists given prior to flumazenil. Flumazenil has successfully reversed the effects of the agonists midazolam, diazepam, lorazepam, and flunitrazepam. The onset is rapid, with peak effect occurring in 1 to 3 minutes, [32] which coincides with the detection of ^{11}C-flumazenil in human brain. [99] Flumazenil reverses the agonist by replacing it at the benzodiazepine receptor, and its onset and duration are governed by the law of mass action (see Eq. 1). A predicted therapeutic plasma level for flumazenil is 20 ng/mL [90] ; however, because the relative binding characteristics of agonist and antagonist in part dictate benzodiazepine receptor occupation by the residual agonist, different doses and plasma levels of flumazenil are required to reverse the effects of particular agonists. These reactions have not been fully studied, but it is known that higher doses of flumazenil are required for reversal of lorazepam than of diazepam, [97] lorazepam being more potent than diazepam. Although it is too soon to be certain, it does not appear that flumazenil administration after long-term benzodiazepine use produces severe withdrawal reactions.

The duration of action of flumazenil is determined by its dose, the dose of the agonist, and the specific agonist that is being reversed. The duration is dictated by the factors given in Equation 1. Studies have shown that during a constant infusion of agonist, the duration of flumazenil action is dependent on the dose, but 45 to 90 minutes of antagonism can be expected after an intravenous dose of 3.0 mg or 2 to 3 hours after a dose of 0.8 mg/kg. [100] [101] This is an artificial setting, because in clinical practice flumazenil is given after administration of agonist has been discontinued.

Flumazenil is devoid of the respiratory and cardiovascular depressant effects of benzodiazepine receptor agonists. A relatively large dose of flumazenil (0.1 mg/kg) given to volunteers did not produce significant respiratory depression. [102] However, when flumazenil is given in the presence of agonists, there are significant respiratory effects, because it reverses respiratory depression caused by the agonists (e.g., when given to volunteers made apneic with midazolam [103]). The reversal of midazolam-induced (0.13 mg/kg) respiratory depression with flumazenil (1.0 mg/kg) lasts between 3 and 30 minutes. [46] Other agonists and other doses would have different durations of antagonism of respiratory depression. If respiratory depression is related to opioid administration, flumazenil will not reverse it. [104] Incremental doses, up to 3 mg intravenously, in patients with ischemic heart disease had no significant effect on cardiovascular variables. [105] Administration of flumazenil to patients given agonists is remarkably free of cardiovascular effects, [32] [106] [107] [108] unlike the experience of opioid reversal with naloxone. Of particular interest is the effect on plasma catecholamines of benzodiazepine receptor agonist reversal with flumazenil, because this effect on catecholamines is the suspected mechanism of hyperdynamic response in opioid reversal. Although flumazenil does reverse sedation, it is not associated with significantly higher catecholamines than are found in patients receiving saline, [106] [107] [108] [109] [110] but the rise in catecholamines that accompanies arousal is more rapid after flumazenil. [109]

Uses and Doses

The relatively few uses for a benzodiazepine antagonist (Table 9-6) include the diagnostic and therapeutic reversal of the effects of benzodiazepine receptor agonists. [111] For diagnostic use in suspected benzodiazepine overdose, flumazenil may be given in incremental intravenous doses of 0.2 to 0.5 mg up to 3 mg. If there is no change in CNS sedation, it is unlikely that CNS depression is based solely on benzodiazepine overdose. More commonly in anesthesia, flumazenil is used to reverse the sedation of a patient who remains depressed after administration of a benzodiazepine for conscious sedation for a general anesthesia. Flumazenil reliably reverses the sedation, respiratory depression, and amnesia of benzodiazepines. However, there is now evidence of differential reversal effects on the different agonist actions. Thus, flumazenil tends to reverse the hypnotic and respiratory effects more than the amnesic effects of the agonist benzodiazepine. [104] [112] [113] The dosage guidelines are given in Table 9-6 , but it must be emphasized that large-scale dosing studies have not yet been completed. The dose varies with the particular benzodiazepine being reversed, and the duration of reversal is dependent on the kinetics both of the agonist and of flumazenil. Surveillance is recommended if a long-lasting benzodiazepine is reversed with a single administration of flumazenil because of the relatively short-lived effect. Flumazenil may be administered by continuous infusion to prevent resedation with longer-lasting benzodiazepine receptor agonists. It is postulated that the availability of flumazenil will extend the usefulness of benzodiazepine agonists, although it will not necessarily alter the safety of this class of drugs.

Side Effects and Contraindications

Flumazenil has been given in large oral and intravenous doses with remarkably few toxic reactions. [32] It is free of local

TABLE 9-6 -- Uses and Doses of Flumazenil

Reversal of benzodiazepines [a]	0.1-0.2 mg repeated [b] up to 3.0 mg
Diagnosis in coma	0.5 mg repeated up to 1.0 mg

[a] The dose required to reverse each benzodiazepine (BZD) depends on residual BZD and the particular BZD (i.e., higher doses are required for more potent BZDs) (see text).
[b] The degree of reversal should be titrated by repeating 0.2-mg increment every 1-2 min until desired level of reversal is achieved.

or tissue irritant properties, and there are no known organotoxicities. Like all benzodiazepines, it appears to have a high safety margin, probably higher than those of agonists, because it does not produce prominent CNS depression. Unless it is found that benzodiazepine reversal in patients who have a long-term history of benzodiazepine use causes withdrawal reactions, including seizures, there is no current contraindication for the use of flumazenil. An important caution is that resedation could occur because of the relatively short half-life of the drug.

PHENCYCLIDINES (KETAMINE)

History

Phencyclidine was the first drug of its class to be used for anesthesia. It was synthesized by Maddox and introduced into clinical use in 1958 by Greifenstein et al [114] and in 1959 by Johnstone et al. [115] Although phencyclidine proved useful as an anesthetic, it produced unacceptably high adverse psychologic effects (hallucinations and delirium) in the postanesthetic recovery period. Cyclohexamine, a congener of phencyclidine, was tried clinically in 1959 by Lear and coworkers, [116] but it was found to be less efficacious than phencyclidine in terms of analgesia and yet to have as many adverse psychotomimetic effects. Neither of these drugs is used clinically today, although phencyclidine is available for illicit recreational use. Ketamine (Ketalar) was synthesized in 1962 by Stevens and was first used in humans in 1965 by Corssen and Domino. [117] It was chosen from among 200 phencyclidine derivatives and proved to be the most promising in laboratory animal testing. Ketamine was released for clinical use in 1970 and is still used in a variety of clinical settings. Ketamine is different from most other anesthetic induction agents because it has significant analgesic effect. It usually does not depress the cardiovascular and respiratory systems, [118] [119] but it does possess some of the worrisome adverse psychologic effects found with the other phencyclidines.

Physicochemical Characteristics

Ketamine (Fig. 9-12) has a molecular weight of 238 kd, is partially water soluble, and forms a white crystalline salt with a negative log of the acid ionization constant (pK_a) of 7.5. [118] [119] It has a lipid solubility five to ten times that of thiopental. [120] Ketamine is prepared in a slightly acidic (pH 3.5-5.5) solution and comes in concentrations of 10-, 50-, and 100-mg ketamine base per milliliter of sodium chloride solution containing the preservative benzethonium chloride. The ketamine molecule contains a chiral center and therefore occurs as two resolvable optical isomers or enantiomers (11-12), the commercial preparation being a racemic mixture of both isomers [S-(+) and R-(-)] in equal amounts. [118]

Metabolism

Ketamine is metabolized by the hepatic microsomal enzymes responsible for most drug detoxification. The major pathway involves *N*-demethylation to form norketamine (metabolite I), which is then hydroxylated to hydroxynorketamine. These products are conjugated to water-soluble glucuronide derivatives and are excreted in the urine. [118] [119] [121] The activity of the principal metabolites of ketamine has not been well studied, but norketamine (metabolite I) has been shown to have significantly less (between 20 and 30%) activity than the parent compound. [122] [123] [124] Little is known about the activity of the other metabolites, but it is probable that ketamine is the major active drug.

Pharmacokinetics

The pharmacokinetics of ketamine have not been as well studied as those of many other intravenous anesthetics. Ketamine pharmacokinetics have been examined after bolus administration of anesthetizing doses (2 to 2.5 mg/kg), [125] following a subanesthetic dose (0.25 mg/kg) [125] [126] and after continuous infusion (steady-state plasma level
2,000 ng/ mL). [127] Regardless of the dose, ketamine plasma disappearance can be described by a two-compartment model. Table 9-3 contains the pharmacokinetic values from bolus administration studies. [125] Of note is the rapid distribution reflected in the relatively brief slow distribution half-life of 11 to 16 minutes (Fig. 9-13) . The high lipid solubility of ketamine is reflected in its relatively large volume of distribution, nearly 3 L/kg. Clearance is also relatively high, ranging from 890 to 1,227 mL/min, which accounts for the relatively short elimination half-life of 2 to 3 hours. The mean total

Figure 9-12 Stereoisomers of ketamine as it is formulated.

Figure 9-13 Simulated time course of plasma levels of ketamine following an induction dose of 2.0 mg/kg. Plasma levels required for hypnosis and amnesia during surgery are 0.7 to 2.2 mug/mL, with awakening usually occurring at levels lower than 0.5 mug/mL.

body clearance (1.4 L/min) is approximately equal to liver blood flow, which means that changes in liver blood flow affect clearance. Thus, the administration of a drug such as halothane, which reduces hepatic blood flow, reduces ketamine clearance. [128] [129]

Pharmacology

Effects on the Central Nervous System

Ketamine produces dose-related unconsciousness and analgesia (Chs. 35 and 52) . The anesthetized state has been termed *dissociative anesthesia* because patients who receive ketamine alone appear to be in a cataleptic state, unlike other states of anesthesia that resemble normal sleep. The ketamine-anesthetized patients have profound analgesia but keep their eyes open and maintain many reflexes. Corneal, cough, and swallow reflexes may all be present but should not be assumed to be protective. [130] There is no recall of surgery or anesthesia, but amnesia is not as prominent with ketamine as with the benzodiazepines. Because ketamine has a low molecular weight, a pK_a near the physiologic pH, and relatively high lipid solubility, it crosses the blood-brain barrier rapidly and therefore has an onset of action within 30 seconds of administration. The maximal effect occurs in about 1 minute. After ketamine administration, pupils dilate moderately and nystagmus occurs. Lacrimation and salivation are common, as is increased skeletal muscle tone, often with coordinated but seemingly purposeless movements of the arms, legs, trunk, and head. Although there is great interindividual variability, plasma levels of 0.6 to 2.0 mug/mL are considered the minimum concentrations for general anesthesia, [127] [128] but children may require slightly higher plasma levels (0.8-4.0 mug/mL). [131] The duration of ketamine anesthesia after a single administration of a general anesthetic dose (2 mg/kg IV) is 10 to 15 minutes [119] (see Fig. 9-13) , and full orientation to person, place, and time occurs within 15 to 30 minutes. [132]

The S enantiomer enables quicker recovery (by a couple of minutes) than the racemic mixture. [133] This is thought to be due to the lower dose necessary to produce

an equianesthetic effect and to the 10 percent faster hepatic biotransformation. [134]

The duration of ketamine anesthesia is determined by the dose; higher doses produce more prolonged anesthesia, [135] and the concurrent use of other anesthetics also prolongs the time of emergence. Because there is a reasonably good correlation between blood level of ketamine and CNS effect, it appears that ketamine's relatively short duration of action is due to its redistribution from the brain and blood to the other tissues in the body. Thus, the termination of effect after a single bolus administration of ketamine is caused by drug redistribution from the well-perfused to the less well-perfused tissues. Concomitant administration of benzodiazepines, a common practice, may prolong ketamine's effect. [136] When used in combination with a benzodiazepine, the S enantiomer was no different in terms of awareness at 30 minutes, but it was significantly better at 120 minutes than the racemic mixture. [137] Analgesia occurs at considerably lower blood levels than loss of consciousness. The plasma level at which pain thresholds are elevated is 0.1 g/mL or higher. [128] This means that there is a considerable period of postoperative analgesia after ketamine general anesthesia and that subanesthetic doses can be used to produce analgesia.

The primary site of CNS action of ketamine appears to be the thalamoneocortical projection system. [138] The drug selectively depresses neuronal function in parts of the cortex (especially association areas) and thalamus while simultaneously stimulating parts of the limbic system, including the hippocampus. This process creates what is termed a *functional disorganization* [119] of nonspecific pathways in midbrain and thalamic areas. [139] [140] There is also evidence that ketamine depresses transmission of impulses in the medial medullary reticular formation, which is important to transmission of the affective-emotional components of nociception from the spinal cord to higher brain centers. [141] Blockade of CNS sodium channels has been shown not to be the mechanism of action by which ketamine produces anesthesia. [142] There is some evidence that ketamine occupies opiate receptors in the brain and spinal cord, and this property could account for some of the analgesic effects. [118] [119] [143] [144] The S-(+) enantiomer has been shown to have some opioid mu-receptor activity, accounting for part of its analgesic effect. [145] *N*-Methyl- D-aspartate (NMDA) receptor interaction may mediate the general anesthetic effects as well as some analgesic actions of ketamine. [146] [147] [148] The spinal cord analgesic effect of ketamine is postulated to be due to inhibition of dorsal horn wide dynamic range neuronal activity. [149] Although some drugs have been used to antagonize ketamine, no specific receptor antagonist is yet known that reverses all the CNS effects of ketamine.

Ketamine increases cerebral metabolism, CBF, and intracranial pressure (ICP). Because of its excitatory CNS effects, which can be detected by generalized EEG development of theta-wave activity [135] as well as by petit mal seizure-like activity in the hippocampus, [150] ketamine increases $CMRO_2$. Whereas theta-wave activity signals the analgesic activity of ketamine, alpha waves indicate its absence. There is an increase in CBF, which appears higher

than the increase in $CMRO_2$ would mandate. With the increase in CBF as well as the generalized increase in sympathetic nervous system response, there is an increase in ICP after ketamine. [151] [152] The increase in $CMRO_2$ and CBF can be blocked by the use of thiopental [153] or diazepam. [152] [154] Cerebrovascular responsiveness to carbon dioxide appears to be preserved with ketamine; therefore, reducing Pa CO_2 attenuates the rise in ICP after ketamine [152] (Ch. 56) .

Ketamine, like other phencyclidines, produces undesirable psychologic reactions, which occur during awakening from ketamine anesthesia and are termed *emergence reactions.* The common manifestations of these reactions, which vary in severity and classification, are vivid dreaming, extracorporeal experiences (sense of floating out of body), and illusions (misinterpretation of a real, external sensory experience). [155] These incidents of dreaming and illusion are often associated with excitement, confusion, euphoria, and fear. [119] They occur in the first hour of emergence and usually abate within 1 to several hours. It has been postulated that the psychic emergence reactions occur secondary to ketamine-induced depression of auditory and visual relay nuclei, leading to misperception and/or misinterpretation of auditory and visual stimuli. [118] Their incidence ranges from as low as 3 to 5 percent [118] [119] to as high as 100 percent. [155] A clinically relevant range is probably 10 to 30 percent of adult patients who receive ketamine as a sole or major part of the anesthetic technique.

Factors that affect the incidence of emergence reactions are age, [156] dose, [119] gender, [157] psychologic susceptibility, [158] and concurrent drugs. Playing music during anesthesia does not attenuate the incidence of psychotomimetic reactions. [159] Pediatric patients do not report as high an incidence of unpleasant emergence reactions as do adult patients, nor do men as compared with women. Larger doses and rapid administration of large doses seem to predispose patients to a higher incidence of adverse effects. [160] [161] Finally, certain personality types seem prone to the development of emergence reactions. Patients who score high in psychotism on the Eysenck Personality Inventory are prone to develop emergence reactions, [158] and people who commonly dream at home are more likely to have postoperative dreams in the hospital after ketamine. [160] Numerous drugs have been used to reduce the incidence and severity of postoperative reactions to ketamine [118] [119] [162] ; the benzodiazepines seem to be the most effective group of drugs to attenuate or to treat ketamine emergence reactions. Mid-azolam, [118] lorazepam, [163] and diazepam [164] are useful in reducing reactions to ketamine. The mechanism is not known, but it is probable that both the sedative and amnesic actions of the benzodiazepines make them superior to other sedative-hypnotics. Midazolam has also been shown to reduce the psychotomimetic effect of the S enantiomer. [165]

Effects on the Respiratory System

Ketamine has minimal effects on the central respiratory drive as reflected by an unaltered response to carbon dioxide. [166] There can be a transient (1-3-min) decrease in minute ventilation after the bolus administration of an anesthetizing dose of ketamine (2 mg/kg IV). [135] [167] [168] Unusually high doses can produce apnea, [169] but this is seldom seen. Arterial blood gases are generally preserved when ketamine is used alone for anesthesia or analgesia. However, with the use of adjuvant sedatives or anesthetic drugs, respiratory depression can occur. Ketamine has been shown to affect ventilatory control in children and should be considered a possible respiratory depressant when the drug is given to them in bolus doses. [170] [171]

Ketamine is a bronchial smooth muscle relaxant. When it is given to patients with reactive airway disease and bronchospasm, pulmonary compliance is improved. [172] [173] Ketamine is as effective as halothane or enflurane in preventing experimentally induced bronchospasm. [174] The mechanism for this effect is probably a result of the sympathomimetic response to ketamine, but there are isolated bronchial smooth muscle studies showing that ketamine can directly antagonize the spasmogenic effects of carbachol and histamine. [175] Owing to its bronchodilating effect, ketamine has been used to treat status asthmaticus unresponsive to conventional therapy. [176]

A potential respiratory problem, especially in children, is the increased salivation that follows ketamine administration. This can produce upper airway obstruction, which can be further complicated by laryngospasm. The increased secretions may also contribute to or may further complicate laryngospasm. In addition, although swallow, cough, sneeze, and gag reflexes are relatively intact after ketamine, there is evidence that silent aspiration can occur during ketamine anesthesia. [130]

Effects on the Cardiovascular System

Ketamine also has unique cardiovascular effects; it stimulates the cardiovascular system and is usually associated with increases in blood pressure, heart rate, and cardiac output (see Table 9-4) . Other anesthetic induction drugs either cause no change in hemodynamic variables or produce vasodilation with cardiac depression. The S enantiomer, despite hope that reducing the dose by half (equi-anesthetic potency) would attenuate side effects, is equivalent to the racemic mixture regarding hemodynamic response. [165] The increase in hemodynamic variables is associated with increased work and myocardial oxygen consumption. The healthy heart is able to increase oxygen supply by increased cardiac output and decreased coronary vascular resistance, so that coronary blood flow is appropriate for the increased oxygen consumption. [177] The hemodynamic changes are not related to the dose of ketamine (e.g., there is no hemodynamic difference between administration of 0.5 and 1.5 mg/kg IV). [178] It is also interesting that a second dose of ketamine produces hemodynamic effects less than or even opposite to those of the first dose. [179] The hemodynamic changes after anesthesia induction with ketamine tend to be the same in healthy patients and in those with a variety of acquired or congenital heart diseases. [168] [178] [180] [181] [182] In patients with congenital heart disease, there are no significant changes in shunt directions or fraction [183] or systemic oxygenation after ketamine induction of anesthesia. [184] In patients who have elevated pulmonary artery pressure (as with mitral valvular and some congenital lesions), ketamine

seems to cause a more pronounced increase in pulmonary than systemic vascular resistance. [182] [183] [185] [186]

The mechanism by which ketamine stimulates the circulatory system remains enigmatic. It appears not to be a peripheral mechanism such as baroreflex inhibition, [187] [188] but rather to be central. [189] [190] [191] There is some evidence that ketamine attenuates baroreceptor function via an effect on NMDA receptors in the nucleus tractus solitarius. [192] Ketamine injected directly into the CNS produces an immediate sympathetic nervous system hemodynamic response. [193] Ketamine also causes the

sympathoneuronal release of norepinephrine, which can be detected in venous blood. [194] Blockade of this effect is possible with barbiturates, benzo-diazepines, and droperidol. [191] [193] [194] [195] Ketamine *in vitro* probably has negative inotropic effects. Myocardial depression has been demonstrated in isolated rabbit hearts, [196] intact dogs, [197] chronically instrumented dogs, [198] and isolated canine heart preparations. [199] However, in isolated guinea pig hearts, ketamine was the least depressant of all the major induction drugs. [200] The finding that ketamine may exert its myocardial effects by acting on myocardial ionic currents (which may exert different effects from species to species or among tissue types) may explain the tissue and animal model variances in direct myocardial action. [201]

The centrally mediated sympathetic responses to ketamine usually override the direct depressant effects of ketamine. There are some peripheral nervous system actions of ketamine that play an undetermined role in the hemodynamic effects of the drug. Ketamine inhibits intraneuronal uptake of catecholamines in a cocaine-like effect [202] [203] and inhibits extraneuronal norepinephrine uptake. [204] [205]

Stimulation of the cardiovascular system is not always desirable, and certain pharmacologic methods have been used to block the ketamine-induced tachycardia and systemic hypertension. Successful methods include use of adrenergic antagonists (both alpha and beta), as well as a variety of vasodilators [206] and clonidine. [207] However, probably the most fruitful approach has been prior administration of benzodiazepines. Modest doses of diazepam, flunitrazepam, and midazolam all attenuate the hemodynamic effects of ketamine. It is also possible to lessen the tachycardia and hypertension caused by ketamine by using a continuous infusion technique with or without a benzodiazepine. [208] Other general anesthetics, particularly the inhalation anesthetics, [209] blunt the hemodynamic effect of ketamine. Ketamine can produce hemodynamic depression in the setting of deep anesthesia, when sympathetic responses do not accompany its administration.

Uses

The many unique features of ketamine pharmacology, especially its propensity to produce unwanted emergence reactions, have placed ketamine outside the realm of routine clinical use. Nevertheless, ketamine has an important niche in the practice of anesthesiology when its unique sympathomimetic activity and bronchodilating capabilities are indicated during induction of anesthesia. It is used for premedication, sedation, induction and maintenance of general anesthesia.

Induction and Maintenance of Anesthesia

Poor-risk patients (ASA class IV) with respiratory and cardiovascular system disorders (excluding ischemic heart disease), represent the majority of candidates for ketamine induction; this is particularly true for patients with bronchospastic airway disease or patients with hemodynamic compromise based either on hypovolemia or cardiomyopathy (not coronary artery disease). Ketamine bronchodilation and profound analgesia allowing the use of high oxygen concentrations make ketamine an excellent choice for induction in patients with reactive airway disease. Otherwise healthy trauma victims whose blood loss is extensive are also candidates for rapid-sequence anesthesia induction with ketamine. [210] Patients with septic shock may also benefit from ketamine. [211] However, ketamine's intrinsic myocardial depressant effect may manifest in this situation if trauma or sepsis has caused depletion of catecholamine stores prior to the patient's arrival in the operating room. Use of ketamine in these patients does not obviate the need for appropriate preoperative preparation, including restoration of blood volume. Other cardiac diseases that can be well managed with ketamine anesthesia are cardiac tamponade and restrictive pericarditis. [212] The finding that ketamine preserves heart rate and right atrial pressure through its sympathetic stimulating effects makes ketamine an excellent anesthetic induction and maintenance drug in this setting. Ketamine is also often used in patients with congenital heart disease, especially those in whom the propensity for right-to-left shunting exists. Use of ketamine has also been reported in a patient susceptible to malignant hyperthermia who had a large anterior mediastinal mass, [213] when spontaneous ventilation was required and inhalation anesthetics were contraindicated. [213] [214] [215]

Ketamine combined with diazepam or midazolam can be given by continuous infusion to produce satisfactory cardiac anesthesia for patients with valvular and ischemic heart disease (Ch. 49) . The combination of a benzodiazepine [206] or of a benzodiazepine plus sufentanil [216] with ketamine attenuates or eliminates the unwanted tachycardia and hypertension as well as postoperative psychologic derangements. With this technique, there are minimal hemodynamic perturbations, profound analgesia, dependable amnesia, and an uneventful convalescence. No comparison of this technique with a continuous benzodiazepine-opioid technique has been made.

Low-dose ketamine as an analgesic has been used following thoracic surgery, [217] in which its lack of respiratory depressant properties and its equivalent pain relief as compared with meperidine make it a third choice when one wishes to avoid narcotics because of their respiratory depressant effects and when there is reason also to avoid non-steroidal agents such as ketorolac. Additional analgesic use can be considered in asthmatic patients. [218]

Sedation

Ketamine is particularly suited for sedation of the pediatric patient undergoing procedures away from the operating

room. Pediatric patients have fewer adverse emergence reactions [156] than adults, and this feature makes the use of ketamine in pediatrics more versatile. Ketamine is used for sedation and/or general anesthesia for the following pediatric procedures: cardiac catheterization, radiation therapy, radiologic studies, dressing changes, [219] and dental work. [136] Caution is advised in use of ketamine for cardiac catheterization in pediatric patients with elevated pulmonary vascular resistance, because this can be increased by ketamine. [220]

Ketamine is often used repeatedly in the same patient. Unfortunately, the literature does not provide information on how many times ketamine anesthesia can safely be administered to one individual, whether frequency of administration is related to tolerance following multiple administrations, and whether or not there are detrimental effects of frequent/long-term use.

Usually, a subanesthetic dose (
1.0 mg/kg IV) is used for dressing changes; this dose gives adequate operating conditions but a rapid return to normal function, including the resumption of eating, which is important in maintaining proper nutrition in burn patients. [118] [119] Often, ketamine is combined with premedication of a barbiturate or benzodiazepine and an antisialagogue (e.g., glycopyrrolate) to facilitate management. The premedications reduce the dose requirement for ketamine, and the antisialagogue reduces the sometimes troublesome salivation.

In adults and children, ketamine can be used as a supplement or an adjunct to regional anesthesia, extending the usefulness of the primary (local anesthetic) form of anesthesia. In this setting, ketamine can be used prior to the application of painful blocks, [221] but more commonly it is used for sedation or supplemental anesthesia during long or uncomfortable procedures. When used for supplementation of regional anesthesia, ketamine (0.5 mg/kg IV) combined with diazepam (0.15 mg/kg IV) is better accepted by patients and is not associated with greater side effects as compared with unsedated patients. [222] Ketamine in low doses can also be combined with nitrous oxide and propofol for the supplementation of conduction or local anesthesia. These techniques of ketamine administration are used in outpatient and inpatient settings, and although patients are comfortable and cooperative, dreams and other unpleasant emergence reactions can occur. [118] In outpatients, premedication with midazolam, concurrent propofol infusion, and intermittent ketamine (for analgesia) in doses less than 3 mg/kg are recommended. [223]

Doses and Routes of Administration

Ketamine can be administered intravenously, intramuscularly, orally, nasally, and rectally. [224] Most clinical use involves the intravenous and intramuscular routes, by which the drug rapidly achieves therapeutic levels. The dose depends on the desired therapeutic effect and on the route of administration. Table 9-7 contains general recommended doses for the intravenous and intramuscular administration of ketamine for various therapeutic goals. [118] Because of their side effects, most anesthetic drugs require that dosage be reduced in elderly and seriously ill patients; such a recommendation probably is prudent with ketamine, although data supporting this are not available. Patients who have been

critically ill for a prolonged period may have exhausted their catecholamine stores and may exhibit the circulatory depressant effects of ketamine. [225] Ketamine can be given epidurally and intrathecally for operative and postoperative pain control. The dose used in cancer pain is 1.0 mg (with benzethorium chloride as preservative and 0.05 mg morphine) twice daily, with additional morphine as required. [226] The peak action after intravenous administration occurs in 30 to 60 seconds. Onset occurs in about 5 minutes, with peak effect in about 20 minutes after intramuscular administration. An oral dose of 3 to 10 mg/kg generates a sedative effect in 20 to 45 minutes. The continuous infusion of intravenous ketamine with or without concomitant drugs is a satisfactory method to keep blood levels in the therapeutic range. The use of concomitant drugs such as benzodiazepines permits a lower dose requirement for ketamine while enhancing recovery by reducing emergence reactions. The interaction of ketamine with propofol is strictly additive and not synergistic; thus, the dose of each would be reduced by about half when used together for induction. [227]

For sedation, ketamine may be given intramuscularly if the patient wishes to avoid awareness of intravenous catheter placement. It has also been administered orally in doses of 3 to 10 mg/kg, with 6 mg/kg providing optimal conditions in 20 to 25 minutes in one study and 10 mg/kg providing sedation in 87 percent of children within 45 minutes in another study. [228] [229] In at least one case, deep sleep was produced by a supposedly sedative oral dose. [230]

Side Effects and Contraindications

The common psychologic emergence reactions are discussed earlier. Contraindications to ketamine relate to specific pharmacologic actions and patient diseases. Patients with increased ICP and with intracranial mass lesions should not receive ketamine because it can increase ICP and has been reported to cause apnea on this basis. [231] The S-(+) enantiomer also increases CBF and is probably similarly contraindicated. [232] Ketamine is also contraindicated in patients with an open eye injury or other ophthalmologic disorder, in whom a ketamine-induced increase in intraocular pressure would be detrimental (Ch. 63) . Because ketamine has a propensity to cause hypertension and tachycardia, with a commensurate increase in myocardial oxygen consumption, it is contraindicated as the sole anesthetic in patients with ischemic heart disease. [181] Likewise, it is unwise to give

ketamine to patients with vascular aneurysms because of the possible sudden change in arterial pressure. Psychiatric disease such as schizophrenia or a history of adverse reaction to ketamine or one of its congeners also constitutes a contraindication. [119] One should also consider carefully using ketamine when there is a possibility of postoperative delirium from other causes (e.g., delirium tremens, possibility of head trauma) and a ketamine-induced psychomimetic effect would cloud the differential diagnosis.

Other side effects include potentiation of nondepolarizing neuromuscular blockade by an undefined mechanism. [233] [234] Finally, because ketamine's preservative, chlorobutanol, has been demonstrated to be neurotoxic, subarachnoid administration is contraindicated. [235] It is probably unwise to administer the drug epidurally for this reason.

ETOMIDATE

History

Etomidate (Amidate, Hypnomidate) was synthesized [236] in 1964 and was introduced into clinical practice [237] in 1972. Its properties include hemodynamic stability, minimal respiratory depression, cerebral protection, and pharmacokinetics enabling rapid recovery following either a single dose or a continuous infusion. In animals, etomidate also provides a wider margin of safety (median effective dose/median lethal dose [ED_{50} /LD_{50}]) than thiopental (26.4 versus 4.6). [238] These beneficial properties led to widespread use of etomidate for induction, for maintenance of anesthesia, and for prolonged sedation in critically ill patients. Anesthesiologists' enthusiasm for etomidate, however, was tempered by reports that the drug can cause temporary inhibition of steroid synthesis after both single doses and infusions. [239] [240] [241] This effect, combined with other minor disadvantages (e.g., pain on injection, superficial thrombophlebitis, myoclonus, and a relatively high incidence of nausea and vomiting) led to several editorials [242] [243] [244] questioning the role of etomidate in modern anesthetic practice. Use of the drug waned significantly following those editorials, but it has been expanding over the past several years owing to a rediscovery of etomidate's beneficial physiologic profile combined with a lack of any new reports describing clinically significant adrenocortical suppression.

Physicochemical Characteristics

Etomidate is an imidazole derivative (R-(+)-pentylethyl-1H-imidazole-5 carboxylate sulfate). [238] Its chemical structure is illustrated in Figure 9-14 . Etomidate exists as two isomers, but only the (+) isomer is active as a hypnotic. [245] Its molecular weight is 342.36 kd. [245] Etomidate is water insoluble and is unstable in a neutral solution. It therefore has been formulated with several solvents. [246] Currently, it is supplied as a 2-mg/mL propylene glycol (35% by volume) solution with a pH of 6.9 and an osmolality of 4,640 mOsm/L. Unlike sodium thiopental, when etomidate is mixed with other commonly used anesthetic agents such as neuromuscular blockers, vasoactive drugs, or lidocaine, it does not cause precipitation. [247]

Figure 9-14 The structure of etomidate, an imidazole derivative.

Metabolism, Induction, and Maintenance of Anesthesia

Etomidate is metabolized in the liver primarily by ester hydrolysis to the corresponding carboxylic acid of etomidate (major metabolite) or by *N*-dealkylation. [245] The main metabolite is inactive. [247] Only 2 percent of the drug is excreted unchanged, the rest being excreted as metabolites by the kidney (85%) and bile (13%). [247]

Etomidate has been used for both induction and maintenance of anesthesia (Table 9-8) . The induction dose of etomidate varies from 0.2 to 0.6 mg/kg, [237] [246] [248] [249] and it is reduced by premedication with an opiate, a benzodiazepine, or a barbiturate. [237] Onset of anesthesia following a routine induction dose of 0.3 mg/kg etomidate is rapid (one arm-brain circulation) and is equivalent to that obtained with an induction dose of thiopental or methohexital. [237] [246] [250] The duration of anesthesia following a single induction dose is linearly related to the dose--each 0.1 mg/kg administered provides about 100 seconds of sleep. [251] Repeat doses of etomidate, either by bolus or infusion, prolong the duration of hypnosis. Recovery following etomidate is still usually rapid. [237] [248] [252] [253] [254] [255] [256] The addition of small doses of fentanyl with etomidate for short surgical procedures reduces the required dose of etomidate and allows earlier awakening. In children, induction by rectal administration of etomidate has been obtained with 6.5 mg/kg. Hypnosis occurs in 4 minutes. At this dose, hemodynamics are unaltered, and recovery is still rapid. [257]

Various infusion schemes have been devised to utilize etomidate as a maintenance agent for the hypnotic component of anesthesia. Most regimens aim to achieve a plasma level of 300 to 500 ng/mL, which is the concentration necessary for hypnosis. [258] [259] [260] [261] Both two- and three-stage infusions have been successfully used. These consist of an initial rapid infusion of 100 mug/kg/min for 10 minutes followed by 10 mug/kg/min thereafter, [261] or of 100 mug/kg/min for 3 minutes, 20 mug/kg/min for 27 minutes, and 10 mug/kg/min thereafter. [258]

TABLE 9-8 -- Uses and Doses of Etomidate

Induction of general anesthesia	0.2-0.6 mg/kg IV
Maintenance of general anesthesia	10 mug/kg/min IV with N_2 o and an opiate
Sedation and analgesia	5-8 mug/kg/min IV only for short periods of sedation because of inhibition of corticosteroid synthesis

Loss of consciousness with these techniques occurs after 100 to 120 seconds. [258] The infusion is usually terminated 10 minutes prior to desired awakening. [258]

Pharmacokinetics

The pharmacokinetics of etomidate has been calculated following single bolus doses and following continuous infusion [258] [259] [262] [263] [264] (see Table 9-3) . The time course of plasma disappearance after a 0.3-mg/kg bolus is shown in Figure 9-15 . The kinetics of etomidate are best described by an open three-compartment model. [262] [263] [264] The drug has an initial distribution half-life of 2.7 minutes, a redistribution half-life of 29 minutes, [262] [264] and an elimination half-life that varies from 2.9 to 5.3 hours. [258] [259] [262] [263] [264] Clearance of etomidate by the liver is high (18-25 mL/kg/min), with a hepatic extraction ratio of 0.5:0.9. [246] [258] [262] [263] [264] Thus, drugs affecting hepatic blood flow alter its elimination half-life. Because redistribution is the mechanism whereby the effect of a bolus of etomidate is dissipated, hepatic dysfunction should not appreciably alter recovery from its hypnotic effect. The volume of distribution at steady state is 2.5 to 4.5 L/kg. [258] [259] [262] [263] [264] Etomidate is 75 percent protein bound. [265] Pathologic conditions altering serum proteins (e.g., hepatic or renal disease) vary the amount of the free (unbound) fraction and may cause a given dose to have an exaggerated pharmacodynamic effect. [265]

In patients with cirrhosis, the volume of distribution is doubled, whereas clearance is normal; the result is an elimination half-life that is twice normal. [266] It is likely that the initial distribution half-life and clinical effect are unchanged. Increasing age is associated with a smaller initial volume of distribution and a decreased clearance of etomidate. [267] The relatively short elimination half-life and the rapid clearance of etomidate make it suitable for administration in a single dose, in multiple doses, or in a continuous infusion.

Pharmacology

Effects on the Central Nervous System

The primary action of etomidate on the CNS is hypnosis (Ch. 52) , which is achieved in one arm-brain circulation following a normal induction dose (0.3 mg/kg). [246] [268] Etomidate has no analgesic activity. Plasma levels required during the maintenance of anesthesia are approximately 300 to 500 ng/mL, those for sedation are 150 to 300 ng/mL, and those for awakening are 150 to 250 ng/mL [258] [260] [261] [268] (see Fig. 9-15) . The mechanism by which etomidate produces hypnosis is not fully elucidated; however, it may be in part related to the GABA-adrenergic system, because its action may be antagonized by GABA antagonists. [269]

At a dose of 0.2 to 0.3 mg/kg, etomidate reduces CBF (by 34%) and $CMRO_2$ (by 45%) without altering mean arterial pressure. [270] Thus, cerebral perfusion pressure is maintained or increased, and there is a beneficial net increase in the cerebral oxygen supply/demand ratio. [270] Etomidate given in

Figure 9-15 Simulated time course of plasma levels of etomidate following an induction dose of 0.3 mg/kg. Plasma levels required for hypnosis during surgery are 300 to 500 ng/mL, with awakening usually occurring at levels lower than 225 ng/mL.

doses sufficient to produce EEG burst suppression acutely lowers ICP by up to 50 percent in patients with already raised ICP, returning raised ICP to almost normal values. [271] [272] The decrease in ICP is maintained in the period immediately following intubation [272] (Ch. 52) . To maintain the effects of etomidate on ICP, high infusion rates (60 mug/kg/min) are necessary. [273] In contrast to the situation with other neuroprotective agents such as thiopental, reduction of ICP and maintenance of burst suppression are not associated with a drop in mean arterial blood pressure. [272] Because cerebral vascular reactivity is still maintained following etomidate administration, [273] hyperventilation theoretically may further reduce ICP when used in conjunction with etomidate. In animals, etomidate has reduced brain disease following acute cortical ischemic insult. [274] In 1993, Takanobu et al [275] reported the neuroprotective qualities of etomidate to be equal to those of thiopental and superior to those of isoflurane in a rat model. Other investigators disagree on etomidate's neuroprotective qualities. [276] Deeper structures such as the brain stem may not be afforded ischemic protection by etomidate. [277]

A dose of 0.3 mg/kg rapidly reduces intraocular pressure by 30 to 60 percent. [278] The decrease in intraocular pressure following a single dose lasts 5 minutes, but the reduction may be maintained by an infusion of 20 mug/kg/min. [278] (Ch. 63) .

Etomidate produces changes in the EEG similar to those produced by the barbiturates. [279] There is an initial increase in alpha amplitude with sharp beta bursts followed by mixed delta-theta waves, with delta-wave activity predominating prior to the onset of periodic burst suppression. [279] The absence of beta waves in the initial phase of induction with etomidate is the major difference in EEG changes as compared with thiopental. [279] Etomidate has been associated with grand mal seizures [280] [281] and has been shown to produce increased EEG activity in epileptogenic foci. This feature has proved useful for intraoperative mapping of seizure foci prior to surgical ablation. [281] [282] Etomidate is also associated with a high incidence of myoclonic movement. [248] [253] Myoclonus is not thought to be associated with seizure-like EEG activity. [279] Giving etomidate to unpremedicated patients

caused an increase in EEG activity in 22 percent of patients versus 17 percent of those receiving thiopental. [283] The myoclonic movement is believed to result from activity either in the brain stem or in deep cerebral structures. [237]

The effect of etomidate on auditory evoked potentials is similar to that produced by the inhaled anesthetics, with a dose-dependent increase in latency and a decreasing amplitude of the early cortical components (Pa and Nb). [284] Amplitude and latency of upper limb cortical somatosensory evoked potentials are positively affected following 0.4 mg/kg etomidate, which could theoretically obscure neurologic injury during positioning immediately following induction of anesthesia. [285] Brain-stem evoked responses are unaltered following etomidate administration. [284] Because amplitude depression is less, etomidate may be superior to propofol as an induction agent when monitoring of motor evoked responses to transcranial stimulation monitoring is indicated. [286]

Effects on the Respiratory System

Etomidate has minimal effect on ventilation. It does not induce histamine release either in healthy patients or in patients with reactive airway disease. [287] Ventilatory response to carbon dioxide is depressed by etomidate, but the ventilatory drive at any given carbon dioxide tension is greater than that following an equipotent dose of methohexital. [288] Similarly, the response to occlusion pressure is less depressed following etomidate than following an equivalent dose of methohexital. [289] Induction with etomidate produces a brief period of hyperventilation, [290] [291] sometimes followed by a similarly brief period of apnea, [291] which results in a slight (±15%) increase in Pa CO_2 but no change in the partial pressure of arterial oxygen (Pa O_2). [290] [292] The incidence of apnea is altered by premedication. [254] [293] Hiccups or coughing may accompany etomidate induction, with an incidence similar to that following methohexital induction. [246]

Effects on the Cardiovascular System

The minimal effect of etomidate on cardiovascular function sets it apart from other fast-acting induction agents [290] [292] [293] [294] [295] [296] (see Table 9-4) . An induction dose of 0.3 mg/kg of etomidate given to cardiac patients for noncardiac surgery results in almost no change in heart rate, mean arterial pressure, mean pulmonary artery pressure, pulmonary capillary wedge pressure, central venous pressure, stroke volume, cardiac index, and pulmonary and systemic vascular resistance. [292] A relatively large dose of etomidate, 0.45 mg/kg (which is 50% larger than a normal induction dose), [293] also produces minimal changes in cardiovascular parameters. In patients with ischemic heart disease or valvular disease, [292] [295] etomidate (0.3 mg/kg) produces similar minimal alterations in cardiovascular parameters. In patients with mitral or aortic valve disease, etomidate may produce greater changes in mean arterial pressure (an approximate 20% decrease) [290] [297] than in patients without cardiac valvular disease. Following induction (18 mg) and infusion (2.4 mg/min), etomidate produces a 50 percent decrease in myocardial blood flow and oxygen consumption and a 20 to 30 percent increase in coronary sinus blood oxygen saturation. [298] The myocardial oxygen supply/demand ratio is thus well maintained. [296] [298] There is minimal effect on the QT interval. [299]

The hemodynamic stability seen with etomidate may be due in part to its unique lack of effect both on the sympathetic nervous system and on baroreceptor function. [300] However, etomidate, lacking analgesic efficacy, may not totally ablate the sympathetic response to laryngoscopy and intubation. [250] [253] For the smoothest hemodynamic induction/intubation sequence, a low dose (1.5-5.0 mug/kg) of fentanyl is often combined with etomidate. [297] [301]

Endocrine Effects

The concern surrounding the endocrine effects of etomidate stems from a letter by Ledingham et al [302] in 1983 concerning ICU patients receiving long-term sedative infusions of etomidate while being mechanically ventilated for 5 days or longer. These investigators noted that in this subset of mechanically ventilated multiple trauma patients, the mortality rate was higher for 1981 to 1982 than among similar patients treated during 1979 to 1980. The earlier group had received primarily morphine and benzodiazepines for sedation, whereas patients in 1981 to 1982 had received primarily etomidate for sedation. It was postulated that adrenocortical suppression secondary to long-term etomidate infusion was the cause of the increased mortality. [239] Another ICU with similar patients receiving etomidate did not note an increased mortality; these patients received high-dose steroids as part of the trauma protocol. [302] This finding helped to confirm that hypothesis.

The specific endocrine effects manifested by etomidate are a dose-dependent reversible inhibition of the enzyme 11-beta-hydroxylase, which converts 11-deoxycortisol to cortisol, and a relatively minor effect on 17-alpha-hydroxylase [303] [304] (Fig. 9-16) . This results in an increase in the cortisol precursors 11-deoxycortisol and 17-hydroxyprogesterone as well as

Figure 9-16 Pathway for the biosynthesis of cortisol and aldosterone. The sites at which etomidate affects cortisol-aldosterone synthesis by its action on 11-beta-hydroxylase (major site) and

17-alpha-hydroxylase (minor site) are illustrated.

an increase in adrenocorticotropic hormone (ACTH). The blockade of 11-beta-hydroxylase and, to a lesser extent, 17-alpha-hydroxylase [303] appears to be related to the free imidazole radical of etomidate-binding cytochrome P-450. [304] [305] [306] This results in inhibition of ascorbic acid resynthesis, which is required for steroid production in humans. [305] [306] The blockade of the cytochrome P-450-dependent enzyme 11-beta-hydroxylase also results in decreased mineralocorticoid production and an increase in intermediaries (11- deoxycorticosterone). [240] [241] [243] Vitamin C supplementation restores cortisol levels to normal following the use of etomidate. [306] Because minor adrenocortical suppressive effects were shown to follow even single bolus doses, [240] [303] [307] concerns about the use of etomidate for anesthetic induction arose. [242] No large prospective studies have been done, but several smaller studies have provided some insight into the exact nature of adrenocortical suppression following an induction dose.

Duthie et al [308] demonstrated that in otherwise healthy patients undergoing minor peripheral surgery, plasma cortisol levels were slightly depressed from the preinduction levels for up to 1 hour postoperatively. The nadir of mean cortisol levels did not fall out of the normal range. 11- Deoxycorticosterone, substrate for the etomidate-inhibited 11-beta-hydroxylase, peaked at very high levels when compared with the thiopental control group. [308] In another study, patients undergoing orthopedic surgery were given an etomidate induction followed by an infusion of etomidate (average total dose 68 mg). Temporary adrenocortical suppression, as measured by a reduced response to ACTH stimulation, was documented for 6 hours postoperatively and returned to normal by 20 hours postoperatively. Postoperative cortisol levels in the etomidate study patients were not significantly different from those in a group who received a midazolam induction. As in the study of Duthie et al [308] mean cortisol levels in the etomidate group remained in the normal range at all times postoperatively. [309] Other studies have shown similar results when evaluating etomidate induction doses; none reported adverse outcomes secondary to short-term adrenocortical suppression. [240] [241] [303] [307] [308] [309] [310]

However, in each of the prospective etomidate studies documenting adrenocortical suppression without associated clinical sequelae, a conclusion of safety was not forthcoming. The reason was that these studies did not address high-stress procedures, in which the benefit of a high cortisol level in response to a major stress could be desirable and etomidate's blockade of the response to ACTH could be detrimental. As part of a quality assurance program, we addressed this issue with a small, retrospective analysis of etomidate induction for high-stress procedures (vascular, thoracic, major intra-abdominal, and major retroperitoneal surgery) in 1993. [249] Indices of adrenocortical function and perioperative outcome in patients who received induction doses of etomidate were compared with those in a control group who received thiopental. The incidence of perioperative wound infection, sepsis, miscellaneous infection, myocardial infarction, and hypotension and the need for perioperative vasopressor/inotropic support were evaluated, along with postoperative serum sodium levels. No difference was found between patients receiving etomidate and those receiving other induction agents for these high-stress procedures. In 1994, the cortisol levels during and after coronary artery bypass surgery were compared in patients receiving total intravenous anesthesia with etomidate/fentanyl (mean etomidate dose of 87 ± 3 mg) versus midazolam/fentanyl. Except for the first hour after induction, cortisol levels were the same or higher in the etomidate group compared with the midazolam group, a finding implying that the body's ability to respond to a high surgical stress was still intact despite relatively high doses of etomidate. This study is further proof that etomidate is probably safe for use in major surgery. [311]

In summary, three facts suggest that the issue of temporary adrenocortical suppression following induction doses of etomidate is not clinically significant: (1) there are no known reports of any negative clinical outcome associated with an etomidate induction despite millions of uses; (2) following etomidate induction, the nadir of cortisol levels usually remains in the low normal range and the adrenocortical suppression is a relatively short-lived phenomenon; and (3) high-stress surgery can overcome the temporary adrenocortical suppression caused by etomidate.

Other Effects

Although etomidate provides stable hemodynamics and minimal respiratory depression, it is associated with several adverse effects when it is used for induction. These are nausea and vomiting, pain on injection, myoclonic movement, and hiccups. [237] [246] [248] [252] [253] [254] [255] Etomidate has been associated with a high (30 to 40 percent) incidence of nausea and vomiting. [248] [253] [254] [255] [256] This compares with a reported incidence of 10 to 20 percent with methohexital [246] [254] or thiopental, [253] [312] but some studies have shown no difference. [249] [253] Addition of fentanyl to etomidate further increases the incidence of nausea and vomiting. [248] [253] Nausea and vomiting constitute the most common reasons for patients to rate anesthesia with etomidate unsatisfactory. [255] It seems prudent to avoid etomidate in patients predisposed to nausea and vomiting.

Superficial thrombophlebitis of the vein used may occur 48 to 72 hours after etomidate injection. [313] The incidence may be as high as 20 percent when etomidate is given alone through a small (21-gauge) intravenous needle. Intra-arterial injection of etomidate is not associated with local or vascular disease. [237] Pain on injection, similar in incidence to that with propofol, [314] can be essentially eliminated by injecting lidocaine immediately before injection of etomidate; as little as 20 to 40 mg may be enough. [315] Pain on injection is further reduced by using a large vein. [237] [252] Less successful but somewhat efficacious is premedication with benzodiazepine plus a narcotic. [253] [256] The incidence of pain on injection varies from 0 to 50 percent. The incidence of muscle movement (myoclonus) and of hiccups is also highly variable (0-70%), but myoclonus is reduced by premedication with either a narcotic or benzodiazepine. [256] Both fast and slow injection techniques have also been advocated for reducing myoclonus. [252] [256]

Etomidate enhances the neuromuscular blockade of nondepolarizing neuromuscular blockers. [316] [317] Hepatic function is unaltered by etomidate. [246] [262] *In vitro,* etomidate inhibits aminolivulinic acid synthetase, but it has been administered to patients with porphyria without inducing an acute attack of porphyria. [312]

The carrier for etomidate, propylene glycol, has also been reported to have some negative effects. Some reports suggest that propylene glycol can be associated with a small degree of hemolysis. [318] Additionally, high-dose prolonged infusion has been reported to result in propylene glycol toxicity (a hyperosmolar state). [319]

Uses

The use of etomidate is most appropriate in patients with cardiovascular disease, reactive airway disease, intracranial hypertension, or any combination of disorders indicating the need for an induction agent with limited or beneficial physiologic side effects. The hemodynamic stability of etomidate is unique among the rapid-acting induction agents.

Etomidate has been primarily used in sick patients. In multiple studies, etomidate has been used for induction in patients with a compromised cardiovascular system who are undergoing coronary artery bypass surgery or valve surgery, in patients requiring induction of general anesthesia for percutaneous transluminal coronary angioplasty, and in other similar situations. [297] [301] [320] In cardiovascular surgery, particularly surgery for aortic aneurysms, etomidate is an excellent anesthetic induction agent. When etomidate is used in combination with fentanyl, titrating etomidate up to 0.6 mg/kg maintains blood pressure and heart rate in a narrow range, preserving coronary perfusion pressure in these patients with probable coronary artery disease while blunting the response to intubation and avoiding unnecessary stress on the aneurysm. For cardiothoracic procedures, especially cardiac and lung transplantation, the required rapid-sequence induction and hemodynamic stability make etomidate the induction agent of choice. For patients with concomitant coronary artery disease and reactive airway disease, etomidate induction does not release histamine, and a relatively large dose (0.6 mg/kg) may be titrated to provide a deep level of anesthesia for intubation without compromising hemodynamics and coronary perfusion pressure. For cardioversion, the rapid onset, quick recovery, and maintenance of blood pressure in these sometimes hemodynamically tenuous patients, combined with continued spontaneous respiration, make etomidate an acceptable choice, [314] although there is one report of myoclonus interfering with electrocardiographic evaluation. [321] Although definitive proof of etomidate's neuroprotective effect in humans is lacking, the combination of animal data and anecdotal reports of successful use of etomidate in neurosurgical procedures such as giant aneurysm clippings makes etomidate a reasonable choice during neurosurgical induction. [261] [272] [274] [322] In addition, etomidate should be considered as an agent to reduce raised ICP when maintenance of cerebral or coronary perfusion pressure is also important. Trauma patients with questionable volume status may be well served by an etomidate induction. Although the indirect sympathomimetic effect seen with ketamine induction is absent, there is no direct myocardial depression and no confusion in the differential diagnosis of postoperative delirium. This is especially important in patients whose trauma may be related to drug and/or alcohol use.

During an infusion, hemodynamic status is well maintained, and adequate spontaneous ventilation is pres-ent. [88] [323] The incidence of pain on injection and of myoclonus and thrombophlebitis tends to be less with an infusion technique. [258] [260] [323] A concentrated form of etomidate used for continuous infusion in Europe is not

available in the United States.

Short-term sedation with etomidate is useful in hemodynamically unstable patients, such as those requiring cardioversion [314] or those requiring sedation following an acute myocardial infarction or with unstable angina for a minor operative procedure [301] or for intubation both in the emergency room and in the ICU. In addition, etomidate has been used to produce short-term sedation for placement of retrobulbar block and for electroconvulsive therapy instrumentation, during which maintenance of spontaneous respirations and quick recovery are important features. When used during electroconvulsive therapy, etomidate can produce longer seizures compared with other hypnotics. [324]

Prolonged sedation for patients in the ICU, although initially popular following the release of etomidate, is now contraindicated owing to inhibition of corticosteroid and mineralocorticoid production, with subsequent increase in morbidity. [239] [242] [302]

PROPOFOL

History

Propofol (Diprivan) is the most recent intravenous anesthetic to be introduced into clinical practice. Work in the early 1970s on substituted derivatives of phenol with hypnotic properties resulted in the development of 2,6-di-isopropofol. [325] The first clinical trial, by Kay and Rolly [326] and reported in 1977, confirmed the potential of propofol as an anesthetic induction agent. Propofol is insoluble in water and therefore was initially prepared with Cremophor EL (BASF A.G.). Because of anaphylactoid reactions associated with Cremophor EL in this early formulation of propofol, [327] the drug was reformulated in an emulsion. Propofol has been used for induction and maintenance of anesthesia as well as for sedation.

Physicochemical Characteristics

Propofol (Fig. 9-17) is one of a group of alkylphenols that have hypnotic properties in animals. [328] The alkylphenols are oils at room temperature and are insoluble in aqueous solution, but they are highly lipid soluble. The present formulation consists of 1 percent (wt/vol) propofol, 10 percent soybean

Figure 9-17 The structure of propofol, an alkylphenol derivative.

oil, 2.25 percent glycerol, and 1.2 percent purified egg phosphatide. In the United States, disodium edetate (0.005%) was added as a retardant of bacterial growth. Propofol has a pH of 7 and appears as a slightly viscous, milky white substance. Propofol is available as a 1 percent solution in 20-mL clear glass ampules, 50- and 100-mL vials, and in 50-ml prefilled syringes. It is stable at room temperature and is not light sensitive. If a dilute solution of propofol is required, it is compatible with 5 percent dextrose in water.

Metabolism

Propofol is rapidly metabolized in the liver by conjugation to glucuronide and sulfate [329] to produce water-soluble compounds, which are excreted by the kidneys. [329] Less than 1 percent propofol is excreted unchanged in urine, and only 2 percent is excreted in feces. [329] The metabolites of propofol are thought not to be active. Because clearance of propofol exceeds hepatic blood flow, extrahepatic metabolism or extrarenal elimination has been suggested. Extrahepatic metabolism has been confirmed during the anhepatic phase of patients receiving a transplanted liver. [330] [331] The lungs do not seem to be the site of this extrahepatic metabolism; however, in *in vitro* studies with human kidney and small intestine, microsomes in these tissues demonstrated an ability to form propofol glucuronide. [332] Propofol itself results in a concentration-dependent inhibition of cytochrome P-450 and thus may alter the metabolism of drugs dependent on this enzyme system. [333]

Pharmacokinetics

The pharmacokinetics of propofol following a wide range of doses as well as following continuous infusions has been evaluated by numerous investigators, [329] [334] [335] [336] [337] [338] [339] and it has been described by both two- and three-compartment models (see Table 9-3) . Following a single bolus injection, whole blood propofol levels decrease rapidly as a result of both redistribution and elimination (Fig. 9-18) . The initial distribution

Figure 9-18 Simulated time course of whole blood levels of propofol following an induction dose of 2.0 mg/kg. Blood levels required for anesthesia during surgery are 2 to 5 mug/mL, with awakening usually occurring at a blood level lower than 1.5 mug/mL.

half-life of propofol is 2 to 8 minutes. [329] [335] In studies using a two-compartment model, the elimination half-life has varied from 1.0 to 3 hours. [329] [334] [336] [339] Studies in which the disposition of propofol was better described by a three-compartment model have given initial and slow distribution half-lives of 1 to 8 minutes and 30 to 70 minutes and an elimination half-life of 4 to 23.5 hours. [335] [336] [337] [339] [340] This longer elimination half-life is indicative of a deep compartment with limited perfusion, which results in a slow return of propofol back to the central compartment. Owing to the rapid clearance of propofol from the central compartment, the slow return of propofol from this deep compartment contributes little to the initial rapid decrease in propofol concentrations. The context-sensitive half-time for propofol (see Fig. 9-5) for infusions of up to 8 hours is less than 40 minutes. [341] Because the required decrease in concentration for awakening following anesthesia or sedation with propofol is generally less than 50 percent, recovery from propofol remains rapid even following prolonged infusions. The volume of distribution of the central compartment has been calculated as 20 to 40 L, and the volume of distribution at steady state has been calculated as 150 to 700 L. [329] [334] [335] [336] [337] [338] [339] The clearance of propofol is extremely high--1.5 to 2.2 L/min. [329] [334] [335] [336] [337] [338] [339] This exceeds hepatic blood flow, and extrahepatic metabolism has been demonstrated. [330] [331] The equilibrium constant for EEG effect for propofol is 0.291 min^{-1} , and the half-life of equilibrium between plasma concentration and EEG effect is 2.4 minutes based on suppression of the EEG. The time to peak effect is 92 seconds. [342]

The pharmacokinetics of propofol may be altered by a variety of factors (e.g., gender, weight, preexisting disease, age, and concomitant medication). [335] [336] [339] [343] [344] Propofol may impair its own clearance by decreasing hepatic blood flow. [345] Probably of greater clinical significance is that propofol may alter its own intercompartmental clearances because of its effects on cardiac output. Women have a higher volume of distribution and higher clearance rates, but the elimination half-life is similar for males and females. [335] [339] The elderly have decreased clearance rates but a smaller central compartment volume. [336] [339] In addition, patients presenting for coronary artery bypass surgery seem to have different pharmacokinetic parameters compared with other adult populations. When a patient is placed on a cardiopulmonary bypass machine, there is an increase in the central volume and initial clearance, thus necessitating higher initial infusion rates to maintain the same propofol plasma concentration. [346] Children have a larger central compartment volume (50%) and a more rapid clearance (25%). [347] In children older than 3 years, volumes and clearances should be weight adjusted [348] (Ch. 59) . Children less than 3 years of age also demonstrate weight-proportional pharmacokinetic parameters but with greater central compartment and systemic clearance values than in adults or older children [348] . This finding explains the higher dosing requirements in this age group. [349] Hepatic disease appears to result in a larger steady-state and central compartment volumes; clearance is unchanged, but the elimination half-life is slightly prolonged. [343] The effect of fentanyl administration on propofol pharmacokinetic parameters is controversial. Some studies suggest that fentanyl may reduce intercompartmental and total body clearance rates as well as volumes of distribution. [350] When propofol was administered with alfentanil at similar infusion rates, the measured propofol concentrations were 22 percent greater than

when propofol was administered alone. [351] A separate study found that fentanyl did not alter propofol pharmacokinetics following a single dose of both drugs. [352] Some of these differences in propofol pharmacokinetics when given with an opioid may be explained by studies in cats that showed that pulmonary uptake of propofol is reduced by 30 percent when propofol is administered immediately following fentanyl but not if it is administered 3 minutes later. [353] In addition, *in vitro* studies on human hepatocytes demonstrated that propofol inhibited in a dose-dependent manner the enzymatic degradation of both sufentanil and alfentanil. [354] Propofol kinetics are unaltered by renal disease. [344]

Pharmacology

Effects on the Central Nervous System

Propofol is primarily a hypnotic. The exact mechanism of its action has not yet been fully elucidated; however, evidence suggests that it acts by promoting the function of the beta$_1$ subunit of GABA through activation of the chloride channel and thereby enhancing inhibitory synaptic transmission. [355] [356] [357] Propofol also inhibits the NMDA subtype of glutamate receptor through modulation of channel gating. [358] [359] This action may also contribute to the drug's CNS effects. The hypnotic action of propofol is pressure reversible, and it adheres to the correlation exhibited by other general anesthetics between anesthetic potency and octanol/water distribution coefficient. [360] Unlike barbiturates, propofol is not antianalgesic. [361] Propofol at subhypnotic doses helps in the diagnosis and treatment of central, but not neuropathic, pain. [357]

The onset of hypnosis following doses of 2.5 mg/kg is rapid (one arm-brain circulation), with a peak effect seen at 90 to 100 seconds. [362] [363] The ED_{50} of propofol is 1 to 1.5 mg/kg following a bolus. [362] [364] [365] [366] The duration of hypnosis is dose-dependent, being 5 to 10 minutes following 2 to 2.5 mg/kg. [362] [367] Age markedly affects the 95 percent effective dose (ED_{95}) induction dose of propofol, being highest at ages less than 2 years (ED_{95} 2.88 mg/kg) and decreasing with increasing age. [368] At subhypnotic doses, propofol provides sedation and amnesia. [369] [370] [371] Propofol infusions of at least 2 mg/kg/h were necessary to provide amnesia in unstimulated volunteers. [372] Awareness during surgery at higher infusion rates has been reported. [373] During surgical procedures, extremely high infusion rates may be necessary to prevent awareness if propofol is used as the sole anesthetic. [374] Propofol alters mood following short surgical procedures to a lesser extent than thiopental. [375] Propofol also tends to produce a general state of well-being. [375] Hallucinations, [376] sexual fantasies, and opisthotonos [377] have been reported following propofol administration.

The effect of propofol on the EEG as assessed after 2.5 mg/kg followed by an infusion demonstrates an initial increase in alpha rhythm followed by a shift to gamma and theta frequency. High infusion rates produce burst suppression. [378] EEG power analysis indicates that amplitude increases after induction but is thereafter unaltered at propofol blood concentrations of 3 to 8 mug/mL. [379] At propofol concentrations greater than 8 mug/mL, amplitude markedly decreases, with periods of burst suppression. [379] There is a strong correlation between the logarithm of blood concentration of propofol and the percentage of activity content, and there is an inverse correlation with percentage of activity content. [379] The bispectral (BIS) index is a new derivative of the EEG. Propofol causes a concentration-dependent decrease in the BIS index, with 50 and 95 percent of patients unable to respond to a verbal command at a BIS value of 63 and 51, respectively (Fig. 9-19) . The propofol concentration at which 50 percent of volunteers failed to respond to verbal command was 2.35 mug/mL. Lack of recall was observed in

Figure 9-19 The relationship between the bispectral (BIS) index and probability of consciousness (i.e., response to verbal command) using the logistic regression analysis for volunteers receiving propofol, isoflurane, or midazolam. The probability of response was no different among the three different anesthetics used. It can also be noted that 95 percent of the volunteers were unconscious with a BIS index of 50 or less.

95 percent of patients at a BIS value of 77. [380] Propofol produces a decrease in amplitude of the early components of somatosensory evoked potentials, [381] as well as a small nonsignificant increase in latency of the P_{40} and N_{50} components. [381] Like other intravenous anesthetics, propofol does not alter brain-stem auditory evoked potentials. [382] There are, however, a dose-dependent prolongation of latency and a decrease in amplitude of cortical middle latency auditory potentials, which are concentration-dependent. [382] Auditory evoked potentials show an abrupt change in the auditory evoked potential index between awake and nonresponsive patients. This finding differs from the BIS index, which tends to show a trend of decreasing BIS values and increasing sedation and loss of consciousness with propofol administration. [383]

The effect of propofol on epileptogenic EEG activity is controversial. Initial studies in mice indicated that propofol neither induced convulsions nor provided anticonvulsant activity. [384] Several more recent reports have shown in a variety of models a direct anticonvulsant effect of propofol, which is dose-dependent. [385] [386] In a few reports, propofol has been used to treat epileptic seizures. [387] [388] Propofol also results in a shorter duration of motor and EEG seizure activity following electroconvulsive therapy as compared with methohexital. [389] Interestingly, propofol has been associated with grand mal seizures and has been used for cortical mapping of epileptogenic foci. [390] [391] In 17 patients undergoing cortical resection for intractable epilepsy, 2 mg/kg propofol resulted in markedly reduced or ablated seizure activity. [392] When propofol was administered at sedative doses in 14 patients with complex seizure disorders, no effect on seizure activity was noted. [393] There have been a few reports of convulsions following propofol administration that have occurred several (6) days following anesthesia. Although the majority of these patients had a history of previous convulsions, a few did not. The incidence of this adverse effect is rare (1 in 50,000 administrations). [394] There have also been reports of tolerance developing to propofol following either repeat anesthesia or prolonged infusions (days). [395] [396] There have not been reports of acute tolerance during a single case of anesthesia. In addition to tolerance, addiction to propofol has been reported. [397]

Propofol decreases ICP in patients with either normal or increased ICP [398] [399] [400] [401] [402] (Ch. 52) . In patients with normal ICP, the decrease in ICP (30%) is associated with a small decrease in cerebral perfusion pressure (10%). [401] The addition of small doses of fentanyl and of supplemental doses of propofol ablates the rise of ICP secondary to endotracheal intubation. [401] Normal cerebral reactivity to carbon dioxide and autoregulation are maintained during a propofol infusion. [398] [403] [404] In patients with elevated ICP, the decrease in ICP (30-50%) is associated with significant decreases in cerebral perfusion pressure [399] [405] and therefore may not be beneficial. Propofol reduces $CMRO_2$ 36 percent. [398] With a background of 0.5 percent enflurane, propofol still reduces $CMRO_2$ by 18 percent, whereas lactate and glucose metabolism remains unchanged. [402] By measuring arteriovenous oxygen content difference, cerebral metabolic autoregulation is maintained during burst suppression with propofol. [406] Propofol administered to burst suppression results in significantly better neurologic outcome and less brain tissue injury in an incomplete ischemia model in rats, as compared with fentanyl. [407] Propofol also provides cerebral protective effects following an acute ischemic insult to the same degree as either halothane or thiopental. [408] [409] The neuronal protective effect of propofol may be due to the attenuation of changes in adenosine triphosphate, calcium, sodium, and potassium caused by hypoxic injury. [410] Propofol acutely reduces intraocular pressure by 30 to 40 percent. [411] [412] As compared with thiopental, propofol produces a greater decrease in intraocular pressure, and following a small second dose, it is more effective in preventing a rise in intraocular pressure secondary to succinylcholine and endotracheal intubation. [412]

The propofol Cp_{50} for loss of response to verbal command in the absence of any other drug is 2.3 to 3.5 mug/mL. [413] [414] [415] The propofol Cp_{50} (arterial whole blood concentration) to prevent movement on skin incision is 16 mug/mL. This is markedly reduced by increasing concentrations of fentanyl or alfentanil. [413] [414] [416] The propofol Cp_{50} for skin incision when combined with benzodiazepine premedication (lorazepam 1-2 mg) and 66 percent nitrous oxide is 2.5 mug/mL (venous). [417] This concentration is reduced to 1.7 mug/mL when morphine (0.15 mg/kg) rather than lor-azepam is used for premedication. [418] The concentration of propofol (when combined with 66% nitrous oxide) required during minor surgery varies from 1.5 to 4.5 mug/mL, [338] [339] and that for major surgery varies from 2.5 to 6 mug/mL. [419] Awakening usually occurs at concentrations lower than 1.6 mug/mL, [338] [339] [367] and orientation occurs at concentrations lower than 1.2 mug/mL. [338] [339] Age also affects the propofol concentration required to provide adequate anesthesia. [339]

Effects on the Respiratory System

Propofol affects the respiratory system in a manner qualitatively similar to the action of barbiturates. [420] [421] [422] Apnea occurs after an induction dose of propofol; the incidence and duration of apnea appear dependent on dose, speed of injection, and concomitant premedication. An induction dose of propofol results in a 25 to 30 percent incidence of apnea. [419] [420] The apnea occurring with propofol, however, may be prolonged to more than 30 seconds. The incidence of prolonged apnea (>30

seconds) is further increased by addition of an opiate, either as premedication or just prior to induction, [419] [420] [423] and it is greater with propofol than with other commonly used intravenous induction agents. [420] [423] The onset of apnea is usually preceded by marked tidal volume reduction and tachypnea. [422] Following a 2.5-mg/kg induction dose of propofol, the respiratory rate is significantly decreased for 2 minutes, [420] and minute volume is significantly reduced for up to 4 minutes, a finding that indicates a more prolonged effect of propofol on tidal volume than on respiratory rate.

A maintenance infusion of propofol (100 mug/kg/min) results in a 40 percent decrease in tidal volume and a 20 percent increase in respiratory frequency, with an unpredictable change in minute ventilation. [422] Doubling the infusion rate from 100 to 200 mug/kg/min causes a further moderate decrease in tidal volume (455-380 mL) but no change in respiratory frequency. [422] The ventilatory response to carbon dioxide is also decreased during a maintenance infusion of propofol. [422] At 100 mug/kg/min, there is a 58 percent

reduction in the slope of the carbon dioxide-response curve. [422] This is similar to the 50 percent depression of carbon dioxide responsiveness measured with 1 MAC of halothane [424] or after a brief infusion of 3 mg/kg/min of thiopental. [425] Doubling the infusion rate (and presumably the blood level) of propofol results in only a minimal further decrease in carbon dioxide responsiveness. [422] This is in contrast to halothane, with which use of twice the MAC results in halving the carbon dioxide response. [424] Propofol, 1.5 to 2.5 mg/kg, results in an acute (13-22%) rise in Pa CO_2 and a decrease in pH. [426] [427] [428] Pa O_2 does not change significantly. [426] [427] [428] These changes are similar to those seen following an induction dose of thiopental. [427] [428] During a maintenance infusion of propofol (54 mug/kg/min), Pa CO_2 is moderately increased from 39 to 52 mm Hg. [429] Doubling this infusion rate does not result in a further increase in Pa CO_2 . [429] Propofol (50-120 mug/kg/min) also depresses the ventilatory response to hypoxia. [430]

Propofol induces bronchodilation in patients with chronic obstructive pulmonary disease. [431] Propofol, however, does not appear to provide as effective bronchodilating properties as halothane. [432]

Effects on the Cardiovascular System

The cardiovascular effects of propofol have been evaluated following its use both for induction and for maintenance of anesthesia [298] [426] [427] [428] [429] [433] [434] [435] [436] [437] [438] (see Table 9-4) . The most prominent effect of propofol is a decrease in arterial blood pressure during induction of anesthesia. Independently of the presence of cardiovascular disease, an induction dose of 2 to 2.5 mg/kg produces a 25 to 40 percent reduction of systolic blood pressure. [298] [426] [427] [428] [429] [433] [434] [435] [436] [437] [438] Similar changes are seen in mean and diastolic blood pressure. The decrease in arterial pressure is associated with a decrease in cardiac output/cardiac index (15%), [427] [429] [436] [437] [438] stroke volume index (20%), [429] [437] [438] and systemic vascular resistance (15-25%). [427] [429] [436] [437] Left ventricular stroke work index is also decreased (by 30%). [437] When looking specifically at right ventricular function, propofol produces a marked reduction in the slope of the right ventricular end-systolic pressure-volume relationship. [439] In patients with valvular heart disease, pulmonary artery and pulmonary capillary wedge pressure are also reduced, a finding that implies that the resultant decrease in pressure is due to a decrease in both preload and afterload. [426] The decrease in systemic pressure following an induction dose of propofol appears to be due to both vasodilation and myocardial depression. Both the myocardial depressant effect and the vasodilation appear to be dose-dependent and plasma concentration-dependent. [440] The vasodilatory effect of propofol appears to be due both to a reduction in sympathetic activity [441] and to a direct effect on intracellular smooth muscle calcium mobilization. [442] [443]

Heart rate does not change significantly after an induction dose of propofol. It has been suggested that propofol either resets or inhibits the baroreflex, thus reducing the tachycardic response to hypotension. [300] [444] Propofol has no direct effect on sinoatrial node function or on normal atrioventricular and accessory pathway conduction. [445]

During maintenance of anesthesia with a propofol infusion, systolic pressure remains between 20 and 30 percent below preinduction levels. [429] [437] In patients allowed to breathe room air during a maintenance infusion of 100 mug/kg/min of propofol, there is a significant decrease in systemic vascular resistance (30%), but cardiac index and stroke index are unaltered. [437] In contrast, in patients receiving a narcotic premedication and nitrous oxide with an infusion of propofol (54 and 108 mug/kg/min) for maintenance during surgery, systemic vascular resistance is not significantly decreased from baseline, but cardiac output and stroke volume are decreased. [429] This is probably explained by the observation that propofol infusions produce a dose-dependent lowering of sympathetic nerve activity, thereby attenuating the reflex responses to hypotension. In the presence of hypercarbia, the reflex sympathetic responses are better maintained. [416] Increasing the infusion rate of propofol from 54 to 108 mug/kg/min (blood concentration 2.1-4.2 mug/mL) produces only a slightly greater decrease in arterial blood pressure (10%). [429] The peak plasma concentrations obtained following a bolus dose are substantially higher than those seen with a continuous infusion. Because the vasodilatory and myocardial depressant effects are concentration-dependent, the decrease in blood pressure from propofol during the infusion phase is much less than that seen following an induction bolus. When propofol was compared with midazolam for sedation after coronary revascularization, propofol resulted in a 17 percent lower incidence of tachycardia, a 28 percent lower incidence of hypertension, and a 17 percent greater incidence in hypotension. These differences in hemodynamic parameters resulted in no difference in the number or severity of ischemic events between the two groups. [439]

Heart rate may increase, [428] [435] decrease, [426] [434] or remain unchanged [433] when anesthesia is maintained with propofol. An infusion of propofol results in a significant reduction in both myocardial blood flow and myocardial oxygen consumption, [298] [435] a finding that suggests that the global myocardial oxygen supply/demand ratio is preserved.

Other Effects

Propofol, like thiopental, does not potentiate neuromuscular blockade produced by both nondepolarizing and depolarizing neuromuscular blocking agents. [446] [447] Propofol produces no effect on the evoked electromyogram or twitch tension [446] ; however, good intubating conditions after propofol alone have been reported. [448] Propofol does not trigger malignant hyperpyrexia and is probably the anesthetic of choice in patients with this condition. [449] [450]

Propofol following a single dose or a prolonged infusion does not affect corticosteroid synthesis or alter the normal response to ACTH stimulation. [451] Propofol in the emulsion formulation does not alter hepatic, hematologic, or fibrinolytic function. [452] [453] [454] However, lipid emulsion per se reduces *in vitro* platelet aggregation. [455] Anaphylactoid reactions to the present formulation of propofol have been reported. In at least some of the patients, the immune response was entirely due to propofol and not to the lipid emulsion. A high percentage of the patients developing the anaphylactoid response to propofol had a previous history of allergic responses. In patients with multiple drug allergies, propofol should be used with caution. [456] In most people, the present preparation does not trigger histamine release. [457]

Propofol also possesses significant antiemetic activity at low (subhypnotic) doses. [458] It has been used successfully to treat postoperative nausea in a bolus dose of 10 mg. [459] It has also been used successfully to treat refractory postoperative nausea and vomiting. [460] The median concentration of propofol that was associated with an antiemetic region was 343 ng/mL. [461] This concentration can be achieved by a propofol infusion of 10 to 20 ng followed by 10 mug/kg/min. Propofol used as a maintenance anesthetic during breast surgery was more effective than 4 mg of ondansetron given prophylactically in preventing postoperative nausea and vomiting. In the same study, the maintenance propofol infusion was also superior to adding propofol only at the end of the procedure (sandwich technique). [462] The difference in efficacy of propofol in preventing postoperative nausea and vomiting between the propofol maintenance method and the sandwich technique is that the propofol concentration drops rapidly after the sandwich technique below the therapeutic concentration, whereas with the maintenance technique, although the propofol concentration decreases rapidly to allow awakening, any further decrease is much slower and is maintained above therapeutic concentrations for several hours. Propofol as an infusion of 1 mg/kg/h (17 mug/kg/ min) has also provided excellent antiemetic action following anticancer chemotherapy. [463] The antiemetic effect of propofol has been shown not to be due to an action on dopamine-2 receptors. [464] Propofol at subhypnotic doses has also been reported to relieve cholestatic pruritus and was as effective as naloxone in treating pruritus induced by spinal opiates. [465] Propofol causes a dose-dependent decrease in the thermoregulatory threshold for vasoconstriction, but it has little effect on the sweating threshold. [466]

Propofol only decreases polymorphonuclear leukocyte chemotaxis but not adherence phagocytosis and killing. This action contrasts with the effect of thiopentone, which inhibits all these chemotactic responses. [467] However, propofol inhibits phagocytosis and killing of *Staphylococcus aureus* and *Escherichia coli.*[468] These

findings are particularly pertinent in view of the observation of increased life-threatening systemic infections associated with the use of propofol. [464] [469] It was also noticed that opened vials and syringes of propofol in hospitals where these infections occurred had positive cultures for the offending organisms. The intralipid that acts as the solvent for propofol is an excellent culture medium. Ethylenediaminetetra-acetic acid has been added to the formulation of propofol in an attempt to retard such bacterial growth. Strict aseptic technique must still be observed.

Uses

Induction and Maintenance of Anesthesia

Propofol is suitable for both the induction and maintenance of anesthesia and has also been approved for use in neurologic and cardiac anesthesia (Table 9-9) . The induction dose varies from 1.0 to 2.5 mg/kg, [362] [470] [471] and the ED_{95} in unpremedicated adult patients is 2.25 to 2.5 mg/kg. [470] [472] Premedication with an opiate and or a benzodiazepine

TABLE 9-9 -- Uses and Doses of Propofol

Induction of general anesthesia	1-2.5 mg/kg IV dose reduced with increasing age
Maintenance of general anesthesia	50-150 mug/kg/min IV combined with N_2 o or an opiate
Sedation	25-75 mug/kg/min IV

markedly reduces the induction dose. [365] [366] [473] Increasing age also reduces the dose of propofol required to induce anesthesia. [474] [475] A dose of 1 mg/kg (with premedication) to 1.75 mg/kg (without premedication) is recommended for inducing anesthesia in patients older than 60 years of age. [475] To prevent hypotension in sicker patients or in patients presenting for cardiac surgery, a fluid load should be administered as tolerated, and the propofol should be administered in small incremental doses (10-30 mg) until the patients lose consciousness. The ED_{95} (2.0-3.0 mg/kg) for induction is increased in children, primarily because of pharmacokinetic differences. [472] [479]

Propofol, when used for induction of anesthesia in briefer procedures, results in a significantly quicker recovery and an earlier return of psychomotor function as compared with thiopental or methohexital, irrespective of the agent used for maintenance of anesthesia. [478] [479] [480] The incidence of nausea and vomiting when propofol is used for induction is also markedly lower than following the use of other intravenous induction agents, probably because of the antiemetic properties of propofol. [472] [479]

Because of its pharmacokinetics, propofol provides a rapid recovery and is thus superior to barbiturates for maintenance of anesthesia, [480] [481] [482] and it appears equal to enflurane and isoflurane. [364] [478] [483] Recovery from desflurane is slightly more rapid than recovery from propofol. [484] Propofol can be given as intermittent boluses or as a continuous infusion for maintenance. [453] Following a satisfactory induction dose, a bolus of 10 to 40 mg is needed every few minutes to maintain anesthesia. Because these doses need to be given frequently, it is more suitable to administer propofol as a continuous infusion.

Several infusion schemes have been used to achieve adequate plasma concentrations of propofol. [480] [485] Following an induction dose, an infusion of 100 to 200 mug/kg/min is usually needed. [339] [364] [417] [418] [478] [480] [481] [482] The infusion rate is then titrated to individual requirements and the surgical stimulus. When combined with propofol, morphine, fentanyl, or alfentanil reduces its required infusion rate and concentration. [413] [414] [417] [418] [486] Because opioids alter the concentration of propofol required for adequate anesthesia, the relative dose of either opioid and propofol will markedly affect the time from termination of drug to awakening and recovery. Illustrated in Figure 9-20 is the relationship between the concentration of propofol and alfentanil that will prevent a somatic response in 50 percent of patients combined with the time to awakening (on the Z axis) for that specific combination. [487] The infusion rate required to achieve the combination with the shortest recovery is propofol, 1 to 1.5 mg/kg followed by 140 mug/kg/min for 10 minutes followed by 100 mug/kg/min, and alfentanil, 30 mug/kg followed by an infusion of 0.25 mug/kg/min, or fentanyl, 3 mug/kg followed by

Figure 9-20 The interaction between propofol and alfentanil for movement at skin incision is shown. The solid line intersecting the X and Y axes represents the concentration of propofol and alfentanil at which 50 percent of patients did not move on skin incision. Noted as the concentration of alfentanil increases, the concentration of propofol required to prevent movement on skin incision decreases until a plateau is reached at an alfentanil concentration of approximately 200 ng/mL. At higher alfentanil concentrations, there is no further reduction in the amount of propofol required to ensure absence of movement at skin incision. This concentration of propofol is approximately 2.5 mug/mL, close to the concentration of propofol required for loss of consciousness in the absence of any opioid. The solid line on the Z axis represents the time to awakening and spontaneous ventilation when the indicated concentration of propofol and alfentanil is administered. Note the shortest recovery period with the optimal combination to prevent movement at 50 percent of patients is a propofol concentration of 3.5 mug/mL with an alfentanil concentration of 85 ng/mL. Note also that increasing either the propofol concentration or the alfentanil concentration from this ideal com-bination results in a prolongation in recovery time. This prolongation in recovery time is more marked with an increase in alfentanil concentration than with an increase in propofol concentration.

0.02 mug/kg/min. Propofol has also been used as a single mixture with alfentanil, containing 1 mg alfentanil (2 mL) to 400 mg propofol (40 mL). When this mixture was administered at infusion rates commonly used for propofol (i.e., 166 mug/kg/min for 10 min, 133 mug/kg/min for 10 min, and 100 mug/kg/min thereafter), it provided an outcome equal to that obtained by using the two drugs as separate infusions. [488]

Increasing age is associated with a decrease in propofol infusion requirements, [489] [490] whereas these requirements are higher in children and infants. [347] The blood levels of propofol alone for loss of consciousness are 2.5 to 4.5 mug/mL, and the blood concentrations (when combined with nitrous oxide) required for surgery are 2.5 to 8 mug/ mL. [338] [339] [367] [417] [418] [483] Similar concentrations are necessary when propofol is combined with an opioid for a total intravenous technique. The knowledge of these levels and of the pharmacokinetics of propofol has enabled the use of pharmacokinetic model-driven infusion systems to deliver propofol as a continuous infusion for the maintenance of anesthesia. [364] [485] [491] [492]

For short (<1 h) body surface procedures, the advantages of a more rapid recovery and decreased nausea and vomiting are still evident. [478] However, if propofol is used for longer or major procedures, both speed of recovery and the incidence of nausea and vomiting are similar to those following thiopental/isoflurane anesthesia. [364] [478] A meta-analysis of recovery data following either propofol for maintenance or the newer volatile anesthetics indicated only minor differences in times to reach recovery goals; however, the incidence of nausea and vomiting remained significantly lower in the patients administered propofol for maintenance. [493]

Several studies have investigated the utility of propofol as a maintenance infusion regimen for cardiac surgery. Using reduced and titrated doses of propofol for induction and titrated infusion rates of 50 to 200 mug/kg/min combined with an opioid for maintenance, propofol provided intraoperative hemodynamic control and ischemic episodes similar to those with either enflurane/opioid or a primary opioid technique. [494] [495] [496] [497]

Sedation

Propofol has been evaluated for sedation during surgical procedures [369] [370] [498] [499] and for patients receiving mechanical ventilation in the ICU. [500] [501] [502] Propofol by continuous infusion provides a readily titratable level of sedation and a rapid recovery once infusion is terminated, irrespective of the duration of the infusion. [370] [498] [501] [503] In a study of patients sedated in the ICU for 4 days with propofol, recovery to consciousness was rapid (
10 min). Both the rate of recovery and the decrease in plasma concentration were similar at 24 and at 96 hours, when the infusion was discontinued. In addition, the plasma concentrations required for sedation and for awakening were similar at 24 and 96 hours, a finding that implies that tolerance to propofol did not occur. [503] As noted earlier, there have been more recent reports of tolerance with propofol. Infusion rates required for sedation to supplement regional anesthesia in healthy patients are half or less than those required for general anesthesia (i.e., 30-60 mug/kg/min). [369] [498] In elderly patients (older than 65 years) and in sicker patients, the infusion

rates that are necessary are markedly reduced. [369] [500] [501] Thus, it is important to titrate the infusion individually to the desired effect. A 1992 report [504] linked propofol with several deaths in children requiring sedation for mechanical ventilation secondary to upper respiratory tract infections. The likelihood that propofol was the primary cause has been challenged. However, propofol is not yet approved for ICU sedation in children, and it should not be used for this purpose until definitive studies assessing the drug's safety in this population are completed. No such adverse experiences have been reported in adults. A potential advantage of propofol for sedation of ICU patients is that it appears to possess antioxidant properties. [505]

Generally, at propofol infusion rates greater than 30 mug/kg/min, patients are amnesic. [498] [501] In comparison with midazolam when used to maintain sedation, propofol provides equal or better control and more rapid recovery. [370] [498] [501] In mechanically ventilated patients, more rapid recovery translates to more rapid extubation when sedation is terminated. [501] The use of propofol for sedation following cardiac surgery to provide fast tracking has shown that patients can be extubated rapidly using this technique. [506] The incidence of unwanted cardiovascular changes and of ischemic events was similar when propofol or midazolam was used for sedation in patients after coronary artery bypass surgery. [439] Propofol has also been used successfully in patient-controlled sedation. Propofol was rated better than midazolam when used by this technique, probably owing to its much more rapid onset and offset. [507]

Side Effects and Contraindications

Induction of anesthesia with propofol is associated with several side effects. These include pain on injection, myoclonus, apnea, decrease in arterial blood pressure, and, rarely, thrombophlebitis of the vein into which propofol is injected. Pain on injection is less than or equal to that with etomidate, equal to that with methohexital, and greater than after thiopental. [314] [452] [477] Pain on injection is reduced by using a large vein, avoiding veins in the dorsum of the hand, and adding lidocaine to the propofol solution. [452] Myoclonus occurs more frequently following propofol than following thiopental but less frequently than following etomidate or methohexital. [477] Apnea following induction with propofol is common. The incidence of apnea may be similar to that following thiopental or methohexital; however, propofol produces a greater incidence of apnea lasting longer than 30 seconds. [417] [423] The addition of an opiate increases the incidence of apnea, especially prolonged apnea. [417] [419]

The most significant side effect on induction is the decrease in systemic blood pressure. Addition of an opiate just prior to induction of anesthesia appears to augment the decrease in arterial blood pressure. [438] Perhaps slow administration and lower doses in adequately prehydrated patients may attenuate the decrease in arterial blood pressure. Conversely, the effects of laryngoscopy and endotracheal intubation and the increases in mean arterial pressure, heart rate, and systemic vascular resistance are less significant following propofol than thiopental. [434] [438]

DROPERIDOL

History

General anesthesia with inhaled anesthetics and barbiturates depresses the entire CNS in a nonspecific manner. Laborit and Huguenard [508] [509] in the 1950s sought an anesthetic technique that would produce "artificial hibernation" devoid of circulatory and respiratory depression. Their concept was to use drugs that would produce neurovegetative blockade (multifocal inhibition) of cellular, autonomic, and endocrine mechanisms normally activated in response to stress. [510] The first attempt at developing this concept was the lytic cocktail, containing an analgesic (meperidine), two tranquilizers (chlorpromazine and promethazine), and atropine. Although this combination of drugs did enjoy widespread use for conscious sedation, it produced respiratory depression. It was not used for general anesthesia. Janssen [511] synthesized haloperidol, the first member of the butyrophenones, which became the primary neuroleptic component in neuroleptanesthesia (NLAN). DeCastro and Mundeleer [512] in 1959 combined haloperidol with phenoperidine (a meperidine derivative also synthesized by Janssen) in the forerunner to the current practice of NLAN. Droperidol, a derivative of haloperidol, and fentanyl (a phenoperidine congener), both again synthesized by Janssen, were used by DeCastro and Mundeleer [512] in a combination they reported to be superior to haloperidol and phenoperidine. This NLAN combination produced more rapid onset of analgesia, less respiratory depression, and fewer extrapyramidal side effects. The fixed combination of droperidol and fentanyl, marketed as Innovar in the United States, is the drug currently used for NLAN.

Droperidol is a butyrophenone, a fluorinated derivative of phenothiazines [510] (Fig. 9-21) . Butyrophenones produce CNS depression, characterized by marked apparent tranquility and cataleptic immobility. They are potent antiemetics. Droperidol is a potent butyrophenone, and like the others, it produces its action centrally at sites where dopamine, norepinephrine, and serotonin act. It has been postulated that butyrophenones may occupy GABA receptors on the postsynaptic membrane, thereby reducing synaptic transmission and resulting in a build-up of dopamine in the intersynaptic cleft. [510] [511] An imbalance in dopamine and acetylcholine is thought to occur, which results in alteration in normal transmission of signals in the CNS. The chemoreceptor trigger zone is the emetic center, and "red" astrocytes transport neurolept molecules from the capillary to dopaminergic synapses in the chemoreceptor trigger zone, where they occupy GABA receptors (Fig. 9-22) (Figure Not Available) . This is

Figure 9-21 Structure of droperidol, a butyrophenone derivative.

thought to be the mechanism by which droperidol exerts its antiemetic effect. [513]

Metabolism and Pharmacokinetics

Droperidol is biotransformed in the liver into two primary metabolites. [514] Its plasma decay can be described by a two-compartment model. The pharmacokinetics [515] is shown in Table 9-3 . The clearance of droperidol is relatively large (14 mL/kg/min), and its elimination half-life is relatively short (103-134 min). [515] [516] Its time course of disappearance from plasma is similar to that of fentanyl (Fig. 9-23) , yet the discrepancy in duration of effect of the two has been the subject of criticism, because both are formulated together in Innovar. The seemingly longer CNS action of droperidol has prompted some investigators to postulate that droperidol has a propensity to occupy CNS receptors [515] and that it has greater receptor binding than fentanyl.

Pharmacology

Effects on the Central Nervous System

The effects of neuroleptanesthetics on human CBF and $CMRO_2$ have not been studied. In dogs, droperidol causes potent cerebral vasoconstriction, producing a 40 percent reduction in CBF (Ch. 54) . No significant change in $CMRO_2$ occurs during droperidol administration. [517] The EEG in conscious patients shows some reduction in frequency in the range, with occasional slowing to the range. [518] The extrapyramidal and malignant neuroleptic syndrome that sometimes follows droperidol use is discussed later in connection with Innovar.

Effects on the Respiratory System

When used alone, droperidol has little effect on the respiratory system. [519] Droperidol (0.044 mg/kg) given to surgical patients produced a slight reduction in respiratory rate, [520] and droperidol (3 mg IV) had no significant effect on tidal volume in volunteers. [521] More detailed respiratory studies are not available.

Effects on the Cardiovascular System

The predominant cardiovascular effect of droperidol is vasodilation with a decrease in blood pressure (see Table 9-4) .

Figure 9-23 Simulated time course of plasma levels of fentanyl and droperidol after an induction dose of fentanyl 5 mug/kg and droperidol 25 mug/kg. Note the parallel plasma disappearance of the drugs.

This effect is considered to be a result of moderate alpha-adrenergic blockade. [514] [522] [523] Importantly, the dopamine-induced increase in renal blood flow (renal artery flowmeter methodology) is not significantly impaired by administration of droperidol. [524] Droperidol has little effect on myocardial contractility. [525] It seems to possess some antiarrhythmic effects that are much like those of quinidine. [525] [526]

Uses

Droperidol is used as an NLAN component (see *Innovar*) and as an antiemetic component in general anesthesia. It is an effective antiemetic, [527] the dose for this use varying between 10 and 20 mug/kg (0.6 and 1.25 mg for a 70-kg person). [528] These doses of droperidol, given at the start of anesthesia for operations lasting 1 hour, reduce the incidence of nausea and vomiting by about 50 percent. These doses given at induction have little effect on wake-up time, but should they be given at the end of surgery, there could be some residual hypnotic effect. Droperidol is also effective in pediatric patients [529] when the drug is given orally (300 mug/kg), and the effect can be enhanced when combining it with oral metoclopramide (0.15 mg/kg) Overall antiemetic efficacy of droperidol alone is probably less than that of ondansetron and is associated with more sedation, but costs are less.

A newer use for droperidol is as an antiemetic given as an adjunctive drug intermittently or with continuous infusion for postoperative pain relief as part of a patient-controlled regimen [530] [531] or as epidural supplements to opioids. [532] When used in this fashion, droperidol effectively reduces nausea, but it does increase sedation.

INNOVAR

Innovar is a combination of droperidol and fentanyl in a ratio of 5:1 (droperidol 2.5 mg/mL and fentanyl 50 mug/mL). Lactic acid is added for adjustment of pH to 3.5. The pharmacologic effects of Innovar are those of its two component drugs. Droperidol produces hypnosis, sedation, and anti-emetic effects, whereas fentanyl produces analgesia. There is no apparent synergistic or supra-additive effect of the two drugs, but simply an additive effect (i.e., the effects of each drug add to those of the other). Recovery from NLAN produced by Innovar is usually prompt after cessation of nitrous oxide administration, and consciousness returns within 3 to 5 minutes. [510] In the recovery period, patients tend to be drowsy, detached, and free of pain, nausea, and vomiting.

Pharmacology

Effects on the Respiratory System

Innovar produces respiratory depression in a dose-related fashion. The respiratory effects are peripheral and central and are due to fentanyl. The peripheral effects involve truncate rigidity, and the central respiratory depression is a result of fentanyl's action at the respiratory center. Both respiratory rate and tidal volume are reduced by Innovar [521] [533] [534] [535] the contribution of droperidol to this effect is limited. [536] Innovar and/or the combination of droperidol with fentanyl will reduce respiratory function more than droperidol alone. [520] [521] Respiratory depression can be antagonized by administration of an opioid competitive antagonist.

Effects on the Cardiovascular System

The primary cardiovascular effect of Innovar is a decrease in arterial blood pressure [534] because of the droperidol component, which produces alpha-adrenergic blockade. Heart rate decreases as a result of a fentanyl-induced increase in vagal tone. Despite these changes, Innovar does not significantly reduce cardiac output in patients with adequate blood volumes. The antiarrhythmic properties of droperidol are those present in Innovar. [537]

Uses

NLAN may be induced with droperidol and fentanyl (or other opioids) separately or with the drug Innovar. Innovar should be used with caution during induction because of possible vasodilation and hypotension. It is recommended that a test dose of 1 to 2 mL be administered prior to induction of NLAN with Innovar. If the components are given separately, droperidol should be administered first, in a dose of about 5 to 10 mg (5-150 mug/kg), and followed by incremental doses of fentanyl in 50- to 100-mug increments. The usual induction dose of Innovar is 0.1 to 0.15 mL/kg (Table 9-10) in fit adults, and this is almost always administered with nitrous oxide and a muscle relaxant. It is recommended that 200 to 300 mL of balanced salt solution be administered prior to induction and that hypotension be treated with further fluid administration. Elderly and other high-risk patients require less Innovar for induction of anesthesia. Supplementation of anesthesia during NLAN should be with fentanyl and not with Innovar. The reasons are that the prolonged duration of action of droperidol will produce postoperative somnolence if the drug is repeated during the operation, and analgesia is required to blunt stress responses.

Innovar in markedly reduced doses can be used for intravenous sedation during conduction anesthesia or selected diagnostic procedures performed using local anesthesia. The customary dose of Innovar for sedation is about 2 to 4 mL in divided doses titrated to the desired level of sedation. Innovar has been used for many types of procedures and can be safely used in most. Operations that are particularly suited for Innovar

1-2 mL IM	

[a] Dose should be reduced in hypovolemic and other high-risk patients. Each milliliter of Innovar contains droperidol 2.5 mug and fentanyl 50 mug.

are those with a high incidence of postoperative nausea and vomiting (e.g., middle ear surgery). Small doses of droperidol or Innovar may be helpful in outpatient procedures that are associated with nausea and vomiting. Innovar may also be used as a sedative-analgesic for sedation during diagnostic and surgical procedures. It does not produce reliable amnesia.

Side Effects and Contraindications

Innovar is not associated with organ toxicity or with tissue or venous irritation. However, it does have several adverse effects. Muscle rigidity is a consequence of the fentanyl component and is more of a problem if large doses are given rapidly. Treatment and prevention include giving a muscle relaxant with the Innovar. Respiratory depression is also a result of the fentanyl and can be reversed with an opioid antagonist, but this can also reverse the analgesia and may precipitate hypertension. Hypotension from the droperidol component is a common side effect of Innovar and can be treated with intravascular blood volume expansion or an alpha-adrenergic agonist (e.g., phenylephrine). Prolonged somnolence or detachment is a result of the droperidol and is related to dose. Although this has been reversed with physostigmine (2 mg), physostigmine is not a specific antagonist, and the possibility that resedation may occur is real, because droperidol clearance is less than that of physostigmine. Extrapyramidal complications, manifested by dyskinesia, especially of the face, neck, and pharyngeal muscles, with speech and swallowing difficulties, grimacing, trismus, oculogyric spasms, and torticollis, occur in a small percentage of patients given Innovar [538] and are due to the droperidol component. Droperidol in doses as low as 0.65 mg can produce extrapyramidal reactions, [539] which may be treated with diphenhydramine or benztropine. Some patients have an unusual psychologic reaction, particularly when Innovar is used as a premedicant, and patients have refused to have surgery after Innovar premedication. Patients

report hallucinations and bizarre sensations of weightlessness and loss of body image; these reactions can be successfully treated with a benzodiazepine. A final and rare complication of Innovar is the malignant neuroleptic syndrome, [540] [541] characterized by hyperthermia, muscular rigidity, and autonomic instability. The muscular hypertonicity is lead-pipe. Although this reaction can be distinguished from malignant hyperthermia by the temperature course (which is lower) and muscle biopsy studies, dantrolene has been successfully used to treat the syndrome. [542] Bromocriptine, a central dopamine agonist, has also been used (2.5-10 mg PO tid) to treat this syndrome, which is mostly encountered in patients taking butyrophenones and phenothiazines for psychiatric disturbances.

alpha-ADRENERGIC AGONISTS: DEXMEDETOMIDINE

History

Adrenergic receptors were first differentiated into alpha and beta by Ahlquist, based on their responses to various amines. [543] The alpha$_2$ -adrenergic agonists provide sedation, anxiolysis, and hypnosis, as well as analgesia and sympatholysis. An excellent review and an editorial concerning their pharmacology and potential uses in anesthesia have been published. [543] [544] The initial impetus for the use of alpha $_2$ -agonists in anesthesia resulted from observations made in patients during anesthesia who were receiving clonidine therapy. [543] [545] [546] This was soon followed by a description of the MAC reduction of halothane by clonidine. [547] Clonidine is currently the only available alpha $_2$ -agonist approved for administration, and this is only for the treatment of hypertension; however, dexmedetomidine is undergoing extensive evaluation for perioperative use.

Physicochemical Characteristics

Medetomidine is a highly selective alpha $_2$ -adrenergic agonist. Dexmedetomidine is its specific stereoisomer, which is available as a parenteral formulation. Its structure is illustrated in Figure 9-24 .

Metabolism and Pharmacokinetics

The exact metabolic pathways for dexmedetomidine in humans have not been fully described. It is believed that the drug is first hydroxylated and subsequently undergoes either dehydrogenation to form a carboxylic acid derivative or glucuronidation. Dexmedetomidine is 90 percent protein bound, and its concentration ratio between whole blood and plasma is 0.66. Dexmedetomidine has profound affects on cardiovascular parameters and thus appears to effect its own pharmacokinetics. At high doses, there is marked vasoconstriction, which probably reduces the drug's volumes of distribution. Thus, in essence, dexmedetomidine displays nonlinear pharmacokinetics. [548] Because it is likely that this agent will only be administered within a narrow therapeutic range of 0.5 to 1.0 ng/mL, it is preferable to describe the pharmacokinetic parameters within this dosage range. Within this range, Dyck et al [548] found that its pharmacokinetics is best described by a three-compartment model (Table 9-11) . These pharmacokinetic parameters appear to be unaltered by age or weight, but clearance is a function of height. [548] The elimination half-life of dexmedetomidine is 2 to 3 hours, with a context sensitive half-time ranging from 4 minutes after a 10-minute infusion to 250 minutes following an 8-hour infusion. An intramuscular injection of 2 mug/kg of dexmedetomidine into the deltoid muscle had a bioavailability of 73(±11) percent with a time to peak concentration of 13(±18) minutes and resulted in a peak plasma concentration

of 0.8(±3) ng/mL. [549] Injection into the gluteus muscle, however, results in a much longer time to peak effect of approximately 90 minutes. [550]

Pharmacology

Effects on the Central Nervous System

The alpha$_2$ -agonists produce their sedative hypnotic effect by an action on alpha $_2$ -receptors in the locus caeruleus and an analgesic action both at alpha $_2$ -receptors within the locus caeruleus and the spinal cord. [551] The alpha$_2$ -agonists appear to inhibit ion conductance through L- or P-type calcium channels and facilitate conductance through voltage-gated calciumactivated potassium channels. [552] The alpha$_2$ -agonists have the advantage that their effects are readily reversible by alpha$_2$ -adrenergic antagonists (e.g., atipamezole). [553] Like other adrenergic receptors, the alpha $_2$ -agonists also demonstrate tolerance following prolonged administration. [554] Rats rendered tolerant to morphine also show a decrease in efficacy of both hypnotic and analgesic effects of dexmedetomidine. As tolerance to the opioid recovered, there was a more rapid recovery of the hypnotic effect of dexmedetomidine than its analgesic efficacy. [555] These data would tend to indicate a possible cross-tolerance across receptors.

In a model of focal ischemia in rabbits, dexmedetomidine, administered at doses that reduced the MAC of halothane by 50 percent, resulted in less cortical neuronal damage than when halothane was administered alone at equi-effective MAC concentrations. [556] Little is known of the effects of dexmedetomidine alone on ICP and CBF. In dogs, in the presence of volatile anesthetics and dexmedetomidine, CBF was decreased and oxygen consumption was maintained. [557] [558] CBF velocity, as measured by transcranial Doppler, decreased with increasing concentrations of dexmedetomidine in parallel with decreasing mean arterial pressure and increasing arterial carbon dioxide. [559] In a rat seizure model, dexmedetomidine demonstrated significant proconvulsant action, which is consistent with previous findings that inhibition of central nor-adrenergic transmission facilitates seizure expression. [560] This finding, however, is in contrast to an anticonvulsant effect shown in rats following kainic acid-induced seizures. [561] As yet, in the limited number of administrations of dexmedetomidine, there have been no reports of seizures in humans. Dexmede-tomidine is also able to reduce muscle rigidity following high-dose opioid administration. [562] In resting volunteers, dexmede-tomidine increased growth

hormone secretion in a dosedependent manner, but it had no effect on other pituitary hormones. [550] [563]

Effects on the Respiratory System

Doses of 1 to 2 mug/kg of dexmedetomidine induce a mild increase in Pa CO_2 (45 mm Hg) and a rightward shift and depression of the carbon dioxide-response curves. The changes in respiration are mainly a decrease in tidal volume with little change in respiratory frequency. [558] When combined with alfentanil, dexmedetomidine enhances analgesia without causing further respiratory depression.

Effects on the Cardiovascular System

The basic effects of alpha$_2$ -agonists on the cardiovascular system are decreased heart rate, decreased systemic vascular resistance, and indirectly decreased myocardial contractility, cardiac output, and systemic blood pressure. By developing highly selective alpha-agonists, it has been hoped to decrease some of these adverse cardiovascular effects and to maximize the desirable hypnotic-analgesic properties. Thus far, dexmedetomidine is the most selective alpha $_2$ -agonist that is likely to be used in clinical practice. The hemodynamic effects of dexmedetomidine in humans have shown a biphasic response. An acute intravenous injection of 2 mug/kg resulted in an initial increase in blood pressure (22%) and decrease in heart rate (27%) from baseline that occurred at 5 minutes following injection. This initial increase in blood pressure is probably due to the effect of dexmedetomidine on peripheral alpha $_2$ -receptors. Heart rate returned to baseline by 15 minutes, and blood pressure gradually drifted down to approximately 15 percent below baseline by 1 hour. Following an intramuscular injection of the same dose, the initial increase in blood pressure was not seen, and both heart rate and blood pressure remained within 10 percent of baseline. [549] In dogs, oral doses of dexmedetomidine both alone and in the presence of halothane did not alter baroreflex activity. In several studies following both intramuscular and intravenous administration, dexmedetomidine caused, in a small percentage of patients, profound bradycardia (<40 beats/min) and occasionally sinus arrest/pause. Generally, these episodes resolved spontaneously or were readily treated without adverse outcome by anticholinergics. In animal models, dexmedetomidine demonstrated some beneficial effects on the ischemic heart through decreased oxygen consumption and redistribution of coronary flow from nonischemic zones to ischemic zones following acute brief occlusion. [564] Thus far, human studies have not shown clear clinical benefits of dexmedetomidine infusions in patients at risk for myocardial ischemia.

Other Effects

A frequently reported side effect of dexmedetomidine has been a dry mouth, which is due to a decrease in saliva production. [565]

Uses

Unlike the other drugs described in this chapter, dexmedetomidine is not indicated for the induction of anesthesia. Its role is likely to be as a preoperative sedative, an adjuvant during anesthesia to reduce hypnotic and opioid requirements, and possible postoperatively in patients at high risk for myocardial ischemia.

Sedation

As a premedicant, dexmedetomidine, at intravenous doses of 0.33 to 0.67 mug/kg given 15 minutes prior to surgery, appears efficacious while minimizing the cardiovascular side effects of hypotension and bradycardia. [566] Within this dosage range, dexmedetomidine reduces thiopental requirements (by 30%) for short procedures, [566] [567] reduces the requirements of volatile anesthetics (by 25%), and as compared with 2 mug/kg fentanyl, more effectively attenuates the hemodynamic response to endotracheal intubation. [568] Dexmedetomidine has also been evaluated as an intramuscular injection (2.5 mug/kg) with or without fentanyl administered 45 to 90 minutes prior to surgery. This regimen was compared with intramuscular midazolam plus fentanyl and was found to provide equal anxiolysis, reduced response to intubation, lower volatile anesthetic requirements, and a lower incidence of postoperative shivering but a higher incidence of bradycardia. Atipamezole, a selective alpha $_2$ -antagonist, at 50 mug/kg was effective in reversing the sedation of dexmedetomidine, 2 mug/kg intramuscularly, when used to provide sedation for brief operative procedures. [553] This reversal of effects resulted in a more rapid recovery than occurred after equi-sedative doses of midazolam.

Clonidine, in doses of 3 to 5 mug/kg orally, usually given 30 to 90 minutes prior to surgery, similarly reduces the MAC of the potent volatile anesthetics (by 30-50%), reduces opioid requirements, attenuates the hemodynamic responses to intubation, and generally provides a more stable hemodynamic profile intraoperatively, [543] [569] [570] although significant bradycardia and hypotension during and immediately after induction have been observed. This reduction in anesthetic requirements also translates into a more rapid awakening after surgery. [571] Clonidine also reduces intraocular pressure, reduces perioperative catecholamines, decreases postoperative analgesic requirements, and prevents the usual deterioration in renal function following aortocoronary bypass. [538] [543] [571] [572] As with clonidine, with dexmedetomidine intraocular pressure is decreased (33%), catecholamine secretion is reduced, perioperative analgesic requirements are less, and recovery is more rapid. [573] [574]

Maintenance of Anesthesia

Dexmedetomidine has also been used as a maintenance infusion starting with a loading dose of 170 ng/kg/min for 10 minutes followed by an infusion of 10 ng/kg/min. This resulted in a plasma concentration of slightly less than 1 ng/ mL, so that dexmedetomidine, after induction with thiopental and combined with 70 percent nitrous oxide, reduced isoflurane requirements by 90 percent as compared with a control group. [575] The interaction of dexmedetomidine, fentanyl, and enflurane on MAC reduction and hemodynamics has been evaluated in dogs. This triple combination is complex, but it appears that dexmedetomidine further enhances the MAC reduction of enflurane by fentanyl. This triple interaction, however, does not seem to reduce the likelihood of hypotension or bradycardia in providing adequate anesthesia. [576] In patients presenting for vascular surgery, three infusion rates of dexmedetomidine were compared with a placebo infusion starting 1 hour prior to surgery and administered until 48 hours after surgery. In the groups receiving dexmedetomidine, more vasoactive agents were required to maintain hemodynamics intraoperatively, but less tachycardia was noted postoperatively. No other significant differences were noted between the groups. [577] There are currently large studies evaluating the use of a maintenance infusion of dexmedetomidine for several surgical procedures. The results of these studies are likely to more clearly define the role of dexmedetomidine as a possibly useful adjuvant during anesthesia.

The alpha$_2$ -adrenergic agonists possess many important characteristics that are valuable for anesthesia. It would appear, however, that at anesthetic concentrations in humans, the cardiovascular effects (hypotension and/or bradycardia) of these drugs may be their major drawback, preventing them from being used as the primary anesthetic and thereby limiting their role to that of an adjuvant for other anesthetic drugs. The exact role of dexmedetomidine either as a premedicant or as an intravenous anesthetic adjuvant is still to be determined.

SUMMARY

Many different intravenous drugs are available for use in the care of patients requiring general anesthesia. The selection of a particular drug must be based on the individual patient's need for hypnosis, amnesia, and analgesia. Drug selection must match the physiology and/or the pathophysiology of the individual patient with the pharmacology of the particular drug. Thus, for example, a patient in shock who requires anesthesia induction should receive the drug that will produce rapid onset of effect without causing further hemodynamic compromise. The knowledge of the clinical pharmacology of each of the intravenous anesthetic drugs enables the clinician to induce and maintain sedation and/or general anesthesia safely and effectively. There is no single perfect drug for any particular patient, but rather the informed practitioner wisely employs the appropriate drug or drugs in the practice of good anesthesia care.

Chapter 10 - Intravenous Opioid Anesthetics

Peter L. Bailey
Talmage D. Egan
Theodore H. Stanley

INTRODUCTION

Significant advances continue to be made in the science and practice of anesthesia. The number of scientific reports concerning opioids continues to exceed 3,000 citations per year. Research interests range from molecular genetics and the biology of opioids through the neurosciences to many clinical specialties. Such a voluminous amount of information presents obvious difficulties for the writer as well as the reader of textbook chapters on opioid pharmacology. It has thus become impossible to create a chapter that is simultaneously comprehensive and useful for clinical anesthesia practitioners. In this fifth edition chapter, discussions of older agents and techniques, which are no longer a part of modern practice, are minimized. The interested reader should refer to earlier editions of this textbook for discussions of formerly used agents and techniques.

Opioids have been administered for hundreds of years to allay anxiety and to reduce the pain associated with surgery. Many of these compounds not only are used as premedicants and analgesics during and after anesthesia and surgery, but also serve as intravenous (IV) anesthetics. In this chapter, the pharmacology and use of opioids in contemporary anesthetic practice are reviewed. The terms "opioid" and "opiate" are used to describe drugs that specifically bind to any of several subspecies of opioid receptors and share some of the properties of one or more of the naturally occurring endogenous opioids. The term "narcotic" is Greek in origin and means "to numb or deaden." It can refer to non-opioid compounds as well and is avoided.

HISTORY

Although morphine-like alkaloids had been used for analgesia and sedation for centuries, the isolation of morphine as the active ingredient from opium by Serturner in the early 1800s and the introduction of the syringe and hollow needle to clinical practice by Wood in 1853 finally permitted opioids to be administered in more precisely measured doses. [1] Morphine was, at that time, frequently injected intramuscularly (IM) for preoperative medication, as a supplement during ether or chloroform anesthesia, and postoperatively for analgesia. Late in the nineteenth century, large amounts of morphine (1 to 2 mg kg^{-1}) plus scopolamine (1 to 3 mg 70 kg^{-1}) were administered in divided doses IV, IM, or both, as a complete anesthetic. [2] Although initially popular, this technique rapidly fell into disfavor because of an increase in operative morbidity and mortality. [3] For the next 30 to 40 years, anesthesiologists rarely used opioids intraoperatively.

Introduction of the short-acting barbiturates as IV anesthetics and popularization of the concept of "balanced anesthesia" led to renewed interest in opioids as anesthetic agents. [4] Important events in this development were the synthesis of meperidine in 1939 and its use for anesthesia with nitrous oxide (N_2O), with or without *d*-tubocurarine. [5] In 1942, nalorphine (N-allylnormorphine), a mixed agonistantagonist, was introduced. Although an analgesic itself, nalorphine was recognized as an antagonist capable of reversing morphine-induced respiratory depression and inducing abstinence syndrome in addicted individuals. [6] The development of naloxone, as a purer antagonist, followed shortly.

Many variations of the "N_2O-narcotic" or balanced anesthesia technique became popular. At first, thiopental for induction and maintenance of anesthesia, *d*-tubocurarine, and opioids such as morphine, meperidine, or alphaprodine were commonly employed. After the introduction of Innovar-N_2O anesthesia [7] (Innovar consists of the butyrophenone droperidol and the opioid fentanyl), various IV supplements were employed, including hypnotics, sedatives, tranquilizers, and additional analgesics. These techniques were often termed "balanced anesthesia," because each IV compound was selected and administered to achieve a specific effect, such as analgesia, unconsciousness, amnesia, muscle relaxation, or abolition of autonomic reflexes.

Following this, opioids and sedative-hypnotics were, and continue to be, administered IV during anesthesia in combination with potent inhaled anesthetics. Benefits attributed to such techniques are that IV agents reduce the concentrations of inhaled anesthetics required for anesthesia, result in less depression of cardiovascular and other organ systems, and allow for better recovery from anesthesia.

Lowenstein et al [8] and Stanley and Webster [9] reintroduced the practice of administering large doses of opioids as primary or sole anesthetics. Morphine (0.5 to 3.0 mg kg^{-1}), administered IV to patients while they breathed 100 percent O_2, did not alter the cardiovascular dynamics in those patients who did not have cardiac disease and in many cases improved the cardiovascular status of those with significant valvular disease. [8] These reports led to additional studies evaluating morphine and other opioids as sole anesthetics for patients with poor cardiovascular reserve who were undergoing major operative procedures. [10] [11] [12] Unfortunately, problems with incomplete amnesia, [13] histamine release, [14] prolonged postoperative respiratory depression, [15] [16] increased blood volume requirements secondary to marked venovasodilation, [11] hypotension, and hypertension [10] diminished the popularity of morphine as a sole anesthetic. [13] Large doses of fentanyl do not produce many of the unwanted adverse hemodynamic effects associated with large doses of morphine.

The synthetic opioid fentanyl remains popular as an IV supplement in combination with an inhaled anesthetic, as a component of balanced anesthesia, and also administered in larger doses as a primary or sole anesthetic. Unfortunately, large doses of fentanyl also cause significant postoperative respiratory depression, which militates against this application

in patients who may otherwise meet tracheal extubation criteria shortly after surgery.

More recently, sufentanil, alfentanil, and remifentanil were introduced into clinical practice. Each of these agents offers potentially significant clinical advantages, in addition to greater therapeutic indexes in animal models (Table 10-1) . Sufentanil alone is more potent and is possibly more effective than fentanyl as a primary or sole anesthetic. Alfentanil is very rapid in its onset and may be more predictable in terms of determining the dose required to produce effective plasma drug levels and to obtund the response to many surgical stimuli when it is administered with N_2O. [17] Predictability has been a problem with opioids: plasma concentrations following a standard dose can vary up to 5-fold. Similarly, variability in therapeutic plasma levels, which effectively block a defined response to a stimulus in 50 percent of patients (i.e., Cp_{50}), has also been 3- to 5-fold. Both plasma concentrations of sufentanil and alfentanil decline more rapidly than those of fentanyl and result in more rapid patient recovery after the termination of IV infusions of these drugs. [18]

Remifentanil is also very rapid in its onset and has an ultrashort duration of action, which is independent of the length of time the drug is administered. Among the modern opioids currently employed, this feature is unique and allows for the rapid dissipation of even profound opioid action at the end of surgery.

Other developments include continued improvements in the understanding of drug pharmacokinetics and pharmacodynamics and advances in computer-assisted mechanical drug delivery systems (Ch. 11) . In addition, anesthesiologists continue to play an important role in advancing the treatment of pain. Resistance to the

concept of opioids as acceptable and appropriate agents for the treatment of severe chronic pain persists despite expert opinion. However, opioids remain at the center of new and exciting pain control therapies. Newer routes of drug delivery, including the skin and buccal, sublingual, nasal, and rectal mucosal surfaces, continue to be investigated for administering opioid analgesics. These approaches have resulted in transdermal fentanyl patches, sufentanil nasal sprays, oral transmucosal fentanyl citrate applications, and a variety of other approaches.

Reports that postoperative outcome is favorably altered by sufentanil anesthesia or analgesia suggest that opioid-induced stress reduction may be clinically significant. [19] [20] However, numerous other investigations have failed to find outcome differences associated with one anesthetic agent or anesthetic technique compared with another. [21] [22] [23] The lack of compelling evidence that large doses of opioids confer any major advantage, combined with efforts to make anesthesia as cost-effective as possible, have led to moderation in the doses of opioids administered as anesthetics. Nevertheless, opioids continue to occupy an important niche in the anesthesiologist's armamentarium of anesthetic and therapeutic agents.

The prediction and discovery of opioid receptors in the early 1970s preceded the recognition and documentation of endogenous opiate-like compounds (see later). These landmark discoveries introduced an era of prolific research that continues to this day. Ultimately, genetically based investigations will delineate the DNA coding of opioid receptors, the molecular structure of opioid receptors, and will result in definitive descriptions of the molecular biology of opioids. Numerous difficulties that have plagued opioid research are now being solved as a result of genetic research. Cloning of opioid receptors, with expression of single receptor types in separate cell lines, will allow their pharmacologic, functional, and biochemical characteristics to be determined. [24] Ultimately, although an elusive goal to date, the development of pharmacologic agents with the analgesic potency of opioids but without their adverse effect profile is anticipated. Undoubtedly, exciting advances remain on the horizon.

CLASSIFICATION

Several classification systems are available to describe opioids. Opioids can be classified as naturally occurring, semisynthetic, and synthetic (Table 10-2) . Morphine, codeine, and papaverine, the only naturally occurring opioids of clinical significance, are obtained from the poppy plant, *Papaver somniferum.*[*]

Papaverine is devoid of opiate activity, but it does relax smooth muscle. The naturally occurring opioids of significance can be divided into two chemical classes, five-ring structures, entitled the phenanthrenes (morphine and

* Papaveretum is a preparation containing the water-soluble alkaloids of opium with 50 percent anhydrous morphine and the remaining 50 percent a mixture of papaverine, codeine, and thebaine. Papaveretum on a weight basis is approximately half as potent as morphine.

Benzomorphan series (e.g., pentazocine)
Phenylpiperidine series (e.g., meperidine, fentanyl, sufentanil, alfentanil, remifentanil)

codeine), and three-ring compounds, the benzylisoquinoline derivatives (papaverine). Of the naturally occurring opioids, only morphine is of clinical importance in anesthesia.

The semisynthetic opioids are derivatives of morphine in which any one of several changes has been made, such as etherification of one hydroxyl group (codeine), esterification of both hydroxyl groups (heroin), oxidation of the alcoholic hydroxyl to a ketone drug, or reduction of a double bond on the benzene ring (hydromorphone). Thebaine, a relatively inactive opium derivative itself, is a precursor of several derivative compounds used clinically including oxymorphone, oxycodone, and naloxone. Etorphine (M99), another thebaine derivative, is several thousand times more potent than morphine; this compound has been used successfully for immobilization and anesthesia in wildlife management. [25]

Synthetic opioid compounds are divided into four groups: the morphinan derivatives (levorphanol), the diphenyl or methadone derivatives (methadone, *d*-propoxyphene), the benzomorphans (phenazocine, pentazocine), and the phen-ylpiperidine derivatives (meperidine, fentanyl, alfentanil, sufentanil, and remifentanil). The general phenylpiperidine skeletal structure and derivatives meperidine and fentanyl are illustrated in Figure 10-1 . Important opiate receptor research compounds (ketocyclazocine and SKF 10,047) also belong to this group. Although many of these synthetic opioids have been used for IV analgesia or anesthesia experimentally, the phenylpiperidine derivatives currently occupy the predominant role in anesthesia.

Opioids can also be classified as agonists, partial agonists, mixed agonist-antagonists, and antagonists. Although agonist and antagonist opioids alike may bind to effector (receptor) sites, only agonists elicit any effect. Thus, pure antagonist opioids have intrinsic activities or efficacies of 0, and agonist opioids, which at some concentration elicit the full spectrum and magnitude of pharmacophysiologic effects, have intrinsic activities of 1. Partial agonists exhibit intrinsic activities of less than 1. Figure 10-2 (Figure Not Available) illustrates schematically these various types of compounds and their interactions.

Agonists are used most commonly in anesthesia, because the majority of opioid actions sought can be produced in a dose-dependent fashion (see later). Partial agonists, such as buprenorphine, regardless of dose, cannot produce the full magnitude of opioid (mu-receptor-mediated) effects. Nalbuphine is a mixed agonist-antagonist compound that acts as an agonist at one receptor (kappa), thereby producing effects

Figure 10-1 The phenylpiperidine skeleton structure and the synthetic phenylpiperidine opioids meperidine and fentanyl.

such as weak, spinally mediated analgesia, and as an antagonist at another (mu), resulting in its ability to reverse agonist-induced respiratory depression. Naloxone is a relatively pure antagonist that elicits few or no effects on its own at clinical doses, but it acts competitively to displace agonists from opioid receptors, although to different degrees.

Matters are, however, quite complex. For example, low doses of naloxone can effectively reduce adverse effects associated with morphine administration for postoperative pain and, interestingly, can decrease morphine requirements for pain relief, too. [26] Furthermore, the range of intrinsic activities produced by a given

drug can vary depending on numerous factors, such as receptor reserve and differences in coupling systems (e.g., receptor subtypes, G protein systems). Thus, the apparent classification of certain drugs as partial agonists, for example, to explain decreased intrinsic activity may instead simply represent differences in conditions and models studied. [27]

A third and most modern and relevant classification of opioid drugs describes these agents according to their interactions with opioid receptor types and spectrum of elicited effects. The following section details these receptors and what they reveal to us about the pharmacophysiology of opioids.

MECHANISMS OF ACTION

Structure-Activity Relationships

The structural dissimilarities among compounds displaying opiate activity almost defy a common mechanism as the basis for opioid structure-activity relationships. However, a detailed analysis of opioid stereospecificity has been used to

Figure 10-2 (Figure Not Available) Receptor interactions of opioids. Opioid-receptor interactions are illustrated in terms of a lock-and-key diagram with two receptor sites, mu and kappa, and a representative dose-response (DR) curve of analgesic effects. (A) An opioid agonist stimulates both mu- and kappa-receptors. The steep portion of the DR curve is in the clinical dose range (CDR), and analgesia is unlimited. (B) Partial agonists such as buprenorphine combine with the mu-receptor, but they have only limited activity. The DR curve is flatter, with a lower maximum effect. The partial agonist shifts the DR curve for an agonist to the right. (C) The opioid antagonist naloxone can occupy both mu- and kappa-receptors, but it has no intrinsic activity. The antagonist shifts the DR curve for an agonist to the right. (D) The agonist-antagonist opioids (e.g., nalbuphine) may have mixed effects at the mu- and kappa-receptor. Analgesia is kappa-receptor related, whereas blockade occurs at the mu-receptors. This naloxone-like effect would shift the DR curve to a mu-agonist to the right. *(From Hare. [121] Reproduced with permission from Formulary, Vol. 22, 1987. Copyright by Avanstar Communications Inc. Avanstar Communications Inc. retains all rights to this article.)*

describe a hypothetic three-dimensional model of the opiate receptor responsible for opioid activity. [28] Structurally, opioids are complex, three-dimensional compounds that sometimes exist as two optical isomers (e.g., morphine). [29] Usually, only the *l*-rotary isomer is capable of producing analgesia.

A close relationship exists between the stereochemical structure of an opioid compound and the presence or absence

of analgesic activity. [30] In addition, even relatively minor molecular changes, such as the degree of ionization produced by variations in pH, may cause significant alteration in pharmacologic activity of opioid compounds. [30]

The prototype opioid is morphine. Its rigid pentacyclic structure conforms to a T-shape [28] (Fig. 10-3) (Figure Not Available) . Morphine demonstrates several other structural characteristics common to most opioids: a tertiary positively charged basic nitrogen, a quaternary carbon (^{13}C in morphine) that is separated from the basic nitrogen by an ethane chain (-CH_2 -CH_2 -) and is attached to a phenyl group, a phenolic hydroxyl group (in morphine derivatives), or a ketone group (meperidine, methadone), and the presence of an aromatic ring whose center is 4.55 A from the nitrogen atom. [28]

The morphine molecule also contains a phenylpiperidine structure (an aromatic ring attached to a six-membered ring containing five carbons and one nitrogen). This moiety is present in opioids that otherwise seem unrelated to morphine, such as fentanyl (see Fig. 10-1) . [28] Short-chain alkyl group substitution at the basic amino group (the group essential for opioid activity) results in mixed opioid agonistantagonists. [31] Additional hydroxylation of ^{14}C produces opioids with antagonist and no agonist properties. [32] Phenylalanine and, especially, the tyrosine moiety are important structural elements of all opioid compounds (see later), as well as endogenous opioid-like neurotransmitters and modulators. [33] [34] Interestingly, morphine is synthesized by the poppy plant from two tyrosine molecules, and many opiates contain a moiety that bears a configurational similarity to alanine. [28]

Site and Mechanism of Opioid Action

Opioid Receptors

In 1973, three independent teams of investigators described the presence of an "opioid receptor" in nervous tissue and hypothesized that endogenous substances probably stimulate this structure. [35] [36] [37] This rationale was supported by numerous observations, including the finding that naloxone could reverse footshock-induced analgesia. A few years later, the endogenous opiates were discovered (see later).

The original classification of opioid receptors was based on response patterns to three different opioid compounds in the chronic spinal dog model [38] and resulted in the description of three receptor types, named after the drugs used in

Figure 10-3 (Figure Not Available) The T-shaped molecule of morphine. *(From Thorpe [28])*

the studies: mu (morphine), kappa (ketocyclazocine), and sigma (SKF 10,047 or *N*-allylnormetazocine). The "sigma" receptor is no longer considered an opioid receptor but rather a highaffinity binding site for phencyclidine and related compounds. [39] In addition, sigma-receptor-mediated effects are enantio-selective for dextrorotatory, instead of levorotatory, compounds. Finally, sigma-receptor-mediated effects are not naloxone-reversible. In 1977, Lord and colleagues described a binding site in the isolated mouse vas deferens with high affinity for enkephalins. This opioid receptor site was named the delta receptor, after deferens.

The profile of effects thought to be associated with a specific receptor is derived in numerous ways, including the potency and physiologic effects of a variety of agonist and agonist-antagonist interactions, the results of various bioassay and binding studies, structure-activity relationship data, and numerous other screening evaluations. For example, potency often correlates with receptor affinity and is described by the IC_{50} value, defined as the concentration of an agent that lowers the specific binding of ^{3}H-naloxone by 50 percent. The greater the affinity of such an agent for a receptor, the lower the IC_{50} , [31] and the smaller the dose and number of molecules necessary to occupy enough receptors to elicit a certain level of effect. Intrinsic efficacy, a property of drug-receptor interaction, is directly related to the number of spare receptors: the greater the intrinsic efficacy of a drug, the greater the receptor reserve.

Bioassay systems are used to help evaluate potency. The response to transmural electrical stimulation of a number of isolated tissues can be inhibited by opioids. This effect is most likely mediated by the presynaptic inhibition of transmitter release (neuromodulation). The two most important of these systems are the guinea pig ileum and mouse vas deferens. For example, morphine inhibits electrically induced contractions of the isolated guinea pig ileum. Data from these systems correlate well with opioid analgesic potency, [40] as determined by numerous intact animal and clinical evaluations. Biochemical characterizations of opiate receptors also have been used in receptor research. [31] Attempts to purify opioid receptors have been thwarted by their paucity in most tissues and chemical instability during isolation. Some investigators have reported the cloning and sequencing of opioid receptor types. [24] Five cDNAs that belong to the opioid receptor gene family have been cloned, but only three opioid receptor types (mu, delta, kappa), each arising from their own gene, have been pharmacologically defined. Three subtypes of each

receptor have been proposed but have not yet been cloned (Table 10-3) .

The mu-opioid receptor manifests a high affinity for endogenous enkephalin, and the distribution of mu-receptors and enkephalin mRNA is highly correlated. Investigations utilizing opiate receptor knockout mice demonstrate that morphine-induced analgesia is mu-receptor-mediated. [41] Enkephalins also interact with delta-receptors. kappa-Receptors, on the other hand, have high affinity for the endogenous opiate dynorphin.

mu-Receptors are located in both the brain and spinal cord, with highest concentrations in the periaqueductal gray and substantia gelatinosa, respectively. mu-Receptor opioidinduced analgesia is dose-dependent. Pharmacologic distinction of an analgesic mu-receptor (mu_1) and a respiratory depression mu-receptor (mu_2) is suggested, but it remains in

TABLE 10-3 -- Characteristics of Opioid Receptors

question. [42] [43] A mu_3 -receptor may be involved in immune processes because it has significant distribution in astrocytes, endothelial cells, and macrophages. It is not clear whether or not these various receptor subtypes originate from separate genes or from post-translational modifications.

There is no selective systemic agonist available for delta- receptors, and the enkephalins are rapidly degraded. The degree of analgesia that is produced by stimulation of the delta-receptor is unclear (and may be more important at the spinal cord level). mu_1 -Receptors also appear more prominent in supraspinal analgesia, whereas delta-receptors may be more important for spinal analgesia. [44] kappa-Receptors appear to play a role in producing mild to moderate analgesia at the spinal cord level for nonthermal painful stimuli (Table 10-4) . The kappa-receptor agonist ethylketocyclazocine produces sedation and analgesia without causing much respiratory depression. [45] kappa-Receptor activation may explain in part some of the effects (analgesia with limited respiratory depression)

TABLE 10-4 -- Supraspinal and Spinal Sites and Opioid Receptor Types Mediating Analgesia [a]

LOCATION	RECEPTOR SELECTIVITY

[a] Analgesic effects are mediated by mu-, delta-, and kappa-receptors. Receptor-mRNA expression suggests that mu-, delta-, and kappa-receptor-mediated analgesics can act at both supraspinal and spinal levels.

of some mixed agonist-antagonists such as enalbuphine. [38] At least three separate kappa-receptor subtypes have been isolated. $kappa_3$ -receptors are of particular interest because of their high density within the brain and association with supraspinal analgesia, whereas other kappa-receptors relate to spinal analgesia. [46]

Cellular Mechanisms

Opioid receptors belong to the superfamily of G protein- coupled receptors, all of which possess seven membrane-spanning regions. [24] [47] This group constitutes 80 percent of all known receptors and includes muscarinic, adrenergic, gamma-aminobutyric acid (GABA), and somatostatin receptors. The three opioid receptors have high amino acid sequence similarity to somatostatin receptors and very low similarity with all other receptors. The amino acid sequences of the opioid receptors are approximately 60 percent identical to one another, with greatest similarities existing in transmembrane and intracellular regions (Fig. 10-4) (Figure Not Available) . Specific amino acid sequences of the extracellular loops of opioid receptors are key in determining ligand-specific actions. Phosphorylation and glycosylation sites are responsible for a host of opioid-related effects including agonist-induced analgesia and desensitization or uncoupling of the receptor from G proteins. [48] Extracellular

signal-related kinase activation may also contribute to opioid-induced biologic effects. [49]

Studies indicate both presynaptic (indirect) and post-synaptic (direct) facilitatory and inhibitory actions of opioids on synaptic transmission in many regions of the nervous system. Direct inhibitory actions of opioids are mediated by opioid receptors coupled to pertussis toxin-sensitive G_i/G_o proteins and direct excitatory effects via a cholera toxin-sensitive G_s-like protein. The opioid receptor-activated G protein effector systems can be divided into two categories: short-term effectors (K^+ and Ca^{2+} channels) and longer-term effectors involving second messengers such as adenylate cyclase/cyclic adenosine monophosphate (cAMP) and

Figure 10-4 (Figure Not Available) Proposed model for membrane topography of the rat mu-opioid receptor. Amino acid residues of mu-opioid receptor conserved in both delta- and kappa-receptors, in either delta- and kappa-receptors, and in neither delta- nor kappa-receptor are shown by black, gray, and white circles, respectively. Branched structures show the potential *N*-linked glycosylation sites. *(Reprinted from Minami and Satoh, [51] with permission of Elsevier Science.)*

phosphatidylinositol. Both mu- and delta-receptors activate inwardly rectifying K^+ channels and all opioid receptor types can inhibit the opening of voltage-dependent Ca^{2+} channels. mu-Opioid agonists can also directly increase Ca^{2+} entry and cellular Ca^{2+} concentrations. [50] Changes in cAMP may underlie opioid-induced modulation of the release of neurotransmitters such as substance P. These previously mentioned actions account for many of the effects of opioids. For example, K^+ channel effects result in hyperpolarization of neuronal membranes and decreased synaptic transmission. Decreases in Ca^{2+} influx can decrease neurotransmitter mobilization and release. Opioid-induced changes in Ca^{2+} concentration are likely to be a component of the mechanisms of opioid analgesia.

Opioids also have excitatory actions, indirectly by interneuron disinhibition and directly by neuronal excitation, via G_s proteins. This may explain some neuroexcitatory responses to opioids.

Mechanisms of Analgesia

There is significant concordance between specific receptor mRNA expression in the central nervous system (CNS) and binding of specific receptor ligands [51] [52] (see Table 10-4) . Many of these areas are in major ascending and descending pain pathways (Fig. 10-5) . The transport of opioid receptors is thought frequently to underlie differences that exist in receptor mRNA and ligand binding distributions. Research on opioid receptors has entered a new era in which receptors can be examined with dual labeling techniques utilizing both specific ligands and gene structure and mRNA expression. Resultant anatomic studies will help to characterize the phenotype and function of CNS centers, nuclei, and even individual cells. [52]

Numerous studies do demonstrate opioid action and behaviorally defined analgesia in many CNS sites. These include the amygdala, the mesencephalic reticular formation, the periaqueductal gray matter, and the rostral ventral medulla. However, the role of some of the higher brain structures containing opioid receptors in opioid analgesia remains obscure and controversial. The proposed mechanisms by which opioids alter nociception are summarized in Figure 10-5 .

The periaqueductal gray area is one of the regions in the brain stem where microinjections of morphine or direct electrical stimulation produce analgesia that can be blocked with naloxone. [53] [54] [55] Stimulation of periaqueductal gray receptors with morphine, electricity, or endogenous opiate-like peptides results in impulses that alter the degrees of inhibition of different neuronal pools and contribute to reducing the transmission of nociceptive information from peripheral nerves into the spinal cord and up the neuraxis. [55] Opioid actions at the periaqueductal gray area influence, through direct neural connections, the rostral ventromedial region of the medulla. This region of the medulla, in turn, modulates nociceptive transmission neurons in the dorsal horn of the spinal cord. The integrity of such neurotransmitter

Figure 10-5 Diagram illustrating proposed antinociceptive mechanisms of morphine in the central nervous system.

systems connecting the pain-inhibiting system in the brain to the spinal cord is necessary for morphine to exert its full analgesic action. Thus, opioids do not only produce analgesia by direct actions. Whereas opioid application at the spinal cord, for example, produces analgesia at the level of administration, neurally mediated actions at distant CNS sites also enhance analgesia. The systemic administration of opioids activates the analgesic "system" in the CNS. [56]

Local spinal mechanisms, in addition to descending inhibition, underlie the analgesic action of opioids. Opioids act at nerve synapses either presynaptically (as neuromodulators) or postsynaptically (as neurotransmitters) (Fig. 10-6) (Figure Not Available) . [57] The substantia gelatinosa of the spinal cord possesses a dense collection of opiate receptors. [29] [58] Direct application of opioids to these receptors creates intense analgesia. Spinal cord presynaptic substance P release in primary sensory neurons is inhibited by mu-, kappa-, and delta- agonists and is one neuraxial mechanism of opioid analgesia. [59]

Opiate receptors are also localized in the substantia gelatinosa of the caudal spinal trigeminal nucleus, the nucleus receiving pain fibers from the face and hands via branches of the fifth, seventh, ninth, and tenth cranial nerves. [53] Opioids inhibit neuronal excitation of the dorsal horn in response to

Figure 10-6 (Figure Not Available) A schematic diagram illustrating the release of the excitatory transmitters from C fibers and the subsequent effects on a dorsal horn nociceptive neuron. The predominant presynaptic action of opioids (reducing the release of these transmitters) and the postsynaptic action (reducing neuronal activity) are shown. *(From Dickenson [57])*

painful sharp stimulation, and sensations via A delta fibers are reduced. Excitatory postsynaptic potential summation is also blocked by opioids in the dorsal horn blocking the development of dull persistent pain transmitted via C fibers. This summation is much easier to block than to treat and underlies the concept of preemptive analgesia as well as the clinical observation that patient responses to surgery are easier to control with opioids before rather than after stimulation. Opioids also affect second-order neurons by preventing excitatory threshold reductions and receptive field expansions at the spinal cord level. Opioids may also inhibit the early expression of DNA that is integral to transforming cellular characteristics necessary for the development of chronic or persistent pain (see Fig. 10-6) (Figure Not Available) .

Opioids may also produce some analgesia via peripheral mechanisms outside the CNS [60] (Fig. 10-7) (Figure Not Available) . Not all studies confirm this capacity in humans, [61] and the clinical relevance of this phenomenon appears to be negligible. [62] Factors affecting the efficacy of opioid action in the periphery, such as inflammation, may be important. Opioid receptors located on primary afferent neurons are likely sites of action, and immune cells infiltrating inflamed tissue may produce the endogenous ligands for these peripheral receptors.

Several other mechanisms of opioid action have been suggested. Opioid agonists produce a local anesthetic-like effect on the surface of excitable cell membranes that does not involve a stereospecific receptor and may contribute to some of their actions. [63] More recent work suggests that the local anesthetic effects of opioids, most prominent with meperidine, occur at the proximal end of the dorsal root as it passes the dorsal root entry zone. [64] Serotoninergic pathways may also in part modulate opioid-mediated analgesia. [65] Some opioid effects may be elicited at GABA receptors. Finally, it has also been postulated that opioid anesthesia may involve a general membrane effect because of much closer correlations between electroencephalographic (EEG) or anesthetic effects and membrane lipid content as opposed to serum opioid levels. [66]

Tolerance is a diminished response to opioid action and occurs within hours to days or weeks. Tolerance may represent an uncoupling of the usual drug-receptor effect. It may result from downregulation of the number of receptors and/or their affinity for agonists or an uncoupling between the receptor and intracellular second messengers via increases in adenyl cyclase activity. Tolerance may also develop as a result of other compensatory cellular responses to the presence of continuous opioid action that result in the restoration of cAMP homeostasis. [67] The level of expression of mu-opioid receptor mRNA is not static, and its regulation by protein

kinase C activation, with subsequent phosphorylation of opioid receptor protein, contributes to alterations in responsiveness to opioid agents in long-term opioid use. [68] Interestingly, there is little cross-tolerance between most receptor subtypes. In addition, the most potent opioid agonists with the largest receptor reserve, such as sufentanil, appear to be least prone to producing tolerance. [69] Tolerance is surmountable by increasing dose, at least initially.

Receptorology has also helped delineate, through receptor pharmacokinetic studies, how certain drugs can have a duration of action that extends well beyond what the plasma

Figure 10-7 (Figure Not Available) Schematic representation of possible peripheral opioidergic mechanisms. The neuronal cell body is located in the dorsal root ganglion. Opioid receptors are transported toward its central (right) and peripheral (left) terminals. After stimulation with cytokine (interleukin-1) or corticotropinreleasing hormone, opioid peptides are released from monocytes or macrophages (M) or lymphocytes (L). Occupation of neuronal opioid receptors by these ligands decreases the release of excitatory (proinflammatory) neuropeptides (e.g., substance P or calcitonin-gene-related peptide) and the excitability of the primary afferent neuron. *(From Stein [60])*

half-life would predict. For example, buprenorphine's dissociation from the mu-receptor is much slower than fentanyl's and does not parallel plasma concentrations. [70] The high affinity of buprenorphine for mu-receptors also accounts for the difficulty of reversing its effects with naloxone.

Other pharmacologic phenomena have been explained by radioligand-receptor studies. The concentration and proportion of the receptor subtypes can change with time. For example, mu_1 -receptors increase in number and concentration as newborn mice grow and thus provide more analgesia after a similar dose of an opioid agonist. [71] A marked and widespread disappearance of mu- and delta-receptors has been shown to occur in the aging brain. [72] Interestingly, the opposite occurs with benzodiazepine receptors during aging, a finding indicating that these effects are specific and are not representative of a general phenomenon.

The presence of opioid receptors in other areas of the CNS (e.g., basal ganglia, limbic area, cerebral cortex) suggests other roles for the endogenous opiates and their receptors. The cardiovascular system possesses opioid receptors that have been documented by radioligand studies to exist in the heart, the cardiac branches of the vagus and sympathetic nerves, the central cardiovascular regulatory centers, and the adrenal medulla. [73] Receptor-mediated opioid effects, as discussed later, indicate potential roles for and implications of opioids in shock, myocardial ischemia, ischemic preconditioning, and other cardiovascular events.

Endogenous Opioids

Hughes et al [74] first described two brain pentapeptides, methionine-enkephalin and leucine-enkephalin, that shared a four-amino acid sequence (Tyr-Gly-Gly-Phe), had potent affinities for opiate binding sites, and had opiate effects that were reversed by naloxone. Large endogenous opioid peptides, beta-endorphin [75] and dynorphin, [76] have also been described.

Three distinct precursor molecules (coded for by three distinct genes) are at the origin of three families of endogenously produced opioids in humans. The biosynthesis of all these endogenous opiates is complex. Pro-opiomelanocortin, a prohormone with a molecular weight of 30,000, is cleaved to form adrenocorticotropic hormone (ACTH) and beta-lipotropin (beta-LPH). [31] beta-LPH is devoid of opioid activity and, in turn, is cleaved to yield beta-endorphin. [77] The enkephalins have different precursors from those of beta-endorphin, although the amino acid sequence for methionine-enkephalin is contained in beta-LPH (amino acid sequence 61-65). Proenkephalin, a peptide with a molecular weight of 30,000, is the precursor for met-enkephalin and several other enkephalins. [78] Dynorphin, as well as leu-enkephalin, is derived from a third precursor, called prodynorphin. The differential biochemical processing of endogenous opiates parallels regional anatomic differences in endogenous opiate compounds, distribution, and concentration. [31] In spite of their differences, all three families of endogenous opioids possess the common amino acid sequence, *Tyr-Gly-Gly-Phe.*

The endogenous opioids exist in virtually all vertebrate species and in many invertebrates as well. [79] The highest concentrations of beta-endorphin occur in the pituitary gland (anterior and intermediate lobes greater than posterior lobe) and in the medial, basal, and arcuate regions of the hypothalamus. [80] Some long-axoned endorphin-releasing neurons synapse at upper brain-stem locations implicated in nociceptive processes such as the septum, the periaqueductal gray area, and the thalamus. It is unclear whether beta- endorphin exists functionally in the spinal cord. beta-Endorphin also exists outside the CNS, in the small intestine, placenta, and plasma. [81] [82] By contrast, enkephalins are widely distributed in many areas of the CNS (amygdala, globus pallidus, striatum, hypothalamus, thalamus, brain stem, and spinal cord dorsal horn laminae I, II, and V) that receive afferent nociceptive information. Met-enkephalin applied to the ventral surface of the brain stem in cats rapidly depresses ventilation and, to a lesser degree, heart rate and blood pressure. These actions are short-lived and are reversible by naloxone. [83] Enkephalins have also been isolated in the peripheral nervous system (peripheral ganglia, autonomic nervous system, adrenal medulla), as well as the gastrointestinal (GI) tract and plasma. [31]

Dynorphin is found in the hypothalamoneurohypophyseal axis, but as with the other two families of opioids, the role and importance of this finding remain unclear. Dynorphins may function primarily as neuromodulators in the CNS by interacting with mu-, delta-, and kappa-receptors. [84] Electrophysiologic, biochemical, and pharmacologic data support the hypothesis that dynorphin is implicated in specific types of seizures, most notably complex partial (limbic) seizures, that is, those characteristic of temporal lobe epilepsy. [85] kappa-Opioid agonists are effective against limbic seizures. Dynorphins may also play a role in the central control of the cardiovascular system. Dynorphin injected intrathecally at the thoracic level in the rat stimulates blood pressure and heart rate via a nonopioid receptor mechanism. [86] Dynorphin appears to be distributed in other CNS areas relevant to nociception: the periaqueductal gray, limbic system, thalamus, and laminae I and V of the dorsal horn in the spinal cord.

A functional hierarchy exists in nociception and with the endogenous opioids. Primary processing of afferent nociceptive information occurs from peripheral nerve endings to the dorsal horn of the spinal cord. Both dynorphins and enkephalins are active in these areas. Key ascending and descending relay stations for nociception reside in the midbrain, brain stem, and thalamus, and high concentrations of dynorphins, enkephalins, and beta-endorphin can be found in these areas. Higher brain centers involved in the affective dimension of pain (limbic system, amygdala, and cortex) contain significant populations of neurons where dynorphin, enkephalin, and beta-endorphin are found.

beta-Endorphin probably does not play a role in basal nociceptive thresholds but rather modulates nociception during stress, midbrain periaqueductal gray stimulation, and acupuncture. beta-Endorphin administered supraspinally or spinally produces analgesia. [87] Complete elucidation of the role of beta-endorphin in pain perception is still awaited. Enkephalins may play some role in acupuncture-mediated analgesia. Enkephalins may also elicit analgesia through the modulation of substance P release in the dorsal horn. Enkephalins act as inhibitory neurotransmitters. This is consistent with their wide distribution and rapid inactivation throughout the neuraxis. Dynorphin is thought to play a more important role in nociception at the spinal cord level (through activation of the kappa-receptor) than in the brain.

There have been many other roles postulated for endogenous opioids, but they are incompletely defined. For example, mu-receptors can mediate antidiuresis, whereas kappa-receptor activation elicits free water diuresis. The physiologic importance of these phenomena is unknown. Other roles include the modulation of respiratory responses to various stimuli and drugs [88] and participation in the cardiovascular depression seen in shock. [89] beta-Endorphin and met-enkephalin both depress ventilation, whereas dynorphin may not. [90] Several studies demonstrate increases in endogenous opioids in patients with chronic obstructive pulmonary disease. It has been suggested that these opioids serve a protective mechanism that lessens the stress of prolonged dyspnea and reduces excessive increases in the work of breathing. [88] This is especially true in advanced chronic obstructive pulmonary disease in which abnormal ventilation/ perfusion relations do not improve with increased ventilation. [88] Conversely, naloxone may improve ventilation in certain cases of respiratory failure. In certain pathologic conditions (Leigh syndrome, sudden infant death syndrome), increased cerebrospinal fluid (CSF) concentrations of endogenous opioids seem to be associated with apnea. [91] Endogenous opioids may also mediate the placebo effect. [92] The clinical implications of these and other roles for the endogenous opiates remain controversial and unclear. Further information may be obtained in published reviews. [73] [88] [93] [94]

PHARMACODYNAMICS: NEUROPHYSIOLOGIC ACTIONS

In healthy, pain-free volunteers, the administration of IV opioids produces dizziness, drowsiness, lethargy, apathy, and sleep. For example, fentanyl, in low doses resulting in analgesic plasma concentrations (1-2 ng/mL), produces similar sedative, but weaker amnesic effects compared with propofol or midazolam. [95] Initially on IV injection, opioids frequently stimulate coughing, which is of brief duration, followed by cough suppression. Opioids relieve anxiety and the distress of dyspnea. Other respiratory actions, including those that are neurophysiologic, are reviewed in a separate section. Pruritus almost always accompanies other opioid effects. Nausea and vomiting also can result after opioids. More rarely, opioids produce euphoria or dysphoria. [96] Morphine and meperidine, via histamine release, can cause a transient flushing or a hot sensation. The neurophysiologic mechanisms of opioid-induced analgesia and anesthesia are discussed earlier under mechanisms of action.

Are Opioids Anesthetics?

Whether or not opioids alone are capable of producing anesthesia was a subject of debate in the past. [97] [98] [99] Reports of patient awareness during high-dose fentanyl anesthesia highlighted the potential for this problem. [100] [101] A popular model used to examine the anesthetic potential of opioids determines their ability to substitute for volatile anesthetics in dogs subjected to tail-clamp minimum alveolar anesthetic (MAC) evaluations. [102] A consistent reduction, in the range of 60 to 70 percent, in the MAC of potent inhaled anesthetics has been demonstrated with numerous opioids. Although analgesic doses of opioids can decrease the MAC of potent inhaled agents by approximately 50 percent, further, and even very large, increases in opioid doses result in relatively small additional MAC reductions. This finding suggests that, in these models, opioid effects reach a ceiling that is subanesthetic.

Studies in rats demonstrate that opioids reduce the MAC of volatile anesthetics to a greater degree than in other animals [103] (Fig. 10-8) (Ch. 29) . In contrast to investigators using the dog model, these authors concluded that "sufentanil is essentially a complete anesthetic." [103] Sufentanil does result in the greatest MAC reduction of the opioids in the dog, too. [102] Interspecies differences in opioid actions are significant. [104] Some authors argue that a similarity between opioids and associated cardiovascular effects in humans and dogs supports the conclusion that responses of the two species to opioids are similar. [105] [106] Other investigators have found that dogs are not only more resistant to the actions of opioids, but also demonstrate a markedly different profile of effects compared with humans. [107] The rhesus monkey appears to respond to opioids in a fashion more similar to that seen in humans. [108] In addition, the results of motor response evaluations to noxious stimulation in MAC reduction studies do not necessarily predict anesthetic capabilities.

Reports in humans that demonstrate lower thiopental requirements to produce loss of consciousness after sufentanil compared with fentanyl support the notion that sufentanil has greater anesthetic potential compared with fentanyl (Fig. 10-9) (Figure Not Available) . Bowdle and Ward [109] reported that sufentanil (1.3 mug/kg IV) minimized the need for sodium thiopental to produce unconsciousness in nine of ten patients.

The hypnotic effects of midazolam are also significantly potentiated by alfentanil. [110] McEwan et al [111] demonstrated that fentanyl can reduce the MAC of isoflurane at skin incision in patients at least 80 percent (Table 10-5) (Table Not Available) . The relationship between plasma fentanyl concentration and MAC reduction was not linear, and the authors suggested a sub-MAC ceiling exists to the effect of fentanyl on isoflurane MAC reduction. The potency ratios for fentanyl/sufentanil/alfentanil/remifentanil, based on MAC reduction studies in humans, is approximately 1:12: 1/16: 1.2. [112] Although unconsciousness in humans, as defined by unresponsiveness to verbal command, can be produced with opioids

TABLE 10-5 -- MAC and MAC Reduction of Isoflurane by Increasing Concentrations of Fentanyl in Humans

Figure 10-8 Reduction of halothane minimum alveolar concentration in the rat observed with progressively increased sufentanil dosage. *(From Hecker et al [103])*

Figure 10-9 (Figure Not Available) Plot of thiopental requirement for induction of sleep versus opioid dose in surgical patients. Thiopental was administered intravenously in 25-mg increments every 30 seconds until the patient was unconscious. The thiopental requirement was plotted against the opioid dose. Sufentanil and fentanyl doses were plotted on the same scale, using a potency ratio of 1:8. The thiopental requirement was significantly smaller ($P < .0001$) for sufentanil, 0.7 and 1.3 mug/kg, than for equipotent doses of fentanyl (5 and 10 mug/kg, respectively). Only one of the ten patients receiving sufentanil, 1.3 mug/kg, required any thiopental as compared with ten of ten in the fentanyl, 10 mug/kg, group, and eight of ten in the fentanyl, 13 mug/kg, group ($P < .0001$). *(From Bowdle and Ward [109])*

TABLE 10-6 -- Unconsciousness as a Function of Age in 72 Patients Given Fentanyl (30 mug kg^{-1}) for Induction of Anesthesia

(Not Available)

From Bailey et al [217]

alone [113] [114] (Table 10-6) (Table Not Available) , opioid anesthesia can be unpredictable and inconsistent.

The presumed mechanism by which opioids act leaves doubt as to whether they should be expected to produce amnesia or anesthesia. However, the ability of opioids to produce analgesia in subanesthetic concentrations, and loss of consciousness in higher concentrations, may be mediated, at least in part, by different processes. [115] A dual mechanism in the anesthetic action of opioids has been proposed and requires that, in addition to receptor-mediated effects, an opioid must be lipid soluble enough to function as a general anesthetic. [116] Interestingly, a biphasic response has been noted with sufentanil [103] and fentanyl [107] (see Fig. 10-8) .

Awareness Under General Anesthesia

The subject of patient awareness during anesthesia and surgery continues to receive much attention (Ch. 29) . [117] Most clinicians define awareness as "the spontaneous recall of events occurring during general anesthesia and surgery." This is known as explicit memory. There are numerous studies documenting that the registration or retention of mental images or information under general anesthesia also can occur without conscious recollection. [118] [119] This is known as implicit memory. Notably, auditory functioning is left largely intact, even under inhalational anesthesia. [120] It is therefore not necessary or perhaps even possible to block the registration or retention of all information in patients who undergo general anesthesia, irrespective of the anesthetic used. It is rather the consolidation of such material and the conscious recollection of intraoperative events that concern anesthesiologists and patients most.

Awareness has been reported with many anesthetic techniques. [121] [122] Although reports of awareness, particularly with high-dose fentanyl anesthesia, highlighted the significance of this problem, it is now recognized that several factors contribute to its occurrence (Table 10-7) . Particular surgical patient populations, such as those individuals requiring anesthesia for obstetric, major trauma, and cardiac surgery are known to experience a high incidence (7-43%) of awareness. [123] Overall, it appears that up to 1 percent of all patients may experience awareness during general anesthesia.

The ability to monitor for intraoperative awareness remains limited. Clinical signs suggestive of awareness are

TABLE 10-7 -- Factors Cited as Contributing to Awareness

Inadequate anesthetic technique
No premedication
Ultrashort-acting intravenous induction agent
Excessive or unnecessary neuromuscular blockade
Difficult and/or prolonged intubation
Equipment failure
American Society of Anesthesiologists physical status IV or V
Obstetric procedure
Morbid obesity
Cardiac surgery
Inexperience of the anesthesiologist
Bronchoscopy
Pharmacologic autonomic blockade
Anesthesia at high altitude
Increased anesthetic requirement

generally motor and autonomic. Eyelid motion, swallowing, increased spontaneous respiratory effort, coughing, facial grimacing, and extremity or head motion are signs often assumed to indicate inadequate amnesia. Hypertension, tachycardia, mydriasis, tearing, sweating, or salivation may also indicate too light a level of anesthesia. Monitoring for muscle activity as an indicator of awareness is useful because muscle movements usually occur before awareness occurs. Motor signs also frequently occur prior to hemodynamic or autonomic indications of possible awareness. [124]

Other approaches for detecting awareness include evaluation of esophageal motility, isolated forearm technique, and measurement of facial muscle activity. [125] Various measures of CNS activity have included auditory evoked responses and some of its derivatives and the EEG. The raw EEG is complex and of limited value as an awareness monitor. Mathematic techniques and EEG transformations (i.e., power spectrum analysis) have produced some success. [126] Bispectral analysis uses a processed EEG to obtain an index (BIS) that can correlate with sedation and depth of anesthesia for certain drugs, but probably not opioids. [127] Although opioids alone do not substantially alter the BIS except at very high doses, the synergism between opioids and sedative-hypnotics is reflected by the BIS. Whether or not BIS monitoring can improve the detection of awareness and can allow strategies that reduce it remains unproven.

Several measures can be taken to minimize the occurrence of awareness under general anesthesia or the problems that can arise when a patient has such an experience. Preoperative evaluation of patients should include an assessment of their ability to tolerate anesthesia and the role opioids should play in intraoperative management. In selected cases (e.g., cardiac anesthesia) in which opioids may be the primary anesthetic, preoperative discussion of the possibility of awareness may be appropriate. Although pain is not always associated with awareness, a national inquiry in Great Britain documented that 41 percent of patients felt pain during their awareness episode. [120]

The use and misuse of muscle relaxants are thought to contribute often to awareness. The administration of muscle relaxants during balanced anesthesia is often routine, although it is frequently unnecessary, and it removes important motor signs of awareness. Limiting the use of muscle

relaxants to appropriate indications and not employing them as substitutes for anesthesia or to prevent movement in all patients should help to prevent awareness.

Some clinicians attempt to reduce the possibility of awareness by administering one or more sedative-hypnotic drugs during premedication, induction, and/or the maintenance of anesthesia. The administration of supplements (N_2O, diazepam, droperidol) or larger doses of opioids increases the likelihood of amnesia. [128] The use of 0.3 to 0.6 MAC or "MAC awake" concentrations of potent inhalation agents prevents recall and responses to verbal commands in volunteers and may eliminate awareness in patients. However, the doses and concentrations of IV drugs and inhaled agents required to eliminate awareness in patients remain difficult to predict with certainty. [122]

Intraoperative conversation, especially that which contains material meaningful to the patient, should be curtailed during anesthesia and surgery. Although potent stimuli such as laryngoscopy, intubation, skin incision, sternotomy, and aortic root dissection are considered to be the events most frequently associated with awareness, comments about a patient's size or discussion of clinical aspects of the patient's case can cause EEG arousal and are thought to be more likely be recalled. [120]

Intraoperative awareness may or may not be reported by patients postoperatively. In addition, understanding of intraoperative awareness as a phenomenon by medical personnel remains poor. The absence of spontaneous recall or of reports of it from medical colleagues, therefore, does not ensure that awareness under anesthesia did not occur. Traumatic neurosis consisting of nightmares, anxiety, preoccupation with death, and reluctance to discuss the incident is a symptom complex often associated with awareness during surgery. [129] [130] There is a lack of epidemiologic information concerning this and other possible sequelae. Awareness associated with anesthesia is best dealt with by informing patients of its possibility preoperatively and by frank and open discussion of such an episode after an occurrence. Direct explanation and support are considered to be the most helpful approach to a reluctant and fearful patient. [130] Medicolegal actions based on awareness during anesthesia in the United States have occurred.

Finally, many studies have evaluated the potential for intraoperative suggestions (e.g., audiotaped messages) to alter postoperative behavior and events such as pain perception or nausea and vomiting. [122] Results of these reports remain conflicting and controversial, and the implications and potential utility of implicit awareness as a means to modify behavior and outcome remain incompletely defined.

Electroencephalography

The neurophysiologic state produced by large doses of opioids differs from the "general anesthetic" state resulting from inhaled anesthetics (Chs. 29 and 35) . [131]

Increasing concentrations of inhaled anesthetics produce a continuum of EEG changes, eventually resulting in burst suppression and a flat EEG. In contrast, a "ceiling effect" is reached with fentanyl, morphine, sufentanil, and other opioids. Increasing opioid dosage, once this ceiling has been obtained, does not further affect the EEG. [132] Overall, the effects of the mu-agonists fentanyl, alfentanil, sufentanil, and remifentanil on the EEG are consistent among the opioids after allowing for differences in potency and rate of plasma-CNS equilibrium. [133]

Opioids can produce neuroexcitation or arousal. [134] In animals (cats), opioid-induced increases in cerebral oxidative metabolism have implied an analeptic-like effect. Species differences (opioids produce EEG seizure discharges in cats and mice) are now known to account for much of the discrepant findings in EEG studies between animals and humans.

Small doses of fentanyl (200 mug) produce minimal EEG changes, [135] whereas higher doses (30-70 mug kg^{-1}) result in high-voltage slow (delta) waves, suggesting a state consistent with anesthesia. [131] Although transient isolated (usually frontotemporal) sharp wave activity can be observed after large doses of fentanyl and other opioids, it is not generalized.

Sufentanil produces EEG changes that are similar to those seen with fentanyl. These changes are achieved at lower opioid plasma concentrations in the elderly. [136] [137] EEG states consistent with surgical anesthesia have been produced with doses of sufentanil as low as 2.5 mug kg^{-1}. [138] High doses of both fentanyl and sufentanil produce greater EEG changes than morphine. [139]

Although high doses of fentanyl or sufentanil produce similar EEG changes, [139] the effects of large alfentanil doses may be different. [140] Alfentanil (125 mug kg^{-1}) produces less synchronization of the EEG and less change in the relative EEG power in the delta band, a finding suggesting a lesser depth of anesthesia. [140] In addition, EEG spindle activity is common with alfentanil and rare with fentanyl or sufentanil. The latter may represent a specific or unique effect of alfentanil.

EEG is useful in several ways. As an effect site measure, it can be employed to assess onset of drug action and drug potency ratios. For example, EEG data confirm that alfentanil is more rapid acting than fentanyl. Scott et al [141] reported that the lag time between plasma drug concentration and change in the spectral edge is only 1 minute for alfentanil (84 mug kg^{-1} over 6 min) and 6 minutes for fentanyl (8.8 mug kg^{-1} over 6 min) (Figs. 10-10 (Figure Not Available) , 10-11) (Figure Not Available) .

The serum concentration ratio that results in a similar EEG pattern is 75:1 for alfentanil/fentanyl. [141] This contrasts with the reported IV dose ratio in which fentanyl is only three to five times as potent as alfentanil. In a similarly performed study, Scott et al [142] found the half-time of blood-brain equilibration ($t½_{2ke0}$) was not statistically different between fentanyl and sufentanil. Serum drug concentration ratios were 12:1 (fentanyl/sufentanil) at equal (halfmaximal) EEG slowing. Similar studies suggest that fentanyl and remifentanil are 75 and 16 times as potent as alfentanil, respectively. [143] Bowdle and Ward [109] also found similar times to onset of EEG effects for fentanyl and sufentanil. With more rapid sufentanil infusion rates (0.7 mug/kg/min), near maximal EEG effects, corresponding with a failure of patients to respond to command, can be obtained within 3 minutes. [132]

Potency ratios based on EEG studies are similar to those obtained from studies determining the plasma (or whole blood, in the case of remifentanil) drug levels of each opioid necessary to reduce the MAC of isoflurane by 50 percent. Potency ratios for sufentanil/fentanyl/remifentanil/alfentanil

Figure 10-10 (Figure Not Available) Time course of spectral edge and serum alfentanil concentrations. Note the inverted spectral edge axis. Spectral edge changes closely parallel serum concentrations. The alfentanil infusion rate is 1,500 mug/min (solid bar). *(From Scott et al [141])*

are 1: 1/10: 1/80. [111] [144] [145] [146] [147] [148] Based on EEG studies and experimental pain studies performed in humans, trefentanil has a potency that is very similar to that of alfentanil. [149] [150]

EEG analysis may be useful in monitoring the depth of anesthesia. [131] [139] [140] [141] Plasma opioid levels correlate reasonably well with EEG changes, [141] and some patterns (Kcomplexes or an increase in frequency and decrease in wave amplitude) can be used to indicate a possible return of awareness or light anesthesia. [140] However, problems with lead placement and signal processing, as well as high cost and reliability, need to be resolved before EEG analysis can be used as a routine monitor of opioid anesthesia depth. For example, Long et al [151] found emergence of patients from isoflurane but not fentanyl anesthesia to be predictably associated with obvious changes in the overall EEG frequency power spectrum.

Whether or not other forms of EEG, such as BIS, accurately reflect opioid action remains incompletely investigated

Figure 10-11 (Figure Not Available) Time course of spectral edge and serum fentanyl concentrations. Note the inverted spectral edge axis. The spectral edge changes lag behind the serum concentrations changes. The fentanyl infusion rate is 150 mug/min (solid bar). *(From Scott et al [141])*

to date. Work continues toward defining EEG parameters that correlate well with opioid effect. [133] Furthermore, it has been postulated that the EEG may eventually allow determination of the therapeutic windows for many opioid effects. [152]

Sensory Evoked Potentials

Opioids do not appreciably alter somatosensory evoked potentials (SEP) elicited at the posterior tibial or median nerve (Ch. 35) . [153] [154] [155] [156] [157] [158] [159] Changes produced in SEP latencies (increases usually less than 3 ms) and amplitudes (reductions of usually 30-40%) after administration of opioids with or without N_2O are compatible with successful clinical monitoring. Supplementation of alfentanil (100 mug/kg/10 min, then 2 mug/kg/min) with propofol (6 mg/kg/h) instead of N_2O results in a better preservation of early posterior tibial nerve-SEP peaks. [160] Median nerve SEP monitoring is also possible after sufentanil (5 mug/kg). Kimovec et al [161] found this dose of sufentanil produced acceptable and stable SEP alterations that permitted latency changes typically associated with neurologic injury to be noted. Some investigators believe the signal-to-noise ratio is also better preserved with opioid-based techniques than during anesthesia with potent inhaled agents. [153]

Although opioids do not interfere with SEP interpretation, they do inhibit both the velocity and the amplitude of nerve action potential transmission. [154] It follows that opioid-induced SEP changes may occasionally be confused with neurologic injury. [158] Significant variability in opioid effects on SEP amplitude has been reported. Amplitude has been found to decrease, increase, or remain unchanged. [154] [162] Thus, it has been recommended that the administration of opioids should be timed to avoid confusion with other possible causes of SEP change. [162] Fortunately, changes induced by large doses of opioids occur rapidly, and then elicited SEP usually remain stable. [163] In addition, slow IV infusions of opioids generally produce fewer SEP changes than large boluses. [154] Repeated boluses produce less change than the initial injection. [155] Sebel et al [164] did not find a significant correlation between increasing doses of fentanyl and SEP changes. These findings confirm the stability of the SEP signals once opioid-based anesthesia has been established. In addition, the early portions of the SEP signal are more significant in monitoring and are less affected by fentanyl than the latter parts of the SEP. [162]

Combinations of opioids and other IV anesthetics may or may not be compatible with reliable SEP monitoring. Fentanyl (10 mug kg^{-1}), administered as a bolus after midazolam (0.3 mg kg^{-1}), and followed by a fentanyl infusion, causes little change in SEP. [159] Thiopental (5-mg kg^{-1} bolus plus a 2-mg kg^{-1}

h^{-1} infusion), followed by fentanyl (10 mug
kg^{-1}), further decreases SEP amplitudes, but causes little change in latencies. [159] After etomidate (0.3-mg
kg^{-1} bolus plus 2 mg
kg^{-1}
h^{-1} as an infusion), fentanyl (10 mug
kg^{-1}) increases latency and reverses etomidate-induced increases in amplitude. [159] The effects of remifentanil on evoked potentials are similar to those of other fentanyl congeners. [165]

Brain-stem auditory evoked potentials are also minimally altered by analgesic and anesthetic doses of morphine, fentanyl, or sufentanil. [166] [167] [168] Visual evoked potentials during sodium thiopental-fentanyl-N_2O anesthesia show transiently decreased amplitudes and modest but persistent increases in latencies. Much of the disturbance in visual evoked potentials in this technique is due to barbiturate action. [169]

Although some reports document little or no effect of opioids on auditory evoked potentials, others have found dose-dependent effects. [165] Midlatency auditory evoked potentials are similarly affected by the modern opioids and reveal only a slight slowing of cortical stimulus transmission and processing. [170]

Cerebral Blood Flow

Opioids generally produce modest decreases (10-25%) in cerebral metabolic rate (CMR) and intracranial pressure (ICP), although these changes are influenced by the concomitant administration of other agents and anesthetics, as well as by patient conditions (Ch. 19) . Thus, in reports in which vasodilatation is produced by the background anesthetic (e.g., potent inhalation agents), opioids are more likely to cause cerebral vasoconstriction. Opioids also decrease cerebral blood flow (CBF) when combined with N_2O. When there is no background anesthetic, or when the background anesthetic causes cerebral vasoconstriction, opioids usually have no influence or result in a small increase in CBF.

Opioids, in general, are not thought to uncouple CBF and CMR. Endogenous opioids contribute to the regulation of arterial tone, at least in certain experimental models. [171] Endogenous opioid activity is present in cerebral arteries, although exogenously administered opioids were found to exert little effect on pial artery diameter in several animal models. [172] However, differences in species and conditions can affect the results of investigations.

Wahl [173] did find that morphine, as well as some endogenous opiates, produced dose-dependent pial arterial dilatation that became significant at higher drug concentrations. In dogs, intracarotid morphine decreases neurohypophyseal blood flow by up to 40 percent. Intraventricular morphine causes a similar neurohypophyseal effect while increasing CBF to other brain regions. [174]

Fentanyl (100 mug
kg^{-1}) causes dose-related reductions in CBF (maximum 50%) and $CMRO_2$ (maximum 35%) in rats receiving N_2O in O_2. [175] In the piglet, fentanyl and, to lesser degrees, alfentanil and sufentanil decrease arteriolar diameter in a dose-dependent naloxone-reversible manner. [176] Fentanyl alone causes little change in CBF in the dog [177] or lamb. [178] Phenobarbital-fentanyl anesthesia also preserves cerebrovascular responsivity to changes in arterial pressures of CO_2 (Pa_{CO_2}) and O_2 (Pa_{O_2}) and mean arterial blood pressure in the dog. [179]

In human volunteers, positron emission tomography demonstrates that after fentanyl (1.5 mug/kg IV), CBF effects are regionally heterogeneous. [180] In patients undergoing carotid artery surgery, CBF during fentanyl-N_2O or isoflurane (0.75%)-N_2O anesthesia is significantly less than with halothane (0.5%)-N_2O anesthesia (19±2, 24±2, and 34±5 mL/100 g/min, respectively). [181] Balanced anesthesia with fentanyl-N_2O better preserves the cerebrovascular response

to CO_2 in patients with an edematous brain than isoflurane-N_2O anesthesia. [182] Other balanced anesthetic techniques also maintain cerebrovascular CO_2 reactivity in humans. [183] [184]

Sufentanil causes dose-related decreases in CBF (maximum 53%) and $CMRO_2$ (maximum 40%) in the rat. [185] The effect of sufentanil on CBF in the dog may be dose- and time-dependent. [186] [187] Werner et al [186] found that sufentanil (20 mug/kg IV) produces modest (35-40%) decreases in CBF 5 and 10 minutes after opioid administration coupled with decreases in cerebral O_2 consumption. On the other hand, Milde [187] found that sufentanil (10-200 mug/kg) produces transient increases in CBF that peak 2 minutes after drug administration. In a primate model, which is more sensitive to opioids, Bunegin et al [188] found that sufentanil significantly decreases CBF, cerebral perfusion pressure, and $CMRO_2$.

In humans, both sufentanil and fentanyl can, however, increase middle cerebral artery blood flow velocity by approximately 25 percent. [189] Other investigators report that in healthy human volunteers, sufentanil (0.5 mug/kg IV) produces no significant effect on CBF. [190] In patients undergoing carotid endarterectomy, sufentanil (1.5-2.0-mug/kg bolus plus 0.2-0.3-mug/kg/h infusion)-N_2O anesthesia produces CBF effects similar to those of isoflurane (0.75%)-N_2O anesthesia, and CO_2 cerebrovascular reactivity is maintained. [191] In brain-injured patients, sufentanil (3 mug/kg by IV bolus) minimally affects middle cerebral artery blood flow velocity. [192]

In the dog, alfentanil and remifentanil both decrease regional blood flow 40 to 50 percent in the cortex, hippocampus, and caudate, even if blood pressure is maintained with phenylephrine. [193] Alfentanil (25 or 50 mug/kg IV), administered to patients receiving isoflurane (0.4-0.6%)-$N_2$0 anesthesia, produces minimal reductions in middle cerebral artery flow velocity. [194] Absolute CBF values during remifentanil-N_2O anesthesia are similar to CBF values during fentanyl-N_2O and isoflurane-N_2O anesthesia, and cerebrovascular reactivity to CO_2 remains intact. [195]

Cerebral Metabolic Rate

As reviewed earlier in the section on CBF, opioids usually produce mild to moderate decreases in CMR that remain coupled to CBF. Nevertheless, opioid-induced neuroexcitation (see later) and, rarely, focal seizure activity can result in regional increases in brain metabolism. In the rat, for example, fentanyl-induced EEG spike, seizure, and post-EEG seizure phases are all associated with significant increases in CBF. [196] Regional increases in glucose utilization induced by high doses of alfentanil in the rat are associated not only with epileptiform activity, but also with neuropathic lesions. [197]

Intracranial Pressure

Opioids are generally thought to affect ICP minimally (Ch. 52) . For example, under background anesthetic conditions (isoflurane-N_2O), opioids do not cause significant increases in ICP or CSF pressure in patients undergoing craniotomy for supratentorial space-occupying lesions. [198] [199] Some authors report that opioid sedation, in general, does not alter ICP in head-injured patients. [200] However, some reports suggest that potentially deleterious opioid-induced ICP effects can be produced. In patients undergoing craniotomy for excision of supratentorial space-occupying lesions, opioids may produce increases in ICP by one or more mechanisms, especially if intracranial compliance is compromised.

Marx et al [201] reported that CSF pressure increased 190 percent after sufentanil (1 mug/kg) and 120 percent after alfentanil (50 mug/kg) in patients with brain tumors who were anesthetized with thiopental-N_2O-vecuronium. Similar patients experienced a 5 percent decrease in CSF pressure after fentanyl (5 mug/kg). These findings were confirmed for fentanyl and alfentanil by Jung et al. [202] In contrast, Markovitz et al [203] found no impact of alfentanil (70 mug/kg over 6 min) on ICP in hydrocephalic patients aged 1.3 to 20 years who were undergoing shunt revision under isoflurane (0.5%)-N_2O anesthesia. Sperry et al [204] reported that both sufentanil (0.6 mug/kg) and fentanyl (3 mug/kg) caused significant ICP increases in fully resuscitated patients with severe head trauma.

Fentanyl has been reported to exacerbate ICP elevations by others. [205] Still other investigators have demonstrated that sufentanil causes no change in ICP in patients. [206] Whether these discrepancies are due to different ICP or CSF pressure assessment methods, the presence of other drugs, or other reasons is unclear. [204] In addition, if opioids do increase ICP, whether the mechanism is due to direct cerebrovascular dilation and/or is indirectly related to decreases in mean blood and

cerebral perfusion pressure and subsequent compensatory cerebrovasodilation is not resolved. Rapid treatment of opioid-induced cardiovascular effects may attenuate or eliminate associated adverse ICP effects. Regional increases in CMR (see later) may also underlie opioid-induced increases in CBF and ICP. Opioidinduced rigidity can also increase ICP. [207] CSF production and reabsorption do not appear to be affected by fentanyl and, presumably, other opioids. [208] [209] Brain retraction pressure, a clinical correlate of regional cerebral dysfunction, is not affected by fentanyl, sufentanil, or alfentanil in patients. [210] In patients undergoing craniotomy with isoflurane N_2 O-O_2 anesthesia, neither remifentanil (0.5 or 1.0 mug/kg) nor alfentanil (10 or 20 mug/kg) caused an increase in ICP. [198]

Neuroprotection

Although certain early studies suggested potentially adverse effects of mu-opioid agonists on ischemic brain, other studies document that at least certain opioid agents, such as the kappa-agonists, can be neuroprotective (Chs. 19 and 52) at least in animal models of focal ischemia. [211] [212] Animal studies of neurologic injury suggest that anesthesia with opioids improves neurologic outcome compared with the awake state. [213] In addition, spinal cord protection by fentanyl-N_2 O anesthesia is equal to that provided by halothane or spinal lidocaine. [214]

Opioids offer considerable advantages in neuroanesthesia, including the promotion of intraoperative systemic hemodynamic, as well as cerebrovascular stability and a rapid but smooth emergence. Although many studies suggest the

possibility of adverse effects of opioids on regional CMR, CBF, and ICP, opioid-based anesthesia has had an extensive and safe clinical record. The significance of reported opioid-induced changes in CBF and/or ICP and the impact, if any, of such changes on patient outcome is unknown. In the near future, tests that provide direct measures of local brain activity, such as positron emission tomography and functional magnetic resonance imaging, will further advance our understanding of CNS opioid actions.

Muscle Rigidity

Opioids can increase muscle tone and may cause muscle rigidity. Corssen et al [215] reported an 80 percent incidence of some rigidity in patients receiving dehydrobenzperidol (0.44 mg
kg^{-1}) and fentanyl (8.8 mug
kg^{-1}). Grell et al [216] found that a single IV dose of fentanyl (0.5-0.8 mg) consistently produced chest-wall rigidity within 60 to 90 seconds of IV administration. The incidence of rigidity noted with opioid anesthetic techniques varies greatly because of differences in dose and speed of opioid administration, the concomitant use of N_2 O, the presence or absence of muscle relaxants, and patient age. [7] [217] [218] [219] [220]

Opioid-induced rigidity is characterized by increased muscle tone progressing at times to severe stiffness. Clinically significant opioid-induced rigidity usually begins just as, or after, a patient loses consciousness. Mild manifestations of rigidity, such as hoarseness, can occur in conscious patients. Clinically, rigidity is most frequently first observed as wrist flexion. Rigidity can decrease pulmonary compliance and functional residual capacity, may diminish or preclude adequate ventilation, and may cause hypercarbia, hypoxia, and an elevated ICP. [207] [221] [222] [223] Opioid-induced rigidity also increases pulmonary artery and central venous pressures and pulmonary vascular resistance (Table 10-8) . [224] [225] Changes in arterial blood pressure and cardiac output are usually small. [225] Transient increases in plasma fentanyl levels may be induced by rigidity. [226]

Rigidity of the abdominal and/or thoracic muscles (wooden chest syndrome) was thought to underlie opioid-induced impairment of spontaneous or controlled ventilation in the nonparalyzed patient. [224] However, it has been demonstrated that vocal cord closure is primarily responsible for difficult ventilation with bag and mask that follows opioid administration. [227]

TABLE 10-8 -- Potential Problems Associated with Opioid-Induced Rigidity

SYSTEM	PROBLEM

Miscellaneous	
	Oxygen consumption
	Intracranial pressure
	Occluded or dislodged intravenous lines
	Fentanyl plasma levels

CVP, central venous pressure; FRC, functional residual capacity; PAP, pulmonary artery pressure; PVR, pulmonary vascular resistance.

Rigidity occasionally occurs on emergence from anesthesia [228] and may rarely occur hours after the last dose of opioid has been administered. [229] Delayed or postoperative rigidity is probably related to second peaks that can occur in plasma opioid concentrations, as well as other possible causes similar to those underlying the recurrence of respiratory depression. Rigidity has also been reported in a neonate whose mother was anesthetized with an opioid [230] and in newborn infants receiving alfentanil. [221]

Abnormal muscle movements ranging from extremity flexion to single or multiple extremity tonic-clonic movements to global tonic-clonic motions can also occur after the use of opioids. [217] Indeed, tonic-clonic muscle movements and/or rigidity may explain reports describing seizure-like movements after fentanyl and sufentanil. [231] Whether such muscle movements (including rigidity) are part of a spectrum of neuromuscular activity associated with opioids or are manifestations of subcortical seizure activity is unclear (see the next section of this chapter).

The precise mechanism by which opioids cause muscle rigidity is not clearly understood. Muscle rigidity is not due to a direct action on muscle fibers, because it can be decreased or prevented by pretreatment with muscle relaxants. In addition, opioid-induced muscle rigidity is not associated with increases in creatinine kinase, [218] a finding suggesting that little or no muscle damage occurs during this period. Opioids do not have significant effects on neuromuscular conduction and result in only minimal depression of monosynaptic reflexes associated with muscle stretch receptors. [218] [219] Opioid-induced rigidity is probably related to a catatonic state, which can be induced by opioids. [232] Some investigators have suggested that opioids produce rigidity by altering dopamine concentrations within the striatum of the brain. [233] [234] mu-Receptor agonists induce rigidity in the rat, whereas delta- and kappa-agonists do not. [235] Rigidity may be the result of stimulation of GABAergic interneurons, which can be blocked by lesions in the striatum. Striatonigral GABA pathways involved with rigidity can also be affected by both GABA agonists and antagonists. [236] The nucleus pontis raphae is an integral central site concerning opioid-induced rigidity. [222] [237]

Some aspects of opioid-induced catatonia and rigidity (increased incidence with age, muscle movements resembling extrapyramidal side effects) are similar to

Parkinson disease and suggest similarities in neurochemical mechanisms. For example, some components of Parkinson disease not responsive to levodopa may involve endogenous opioid neurotransmitters. [238] Perturbations in endogenous opioid concentrations exist in parkinsonian patients. Parkinsonian patients, particularly if inadequately treated, may experience reactions like dystonia following opioid administration. [239]

Succinylcholine reliably and rapidly terminates rigidity (provided the IV infusion is not impaired by a rigid flexed extremity), eliminates associated cardiovascular changes, and usually permits controlled ventilation. Nevertheless, the unpleasant aesthetics and potential risk posed by opioidinduced rigidity episodes have stimulated the search for preventive measures.

Pretreatment or concomitant use of nondepolarizing muscle relaxants significantly decreases the incidence and severity of rigidity (Table 10-9) (Table Not Available) . [217] [240] [241] Induction doses of

TABLE 10-9 -- Incidence (Percentage) of Patients and Degrees of Rigidity After 30 mug kg^{-1} of Fentanyl in 72 Patients

(Not Available)

From Bailey et al [217]

sodium thiopental and less than anesthetic doses of diazepam and midazolam have also been reported to prevent, attenuate, or successfully treat rigidity. However, other reports discount the reliability of the benzodiazepines in reducing opioid-induced rigidity. [217] Other experimental compounds (ketanserin, amantadine, and $alpha_2$ -agonists) have been suggested to reduce opioid-induced rigidity. Avoidance of rigidity in clinical practice is best achieved by the concomitant administration of a "priming" size dose of a nondepolarizing muscle relaxant and avoiding the rapid administration of large doses of any of the opioids. Although the concomitant administration of a full dose of nondepolarizing muscle relaxant with an opioid during anesthetic induction has been recommended, [242] this method can result in the onset of muscle relaxation prior to unconsciousness. Opioid-induced rigidity, on the other hand, accompanied by apnea, usually indicates unconsciousness. [113]

It is common practice for an anesthesiologist to demonstrate the ability to mask ventilate a patient after the induction of anesthesia prior to the administration of a muscle relaxant. This practice is of questionable utility when opioid-induced rigidity occurs during induction and patients become difficult or impossible to ventilate manually. If a patient presents with the possibility of a difficult airway or other circumstances in which it is important to ascertain that the patient can be manually ventilated prior to neuromuscular blockade, then only small doses of an opioid should be given during induction. Persisting in an attempt to mask ventilate a patient with opioid-induced rigidity will likely result in gastric insufflation and inadequate ventilation or oxygenation until a muscle relaxant is administered. Clinicians should anticipate the need for rapid neuromuscular blockade when doses of opioids are administered that produce rigidity in order to minimize its occurrence and to allow for ventilation and airway management.

Neuroexcitatory Phenomena

Opioids, as well as inhalation (diethyl ether, enflurane, and isoflurane) and other IV (ketamine, methohexital, and propofol) anesthetic agents, can cause neuroexcitatory phenomena. [134] [234] [243] [244] [245] [246] [247] [248] [249] Fentanyl can cause neuroexcitation ranging from delirium to grand mal seizure-like activity. [250] [251] [252] Sufentanil (
5 mug
kg^{-1}) can also produce neuroexcitation including tonic-clonic movements and seizure-like activity. [253] [254] [255] [256] Interestingly, most reports of neuroexcitation with fentanyl or sufentanil involve the elderly, although these responses are occasionally observed in young patients aged 4 to 12 years. [257]

Fentanyl causes EEG seizure activity in cats (20-80 mug
kg^{-1}), [134] rats (200-400 mug
kg^{-1}), [232] and dogs (>1,250 mug
kg^{-1}). [243] Opioids have been implicated as causative in a variety of other types of neuroexcitation ranging from nystagmus, nonspecific eye movements, single extremity flexion, single or multiple extremity tonic or clonic-tonic activity and global (truncal and extremity myoclonic-tonic grand mal seizure-like) activity. [258] [259] [260] [261] However, EEG evidence of seizure activity after fentanyl (
150 mug
kg^{-1}), alfentanil (175 mug
kg^{-1}), and sufentanil (
15 mug
kg^{-1}) is generally lacking in humans. [131] [139] [225] [262] [263] Neither fentanyl nor sufentanil alters thresholds for pilocarpine-induced seizures in the rat. [264]

Animal studies demonstrate that in certain species, opioids cause focal CNS excitation rather than global CNS depression. [265] [266] Generally, these areas are subcortical (in particular the limbic system, which is rich in opiate receptors) and may in part explain the difficulty in documenting neuroexcitatory opioid effects by surface EEG. Focal neuroexcitation on EEG (e.g., sharp and spike wave activity) occasionally occurs in humans after large doses of fentanyl, sufentanil, and alfentanil. [262] The implications of such epileptiform activity are unclear. Such activity is usually of short duration (1-2 min) and is self-limited. It can be terminated by anticonvulsants such as midazolam. Fentanyl (25 mug/kg) has been demonstrated to induce EEG seizure activity documented via epidural electrodes in either temporal lobe in patients with a history of temporal lobe seizures. [267]

Reports of jerking movements and hyperexcitability after morphine are rare, but they are probably similar in origin to rigidity after fentanyl. [10] Morphine has also been reported to produce tonic-clonic activity after epidural and intrathecal administration. [268] [269] Meperidine may also cause CNS excitability. The mechanism is unique and is related to its *N*-demethylation metabolite, normeperidine, which is twice as likely to cause CNS excitation and convulsions as meperidine. Normeperidine has a long elimination half-life (15-40 h) and is chiefly eliminated by the kidney. Normeperidine is also hydrolyzed to normeperidinic acid, which is inactive. [270] Convulsions and myoclonic jerking movements that occur after large doses of meperidine, especially in patients with decreased renal function, are most likely caused by normeperidine and are not antagonized by naloxone. [270]

The mechanisms underlying neuroexcitatory phenomena are not clear. Changes in central catecholamine concentrations in dopaminergic pathways have been proposed as a possible explanation. [271] Other purported mechanisms include opioid-induced increases in glutamate-activated currents, disinhibition of pyramidal cells of the hippocampus, [272] and an increase in the release of excitatory neurotransmitters, such as met- and leu-enkephalin, which possess epileptogenic properties. [245] At least some forms of neuroexcitation are reversible by naloxone. [250] More recent work suggests that certain excitatory opioid actions may be related to their coupling to mitogen-activated protein kinase cascades. [49]

Clinical circumstances do not usually allow for naloxone treatment of opioid-induced neuroexcitation following induction of anesthesia. Such therapy may preclude continuing anesthesia and surgery, or it may result in undesirable hemodynamic alterations. The discontinuation of surgery is also not recommended because there is no known CNS morbidity associated with opioid-related neuroexcitation. Instead, if rigidity or neuroexcitation occurs in an unanticipated fashion, control of the airway and completion of anesthetic induction should proceed. Nevertheless, concern about the potential risk or sequelae of seizures is legitimate. Neuroexcitatory phenomena can alarm operating personnel, lead to physical harm, [273] or at least disconnect IV lines and make appropriate treatment difficult. Local increases in CBF [274] and metabolism [265] are also of theoretical concern because prolonged seizure activity, even if focal, could lead to neuronal injury and/or cellular death. [275] [276] [277] Opioids have been demonstrated to produce limbic system brain damage in rats. [278] To date, no neurologic deficit in humans has been associated with neuroexcitatory opioid effects.

Pupil Size and Opioid Action

Many stimuli and most anesthetic agents, including atropine, barbiturates, opioids, ephedrine, and halothane, affect pupillary diameter. These effects are mediated via several mechanisms, including alterations in sympathetic and parasympathetic tone. Opioids constrict the iris, and the time course of the response appears related to plasma opioid levels, even in the presence of potent inhalation agents. [279] [280] Opioids release cortical inhibition of the Edinger-Westphal nucleus, resulting in pupillary constriction. Direct effects on the iris are also possible.

Few studies have systematically examined the response of the pupil to different anesthetic techniques. The changes in pupil size associated with opioid action may be too small to be of clinical utility in assessing the degree of opioid effect. Cardiac surgery or neurologic deficit and other factors such as eye color, age, pain, and ambient light can affect the size and/or rate of change of pupillary diameter to stimuli. [281] [282] Nevertheless, clinicians often use pupillary size to assess opioid action. Peacock et al [283] did find a significant inverse correlation between pupil size and plasma codeine concentrations in volunteers. It has been demonstrated that, in a dose-dependent manner, alfentanil attenuates the reflex pupillary dilatation that normally follows noxious stimulation in anesthetized individuals. [284]

Thermoregulation and Shivering

Studies demonstrate that opioid ligands and receptors have a functional role in thermoregulation. [285] Opioid-based anesthesia probably reduces thermoregulatory thresholds to a degree similar to that of the potent inhaled agents. [286] [287] However, meperidine is unique among opioids in its ability effectively to terminate or attenuate shivering in approximately 70 to 80 percent of patients. [288] [289] [290] This is likely related to non-mu-opioid receptor-related actions of meperidine. The special antishivering effect of meperidine is primarily related to a reduction in the shivering threshold. [291] From 25 to 50 mg of meperidine IV is usually effective. Meperidine (IV or epidurally) is also effective in treating shivering that occurs during epidural anesthesia. [289] [292] Shivering related to blood product transfusions can also be treated with meperidine. [293] Alfentanil, morphine, and fentanyl are not as effective as meperidine in the treatment of postoperative shivering, although epidural sufentanil and fentanyl may reduce or prevent shivering in obstetric patients receiving regional anesthesia. [294] [295]

Pruritus

The mechanism and physiologic significance of opioid-induced pruritus are unknown. Histamine release, once thought to underlie this phenomenon, is not causative because non-histamine-releasing opioids also produce pruritus. Opioid-induced pruritus is not a manifestation of an allergic reaction, although medical records frequently indicate this. Drug solution preservatives do not cause the itching associated with opioid administration. Naloxone reverses opioid-induced itching, and this finding supports a receptor-mediated central mechanism for pruritus. A "scratching center" that lies in the medulla oblongata in animals may have an anatomic correlate in humans. [296] In addition, pruritus induced by spinal opioid actions in the substantia gelatinosa may be referred to a remote site by neural transmission. Thus, facial itching may not necessarily be a manifestation of direct opioid action at the level of the trigeminal nucleus, but rather, it may be a reflection of opioid-triggered neural transmission at a distant site. Why the face, and in particular the nose, is so prone to pruritus, even after spinal opioids, is unclear. Teleologically, nasal scratching may stimulate ventilation, may counter opioid-induced respiratory depression, and may be protective. Interestingly, cholestasis is ameliorated by opiate antagonists. [297]

PHARMACODYNAMICS: RESPIRATORY ACTIONS

The roles and actions of opioid receptors and endogenous, as well as exogenous opioids, in respiration have been thoroughly reviewed. [90] The respiratory-depressant actions of opioids represent their single most serious adverse effect. Although significant adverse events related to opioid-induced respiratory depression are presumably preventable, they persist with a perioperative incidence of approximately 0.1 to 1 percent, no matter what the route of administration. [298] A review of the respiratory actions of opioids should also consider the potentially beneficial respiratory effects obtained by the use of opioids.

Therapeutic Effects

Pain and/or anxiety can induce excessive spontaneous ventilation resulting in respiratory alkalosis. Certain brain-stem diseases also induce hyperventilation. [299] [300] Opioids, by decreasing both pain and central ventilatory drive, are effective agents in such conditions. [299] [300] The lack of adequate

pain relief can also cause postoperative respiratory dysfunction. [301] Although large doses of opioids can impair ventilation and decrease pulmonary compliance (see the section on rigidity), opioid analgesic therapy can improve synchronous breathing and decrease voluntary muscle tone, resulting in improved dynamic total respiratory compliance in awake but mechanically ventilated patients in the intensive care unit. [302]

The antitussive actions of opioids are well known and central in origin. Curiously, fentanyl, sufentanil, and alfentanil elicit a brief cough in up to 50 percent of patients when injected by IV bolus. [303] A pulmonary chemoreflex, mediated by C-fiber receptors (also known as J receptors), may underlie this phenomenon. The cough reflex after opioid injection is not likely to be vagally mediated because atropine pretreatment does not effect it. [304] Opioids may elicit cough by stimulating irritant receptors in tracheal smooth muscle. Interestingly, pretreatment with inhaled beta-adrenergic agonists significantly reduces the incidence of cough associated with IV opioid injection. [304]

Opioids are also excellent agents for depressing upper airway, tracheal, and lower respiratory tract reflexes. The exact mechanisms underlying this clinical observation are not clear. Opioid receptors have been demonstrated in smooth muscles of the trachea and bronchi, as well as alveolar walls, but not in the small airways. [305] Alveolar wall receptors may be associated with J receptors, and the tracheal receptors may be prejunctional opioid receptors on C-afferent nerve fibers. It has been suggested that trachealis muscle contractile responses can be attenuated by kappa- and mu-opioid receptor agonists, [306] although other investigators suggest that opioids can cause constriction. The clinical significance and relevance of opioid-induced effects on airway resistance remain controversial. [307]

Opioids blunt or eliminate somatic and autonomic responses to tracheal intubation. Opioids allow patients to tolerate endotracheal tubes without coughing or "bucking," which when pronounced can lead to hypoxemia, hypercarbia, hemodynamic instability, and other deleterious effects. Impaired gas exchange results from the marked disturbance in ventilatory pattern as well as loss of lung volume that bucking produces. Thus, on emergence from general anesthesia, patients anesthetized with a potent inhalation agent and no opioid routinely cough and buck prior to regaining consciousness and responsiveness, whereas patients adequately treated with opioids can awaken without such disturbances, even while they are still tracheally intubated.

Opioids can also help to avoid increases in bronchomotor tone. Opioids have long been used in the treatment of acute asthma because of these actions. Opioids also relieve dyspnea and other symptoms of respiratory distress associated with conditions such as asthma and heart failure. Fentanyl also has antimuscarinic, antihistaminergic, and antiserotoninergic actions and may be more effective than morphine in patients with asthma or other bronchospastic diseases. [308] Opioids can blunt the pulmonary vasoconstrictive response to tracheobronchial stimulation that can occur with suctioning. [309]

Certain IV agents, including opioids, minimally alter pulmonary gas exchange. [310] The minimal impact of opioids on hypoxic pulmonary vasoconstriction [311] (in contrast to the potent inhalation agents), coupled with associated hemodynamic and bronchomotor stability, as well as the stability of tone, contributes to the minimal interference with pulmonary gas exchange observed after opioids and many other IV anesthetics. Opioids such as fentanyl also do not impair the lungs' ability to prevent venous air emboli from reach-ing the systemic arterial circulation as much as does halothane. [312]

Nontherapeutic Effects

Endogenous opioid peptides are widely distributed in brain-stem nuclei regulating respiration. [91] High concentrations of opiate receptors have been found in many of the supraspinal brain respiratory centers including the nucleus solitarius, nucleus retroambigualis, and nucleus ambiguus. [90] [313] Specific chemosensitive brain areas also mediate opioid-induced respiratory effects. [88] [91] Opioids interfere with pontine and medullary respiratory centers that regulate respiratory rhythmicity.

All mu-receptor stimulating opioids cause dose-dependent depression of respiration in humans [314] primarily through a direct action on brain-stem respiratory centers. [315] [316] Controversy persists as to whether different subclasses of mu- opioid receptors have disparate roles in opioid-induced respiratory depression. [317] How the various respiratory centers involved with ventilatory drive, respiratory rhythm generation, chemoreception, and neural integration are affected by opioids is also unclear. The stimulatory effect of CO_2 on ventilation is significantly reduced by opioids. Thus, the slopes of the ventilatory and occlusion pressure responses to CO_2 are decreased, and minute ventilatory responses to increases in Paco2 are shifted to the right (Fig. 10-12) . In addition, the apneic threshold and resting end-tidal P_{CO_2} are increased by opioids.

Opioids also decrease hypoxic ventilatory drive. [318] [319] In fact, carotid body chemoreception and hypoxic drive are

Figure 10-12 A graphic representation of the ventilatory response to progressive hypercapnia. In this illustration, the slope of line A is approximately 2 L min^{-1} $mm\ Hg^{-1}$, although a wide range of responses in humans exists. The slope of the ventilatory response to CO_2 is reduced to 1 and 0.5 in lines B and C, respectively. Lines B and C are also shifted to the right of line A. Lines B and C have the same intercept along the X axis, indicating no displacement or shift of line C compared with line B.

blunted or eliminated by low, analgesic doses of opioids. Opioids also blunt the increase in respiratory drive normally associated with increased loads such as increased airway resistance. [318]

Respiratory rate is usually drastically slowed in overt opioid overdose, although hypoxic CNS insult can counter this effect. Opioids can usually be titrated to effect, especially in anesthetized patients, by observing dose-dependent decreases in the spontaneous respiratory rate. However, respiratory rate, especially in the postoperative setting, cannot serve as a reliable index of the magnitude of opioid-induced respiratory depression. [9C] [320] High doses of opioids usually eliminate spontaneous respirations without necessarily producing unconsciousness. Patients receiving high doses of opioids may still be responsive to verbal command and often breathe when directed to do so.

Opioid-induced effects on the control of respiratory rhythm and pattern include increased respiratory pauses, delays in expiration, irregular and/or periodic breathing, and decreased, normal, or increased tidal volume. The prolonged expiratory time in the respiratory cycle induced by opioids frequently results in greater reductions in respiratory rate than in tidal volume. Fentanyl depresses respiratory drive, phase timing, and activation of respiratory muscles, whereas enflurane only decreases respiratory drive. [321]

Peak onset of respiratory depression after an analgesic dose of morphine is slower than after comparable doses of fentanyl: 30±15 minutes versus 5 to 10 minutes. [314] This effect is due in part to the lower lipid solubility of morphine. Because of its low lipid solubility, plasma concentrations and onset of action of morphine are nearly identical after IV and IM administration. [322] Thus, it could be argued that the selection of morphine as an IV analgesic is not the most ration-al choice for acute pain control in the immediate postoperative period.

Respiratory depression induced by small doses of morphine usually lasts longer than after equipotent doses of fentanyl. [323] Downes et al [324] found that IV fentanyl (100 and 200 mug
70 kg^{-1}). These investigators also noted a faster onset and peak effect after fentanyl than after meperidine. [324] Even though fentanyl has a shorter onset and quicker recovery than morphine and meperidine, small doses (2 mug
kg^{-1}) produce respiratory depression for longer than is generally appreciated (>1 h). Sufentanil (0.1-0.4 mug
kg^{-1}) produces shorter-lasting respiratory depression and longer-lasting analgesia than fentanyl (1.0-4.0 mug
kg^{-1}). [325]

Although fentanyl (4-8 mug
kg^{-1}) given during induction of anesthesia does not usually produce troublesome postoperative respiratory depression, some investigators have found significant residual respiratory depression 5 or more hours later. [326] [327] Recovery from the ventilatory effects of fentanyl closely parallels the decline of plasma levels (Ch 69). [259] Large or repeated doses, or continuous infusions, increase the time required for lower plasma levels (below the threshold for significant respiratory effects) to be established. Plasma fentanyl concentrations of 1.5 to 3.0 ng
mL^{-1} are usually associated with significant decreases in CO_2 responsiveness. [326]

As discussed earlier, with higher doses of fentanyl (50-100 mug
kg^{-1}), respiratory depression can persist for many hours. Indeed, ventilation may need to be assisted or supported for 6 to 18 hours after induction of anesthesia with large doses of fentanyl. [328] [329] When moderately large (20-50 mug
kg^{-1}) or greater doses of fentanyl are used, the potential need for postoperative mechanical ventilation should be anticipated.

Pharmacokinetic data predict, and studies have demonstrated, that both alfentanil and sufentanil allow more rapid recovery of respiratory function than fentanyl. [18] Alfentanil has more rapid receptor dissociation kinetics than other opioids, thus making respiratory depression less likely after it is employed in anesthesia. [330] Although adequate spontaneous ventilation after alfentanil-N_2O is likely with plasma alfentanil concentrations of less than 200 ng/mL, [331] significant residual respiratory depression can exist at lower levels. The effects of remifentanil, no matter what the dose, dissipate rapidly and completely within 5 to 15 minutes following termination of its administration. The pharmacodynamic effects of alfentanil, sufentanil, and remifentanil on respiratory function are not significantly different from those of fentanyl. High doses of morphine (and probably other opioids) decrease bronchiociliary motion. [332]

Factors Affecting Opioid-Induced Respiratory Depression

Many factors can change both the magnitude and duration of respiratory depression after opioid administration (Table 10-10) . Patients who are sleeping are usually more sensitive to the respiratory-depressant effects of opioids. [333] [334] Even small doses of opioids markedly potentiate the normal right shift of the Pa CO_2 -alveolar ventilation curve that occurs during natural non-rapid eye movement sleep. [333] [334] For several days postoperatively, sleep is associated with hypoxemia. [335] The mechanisms and implications of postoperative sleep disturbances are complex and relate not only to respiratory problems, but also to cognitive and hemodynamic disturbances. [336] Both sleep and morphine relatively spare the diaphragmatic, but decrease the thoracic (ribcage), component of breathing. [337] Sleep also impairs tonic and phasic upper airway muscle activity that accompanies breathing. [338] This can be troublesome when patients have an opioid-based anesthetic and an operation that results

TABLE 10-10 -- Factors Increasing the Magnitude and/or Duration of Opioid-Induced Respiratory Depression

Dose
Intermittent bolus (versus continuous infusion)
Brain penetration/drug delivery
Distribution (cardiac output)
Un-ionized fraction (respiratory alkalosis)
Reuptake from the brain (intraoperative respiratory alkalosis)
Clearance (hepatic blood flow, e.g., intra-abdominal surgery)
Secondary peaks in plasma opioid levels (reuptake of opioid from muscle, lung, fat, intestine)
Ionized opioid at receptor site (postoperative respiratory acidosis)
Sleep
Age
Metabolic alkalosis

in little or no postoperative pain. In such patients, apparently adequate breathing can become insufficient with the onset of sleep. In patients with conditions that impair abdominal breathing or airway function, such as patients with marked obesity or sleep apnea, an increased risk of adverse respiratory events is likely with the administration of opioid analgesia.

Older patients are more sensitive to the anesthetic [217] and respiratory-depressant effects of opioids. [1] Older patients experience higher plasma concentrations of opioids administered on a weight basis. [322] Although older patients tend to have a lower blood volume than younger patients, the precise reason for higher plasma concentrations after similar doses is unknown. Conflicting reports argue for or against differences in pharmacokinetics (decreased clearance, increased elimination half-life) and/or pharmacodynamics (increased brain sensitivity) as the basis for the presence or absence of agerelated increases in sensitivity to fentanyl. [136] [339] Older patients also have more frequent apnea, periodic breathing, and obstruction after morphine than young adults. [340]

Morphine alone produces greater respiratory depression on a weight basis in neonates than adults. Its low lipid solubility normally limits blood-brain barrier penetration. In neonates and infants with incomplete blood-brain barriers, morphine easily penetrates the brain. Neonates are not unduly sensitive to the more lipid-soluble opioids (meperidine, fentanyl, and sufentanil) because penetration of these drugs into the brain is not affected by blood-brain barrier maturity. [341] Endogenous opioid activity may also be increased in the neonate and possibly contributes to the depressed ventilatory response to hypoxia observed in such young individuals. Support for this hypothesis comes from studies demonstrating that naloxone shortens the apneic phase and stimulates the response to hypoxia in newborns but not in older infants. [91]

The respiratory-depressant effects of opioids are increased and/or prolonged when administered with other CNS depressants, including the potent inhaled anesthetics, [342] alcohol, [1] barbiturates, [1] benzodiazepines, [343] and most of the IV sedatives and hypnotics. Drug interactions and synergistic depression of the ventilatory response to hypercarbia and/or hypoxia can result in bradypnea or apnea. Exceptions are droperidol, scopolamine, and clonidine, which do not enhance the respiratory-depressant effects of fentanyl or other opioids. [324] [344] [345] [346] [347] Sedation and sleep may accompany alpha$_2$ -adrenergic agonists and possibly may explain some of their reported mild respiratory-depressant actions. [348]

Pain, particularly surgically induced pain, is thought to counteract the respiratory-depressant effects of opioids. However, the contrary has been suggested by some investigators. [301] [349] For example, certain postsurgical breathing patterns are not predominantly determined by the level or mode of pain relief. [350] Acute pain does not reverse the depression of the ventilatory response to hypoxemia that is produced by sedation with sevoflurane. [351] An investigation of the effect of experimental pain on ventilatory control suggests that pain causes a chemoreflex-independent increase in tonic ventilatory drive. [352]

It is interesting to note that although some acute tolerance to opioid-induced respiratory depression can develop, 5 to 8 months of opioid exposure may be necessary for significant tolerance to the respiratory-depressant actions of opioids on hypoxic ventilatory responses to develop. [90] Cross-tolerance to the respiratory-depressant actions of different opioids also may be neither complete nor predictable. [91] Infants of mothers receiving methadone maintenance demonstrate impaired central chemosensitivity to CO_2 . They may also be at higher than normal risk for sudden infant death syndrome.

Although opioid action is usually dissipated via redistribution and hepatic metabolism, rather than by urinary excretion (see the section on pharmacokinetics), adequacy of renal function may influence the duration of opioid activity. It was previously thought that in renal insufficiency, the more potent respiratory-depressant properties of the morphine metabolite morphine-6-glucuronide (M6G) would become evident as it accumulated. [353] However, one study indicates that M6G is a somewhat weaker respiratory depressant than morphine. [354] Nevertheless, morphine or meperidine and/or some of their metabolites can accumulate in patients with renal insufficiency and may result in greater respiratory depression (see later).

Hypocapnic hyperventilation has been shown to enhance and prolong postoperative respiratory depression after fentanyl (10 and 25 mug kg^{-1}). [326] Intraoperative hypercarbia produces the opposite effects. [355] Possible explanations for these findings include increased brain opioid penetration (increased un-ionized fentanyl with hypocarbia) and removal (decreased CBF with hypocarbia). Decreased liver clearance related to decreased cardiac output and hepatic blood flow may also explain this phenomenon. In addition, intraoperative hyperventilation depletes CO_2 stores and can result in a posthyperventilation hypoventilation syndrome. Following hyperventilation, CO_2 stores are repleted. This process removes CO_2 from the blood and lowers minute ventilatory requirements, resulting in hypoventilation. In this circumstance, a normal Pa $_{CO_2}$ does not necessarily indicate normal or adequate minute ventilatory volumes. In patients who hyperventilate because of anxiety and/or pain, even small doses of IV opioids can result in transient apnea because of acute shifts in apneic thresholds.

Some authors suggest that the administration of opioids in anesthesia leads to increased respiratory problems. [356] [357] However, most of the studies performed to date have failed to isolate perioperative opioid administration as particularly associated with increased respiratory problems [358] Although Beard et al [356] found an increase in adverse respiratory events in the recovery room associated with the use of muscle relaxants and fentanyl, the frequency of a serious problem with fentanyl was rare (1/886 patients). In another study, patients receiving IV morphine for postoperative pain after general anesthesia experienced more respiratory side effects than those who received regional anesthesia. Interestingly, desaturations of significance were always associated with sleep and were related to obstruction, paradoxic breathing, or slow respiratory rates. [359] The analgesic dose of morphine used in the latter study was large (>12 mg $70\ kg^{-1}$ IM).

Recurrence of Respiratory Depression

Delayed or recurring respiratory depression has been reported with most opioids including fentanyl, [344] [360] morphine, [361] meperidine, [362] alfentanil, [363] and sufentanil, [364] [365]

but not remifentanil. Explanations for this phenomenon are not clear and are confounded by the simultaneous occurrence of a variety of clinical events. These include stimulation and pain or their absence, the concomitant administration of different supplemental analgesics and other medications, sleep, level of activity, hypothermia, and hemodynamic alterations. For example, even small doses of benzodiazepines given prior to induction of anesthesia can increase postoperative respiratory problems after balanced anesthesia with an opioid.

Numerous investigators have also noted the occurrence of significant secondary peaks and fluctuations in plasma opioid levels during the elimination phase. [366] [367] The existence of large peripheral compartments (e.g., skeletal muscle) and the variability in drug uptake from them contributes to and can augment this phenomenon. Some investigators have shown secondary peaks in plasma fentanyl levels with parallel changes in CO_2 sensitivity and breathing (Fig. 10-13) (Figure Not Available) . [368] [369] Interestingly, McQuay et al [369] found a higher incidence of second peaks in plasma fentanyl levels (increases of $0.5\ ng/mL^{-1}$) with an infusion technique than after intermittent boluses.

The stomach can sequester up to 20 percent of an IV dose of fentanyl via ion trapping in its acid milieu. It has been postulated that subsequent passage of stomach contents into the alkaline medium of the small intestine leads to reabsorption of significant amounts of fentanyl and results in secondary peaks in fentanyl plasma concentrations and recurrent respiratory depression. This mechanism appears unlikely in view of the high hepatic extraction ratios for fentanyl and most opioids. [370] Other mechanisms for renarcotization include augmented release of fentanyl or other opioids from skeletal muscle into the systemic circulation on rewarming, shivering, motion, or any other condition that enhances muscle perfusion. Plasma fentanyl and probably other opioid levels can also increase significantly on the release of a thigh tourniquet. [371] The pharmacologic management

Figure 10-13 (Figure Not Available) The top panel depicts fentanyl plasma concentrations over time, and the bottom panel depicts the slope of the ventilatory response to CO_2 as a percentage of control over time. Note the second peak in plasma fentanyl concentrations and the corresponding second decrease in the slope of the ventilatory response to CO_2 . *(From Stoeckel et al [366])*

of troublesome respiratory depression is addressed later (see the section on naloxone).

PHARMACODYNAMICS: CARDIOVASCULAR ACTIONS

Opioids are administered not only to provide analgesia, but also to produce or promote stable hemodynamics both in the presence and the absence of noxious stimuli (Ch. 29) . Potent inhaled agents can only suppress hemodynamic responses to noxious stimuli if prestimulation blood pressures are depressed to a point that may be clinically unacceptable. [372] Numerous reports have demonstrated that large doses of opioids, administered as the sole or primary anesthetic, do result in hemodynamic stability throughout the operative period. Other investigators claim the opposite, and the issue remains a matter of debate that is unlikely to be fully resolved.

Many factors can alter the hemodynamic profile achieved during anesthetic induction, tracheal intubation, and surgery, including (1) the degree of beta-adrenergic and/or Ca^{2+} channel blockade, (2) preoperative ventricular function, (3) volume status, (4) patient habits, (5) the administration and type of premedication, and (6) the presence or absence of awareness. [129] [329] [373] [374] [375] [376] In addition, the choice of opioid can have an impact. For example, although some investigators find little difference between fentanyl and sufentanil as primary anesthetics for cardiac surgery, [377] [378] others believe that sufentanil provides better control of intraoperative hemodynamics. [376] [379] [380] [381] [382] [383] Sufentanil also decreases the need for vasodilators during cardiopulmonary bypass (CPB), the post-bypass period, and postoperatively. [376] [384] Although sufentanil alone is probably more effective than equipotent doses of fentanyl, its use does not guarantee complete control of intraoperative blood pressure. [99] [385]

Alfentanil is less reliable than fentanyl and sufentanil in blocking increases in heart rate and blood pressure during anesthetic induction, sternotomy, sternal spread, and aortotomy in patients with ischemic heart disease who undergo coronary artery surgery. [386] [387] [388] Cardiovascular stimulation can occur during and after anesthetic induction with alfentanil. [114] A higher incidence of ischemia during alfentanil anesthesia than with comparable doses of fentanyl or sufentanil has also been reported. [379] The following descriptions summarize the modes and sites of action that underlie the cardiovascular effects of opioids.

Neurologic Mechanisms

The anatomy of opioid receptor distribution within the neuraxis and the widespread association between opioid receptors and cardiovascular and autonomic regulatory areas within the CNS define much of the pharmacophysiologic basis for opioid-induced hemodynamic effects. Endogenous opioid peptides also are associated with the sympathetic and parasympathetic nervous systems, particularly in areas of the brain stem involved in the control of cardiovascular function. [73]

Key areas of the brain stem that integrate cardiovascular responses and maintain cardiovascular homeostasis are the

nucleus solitarius, the dorsal vagal nucleus, the nucleus ambiguus, and the parabrachial nucleus. The nucleus solitarius is the primary central synapse for baroreceptor-mediated reflexes and is an important relay station for peripheral information destined for hypothalamic sympathetic control centers. The nucleus solitarius also projects directly to the intermediolateral nucleus in the spinal cord, the common pathway for preganglionic sympathetic outflow. The nucleus solitarius and parabrachial nucleus play an important role in the hemodynamic control of vasopressin secretion. [389] The nucleus solitarius, dorsal vagal nucleus, nucleus ambiguus, and parabrachial nucleus all have enkephalin-containing neurons and high concentrations of opioid receptors. mu- Opioid receptors dominate in areas such as the nucleus solitarius. The direct administration of mu-agonists into the CNS of animals most commonly, but not always, produces hypotension and bradycardia. [73] [390]

The ventrolateral periaqueductal gray region, a key central site mediating analgesia, also affects hemodynamic control. Different opiate receptor subtypes occupy this site. Direct injection of mu-agonists elicits hypertension and tachycardia in the rat, whereas delta- or kappa-agonists have the opposite or no effect. [391] In addition, activation of mu-opioid receptors suppresses somatosympathetic reflexes transmitted by unmyelinated C-afferent fibers at the level of the spinal cord and modulates them at the brain stem. [392] These actions contribute to the anesthetic capabilities of opioids.

Opioids also can modulate the stress response through receptor-mediated actions on the hypothalamic-pituitary-adrenal axis (see later). Most opioids reduce sympathetic and enhance vagal and parasympathetic tone. If not countered by indirect effects (e.g., catecholamine release) or the coadministration of drugs with anticholinergic or sympa-thomimetic activity (e.g., atropine, ephedrine, or pancuronium), opioids can result in hypotension. Patients who are volume depleted, or individuals depending on high sympathetic tone or exogenous catecholamines to maintain cardiovascular function, are predisposed to hypotension after opioid administration.

Ablation of sympathetic tone can occur after all the modern opioids. Flacke et al [393] have postulated that cardiovascular depression after fentanyl is due to inhibition of central sympathetic outflow that is apart from analgesia or other sensory-depressant effects of the opioid. These investigators found that naloxone reversal of fentanyl-induced cardiovascular depression is blocked by clonidine, an alpha $_2$ -agonist. After eliminating all autonomic tone in dogs, Flacke et al [394] found minimal hemodynamic changes after fentanyl or fentanyl plus large doses of diazepam. They concluded that hypotension induced by fentanyl was indirect, that is, mediated by a decrease in CNS sympathetic vasoregulatory outflow.

Occasionally, opioids produce paradoxic effects. Thomson et al [395] reported the occurrence of a hyperdynamic cardiovascular response to anesthetic induction with high-dose fentanyl in 10 percent of patients and attributed it to central sympathetic activation. Fentanyl increases norepinephrine release from some sympathetic nerve endings, and it may also inhibit its neuronal uptake in dogs.

The predominant and usual effect of opioids on heart rate is to produce bradycardia resulting from stimulation of the central vagal nucleus. [396] [397] [398] Opioid-induced bradycardia is almost totally prevented by bilateral vagotomy or vagal block with atropine. [399] Blockade of sympathetic chronotropic actions may also play a role in opioid-induced bradycardia. [396] In addition, many, even minor, nasal or maxillofacial or other stimuli can also induce or exacerbate bradyarrhythmias via parasympathetic reflexes. [400] [401] Meperidine, in contrast to other opioids, rarely results in bradycardia, but it can cause tachycardia. [402] Tachycardia after meperidine may be related to its structural similarity to atropine, to normeperidine, its principal metabolite, or to early manifestations of its toxic CNS effects.

Cardiac Mechanisms

The direct cardiac actions of opioids, and in particular the effects on myocardial contractile mechanisms, are significantly less than those of many other IV and inhalation anesthetics. Opioid receptors have been demonstrated to exist in cardiac myocytes of several species. Preliminary investigations of the direct effects of opioids on myocytes report complex and conflicting results. For example, Ela et al [403] found that morphine acts by two different pathways in cultured cardiac myocytes, causing both an increase in Ca^{2+} transients and a decrease in myocyte responsiveness to Ca^{2+} .

Contractility

The state of myocardial contractility has an impact on the efficacy of opioids as anesthetics. For example, Wynands et al [404] showed that patients with good left ventricular function become hypertensive more frequently than patients with poor left ventricular function during fentanyl anesthesia for coronary artery surgery. Patients with good myocardial function could increase cardiac index in response to increases in systemic vascular resistance induced by surgical stimuli. Patients with limited myocardial reserve could not always maintain cardiac output in the face of increased systemic vascular resistance. Their blood pressure did not increase and at times decreased.

Some investigators suggest that opioids produce direct positive inotropic effects on the heart. [405] Others report negative inotropic actions with some agents (meperidine) and no direct effects with others (morphine). [406] Vasko and coworkers [407] found that morphine has a significant positive inotropic effect that is dependent on endogenous catecholamine release in dogs. Meperidine has been reported to produce decreases, [408] increases [406] or mixed effects on myocardial contractility in isolated cardiac preparations and intact animals. The ability of meperidine to produce positive inotropic actions may be related to class III antiarrhythmic properties or the mediation of increased intracellular Na^{+} activity via actions on the Na-K pump. [406] However, Strauer [408] found equianalgesic doses of meperidine 20 times more depressant to the contractile element of the isolated cat papillary muscle than morphine. Some investigators suggest that local anesthetic-like effects, and not receptor-related opioid actions, mediate some of the negative inotropic effects of opioids, especially with high drug concentrations. [409] This suggestion is consistent with the greater local anesthetic-like action of meperidine compared with other opioids.

Most evidence indicates that fentanyl produces little or no change in myocardial contractility. [9] [328] [380] [381] Other investigators

have reported negative inotropic effects, [410] [411] [412] [413] positive inotropic effects, [409] or myocardial depression-sparing actions of fentanyl during halothane and enflurane anesthesia. [414] [415] Possible mechanisms of the dose-dependent positive inotropic effects of fentanyl, as well as sufentanil, include catecholamine release or direct myocardial adrenergic activation. Usually, most hemodynamic variables, including heart rate, arterial blood pressure, cardiac output, systemic and pulmonary vascular resistance, and pulmonary artery occlusion or wedge pressure, remain unchanged after large doses of fentanyl. [9] [328] [380] [381] [404] [411] [412] [416]

Miller et al [379] compared anesthetic induction with fentanyl (75 mug kg^{-1}), sufentanil (15 mug kg^{-1}), and alfentanil (125 mug kg^{-1} followed by 5 mug kg^{-1} min^{-1}) in patients premedicated with lorazepam scheduled for coronary artery surgery. Anesthetic induction with fentanyl was associated with the least change in mean arterial pressure and myocardial performance. Although sufentanil did not produce hemodynamic instability, it did cause myocardial depression (Figs. 10-14 (Figure Not Available) , 10-15) (Figure Not Available) . Mild to no depression of cardiac index and pump function has been reported after sufentanil in humans. [380] [381] [385]

Studies in dogs have demonstrated little change in hemodynamics with moderate doses (160 mug kg^{-1}) of alfentanil and transient cardiac stimulation (increases in left ventricular contractility, aortic blood flow velocity, and acceleration) with very large doses (5 mg kg^{-1}). [243] Heart rate, cardiac output, and pulmonary and systemic vascular resistance increased following 5 mg kg^{-1} of alfentanil. Other investigators have reported increases in myocardial contractility, mean aortic, pulmonary artery, left and right atrial pressures, and systemic vascular resistance with lower doses (200 mug kg^{-1}) of alfentanil in dogs. [417] [418] Alfentanil also has direct positive inotropic effects in the rabbit. [405] Some authors have found that alfentanil causes similar decreases in heart rate, blood pressure, and cardiac index as fentanyl, [419] [420] whereas others have reported that alfentanil produces the least desirable hemodynamic profile (more hypotension as well as myocardial ischemia) compared with fentanyl and sufentanil in patients undergoing coronary artery grafting. [379] [413] [421] [422] [423] In dogs, remifentanil produces hemodynamic effects that include decreases in contractility and cardiac output, as well as in heart rate and blood pressure. [424]

Heart Rate and Rhythm

Central neurally mediated mechanisms are the primary mechanism of opioid-induced bradycardia (see earlier). Morphine also has a direct effect on the sinoatrial node [425] [426] and atrioventricular conduction. [427] Asystole may follow opioid-induced bradycardia, and several case reports illustrate predisposing factors (Table 10-11) . [428] [429] [430] [431] [432] Sufentanil and alfentanil appear to be more likely than fentanyl to result in asystole. [379] Premedication with, or concomitant administration of, beta-adrenergic or Ca^{2+} entry blockers can exacerbate bradycardias and may result in asystole after sufentanil. [433] Severe bradycardia and asystole often appear prior to or during laryngoscopy and intubation. Laryngoscopy can relieve or exacerbate bradyarrhythmias or asystole. Periods of asystole, 10 to 12 seconds in duration, may resolve on their own, but they usually respond to atropine (0.4-0.8 mg IV). On occasion, much larger doses of atropine (>1.0 mg), isoproterenol, or a precordial thump may be required to treat severe bradycardia/asystole.

Cardiac Conduction

Opioids may depress cardiac conduction. Fentanyl slows atrioventricular node conduction and prolongs the RR interval, the atrioventricular node refractory period, and Pur-kinje fiber action potential duration. [434] [435] Sufentanil also prolongs action potential duration in isolated canine cardiac

Figure 10-14 (Figure Not Available) Graphic display of the changes in mean arterial pressure (MAP) (A) and heart rate (HR) (B) after anesthetic induction (IND) with sufentanil, fentanyl, and alfentanil. Baseline (BL) and preinduction (PRE) hemodynamics, as well as responses to intubation (INT) and volume loading (VL_1 , VL_2) are also shown for each drug. *(From Miller et al [379])*

Figure 10-15 (Figure Not Available) Systolic function after anesthetic induction with sufentanil, fentanyl, and alfentanil and in response to volume loading (VL). Systolic function, described by the relationship between systolic blood pressure (SBP) and end-systolic volume index (ESVI), was significantly more depressed with sufentanil when compared with alfentanil and fentanyl. *(From Miller et al [379])*

Purkinje fibers. This effect may be related to enhanced Ca^{2+} entry during the plateau phase of the action potential or depression of the outward K^{+} current during terminal repolarization. [436] These effects have been suggested to be mediated via direct membrane actions, as opposed to opioid receptor interactions. [434] [435] [437]

Opioids can also prolong the QT interval. The risk of opioid use in patients with QT abnormalities or taking medications such as quinidine is unknown. [438] However, both sufentanil and alfentanil have been demonstrated to be devoid of electrophysiologic effects on the normal or accessory pathways in patients with Wolff-Parkinson-White syndrome. [439] [440]

Clinically, cardiac conduction disturbances due to opioids are very rare, but they may be more likely to occur in the presence of Ca^{2+} entry or beta-adrenergic blockers. [433] Although the effects of opioids on cardiac conduction could

TABLE 10-11 -- Factors Predisposing Patients to Bradycardia and Asystole During Induction of Anesthesia with Opioids

Presence of beta-adrenergic and/or calcium entry blockade

Muscle relaxants with vagotonic properties (e.g., succinylcholine)
Added vagal stimuli (e.g., laryngoscopy)
Rapid administration of the opioid

theoretically lead to the development of reentry-type dysrhythmias, in practice this rarely occurs. Indeed, the overall effect of opioid anesthesia is antiarrhythmic. [441] [442] Antifi-brillatory effects have been suggested to be produced by fentanyl. [442] [443]

Opioid antagonists (delta and kappa) appear more antiarrhythmogenic than agonists in rats. [444] Although doses of epinephrine sufficient to induce dysrhythmias in dogs are the same during balanced anesthesia with opioids versus halothane or enflurane plus N_2O, the incidence of malignant dysrhythmias (ventricular tachycardia and ventricular fibrillation) is lower with opioids plus N_2O. [436] Studies in humans also demonstrate a lower incidence of severe ventricular dysrhythmias in patients receiving fentanyl versus halothane anesthesia. [445] Some of the electrophysiologic actions of opioids resemble those of class III antiarrhythmic compounds and may underlie the antiarrhythmogenic potential of opioids.

Ischemia

Determining the effects and consequences of opioid action on myocardial ischemia is complex. Results can depend on such factors as the species studied and experimental design. For example, compared with isoflurane, fentanyl anesthesia allows better preservation of myocardial function in a ventricular region subjected to experimental ischemia. [446] During myocardial ischemia in dogs, fentanyl, compared with halothane, also allows better functional compensation in nonischemic left ventricular walls. [447] On the other hand, functional recovery of the stunned myocardium is greater in dogs anesthetized with halothane, compared with fentanyl. [448] Opioids have been found not to protect against ischemia in animal models by some investigators. [449] [450]

Most recently, it has been suggested that opioids can mimic ischemic preconditioning. Schultz et al [451] demonstrated that opioid receptor stimulation results in a reduction in infarct size similar to that produced by ischemic preconditioning. It appears that this phenomenon may be delta-opioid receptor mediated. It also has been reported that the maintenance of intense analgesia into the postoperative period with sufentanil can reduce myocardial ischemia following coronary artery surgery. [20] Further studies are required to better our understanding of the role of exogenously administered opioids, as well as endogenous opioid systems, in myocardial ischemia.

High doses of opioids can maintain myocardial perfusion and the O_2 supply/demand ratio as well as or better than inhalation-based techniques. [452] [453] Helman et al [452] found hemodynamic instability and myocardial ischemia to be more frequent during induction of anesthesia with desflurane compared with sufentanil. Other studies suggest that fentanyl and sufentanil do not provide adequate hemodynamic control in humans during coronary artery surgery, [454] when compared with a potent inhalation agent. [455] [456]

Among the opioids, alfentanil is associated with more myocardial ischemia (as indicated by reversal of myocardial lactate extraction to production and worsening ventricular dia-stolic compliance) than fentanyl or sufentanil in patients having coronary artery surgery. [379] Interestingly, hemodynamic conditions do not reliably indicate ischemia. Kleinman

et al [457] reported that hemodynamic changes were most often absent during ischemia in patients anesthetized with either fentanyl or halothane. Data from a prospective randomized comparison of sufentanil versus enflurane, isoflurane, and halothane for coronary artery surgery revealed no difference in new intraoperative ischemia, the incidence of postoperative myocardial infarction, or death. [22] These results occurred in spite of a greater (2-fold) incidence of hypotension associated with the inhalation agent techniques and a greater (2-fold) incidence of hypertension associated with sufentanil. Tachycardia, the only hemodynamic parameter significantly related to ischemia, occurred with the same frequency with all agents.

Coronary Circulation

Opioids appear to have no significant effect on coronary vasomotion or myocardial metabolism, they do not produce steal phenomena, and they do not diminish the ability of large coronary arteries or coronary arterioles to respond to vasoactive agents. [458] [459] In the dog, although coronary blood flow and myocardial O_2 consumption are reduced by fentanyl, the delivery and use of O_2 remain commensurate with demands of the heart. Regional blood flow distribution ratios also are not altered, and myocardial tissue perfusion is not compromised. [460] Direct intracoronary fentanyl has no effect on left ventricular mechanoenergetics in the dog. [461]

In a study of the effects of opioids and neuroendocrine modulators on porcine coronary arteries, fentanyl, but neither sufentanil nor morphine, antagonized acetylcholineinduced contractions. [462] In this study, none of these opioids affected histamine-induced contractions. The effects of fentanyl were not reversible by naloxone and were thus thought to represent a direct smooth muscle effect. Another report documents that, in humans, fentanyl anesthesia slows the rate of change in coronary vascular resistance induced by pacing. [463] Conclusions regarding the relevance and significance of this finding were limited by the lack of comparative studies. Although the potent inhalation agents do produce coronary artery dilatation, even patients with steal-prone anatomy do not appear to experience more ischemia when anesthetized with isoflurane, halothane, or enflurane versus sufentanil. [464]

Baroreception

Low-pressure baroreceptors at the junction of the great vessels and atria are sensitive to decreases in filling pressure. Stimulation of baroreceptors causes reflex increases in systemic vascular resistance in order to maintain arterial blood pressure. Potent opioids applied in anesthesia usually produce minimal to no decreases in preload and after-load, [9] [385] [465] and little depression of great vessel and atrial baroreceptors, whereas potent inhalation agents such as halothane do. [466]

Opioids may depress arterial baroreflex control of the heart rate induced by hypotension or hypertension, [467] but other reports suggest that this reflex is preserved under opioid anesthesia. [468] Infants, after receiving 10 mug kg^{-1} of fentanyl, do demonstrate significant depression of baroreflex responses. [469] This finding is significant because of the relationship between heart rate and cardiac output, especially in infants.

Cardiogenic Reflex

Some authors have suggested that aortic root dissection causes hypertension via stimulation of a specific cardiogenic reflex. [470] This cardiogenic hypertensive reflex is elicited by serotonin and causes powerful positive inotropic, chronotropic, and dromotropic responses that are neurally mediated. [471] In humans, this reflex may underlie new hypertension during myocardial ischemia, infarct, or surgery. Chemoreceptors between the aorta and the pulmonary artery are the source of the reflex. Many authors have found, for example, that aortic root manipulation is the most provocative stimulus for intraoperative hypertension. Corroborating the role of this reflex is the finding that hypertension after aortic root dissection is not associated with increases in plasma catecholamine concentrations or light levels of anesthesia. [419] Although higher doses of fentanyl or sufentanil can decrease the occurrence of intraoperative hypertension, no dose of any opioid has been shown to prevent all hypertensive responses reliably, especially during cardiac surgery in humans. [99]

Hormonal Mechanisms

Morphine (1-3 mg kg^{-1}) causes histamine release and sympathoadrenal activation. [472] The release of catecholamines by morphine and meperidine follows and parallels histamine release, which can be marked in some patients. [473] [474] Hasbrouck [475] administered up to 595 mg of morphine to patients and documented significant increases in plasma epinephrine and norepinephrine. Increases in blood and urine catecholamine concentrations after morphine are also dose-dependent. [476] [477]

Evaluations of the effects of opioids on histamine release from basophils and mast cells reveal a spectrum of differing effects depending on the cell, its tissue of

origin, and the opioid tested. [478] Increases in plasma histamine after morphine also cause dilatation of terminal arterioles. Histamine can produce direct positive cardiac chronotropic and inotropic actions that are receptor mediated. Stimulation of the renin-angiotensin mechanism also occurs after large doses of morphine. [479]

Hormonal alterations contribute to the cardiovascular changes seen after morphine and include an increase in cardiac index and a decrease in arterial blood pressure and systemic vascular resistance. [480] Increases in sympathetic activity could be detrimental in some patients. Moffitt et al [481] showed that 1 mg kg^{-1} of morphine does not inhibit cardiac lactate production and can produce ischemia with surgical stimulation in patients undergoing coronary artery bypass operations.

Cardiovascular changes after morphine are similar when patients are pretreated with diphenhydramine (a histamine H_1 -antagonist) or cimetidine (a histamine H_2 -antagonist). However, in patients pretreated with both H_1 - and H_2 - antagonists, the cardiovascular responses are significantly attenuated

despite comparable increases in plasma histamine concentrations.

Meperidine also causes histamine release more frequently than most other opioids, including morphine, fentanyl, sufentanil, and alfentanil. Flacke et al [474] found that 5 of 16 patients experienced increased plasma histamine concentrations after meperidine, whereas only 1 of 10 patients receiving morphine had similar changes. Increases in plasma histamine occur most often in females and are highly correlated to the magnitude of subsequent hypotension. [474] Unlike morphine or meperidine, fentanyl, sufentanil, alfentanil, and remifentanil do not produce increases in plasma histamine, and hypotension is less frequent with these opioids.

Although large doses of fentanyl produce significant increases in plasma catecholamines in dogs, [482] large doses of fentanyl (24-75 mug kg^{-1}) decrease rather than increase plasma catecholamine and cortisol concentrations in humans. [483] The effect of fentanyl on plasma catecholamines may be dose-dependent. Hicks et al [410] noted elevated plasma norepinephrine levels after 15 mug kg^{-1} of fentanyl, but normal (baseline) values after 50 mug kg^{-1} in human subjects. Similarly, anesthetic doses of sufentanil usually do not change circulating catecholamine concentrations.

Opioids also may have direct effects on adrenal secretory mechanisms. Met-enkephalin, for example, can be found in the adrenal medulla. Gaumann et al [484] have reported that sufentanil produced 6- to 20-fold increases in adrenal vein concentrations of catecholamines and parallel increases in arterial blood pressures in cats. Interestingly, sufentanil and the accompanying increase in catecholamine levels prevented the hypotension that normally occurred in these animals after a 25 percent loss of blood volume. Thus, although mu-opioid agonists do modulate the adrenal secretory response to pain, the adrenal secretory response to hemorrhage is preserved after sufentanil administration. [484] This may be of clinical benefit when patients hemorrhage, but it also underlies, in part, the inability of opioids to suppress completely some sympathetic responses to major surgical stimuli. [378] [485]

Vascular Mechanisms

Investigations of the effects of opioids on vascular tone in isolated vessels have yielded varying results, depending on such factors as the species studied, the vascular bed examined, and the opioid and particular dose evaluated. [486] Zelis and coworkers [487] found that morphine selectively impairs certain sympathetic reflexes involving peripheral veins. Their data suggest that this response is due to a CNS action of the drug with secondary withdrawal of sympathetic tone. Vasodilation after morphine may also result from a direct effect of morphine on vascular smooth muscle. [488] At high doses, morphine inhibits the presynaptic release of norepinephrine in saphenous vein rings and results in a decreased contractile response to electrical stimulation. [489] This effect is not reversed by naloxone or attenuated by histamine blockers.

Sufentanil can directly relax vascular smooth muscle. [490] Vascular studies evaluating alfentanil, fentanyl, and sufentanil in the dog demonstrate similar direct peripheral vessel smooth muscle relaxation. [491] In the rat aorta, mu-opioid receptor stimulation may modulate norepinephrine-induced responses at low doses, and it may have a direct contractile effect at higher doses. [486] During fentanyl anesthesia, alpha $_1$ -adrenergic responsiveness to phenylephrine is better in patients with good left ventricular function, compared with those with poor left ventricular function. [492]

PHARMACODYNAMICS: HORMONAL RESPONSE

There was considerable interest in the past in the pharmacologic modification of hormonal and metabolic indexes of the stress response to surgical trauma. [493] [494] The term "stress response" has been used extensively to describe the total physiologic process that occurs when patients encounter a significant insult. [495] [496] [497] The main components of the neuroendocrine stress response are the corticotropinreleasing hormone brain centers (e.g., paraventricular hypothalamic nucleus) and the locus caeruleus-norepinephrine/autonomic nervous system. [494] Despite great variability in stimuli, the body's response to an insult has common denominators. These include the release of trophic hormones from the hypothalamus that stimulate the pituitary to release ACTH, growth hormone (GH), renin, prolactin, endorphins, and antidiuretic hormone (ADH). Catabolic hormones including cortisol, catecholamines, glucagon, and thyroxine are also secreted in increased amounts, and plasma concentrations of anabolic hormones such as insulin and testosterone are usually decreased. [497] Plasma concentrations of stress hormones increase during general anesthesia and surgery, often in proportion to the severity of the operative trauma. [483] [498] [499] Increased levels of stress hormones are considered undesirable because they promote hemodynamic instability and intraoperative and postoperative metabolic catabolism. In some circumstances, hormonal and metabolic responses to surgery are extreme and are thought to contribute to operative mortality. [500]

It is thought that there is normal tonic inhibition of specific components of the hypothalamic-pituitary part of the stress response axis by endogenous opioids. Although inhalation anesthetics, in general, do not suppress the stress response, [493] and opioids, to a certain degree, can, it is likely that combinations of different anesthetic agents and techniques provide the best control.

Opioids are capable of reducing the stress response by modulating nociception at several different levels of the neuraxis (see earlier), as well as by influencing centrally mediated neuroendocrine responses. [501] Opioids are potent inhibitors of the pituitary-adrenal axis. [502] Endogenous opioid peptides may serve as stress hormones themselves and not just as modulators of other hormone secretion. This activity is suggested by the finding that beta-endorphin and ACTH are cosynthesized and cosecreted during stress and are in fact derived from the same precursor pro-opiomelanocortin. [503] Different hypothalamic opiate receptors can be stimulated by morphine and may alter hormone secretion. [504] Hall et al [505] believe that the inhibitory effect of fentanyl on surgically induced pituitary hormone secretion is mediated via the hypothalamus. Additionally, there is evidence that distinct

opiate receptors selectively act to impede pain signals arising from different forms of injury. [506] [507]

Morphine

Morphine modifies hormonal responses to surgical trauma in a dose-related fashion. [508] Morphine can prevent ACTH release, suppress surgically induced increases in plasma cortisol, and attenuate the pituitary-adrenal response to surgical stress. [508] [509] Large doses of morphine (4 mg kg^{-1}) can prevent increases in plasma concentrations of cortisol and GH in the pre-bypass period, but not during or after CPB. [508] [510]

Morphine can increase some stress-responding hormones due to increases in plasma histamine release, adrenal medullary release mechanisms, [511] [512] and catecholamine release from sympathetic nerve endings. [513] Morphine increases concentrations of catecholamines in both blood and urine in patients undergoing cardiac valve surgery. [476] Plasma ADH concentrations rise significantly during morphine (1 mg kg^{-1}) plus N_2O anesthesia in humans during surgery before CPB and increase further during bypass. [514] Plasma renin activity also increases markedly in patients anesthetized with morphine (1-3 mg kg^{-1}) and N_2O during cardiac surgery. [479]

Fentanyl

Fentanyl and its congeners are more effective than morphine in modifying hormonal responses to surgery. Fentanyl can abolish the hyperglycemic response to surgery and may reduce cortisol and GH responses better than halothane. [515] [516] The efficacy of fentanyl in controlling the hormonal manifestations of the stress response can be dose-dependent. [517]

Fentanyl, in doses of at least 50 mug kg^{-1}, prevents increases in blood glucose, plasma catecholamine, ADH, renin, aldosterone, cortisol, and GH concentrations before, but not consistently during or after, CPB, even in the presence of maintained opioid blood levels. [483] [518] [519] [520] Fentanyl can stimulate the secretion of some hormones including atrial natriuretic peptide.

In preterm infants undergoing cardiac surgery, fentanyl-N_2O-curare anesthesia is more effective than N_2O-curare anesthesia in suppressing hormonal responses to surgery and postoperative protein breakdown and in decreasing circulatory and metabolic complications. [521] Fentanyl doses greater than or equal to 50 mug/kg can help to reduce the hyperglycemic response to cardiac surgery in pediatric patients to less than 200 mg/dL throughout operation. [522]

Sufentanil

Sufentanil may be superior to fentanyl in modifying the stress response. [383] [523] Sufentanil can eliminate most, if not all, significant hormonal stress responses prior to CPB. [496] [524] However, it has been demonstrated that neither fentanyl nor sufentanil alone can completely block sympathetic and hormonal stress responses and that perhaps no dose-response relationship exists for opioid-associated stress response control. [99] [378] The stress response to CPB is difficult to suppress with sufentanil, as with fentanyl, anesthesia. [496] [524]

Alfentanil

Alfentanil can cause hormone-modifying effects similar to those of sufentanil. [524] Alfentanil (30 mug/kg IV), combined with thiopental (4 mg/kg IV), produces maximal suppression of the catecholamine response to tracheal intubation. [525] Alfentanil (20 mug/kg IV), combined with propofol (2.5 mg/kg IV), effectively blunts the hemodynamic effect, but not the efferent sympathetic nerve activity, associated with rapid increases in the inspired concentration of desflurane. [485] Alfentanil can suppress increases in plasma cortisol and catecholamines before but not during CPB and may prevent increases in ADH and GH throughout coronary artery bypass surgery. [523] Acute hypertensive responses and neuroendocrine responses to surgical stimulation are more effectively suppressed with alfentanil compared with isoflurane or trimethaphan during balanced anesthesia. [526] High-dose alfentanil-N_2O anesthesia (150-mug/kg loading dose plus 3-mug/kg/min infusion) better

suppresses intraoperative cortisol and glucose elevation than droperidol-fentanyl-N_2O anesthesia in patients undergoing abdominal surgery. [527]

Stress Reduction and Outcome

Increases in metabolism and substrate mobilization are part of the stress response. Such responses may be deleterious, especially in very ill patients undergoing major procedures. Increases in plasma catecholamine concentrations may increase cardiac risk, and increases in protein catabolism may delay recovery. Some evidence suggests that anesthetic techniques or agents that minimize this stress response may reduce morbidity and mortality in a variety of circumstances. [19] [20] [528] [529]

Sufentanil appears to be the most likely opioid to modify stress responses and outcome successfully. [19] [20] [529] Other investigators suggest that neither the opioid administered nor the anesthetic technique has an impact on outcome. [22] [23] Anand et al [19] evaluated the impact of sufentanil versus morphine-halothane anesthesia on hormonal and metabolic responses and morbidity and mortality in neonates undergoing cardiac surgery [19] (Ch. 50) . Neonates receiving sufentanil anesthesia (total intraoperative dose was 37±2 mug/kg) also received either infusions of sufentanil (49.3±1.3 mug/kg/24 h) or fentanyl (178±25 mug/kg/24h) for analgesia for the first postoperative day. Neonates anesthetized with halo-thane and morphine (total intraoperative morphine dose was 0.35±0.05 mg/kg) received intermittent morphine (1.45±0.34 mg/kg/24 h) plus diazepam postoperatively. (Curiously, the authors of this study referred to the halothane-morphine anesthesia as a "light" technique and the sufentanil anesthesia as a "deep" technique.) Significant reductions and improvements in hormonal profiles were measured in neonates anesthetized with sufentanil versus halothane-morphine. In addition, neonates anesthetized with sufentanil versus halothane-morphine experienced a

lower incidence of sepsis, metabolic acidosis, and disseminated intravascular coagulation. Most strikingly, a statistically significant difference in postoperative mortality was observed (0 of 30 given sufentanil versus 4 of 15 given halothane plus morphine).

Mangano et al [20] also reported that, after myocardial revascularization, patients receiving intense postoperative analgesia with sufentanil (1 mug/kg/h) experience a decrease in the incidence and severity of electrocardiographically documented ischemia compared with patients receiving intermittent IV morphine (2.2±2.1 mg/h) for postoperative analgesia. This finding may relate in part to the fact that anesthesia-induced reductions in metabolic responses to surgery are usually short-lived. [516] [518] [520]

Major investigative challenges remain in the area of stress response research: many different hormonal changes have been described; the concomitant neural, cellular, immune, and chemical changes have been less well defined, and little is understood or proven with regard to how modifying hormonal responses alters outcome. [530] Interest in cytokines and the inflammatory response to trauma and surgery and in modifying it raises similar issues. [531] Only with additional studies can the question of altering outcome with different anesthetic and/or analgesic techniques be appropriately addressed.

Opiate Tolerance

Patients with a history of opiate tolerance or substance abuse and painful conditions are frequently undertreated with appropriate doses of opioids. [532] Lack of knowledge, legal implications, separation of pain management and addiction specialties of medicine, and associated stigmas all contribute to this problem.

The mechanisms of dependence and tolerance are genetic, molecular, cellular, physiologic, and functional. The molecular and cellular mechanisms of addiction have been reviewed. [533] Long-term opiate agonist administration produces downregulation of prodynorphin gene expression in the brain. [534] In the locus caeruleus, the major noradrenergic nucleus in the brain, long-term opioid exposure results in inhibition of adenylyl cyclase, reduced activity of protein kinase A, and upregulation of the cAMP pathway. These changes restore normal neuronal activity in the presence of the opioid. On removal of the opioid, the upregulated and now unopposed cAMP pathway contributes to activation of locus caeruleus neurons (Fig. 10-16) (Figure Not Available) . This is but one of several mechanisms suggested as contributing to the development of opioid tolerance and withdrawal. [535]

In certain models, receptor downregulation is not essential for the development of tolerance. Changes in mu- receptor density that occur prior to or during the development of tolerance also do not appear to be essential. [536] This finding suggests that some cellular mechanisms that are downstream from the receptor contribute to the development of tolerance. Possible mechanisms involve protein kinase signal transduction cascades that link extracellular signals to cellular changes by regulating target gene expression (see Fig. 10-16) (Figure Not Available) . Interestingly, hibernation reduces the manifestations of opiate dependence in certain animal models. Endogenous opiates also play a role. For example, morphine withdrawal can be attentuated by inhibition of endogenous

Figure 10-16 (Figure Not Available) Scheme illustrating opiate actions in the locus caeruleus (LC). Opiates acutely inhibit LC neurons by increasing the conductance of a K^+ channel (light crosshatch) via coupling with subtypes of G_i and/or G_o proteins and the consequent inhibition of adenylyl cyclase. Reduced levels of cyclic adenosine monophosphate (cAMP) decrease protein kinase A (PKA) activity and the phosphorylation of the responsible channel or pump. Inhibition of the cAMP pathway also decreases phosphorylation of numerous other proteins and thereby affects many additional processes in the neuron. For example, it reduces the phosphorylation state of cAMP response element-binding protein (CREB), which may initiate some of the longer-term changes in LC function. Upward bold arrows summarize the effects of long-term morphine in the LC. Long-term morphine administration increases levels of adenylyl cyclase, PKA, and several phosphoproteins, including CREB. These changes contribute to the altered phenotype of the drug-addicted state. For example, the intrinsic excitability of LC neurons is increased via enhanced activity of the cAMP pathway and Na^+ -dependent inward current, which contributes to the tolerance, dependence, and withdrawal exhibited by these neurons. This altered phenotypic state may be maintained in part by upregulation of CREB expression. *(Reprinted with permission from Nestler. [535] Copyright 1996 American Association for the Advancement of Science.)*

enkephalin catabolism. [537] Much work remains to elucidate fully the complex mechanisms of tolerance. [538] [539]

The implications of acute tolerance to opioids in the clinical setting remain controversial and poorly understood. [540] Acute tolerance to the analgesic actions of opioids can occur rapidly, whereas tolerance to the respiratory-depressant actions of opioids may take months to develop. [541] The more potent opioids, such as sufentanil, because of their greater intrinsic activity and low percentage of receptor occupancy, result in less tolerance. However, morphine does not appear in general to have a clinically relevant ceiling to its analgesic effects, although the severity of side effects may limit dose escalation. Peripheral morphine effects have been suggested to be less prone to tolerance. [542] In animals, intrinsic efficacy is inversely related to the degree of tolerance when opioids are administered by continuous infusion but not once-daily dosing. Thus, the method and schedule of drug

administration may also affect the development of tolerance. [543] [544] However, modifying an opioid administration schedule to modulate the development of tolerance may not always be useful or effective. [545]

Certain patients may appear to be tolerant to opioids, but instead they may suffer from pathophysiologic conditions, such as neuropathies, that are poorly responsive to opioids. [546] Morphine-3-glucuronide (M3G), previously thought to be inert, has been argued to produce functional antagonism of morphine and M6G, especially in certain individuals predisposed to produce large amounts of M3G. However, animal and human data do not support this theory. [546]

Management of the Opioid-Dependent Patient

The anesthetic management of the opioid-addicted patient should be tailored to the patient's specific complex of problems and the planned surgery. Common cardiopulmonary problems include endocarditis, cardiac tamponade, cardiac dysrhythmias, thrombophlebitis, mycotic aneurysm, septic pulmonary and systemic emboli, sepsis, pulmonary edema, bacterial pneumonia, pulmonary aspiration and abscesses, pulmonary hypertension, and talc granulomas. Restrictive lung disease and increased alveolar-arterial O_2 gradients are also not uncommon in addicted patients. [547] [548] [549] Renal disease, especially the nephrotic syndrome, is seven times more prevalent in addicted than in nonaddicted patients. Likewise, addicted patients have a higher incidence of other genitourinary problems [547] and anemia. Long-term morphine administration causes adrenal hypertrophy and impairs corticosteroid secretion. [1] Other problems that occur with increased incidence in opioid abusers are viral and nonviral hepatitis, acquired immunodeficiency syndrome, osteomyelitis, muscle weakness associated with rhabdomyolysis and myoglobinuria, and neurologic complications such as transverse myelitis, encephalitis, and cerebral abscess.

Anesthetic management for the opiate-dependent or addicted patient should include adequate premedication, with opioids, if indicated. There is no ideal anesthetic agent or technique to employ in the chronic addict or in the patient with an acute opiate overdose. Although some opiate addicts may be managed with local or regional anesthesia, associated behavioral and psychologic problems make general anesthesia frequently easier and safer. The patient with an acute opiate overdose manifests hypotension, bradycardia, hypoventilation, relative hypovolemia, meiosis, and a GI tract that must be considered arrested and full of recently ingested material. Maximum effects will produce a comatose and apneic patient who is cyanotic with pinpoint pupils unless anoxic pupillary dilatation has supervened. If spontaneous ventilation has persisted, hypotension, bradycardia, and hypothermia are additional likely signs. Treatment of such a patient follows basic life support. Cardiovascular and respiratory changes can be reversed with increments of naloxone (40-80 mug every 1-2 min IV) until vital signs are adequate. Naloxone has a shorter duration of action than most abused opioids, and renarcotization can occur. Complete opioid reversal may turn the patient into an uncontrollable menace. Support of the circulatory system with fluids and monitoring of arterial blood gases and pulmonary function are also important.

Individuals intoxicated but not overdosed with opioids present in a sedated, "nodding" state with pinpoint pupils, normal to euphoric moods, and a revealing history. Patients who are withdrawing from opiates initially (3-4 h after last "fix") are anxious, fearful, and exhibit drug-seeking behavior. Early withdrawal (8-12 h later) reveals restlessness, sweating, nausea, nasal congestion, rhinorrhea, lacrimation, mydriasis, stomach cramps, and continued drug-seeking behavior. Overt, fully developed withdrawal develops within 1 to 3 days of abstinence and along with early symptoms includes piloerection ("cold turkey"), vomiting, diarrhea, muscle spasms (hence the term "kicking the habit"), fever, chills, hypertension, tachycardia, and severe behavioral disturbances. [550] Commonly used medications for detoxification and/or stabilization of the withdrawing addict are meth-adone, clonidine, acetaminophen, and chloral hydrate (for sleep). Cardiovascular stimulation and some of the other signs and symptoms of acute opiate withdrawal can be treated with beta-adrenergic antagonists and alpha $_2$ -agonists.

Pain relief during the postoperative period should be appropriate for the degree of pain and should end with the resolution of the acute surgical condition. Methadone maintenance can be instituted for more gradual opiate withdrawal. Complete reviews of the anesthetic management of addicted patients are available. [551] [552] [553] Substance abuse among anesthesiologists is reviewed in Chapter 84 .

PHARMACODYNAMICS: RENAL EFFECTS

The control of water and electrolyte balance and of blood pressure has been demonstrated to be influenced in various animal models by opioids. mu-Receptor activation causes antidiuresis and decreases electrolyte excretion. kappa-Receptor stimulation predominantly produces diuresis with little change in electrolyte excretion. Whether these renal-induced opioid actions are directly and/or indirectly mediated via neurohumoral factors is uncertain. Indirect actions may involve inhibiting or altering the secretion of ADH and atrial natriuretic peptide. [554] Animal studies utilizing an opioid with selective peripheral actions suggest that diuretic, natriuretic, and kaliuretic opioid effects are mediated via atrial natriuretic factor release. [555] Dynorphin may be a natural endogenous opiate ligand with kappa-receptor renal actions. The stable dynorphin analogue E-2078 causes kappa-mediated diuretic effects in the isolated perfused rat kidney. [556] Dynorphin analogues may have potential as diuretics of significance.

Antidiuresis after morphine administration has been attributed to a decrease in renal blood flow and glomerular filtration rate. [557] [558] Increases in urine volume and decreases in urinary Na^{+} excretion and urine osmolality have also been reported during fentanyl-O_2 anesthesia. Hunter et al [559] reported decreases in renal plasma flow, glomerular filtration rate, urine volume, and increases in renovascular resistance in dogs anesthetized with N_2O after 25 mug kg^{-1} of fentanyl. Kien et al [560] also noted a 25 percent decrease in renal cortical blood flow that paralleled changes in blood pressure suggesting impairment of autoregulation. Morphine

and meperidine have been reported to decrease renovascular resistance. [561] [562] The relevance of these animal studies is unclear in light of the presence of background anesthetics and species differences.

Anecdotal reports suggest that rarely opioids may contribute to renal failure by a mechanism that is unclear but that is reversible by naloxone. [563] However, in a study comparing halothane and high-dose morphine anesthesia, intraoperative and postoperative urine outputs of 61 patients undergoing similar open heart operations did not differ. [564] Other work has confirmed that large doses of morphine and fentanyl probably do not stimulate ADH release in humans. [7] [258] The absence of increases in plasma ADH, renin, and aldosterone indicate that fentanyl, sufentanil, alfentanil, and probably remifentanil most likely preserve or minimally alter renal function in humans. [519] [523] If renal function does change during opioid anesthesia and surgery, it is probably due to secondary changes in systemic and renal hemodynamics.

Lower urinary tract opioid effects include disturbances of micturition characterized by urinary retention, especially after intrathecal opioid administration. Opioids cause relaxation of bladder smooth muscle. Not all opioid agonists behave similarly, and morphine appears to be particularly potent with regard to producing urodynamic problems. [565] Patients who receive opioids and whose bladders are not catheterized may experience urinary retention.

PHARMACODYNAMICS: GASTROINTESTINAL EFFECTS

Motility

Opioids decrease GI motility, and this action underlies their use as antidiarrheal agents. Whether or not long-term opioid use, the use of opioids for several days prior to sur-gery, or the administration of opioids as part of a rapid sequence anesthetic induction increases the risk of pulmonary aspiration is unknown. [566] Patients receiving parenteral opioid therapy preoperatively are more likely to have "full stomachs" regardless of their "NPO" status.

Opioids produce widespread effects throughout the GI tract by several central and peripheral mechanisms. Such effects are a mixture of inhibitory and excitatory actions. Opioid peptides and their receptors are found throughout the GI tract, especially in the gastric antrum and proximal duodenum. Several opiate receptor subtypes can be demonstrated on myenteric neurons, and both kappa- and mu-receptor agonists regulate cholinergic transmission in the myenteric plexus. kappa-Agonists appear more powerful, and they modulate acetylcholine release by inhibition of *N*-type voltage-sensitive Ca^{2+} channels via a pertussis toxin-sensitive G protein in guinea pig ileum. [567]

Opioids alter lower esophageal sphincter activity, resulting in sphincter relaxation. [568] This probably accounts for the unreliability of spontaneous lower esophageal sphincter contractions as predictors of patient movement to skin incision when opioid-based anesthetics are used, as opposed to potent inhalation agent anesthesia. [569]

Gastric emptying is delayed by opiates, via supraspinal (vagus nerve-mediated) and spinal, as well as peripheral, mechanisms. [570] Morphine and related opioids inhibit electrically evoked acetylcholine release from nerves in the GI tract. Even small doses of alfentanil (5 mug kg^{-1}) slow gastric emptying, but for a shorter period than morphine. Both fentanyl and meperidine reduce antroduodenal motility during balanced anesthesia, but at least partial recovery occurs relatively early (0.5-2.0 h) postoperatively. [571] Both opioids are also associated with an increase in gastric pH.

Fentanyl-supplemented (21 mug/kg total) anesthesia for cardiac surgery delays postoperative recovery of bowel motility in a dose-dependent manner and surprisingly longer than morphine (0.7 mg/kg) (15.2±7.3 versus 8.2±6 h). [572] Epidural opioids reduce GI motility more so than epidural bupivacaine. [573] Intrathecal morphine also reduces GI tract motility, [574] as do mixed agonist-antagonist opioids. Naloxone reverses opioid-induced delays in gastric emptying. [575] [576] Methylnaltrexone, a quaternary naloxone derivative that does not cross the blood-brain barrier, can attenuate morphine-induced delays in gastric emptying. [566] IV, but not IM, metoclopramide (10 mg) also can reverse morphine-induced delays in gastric emptying. [577] Droperidol (2.5 mg IV) does not appear to reverse slowed gastric emptying induced by fentanyl. [578]

Opioid effects on the intestine are complex. The ileum appears to be less sensitive to opioids than the jejunum. In fact, morphine enhances ileal propulsion before decreasing motility. As a result, mouth-to-ileum transit time may not be significantly altered. [579] Opioid effects on the ileum are blocked by naloxone. [579] Opioids increase tone and decrease propulsive activity in most of the intestine (small and large). Electromyographically, this is reflected by an increase in rhythmic stationary (tone) bursts and a decrease in sporadic (propagating) bursts. Some clinicians believe that opioids may be indicated during surgical construction of a continent urinary reservoir because they are superior to anticholinergic drugs for terminal ileal relaxation. [580] GI secretions can be increased by opioids. [552]

Biliary Tree Effects

All opioid agonists increase biliary duct pressure and sphincter of Oddi (choledochoduodenal sphincter) tone in a dose- and drug-dependent manner through opiate receptor-mediated mechanisms [581] [582] (Fig. 10-17) (Figure Not Available) . Morphine-induced spasm of the common bile duct has been documented with ultrasound. [583] Opioid-induced reductions in common bile duct caliber in anesthetized patients are greatest (60% of predrug dimension) with morphine (0.2 mg/kg) and are insignificant after fentanyl (1.5 mug/kg) or sufentanil (0.3 mug/kg). [584] Increases in biliary pressure after opioids are small. [585] There is only a 3 percent incidence of failed intraoperative cholangiograms during fentanyl supplemented (10 mug kg^{-1}) anesthesia. These facts suggest that clinical consequences of opioid-induced biliary tract actions are usually minimal. [586]

Opioid-induced biliary spasm rarely produces severe epigastric pain which can be confused with cholecystitis or myocardial ischemia. [587] Increases in biliary pressure caused by opioids are, with the exception of meperidine, reversible with naloxone. [588] [589] Glucagon (1-3 mg IV), carefully titrated, also reverses opioid-induced biliary spasm.

Although some reports suggest that mixed agents such as nalbuphine and butorphanol can raise biliary pressure as

Figure 10-17 (Figure Not Available) Changes in common bile duct pressure after administration of alfentanil 7.5 ( ) and 15 (Delta) mug/kg and fentanyl, 1.5 ( ) mug/kg (mean values ± SEM). Statistically significant difference in changes from baselines among the groups are indicated as follows: *, $P < .05$; **, $P < .01$; ***, $P < .001$. *(From Hynynen et al [1214])*

much as pure agonists, [585] most studies show that they produce less or little pressure change. [581] [589]

Meperidine has a dual effect on the biliary tract. [588] Meperidine (10^{-6} mol/L) produces an inhibitory effect on the response of the common bile duct to electrical stimulation (antimuscarinic mechanism). Higher concentrations (10^{-4} mol/L) produce an excitatory effect and increase spontaneous contractions via direct smooth muscle stimulation. Neither of these responses is affected by naloxone. In spite of these contrasting actions, meperidine increases biliary pressure in humans.

Intestinal Circulation

The effects of opioids on intestinal circulation are complex and are not completely understood. [590] Low doses of morphine (0.5-1.0 mg kg^{-1}) increase intestinal blood flow (perhaps secondary to histamine release), whereas high doses (1-3 mg kg^{-1}) decrease flow. [591] [592] Decreases in blood flow after morphine are likely related to hypotension or increases in plasma catecholamines. Fentanyl increases intestinal blood flow in a dose-dependent fashion. The increase in blood flow coupled with a substantial and dose-related decrease in intestinal O_2 uptake represents a state of "luxury perfusion" that has been hypothesized possibly to increase mesenteric and portal venous O_2 content, thereby improving hepatic O_2 supply. [591]

Hepatic Effects

Opioids produce mild effects on liver function during anesthesia and surgery. Fentanyl produces some postanesthetic liver dysfunction (small increases in serum glutamate oxaloacetate transaminase or serum glutamate pyruvate transaminase) in rats that is independent of the presence of cirrhosis. [593] These changes are similar to those caused by potent inhalation agents. There is evidence that fentanyl, as well as other anesthetics, can produce hepatic dysfunction or injury in some animal models. [594] Bromosulfophthalein breakdown by the liver, for example, is decreased by morphine in rats. [595]

Alfentanil can also reduce hepatic artery blood flow by more than 50 percent in the dog. [560] Similar decreases in hepatic blood flow caused by morphine, fentanyl, and other opioids can increase the blood levels of other drugs whose elimination depends on hepatic blood flow. [596]

Nausea and Vomiting

The "big little problem" of postoperative nausea and vomiting continues to attract a great deal of interest and to create controversy. [597] [598] Opioids usually increase the incidence of nausea and vomiting when these drugs are used as premedicants, intraoperative agents, or postoperative analgesics. The physiology and prevention of nausea and vomiting are summarized in Figure 10-18 . The interested reader is referred to an extensive review. [599]

Opioids stimulate the chemoreceptor trigger zone in the area postrema of the medulla, possibly through delta-receptors. [600] This action, combined with their actions on the GI tract, promotes nausea and vomiting. Opioids may also have antiemetic properties related to the existence of both emetic and antiemetic brain centers possessing different opiate receptor profiles. [601] There is very little evidence suggesting that any one opioid is consistently more emetogenic

Figure 10-18 Physiology of emesis. The chemoreceptor trigger zone (CRTZ) and the vomiting center (VC) stimulate the upper gastrointestinal tract (UGIT), resulting in emesis. Cholinergic (Chol.) and dopaminergic pathways are integral, and many factors influence nausea and vomiting through these and other mechanisms. RF, reticular formation; ADR, adrenergic. Serotoninergic actions at the chemoreceptor, underlying the efficacy of antiemetics such as ondansetron, are not illustrated.

than another. Nevertheless, in any one particular patient, changing from one opioid to another can influence associated nausea and vomiting. [599]

Many other factors are associated with nausea and vomiting. These include age (emesis is greater in pediatric patients), female gender, surgery during the first 8 days of the menstrual cycle, [602] obesity, history of motion sickness, anxiety, gastroparesis, certain operative procedures (e.g., lapa-roscopy), duration of surgery, and ambulation. Anesthesia-associated factors that increase nausea and vomiting include opioid premedication, pain, gastric distention, airway trauma, balanced anesthesia, and the agents etomidate and N_2O. The use of propofol in balanced or total IV anesthesia (TIVA) significantly reduces the incidence of nausea and vomiting. [603] The incidence of postoperative nausea and vomiting can be as low as 5 to 20 percent after propofol-alfentanil anesthesia.

When opioids are employed, antiemetic prophylaxis should be considered because postoperative nausea and vomiting are of great concern to many patients, can increase cost, and may delay patient recovery and discharge. Some of the more efficacious antiemetic therapies commonly used in anesthesia are as follows:

1. Drugs with anticholinergic activity, in particular sco-polamine [604] (IM, IV, or as a transdermal patch) and, to a lesser degree, atropine. Glycopyrrolate is not effective because it does not penetrate the blood-brain barrier.
2. Butyrophenones, in particular droperidol (0.005-0.07 mg kg^{-1} IV), are most likely effective because of their antidopaminergic properties.
3. Dopamine antagonists, in particular metoclopramide (0.1-0.3 mg kg^{-1} IV), which acts both centrally at the chemoreceptor trigger zone and peripherally on the GI tract. Metoclopramide has a rapid onset but is short acting and thus is more effective if administered at the end of an anesthetic regimen.
4. Serotonin antagonists (e.g., ondansetron) may be among the most efficacious drugs available. They are most effective in high-risk populations, but because ondansetron is associated with a low (3%) incidence of headache and liver enzyme elevation, potential costs and benefits remain controversial. [597] [598]
5. Acupressure at the pericardium 6 meridian point (P-6, Nei-Guan) with acupressure bands. [605]

The appropriate application of these therapies, along with skilled and gentle handling of the airway (which includes appropriate but minimal suctioning and associated trauma), can lead to an acceptable and low incidence of nausea and vomiting even after anesthetic techniques that include opioids.

OTHER OPIOID EFFECTS

Obstetrics

Specific concerns regarding the use of opioids in obstetrics include the question of opioid-induced reproductive or teratogenic actions and the maternal, fetal, and newborn consequences of the use of opioids during and after labor and delivery (Ch. 57).

Morphine, but not fentanyl, can adversely affect *in vitro* fertilization of sea urchin eggs. Thus, fentanyl has been recommended as clinically useful during the harvesting of human ova for subsequent *in vitro* fertilization. [606] Other investigators question whether opioid-induced increases in prolactin may disfavor implantation. [607] Although alfentanil penetrates follicular fluid to a greater extent than fentanyl, it has no effect on cleavage rate and has also been recommended as useful in providing analgesia for oocyte retrieval. [608]

Teratogenic actions of opioids, including fentanyl, sufentanil, and alfentanil, at least in animal models, appear to be

minimal. [609] [610] Older studies evaluating morphine, meperidine, and methadone suggest some teratogenic potential with these drugs, but concomitant respiratory depression and the administration of very high drug doses may have affected study results.

The parenteral administration of opioids prior to delivery in obstetrics remains a commonly used method of analgesia despite known adverse maternal, fetal, and neonatal effects (see later), as well as arguably superior alternatives. In addition to typical adverse effects, aortocaval compression and associated hypotension may be exacerbated by parenteral opioids, especially following morphine or meperidine. Fetal manifestations of maternal opioid administration include decreases in heart rate variability.

Meperidine (12.5-50 mg IV or 50-125 mg IM) has been suggested to result in less neonatal depression than morphine (2-6 mg IV or 4-10 mg IM). [341] Fetal blood-brain barrier immaturity may permit greater than normal brain penetration of the relatively lipophobic morphine compared with meperidine. However, both morphine and meperidine rapidly cross the placenta and result in significant drug levels in the fetus and neonate soon after maternal injection, and drug elimination for both opioids is impaired in the neonate. [611] [612] The elimination half-life of meperidine in the newborn can be as long as 23 hours. [613] Multiple maternal doses of meperidine can result in significant accumulation of the drug and its metabolite normeperidine in the fetus. [614] The neonatal effects of maternally administered meperidine can last up to 3 days. [615] Adverse neonatal effects can occur after either morphine or meperidine administration to mothers. [614] Attempts to minimize neonatal effects of opioids include restricting opioid administration to the first stage of labor.

Because of its high lipid solubility, sufentanil transfer across the placenta should be enhanced. As with most anesthetics, placental transfer is passive for opioids. However, sufentanil is highly bound to plasma proteins, and this impedes placental transfer. In addition, the placenta takes up more sufentanil compared with other opioids such as fentanyl or alfentanil, and this action further blunts its transfer to the fetus. [616] Sufentanil transfer to the fetus may be least when delivery is within 45 minutes of drug administration. Because the placenta can act as a drug depot, it may continue to supply the fetus with sufentanil, especially if delivery occurs more than 45 minutes after drug administration. Fetal acidosis increases opioid transfer from the mother.

Morphine has little effect on the pregnant rat uterus, whereas meperidine can increase uterine contractions in a dose-dependent fashion that is not reversible by naloxone. [617] It has been suggested that labor may be shorter in women receiving meperidine compared with those receiving morphine. Fentanyl (50-100 mug) is devoid of actions on uterine blood flow and tone in sheep. [618] Although fentanyl is a successful agent for analgesia during labor, it is less frequently employed. [619] Fentanyl (50-100 mug q1h IV), compared with meperidine (25-50 mg IV q2-3h), results in less nausea, vomiting, and sedation in the mother and in lower naloxone requirements in newborns. [620]

Opioids have traditionally been omitted from general anesthetic techniques for cesarean section until fetal delivery. More recently, however, mothers with severe pregnancy-induced hypertension or other severe cardiovascular problems have had alfentanil included in the inductionintubation sequence to promote hemodynamic stability. [621] [622] Although at times naloxone reversal of neonatal depression has been required after alfentanil, maternal effects were deemed beneficial. Remifentanil is probably rapidly metabolized by the newborn, and it may offer advantages because of this property.

Morphine and meperidine have been found in the breast milk of mothers receiving IV opioid analgesia. In at least one study, morphine administered to mothers produced less neonatal neurobehavioral depression than meperidine. [623] Repeated dosing with meperidine may produce detrimental effects in a suckling newborn. [624] The potential actions of M6G in the fetus have not been evaluated. Preliminary reports document that a fentanyl infusion of 25 mug/h IV provides effective maternal analgesia and few unwanted maternal or nursing neonatal effects. [625] Although both fentanyl and morphine are concentrated in breast milk in milk-to-plasma ratios of 2 to 3:1, newborn exposure is reported to be insignificant. [626] [627]

Newborns of addicted mothers can exhibit opioid withdrawal and require observation and appropriate treatment. The severity of withdrawal is related to maternal methadone dose and neonatal gestational age. [628] Seizures are more common in term (13/178) than in preterm infants (1/34).

Allergic and Adverse Reactions

True allergic reactions to opioids are rare. [629] Patients often complain of being "allergic" to opioid analgesics because they have experienced adverse side effects, most frequently nausea, vomiting, or pruritus. Most of the adverse reactions to opioids that fall into the category of side effects are discussed in their respective sections of this chapter.

Papaveretum, fentanyl, and meperidine have on occasion been associated with anaphylactic-type reactions [630] [631] [632] [633] and positive intradermal skin tests. Harle et al [633] suggested that compounds likely to cross-react with morphine-reactive antibodies do so because of structural similarities of immunoglobulin E binding sites and include codeine, meperidine, and methadone. Fentanyl, buprenorphine, and naltrexone were predicted to cross-react poorly with morphine-reactive antibodies.

Systemic anaphylactoid reactions to opioids are also rare. More commonly, local reactions occur, and these may be caused by preservatives or histamine. (Ampules of fentanyl do not contain preservatives; however, vials of fentanyl do contain methylparasept and propylparasept.) Levy et al [634] demonstrated that wheal and flare responses on intradermal injection of morphine, meperidine, fentanyl, and sufentanil, but not alfentanil, naloxone, and nalbuphine, were greater than those due to saline. The intensity of the responses was not related to the potency of the mu-receptor agonists, and it was due to a combination of histamine release and direct

vascular actions. Naloxone and antihistamines both only partially attenuated these opioid-induced reactions.

Meperidine is metabolized by the liver to meperidinic acid and normeperidine. Normeperidine is active and has half the analgesic potency and twice the neurotoxicity of meperidine. Oral meperidine produces particularly high normeperidine blood levels. Normeperidine is slow to accumulate (days) and is dependent on renal excretion for elimination. Because of these factors, meperidine is often recommended

only for short-term use in healthy individuals. Meperidine should be avoided in patients with renal dysfunction. CNS adverse effects associated with meperidine include disorientation, hallucinations, tremors, twitches, myoclonus, psychosis, and seizures. The adverse effect rate after meperidine is dose related even in normal dose ranges. Meperidine-induced neurotoxicity is reversible, although effects may persist for several days after terminating drug administration. Treatment is supportive and includes cessation of meperidine, substitution with another opioid for analgesia, and administration of a benzodiazepine for signs or symptoms of CNS irritability. Naloxone administration should be avoided because it can elicit seizures by unmasking excitatory effects when depressant effects are antagonized.

It is now recognized that the pharmacology of morphine is complicated by the fact that at least two of its metabolites, M6G and M3G, are active. This can lead to an increased incidence of adverse effects in some patients. The pharmacology of these metabolites has been the subject of much interest, but their effects remain incompletely understood. M6G, like morphine, is relatively selective for mu-opioid receptors. It is thought that M6G, although not more potent than morphine as a respiratory depressant, may have a longer half-life, and that, especially in patients with renal dysfunction, the accumulation of M6G can lead to an increased incidence of adverse effects, including respiratory depression. Patients with renal dysfunction who receive morphine analgesic therapy may require additional attention. M3G may actually antagonize morphine, and this effect may contribute to both variability in response and resistance to morphine analgesic therapy.

Finally, use and abuse of illicit "designer" opiates, such as 3-methylfentanyl ("China white"), [635] has probably caused several hundred drug overdose deaths. This agent is as potent as sufentanil. The number of deaths related to 3-methylfentanyl has declined. Rapid treatment for drug overdose follows that for other opioids.

Ocular Effects

The use of fentanyl, sufentanil, and alfentanil during induction of anesthesia can help to prevent increases in intraocular pressure. Induction techniques without opioids can lead to increases in intraocular pressure associated with succinylcholine and/or tracheal intubation, whereas pretreatment with an opioid can prevent such problems. [636] [637] Fentanyl, alfentanil, and sufentanil doses as small as 2.5, 10, and 0.1 mug/kg, respectively, and remifentanil, 0.1 to 0.5 mug/kg/min, may be sufficient as long as appropriate anesthetic depth is achieved prior to tracheal intubation. Opioid-droperidol sedation alone also reduces intraocular pressure. [638]

Immune Effects

It is now firmly established that opioids influence neuroimmune function as well as autoimmune regulation. Evidence includes the finding that opioid receptors, with the mu_3 -receptor perhaps most significant, are present on inflammatory cells. Direct effects of opioid agonists and opiate signal molecules include modulation of immune cellular activity, as well as that of specific enzymatic degradation and regulation processes. [639] Opioids also can affect immune function indirectly through neuroendocrine or neuroimmune actions mediated through the hypothalamic-pituitary- adrenal axis and the autonomic nervous system. [640]

Several immune cell populations serve as targets for the effects of opioids including T cells, macrophages, and NK cells. The production of lymphokines and cytokines is also altered following opioid treatment. Met-enkephalin affects both immunocyte activation and chemotaxis. Morphine can suppress monocyte chemotaxis, and long-term exposure to morphine can increase the lethality of certain infections. How opioids alter resistance to infection and what are the details of the mechanisms and effects of opioids on immune function are among the research problems under current investigation. [639] [640]

PHARMACOKINETIC-PHARMACODYNAMIC CONSIDERATIONS

Pharmacokinetic-Pharmacodynamic Variability

Humans exhibit substantial intersubject variability in their response to opioids. [641] [642] This variability is at least 3- to 5-fold and is a function of both pharmacokinetic and pharmacodynamic parameters. Therefore, a single opioid dosage regimen is not appropriate for all patients. Figure 10-19 (Figure Not Available) illustrates the pharmacokinetic (left panel) and pharmacodynamic (right panel) variability for alfentanil and is typical for opioids. Combined pharmacokinetic-dynamic models help to identify sources of variability and strategies to manage them.

Pharmacokinetic-Pharmacodynamic Modeling

Traditionally, the clinical pharmacology of opioids was characterized by simple phenomenologic experiments in which a dose of opioid was administered to an experimental subject and the effects were observed (Ch. 2) . Although such "dose-response" experiments could provide general guidelines for safe and efficacious opioid administration, they could not specifically identify the mechanisms responsible for variability in response. With the advent of modern drug assay technology and the widespread availability of computers, it is now possible to analyze pharmacologic data with combined pharmacokinetic-pharmacodynamic models.

Pharmacokinetic-pharmacodynamic modeling separates drug response into pharmacokinetic and pharmacodynamic components, allowing precise identification of the mechanisms responsible for the variability in drug response. In addition, modeling yields mathematically defined pharmacokinetic-dynamic parameters, which can be employed in computer simulations of opioid pharmacology in a variety of settings.

Figure 10-19 (Figure Not Available) Two examples of opioid pharmacologic variability. The left panel represents alfentanil's pharmacokinetic variability after injection of an identical dose of alfentanil to 45 subjects. The observed concentrations for some subjects at any given time after injection are many times greater than those of other subjects. The right panel shows alfentanil's pharmacodynamic variability when alfentanil is used with nitrous oxide to prevent untoward responses to surgical manipulation during intra-abdominal surgery. Note that the potency of alfentanil for some subjects is several times greater than for others. *(From Maitre et al [743] and Ausems et al [874])*

Pharmacokinetic parameters govern the relationship between opioid dose and the opioid concentrations in the blood (or other body fluid). Pharmacodynamic parameters describe the relationship between opioid concentration in the blood (or other fluid) and opioid effect. Expectations regarding opioid response, including latency to peak effect, and its magnitude and duration are made possible by careful analysis of these pharmacokinetic-dynamic parameters. Dosing schemes that target the appropriate "therapeutic window" in the patient population of interest can then be developed.

Physicochemical Properties

The physicochemical properties of opioids have important pharmacologic implications. Opioids are weak bases. When dissolved in solution, they are dissociated into protonated and free-base fractions, with the relative proportions depending on the pH and pKa. The free base form is always more lipid soluble than the ionized form. Hence, opioid lipid solubility is strongly influenced by the pKa.

A high lipid solubility facilitates opioid transport into the biophase or site of action. Thus, in general, highly lipid-soluble opioids have a more rapid onset of action. However, because the opioid receptor "recognizes" an opioid molecule in the protonated form, the intensity of opioid effect is closely related to the ionized concentration of drug in the biophase. Thus, speed of onset and receptor agonism are complex functions of lipid solubility and the percentage ionized at physiologic pH (Fig. 10-20) .

All opioids are to some extent bound to plasma proteins, including albumin and alpha $_1$ -acid glycoprotein. Opioid molecules that are bound to plasma proteins cannot move from the blood to opioid receptors in the CNS or elsewhere. It is only the un-ionized, unbound fraction that constitutes the "diffusible fraction" and provides the concentration gradient that promotes diffusion of opioid from the blood to the tissue of interest. The concentration of this diffusible fraction (and other factors such as lipid solubility and plasma-tissue partition coefficients) determines the rate at which opioid diffusion takes place.

Differences in the speed of onset of effect between morphine and alfentanil illustrate the impact of lipid solubility and diffusible fraction. Morphine has a high diffusible fraction but is a slow-onset opioid because of its low lipid solubility. Alfentanil, on the other hand, has a high diffusible fraction and adequate lipid solubility, a combination that makes it a very rapid-onset opioid.

Common Pharmacokinetic Features of Opioids

Although each opioid has unique pharmacokinetic features, as a group they share a general pattern of pharmacokinetic behavior. Representative pharmacokinetic parameters for the opioids commonly used in anesthesia are displayed in Table 10-12 .

After IV injection, arterial plasma concentrations of opioids rise to a peak within one circulation time. Thereafter, they exhibit a rapid redistribution phase (sometimes two) and a slower elimination phase typical of drugs whose pharmacokinetics is described by compartmental models.

Opioid pharmacokinetics can be conceptualized in schematic and graphic forms as summarized in Figure 10-21 (Figure Not Available) . [643] After administration into a central compartment, opioids are either eliminated from the central compartment (by excretion or biotransformation) or distributed to peripheral compartments, as depicted in the schematic panel of Figure 10-21 (Figure Not Available) . An alternative representation of these pharmacokinetic processes is shown in the concentration versus time plot in the middle panel of Figure 10-21 (Figure Not Available) , graphically illustrating the distinct distribution and elimination phases characteristic of opioids. These compartments are mathematic

---

Figure 10-20 Distribution of fentanyl within the body compartments at an extracellular pH of 7.4. The accumulation of fentanyl by the tissue is assumed to increase the tissue concentration 13-fold. In

the extracellular space, an equilibrium exists between the ionized fentanyl (F^+), the free base (F), and the fentanyl molecules bound to macromolecules (F_b). The concentration of ionized fentanyl within the interstitial fluid (encircled F^+) determines the pharmacologic effect, because the opioid receptors (U U) are located at the cell surface. Fentanyl as the free base readily penetrates the cells and becomes bound to cytomembranes, lysosomes, and other structures (thick arrows) and thus accumulates in the cell. A small decrease of the extracellular pH shifts the equilibrium between F and F^+ toward higher F^+ concentrations and induces a marked release of fentanyl from the cellular compartment as a result of the decrease of the concentration of F in the interstitium. An increase of the extracellular H^+ concentration by pH 0.2 may roughly double the concentration of ionized fentanyl within the interstitial fluid and accordingly enhance its pharmacologic effect.

constructs and do not represent any particular anatomic region or organ system.

The biexponential equation depicted in the right panel of Figure 10-21 (Figure Not Available) is the mathematic form of the concepts illustrated by the schematic diagram and graphic portions of the figure. This equation (and various modifications of it) provides the quantitative foundation for the computerized modeling process used to estimate opioid pharmacokinetic parameters.

In general, opioids are cleared from the plasma by biotransformation in the liver. For most opioids, the hepatic extraction ratio is high enough that liver blood flow has a substantial influence on opioid clearance. Extrahepatic metabolism is important for some opioids. For example, the kidney plays a role in the conjugation of morphine, whereas blood and tissue esterases are responsible for remifentanil metabolism (discussed later).

As a rule, because of their high lipid solubility, opioids are widely distributed in body tissues. In pharmacokinetic terms, this means that opioids typically have a high apparent volume of distribution at steady state. Because opioids are distributed so widely and so rapidly to various body tissues,

TABLE 10-12 -- Physicochemical and Pharmacokinetic Data of Commonly Used Opioid Agonists

	MORPHINE	MEPERIDINE	FENTANYL	SUFENTANIL	ALFENTANIL	REMIFENTANIL

$t_{½}$ alpha, beta, gamma are the half-lives of a three compartment model; Vd_c, volume of distribution of the central compartment; Vd_{ss}, volume of distribution at steady state.

Figure 10-21 (Figure Not Available) A summary of pharmacokinetic modeling theory for a two compartment model. Depicted schematically, after intravenous administration into a central compartment, drug can either be eliminated or distributed to a peripheral compartment. The process results in distinct distribution and elimination phases of the concentration versus time curve when plotted graphically. The mathematical representation of curves of this shape is the polynomial equation noted. This equation is the basis for the computerized pharmacokinetic modeling process typically applied to opioids. *(Reprinted with permission from Egan, [643] St. Louis, Mosby.)*

redistribution has a prominent impact on the decline of opioid concentration, particularly in the early period after injection.

Opioid uptake by the lung is a significant nuance of opioid pharmacokinetics. The rise-time to peak concentration of an opioid is influenced by the percentage of pulmonary uptake. A very substantial proportion of the initial dose of a highly lipophilic opioid such as fentanyl is taken up by the lung (75%) and subsequently is rapidly released. [644] This process influences peak blood concentration and the time to achieve it.

Pharmacokinetic Features of Individual Drugs

Morphine

Morphine pharmacokinetics is notably different from that of the fentanyl congeners. This difference is in large part due to morphine's comparatively low lipid solubility. Both biexponential and triexponential equations have been used to describe the pharmacokinetics of morphine. After IV injection, morphine is rapidly distributed. [361] [645] [646] [647] [648] [649] [650] In contrast to the fentanyl series, there is relatively little transient first-pass uptake of morphine by the lung. [644] [651]

Morphine's physicochemical properties have important clinical implications. The pKa of morphine (8.0) is greater than physiologic pH, and thus after IV injection only a small percentage (10-20%) is un-ionized. This property, combined with its low lipid solubility, limits the ability of morphine to penetrate tissues. Thus, penetration of morphine into and out of the brain is presumably slower compared with that of other opioids. Morphine's slow brain penetration means that analgesia and respiratory effects are not reflected by plasma levels. Approximately 20 to 40 percent of morphine is bound to plasma proteins, mostly albumin. [649]

Morphine is principally metabolized by conjugation and has a hepatic extraction ratio that is equal to or greater than hepatic blood flow indicating a high clearance (15-30 mL
kg^{-1}
min^{-1}). [652] The kidney appears to play a key role in the extrahepatic metabolism of morphine and may account for nearly 40 percent of its clearance, [653] although there is some controversy about the importance of renal morphine metabolism. [654] [655]

M3G is the major metabolite of morphine, but it does not bind to opioid receptors and possesses little or no analgesic activity. [656] [657] However, M6G accounts for nearly 10 percent of morphine's metabolism and is a more potent mu- receptor agonist than morphine with a similar duration of action. It is now clear the M6G contributes substantially to morphine's analgesic effects even in patients with normal renal function. [658] Interestingly, M6G appears to have a more favorable side effect profile than morphine. [659] *N*-demeth-ylation metabolites of morphine also represent a small percent of its metabolism.

Because of morphine's high hepatic extraction ratio, the bioavailability of orally administered morphine is significantly lower (20-30%) than after IM or subcutaneous injection. [650] As demonstrated in Figure 10-22 (Figure Not Available) , in contrast to IV administration, the hepatic first-pass effect on an orally administered dose of morphine results in substantial levels of M6G. It appears that M6G is in fact the primary active compound when morphine is administered orally. [660]

Meperidine

The plasma concentration versus time decay curve of meperidine is best characterized by a two-compartment model. [661] [662] [663] [664] [665] [666] Unlike morphine, after IV injection, first-pass uptake of meperidine by the lungs is approximately 65 percent. [644] The volume of distribution of meperidine is similar to that of morphine (4±1 L
kg^{-1}), [661] [662] [663] [664] [665] as is its clearance (8-18 mL
kg^{-1}

min^{-1}). [661] [662]

Meperidine's physicochemical properties are similar to those of the fentanyl congeners. Meperidine is more highly bound to plasma proteins than morphine, principally (70%) to alpha$_1$ -acid glycoprotein. In contrast to morphine, meperidine binds only to a minor extent to plasma albumin.

Figure 10-22 (Figure Not Available) Mean plasma concentrations of morphine, morphine-6-glucuronide (M6G), and morphine-3-glucuronide (M3G) after intravenous and oral administration. Note the high concentrations of morphine-6-glucuronide after oral administration. *(From Osborne et al [660])*

Meperidine is even less un-ionized (<10%) than morphine at physiologic pH, but it is significantly more lipid soluble.

As with morphine, a relatively high hepatic extraction ratio results in biotransformation that is dependent on hepatic blood flow. The principal metabolic pathways of meperidine are *N*-demethylation and diesterification, which produces normeperidine, meperidinic acid, and normeperidinic acid as the major metabolites. Little meperidine (<5%) is excreted unchanged in the urine. Normeperidine has analgesic activity and is roughly twice as potent as the parent compound in producing seizures in animals. [667] The greater epileptogenic properties of meperidine cause its therapeutic index to be less than one-tenth that of morphine (5 versus 70).

Normeperidine is dependent on renal clearance mechanisms for elimination. The elimination half-life of normeperidine is considerably greater than that of meperidine, and thus repeated doses can easily produce accumulation of this toxic metabolite in patients with renal disease, potentially producing seizures (see later). [668]

Fentanyl

A three-compartment model is typically used to describe plasma fentanyl concentration decay. [339] [366] [669] [670] The lungs exert a significant first-pass effect and transiently take up approximately 75 percent of an injected dose of fentanyl. [644] [671] As is typical of the fentanyl congeners, at steady state fentanyl's volume of distribution (3-6 L
kg^{-1}) and clearance (10-20 mL
kg^{-1}
min^{-1}) are both high.

Approximately 80 percent of fentanyl is bound to plasma proteins, and significant amounts (40%) are taken up by red blood cells. [672] Because the pKa of fentanyl is high (8.4) at physiologic pH, it exists mostly in the ionized form (>90%). Fentanyl's lipid solubility is also high (see Table 10-12) , a finding that explains in part its large volume of distribution. Bjorkman et al [673] found the tissue/blood partition coefficients of fentanyl to be 2- to 30-fold higher than those of alfentanil. Because fentanyl is distributed so widely in the body, it must ultimately be returned to the blood to be metabolized in the liver. Fentanyl is relatively long acting, in large part because of this widespread distribution in body tissues.

Fentanyl is primarily metabolized in the liver by *N*-dealkylation and hydroxylation. [674] Fentanyl has a high hepatic clearance (approaching hepatic blood flow) and a high hepatic extraction ratio (approaching 1.0). [370] Metabolites begin to appear in the plasma as early as 1.5 minutes after injection. [675] Norfentanyl, the primary metabolite, is detectable in the urine for up to 48 hours after IV fentanyl in humans. [676] The activity of fentanyl's metabolites is unclear, but it is thought to be minimal. Little fentanyl is excreted in the urine unchanged. [366]

Alfentanil

Perhaps more than any other opioid, the pharmacokinetics of alfentanil has been extensively evaluated [370] [677] [678] [679] [680] [681] and discussed. [17] [682] [683] [684] Following IV injection, alfentanil plasma concentrations are described by either two-compartment [370] [677] [678] [681] or three-compartment models. [679] [680] Alfentanil's clearance (4-9 mL
min^{-1}
kg^{-1}) is less than that of fentanyl. A small volume of distribution at steady state (0.4-1.0 L
kg^{-1}) limits drug distribution and tissue drug accumulation and is largely responsible for the short elimination half-life of alfentanil in spite of a lower clearance than fentanyl.

Alfentanil's physicochemical properties make it unique compared with the other fentanyl congeners. Alfentanil is lipid soluble but significantly less so than fentanyl. [682] [685] Alfentanil is also bound to plasma proteins (mostly glycoproteins) in higher proportions (90%) than fentanyl. [370] [678] [680] Alfentanil's most unique physicochemical feature is that at physiologic pH, it is mostly (90%) un-ionized because of its relatively low pKa (6.5). [686] Thus, despite more intense protein binding, the diffusible fraction of alfentanil is higher

---

than fentanyl. This explains, in part, its short latency to peak effect after IV injection. Although not proven, it may be that alfentanil's lower lipid solubility compared with fentanyl makes for less uptake of alfentanil by lipid-rich brain tissue. This may also contribute to alfentanil's rapid onset and offset of effect. [141] [682] [687]

The main metabolic pathways of alfentanil are similar to those of sufentanil and include oxidative *N*-dealkylation and *O*-demethylation, aromatic hydroxylation, and ether glucuronide formation. [688] Reported hepatic extraction ratios vary from 0.3 to 0.5. [370] [680] [689] Oxidative- *N*-dealkylation of alfentanil produces its major metabolite, noralfentanil. Other metabolites include desmethylalfentanil, desmethylnoralfentanil, and a number of other products. [690] [691] The degradation products of alfentanil have little, if any, opioid activity. Little alfentanil (<1%) appears in the urine unchanged due to its protein binding, renal tubular reabsorption and hepatic metabolism.

Patients deficient in the cytochrome P-450 form involved in debrisoquin metabolism do not have an altered disposition of alfentanil. [690] [691] This is consistent with the finding that human alfentanil metabolism may be predominantly, if not exclusively, by cytochrome P-450 3A3/4. [692] Cytochrome P-450 3A3/4 is one of a family of cytochrome P-450 isoenzymes that have distinct but overlapping substrate specificities. [693] This enzyme is known to display at least an 8-fold difference in activity in humans. This may be why patients are occasionally found to have a very low alfentanil clearance and unexpected prolonged effects.

Sufentanil

Until recently, the pharmacokinetics of sufentanil had been inadequately characterized because of poor assay sensitivity. For example, in carefully designed and conducted studies, Bovill et al [694] and Hudson et al [695] reported sufentanil pharmacokinetic parameter sets that had a similar central clearance but a 5-fold difference in steady-state distribution volumes. This difference likely reflected that it is difficult to estimate accurately the distribution and elimination properties of a drug unless it can be detected at the low levels present during the later stages of the concentration decay.

Sufentanil's potency is so great that it continues to exert its effects when the concentrations in the plasma are at very low levels. In order to estimate pharmacokinetic parameters that are meaningful, it was necessary to develop an assay that could measure sufentanil at the low levels observed during the elimination phase. A radioimmunoassay was developed that made adequate characterization of sufentanil's pharmacokinetics possible. [696]

As was suggested by the earlier work of Bovill and Hudson and their colleagues, the pharmacokinetics of sufentanil is adequately described by a three-compartment model. [697] After IV injection, first-pass pulmonary extraction, retention, and release are similar to those of fentanyl. [651] Representative pharmacokinetic parameters include an apparent steady-state distribution volume of 262 L and a central clearance of 0.92 L
min^{-1} in a typical adult. [697]

The pKa of sufentanil at physiologic pH is the same as that of morphine (8.0), and, therefore, only a small amount (20%) exists in the un-ionized form. Sufentanil is twice as lipid soluble as fentanyl and is highly bound (93%) to plasma proteins including alpha $_1$ -acid glycoprotein. This combination of physicochemical properties means that sufentanil has a diffusible fraction that is very similar to that of fentanyl.

Sufentanil's hepatic extraction ratio is very high (0.8), and thus changes in liver blood flow can significantly alter its elimination. The major metabolic pathways of sufentanil include *N*-dealkylation, oxidative *N*-dealthylation, oxidative *O*-demethylation, and aromatic hydroxylation. [698] Major metabolites include *N*-phenylpropanamide. Extensive renal tubular reabsorption leads to little unchanged sufentanil in the urine.

Remifentanil

Remifentanil is a synthetic opioid that has been approved for clinical use in the United States and Europe. [699] Although chemically related to the fentanyl congeners, remifentanil is structurally unique because of its ester linkages. Remifentanil's ester structure renders it susceptible to hydrolysis by blood- and tissue-nonspecific esterases, resulting in rapid metabolism. Remifentanil thus constitutes the first "ultrashort"-acting opioid for use as a supplement to general anesthesia.

Remifentanil's pharmacokinetics is best described by a three-compartment model. It appears that the lungs do not represent a site of significant remifentanil metabolism or sequestration. [700] Its clearance is several times greater than normal hepatic blood flow, consistent with widespread extrahepatic metabolism. Several high-resolution studies in both volunteers and patients have confirmed its very short-acting pharmacokinetic profile. [701] [702] [703] Figure 10-23 (Figure Not Available) contrasts the fall in blood concentrations when remifentanil and alfentanil are given in a crossover fashion to a group of adult male volunteers in doses sufficient to produce profound slowing of the EEG during a 10-minute infusion. [703] Remifentanil concentrations fall very rapidly after termination of an infusion.

Remifentanil's physicochemical properties are characteristic of drugs in the fentanyl family. [704] It is a weak base with a pKa of 7.07. It is highly lipid soluble with an octanol/water partition coefficient of 19.9 at pH 7.4. Like the other fentanyl congeners, remifentanil is highly bound (
70%) to plasma proteins (mostly alpha$_1$ -acid glycoprotein). The remifentanil free base is formulated with glycine. Because glycine has been shown to act as an inhibitory neurotransmitter that causes a reversible motor weakness when injected intrathecally in rodents, remifentanil is not approved for spinal or epidural use. [705] In addition, because remifentanil is unstable in solution for long periods of time, the lyophilized powder must be reconstituted within 24 hours prior to use.

After IV injection, remifentanil undergoes widespread extrahepatic hydrolysis by nonspecific blood and tissue esterases. As depicted in Figure 10-24 (Figure Not Available) , the primary metabolic pathway of remifentanil is de-esterification to form a carboxylic acid metabolite, GI-90291. [699] GI-90291 is dependent on renal clearance mechanisms. *N*-dealkylation of remifentanil to GI-94219 is a minor metabolic pathway. Almost 90 percent of the drug is recovered in the urine in the form of the acid metabolite. Although specific human data

Figure 10-23 (Figure Not Available) The raw concentration versus time data when a group of ten volunteers received (in a cross-over trial) remifentanil and alfentanil in doses sufficient to produce profound slowing of the electroencephalogram. *(From Egan et al [703])*

are not available, evidence from dogs suggests that the remifentanil metabolites are, for practical purposes, completely inactive, even in the face of renal failure. [706] A unique feature of remifentanil metabolism is that its pharmacokinetics is not appreciably influenced by renal or hepatic failure. [707] [708]

Remifentanil metabolism is mediated by nonspecific esterases in blood and tissue. In blood, remifentanil is metabolized primarily by enzymes within the red cell. [709] Remifentanil

Figure 10-24 (Figure Not Available) Remifentanil's metabolic pathway. De-esterification by nonspecific plasma and tissue esterases to form a carboxylic acid metabolite (GI-90291) is the primary metabolic pathway. *N*-dealkylation of remifentanil to GI-94219 is a minor metabolic pathway. *(From Egan [699])*

is not a good substrate for pseudocholinesterase and, therefore, is not influenced by pseudocholinesterase deficiency. [710]

NEW PHARMACOKINETIC-DYNAMIC CONCEPTS IN OPIOID PHARMACOLOGY

Irrelevance of the Terminal Half-Life

Half-life, perhaps the most familiar and widely used concept in pharmacokinetics, is the parameter employed to describe the rate at which drug concentrations decline. However, unlike clearance and volume of distribution, half-life is not a fundamental pharmacokinetic parameter. It is, instead, a derived or calculated parameter. Because the value of half-life is dependent on the primary pharmacokinetic parameters volume of distribution and clearance, half-life is not independently influenced by changes in patient physiology. [643] Alterations in volume of distribution, clearance, or both these parameters that come about as a result of changes in patient physiology affect the value of half-life secondarily.

The clinical relevance of half-life is even more obscure when dealing with opioid multicompartmental models because there are as many half-lives as there are compartments. Although the terminal half-life from multicompartmental models has traditionally been the pharmacokinetic parameter relied on for predictions regarding the duration of opioid effect, it can be grossly misleading. Distribution volumes and clearances can be similarly confusing to apply clinically. This confusion relates to the complex way in which these multiple pharmacokinetic parameters interact.

An opioid whose pharmacokinetics is described by a three-compartment model, for example, has three half-lives, three clearances, and four distribution volumes (the steady-state distribution volume is the sum of the three compartment volumes). Which of these multiple parameters is important? How do they interact? To the dismay of clinicians and pharmacokineticists alike, the interaction of these parameters is not easily predicted. In fact, in most cases, it is virtually impossible to predict without the aid of computers. [643]

No single parameter from a multicompartmental model can be relied on to make predictions about the overall opioid pharmacokinetic profile. The terminal elimination half-life is often used clinically as if it constituted the only pharmacokinetic parameter of importance in predicting the duration of opioid effect. [711] In fact, for drugs described by multicompartmental models, there are numerous half-lives that must be considered, along with a host of other parameters. Each half-life, or other parameter, contributes variably to the prediction of drug concentration at a given time after drug administration. [712] For most opioids, the terminal elimination half-life has very minimal impact on the overall decline in drug concentration within the range of clinical significance because most of the concentration decrease is accounted for by other components of the model. The popularity of the terminal elimination half-life as an indicator of duration of drug effect, given its lack of usefulness, is a clinical tradition that requires reexamination. [701]

The primary shortcoming of half-lives in opioid pharmacology is that they fail to account for the important influence of distribution processes on drug disposition. [713] Distribution processes refer to the net transfer of drug between the central compartment and the peripheral compartments. Depending on the size of the peripheral compartment and the rate at which drug transfer occurs, distribution into or out of the peripheral compartments can have a major impact on the concentration versus time profile.

Figure 10-25 (Figure Not Available) is a hydraulic representation of a pharmacokinetic model for a drug such as sufentanil that illustrates how distribution processes influence the concentration versus time profile. For sufentanil, the volume of one of the peripheral compartments is large, and the rate of transfer into it from the central compartment is slow. Thus, the concentrations in the two compartments come to equilibrium very slowly. If equilibrium has not been reached when a sufentanil infusion is terminated, both elimination from the central compartment and distribution into the slowly equilibrating peripheral compartment can combine to lower central drug concentration. Conversely, if the two compartments have come to equilibrium, the peripheral compartment serves as a reservoir of sufentanil that reenters the central compartment after termination of an infusion, thus impeding the decrease in sufentanil concentration produced by elimination from the central compartment.

Context-Sensitive Half-Time

Computer simulation techniques predict the time necessary to achieve a 50 percent decrease in drug concentration after termination of a variable length continuous infusion to a steady-state drug level (Fig. 10-26) (Figure Not Available) . Using concepts developed by Shafer and Varvel, these simulations are an attempt

Figure 10-25 (Figure Not Available) A hydraulic representation of a three-compartment model in which drug administration and elimination occur in the central compartment. This model could represent the pharmacokinetics of a drug such as sufentanil. The model is composed of three cylindric areas (CA_1) representing the volume of the pharmacokinetic compartments (or buckets using this hydraulic analogy). The height (h_1) of the water level in each compartment represents drug concentrations. The pipes connecting the compartments transfer drug from one compartment to another and to the outside at a rate characterized by the conductance (G_1), denoted by the diameter of the pipe. The water entering the system at a specified rate (r[t]) represents drug administration (see text for complete explanation). *(From Hughes et al [713])*

Figure 10-26 (Figure Not Available) A graphic representation of the context-sensitive half-times for the fentanyl congeners. It simulates the time required for a 50 percent decrease in plasma concentration after termination of a continuous infusion. *(From Egan et al [701])*

to provide "context-sensitive half-times" as proposed by Hughes et al. [713] In this case, the "context" is the duration of a continuous infusion. The context-sensitive half-time has also been referred to as the 50 percent decrement time. [714] Such simulations are intended to provide more clinically relevant meaning to pharmacokinetic parameters.

For example, and perhaps contrary to contemporary established notions, alfentanil does not exhibit a more rapid 50 percent decrease in plasma concentration compared with sufentanil after termination of a continuous infusion until after approximately 8 hours of infusion, despite its short terminal elimination half-life. Thus, sufentanil appears to have more favorable pharmacokinetics for infusions lasting less than 8 hours when the goal is to achieve a rapid 50 percent decrease in concentration. As noted previously, in terms of pharmacokinetic theory, this surprising difference between alfentanil and sufentanil can be explained by the fact that sufentanil's pharmacokinetic model has a large, slowly equil-ibrating peripheral compartment that continues to fill after termination of an infusion, thus contributing to the faster decrease in sufentanil's central compartment concentration.

Remifentanil has a context-sensitive half-time that is markedly shorter than those of the other fentanyl congeners. [701] Remifentanil's context-sensitive half-time is also independent of infusion duration. Hence, despite very long infusions, remifentanil concentrations decrease by 50 percent within 3 to 5 minutes of stopping drug

administration. Clinically, when rapid offset of opioid effect is important, or when the need for opioid effect is highly variable, remifentanil's unique pharmacokinetic profile can be exploited.

Interestingly, for cases of very brief duration, the context-sensitive half-times for sufentanil, alfentanil, and fentanyl are nearly identical. Thus, for brief cases, when the opioid is administered by infusion, there would not be any substantial differences among the three drugs in the time to a 50 percent drop in concentration after stopping a continuous infusion. It should be noted that the shapes and relationships of these curves vary depending on the percentage decrease in concentration required. For some anesthetic techniques, a 50 percent decrease in concentration is not sufficient to permit spontaneous ventilation at the end of the operation (e.g., "high dose" opioid anesthesia for cardiac surgery). In such cases, the 80 percent decrement time (or some other percentage) may be more clinically useful. [714]

Biophase and Latency to Peak Effect

Equilibration delay between peak drug concentration in the blood or plasma and peak drug effect must also be considered in understanding the implications of opioid pharmacokinetic simulations. For many opioids, there is a significant time lag between peak concentration in the plasma and peak drug effect. This time lag, or hysteresis, is a function of drug movement into and action within the effect site, or biophase. [715] [716] The hysteresis is a summation of all the events that can conceivably affect the onset of pharmacologic effect such as drug diffusion to the effect site and receptor binding. Because effect site concentrations lag behind plasma or blood concentrations, pharmacologic effect also lags behind plasma or blood concentrations.

In short, opioids do not act in the plasma or blood. Thus, this lag time must be considered when using plasma or blood simulations of drug concentration in forecasting drug effect. The time lag is particularly important when giving opioids by bolus administration such as during patientcontrolled analgesia (PCA) therapy, whereas for long infusions, the time lag assumes less importance because the biophase and plasma are generally much closer to equilibrium.

For many of the opioids in widespread clinical use, the equilibration delay between peak concentration in the plasma and peak effect has been characterized. Flow of drug to the effect compartment is a first-order process and can be elucidated by estimating k_{ec}, a first-order rate constant for

---

Figure 10-27 (Figure Not Available) A simulation of plasma and effect site concentrations after intravenous fentanyl administration during typical anesthesia. Plasma concentrations are indicated by the solid line and are designated C_p. The effect site concentrations are represented by the dotted line and are labeled C_e. The effect site concentrations lag behind the plasma concentrations. *(Reprinted with permission from Egan, [643] St. Louis, Mosby)*

elimination of drug from the effect compartment. When the k_{ec} parameter is available for an opioid, theoretic effect compartment concentrations can be simulated along with plasma or blood concentrations, thus making the implications of the time lag easily appreciated.

Figure 10-27 (Figure Not Available) is a simulation of fentanyl administration, showing both the plasma and effect site concentrations based on parameters from the literature. Recognizing that drug effect best correlates with effect site concentration, the simulation is quite revealing, illustrating that the time course of drug concentration in the effect site is much smoother than in the plasma. In general, the fentanyl congeners (especially alfentanil and remifentanil) have a short k_{eo} half-life ($t_{1/2}\,k_{eo}$), whereas morphine's blood-brain equilibration time is much longer. [717] Hence, when administered in "equipotent" doses, the fentanyl congeners reach peak effect considerably faster than morphine.

Figure 10-28 (Figure Not Available) contrasts the implications of plasma effect site equilibration delay on the achievement of peak concentrations in the effect site for the fentanyl congeners. Note that alfentanil and remifentanil reach peak concentrations very shortly after bolus administration, whereas fentanyl and sufentanil are slower to reach peak concentration in the effect site. [718] When equipotent doses are given, this simulation is a general guide to the speed of onset of the fentanyl congeners. Alfentanil and remifentanil can be regarded as

---

Figure 10-28 (Figure Not Available) A computer simulation of the time required to reach peak effect site concentration after bolus administration of fentanyl, alfentanil, sufentanil, and remifentanil using pharmacokinetic parameters from the literature. This is a graphic illustration of the plasma-biophase equilibration process for these drugs. C_e is the effect site concentration; a bolus injection was made at time 0. *(From Egan [716])*

very rapid-onset opioids (i.e., short latency to peak effect). Interestingly, after single bolus administration, alfentanil and remifentanil also exhibit a rapid speed of offset because effect site concentrations begin to fall immediately after the rapid peak. [18] Note that gross overdosage of any of these drugs renders these simulations irrelevant because opioid receptor saturation may occur before peak effect site levels are reached.

Slope of the Concentration-Effect Relationship

Although clinicians have traditionally relied on pharmacokinetic parameters in predicting the time course of drug effect, the temporal profile of drug effect is a function of both pharmacokinetic and pharmacodynamic parameters. Computer modeling research has focused attention on the steepness of the concentration-effect relationship as an important parameter in predicting duration of drug effect.

For opioids, the concentration-effect relationship is usually described graphically by a sigmoidal maximum-effect curve in which drug concentration in the site of action is plotted against drug effect. This sigmoid curve is represented mathematically by the following equation:

where E is the predicted effect, E_0 is the baseline effect level, E_{max} is maximal effect, C_e is effect site concentration, gamma is a measure of curve steepness, and EC_{50} is the effect site concentration that produces 50 percent of maximal effect. EC_{50} is the measure of drug potency, which can be compared with other drugs of the same class.

This mathematic representation of the concentrationeffect relationship is appealing not only because it is harmonious with experimental observations, but also because it is consistent with the receptor concept of opioid action. When sufficient numbers of receptors are highly activated, the maximal possible effect is achieved; that is, biologic systems are not capable of an infinite response. Thus, the opioid concentration-effect relationship is well described by a sigmoidal maximum effect curve in which a plateau in drug effect is eventually observed despite enormous increases in opioid concentration.

The gamma parameter of the sigmoidal maximum effect equation is a measure of curve steepness. When gamma is large, the concentration-effect relationship is steep. For drugs with a steep concentration-effect relationship, small changes in drug concentration within the steep portion of the curve produce large changes in drug effect. For drugs that exhibit concentration-effect relationships in which gamma is small, a small change in concentration does not result in such obvious changes in the magnitude of drug effect.

For drugs such as opioids that have a steep concentration-effect relationship, the correlation of effect with concentration is often observed to be binary. In other words, the degree of drug effect is either substantial or it is near negligible. This is because when drug concentration drops much lower than the EC_{50}, the probability of substantial drug effect is minimal, whereas when concentrations are much higher than EC_{50}, the probability of near maximum drug effect is high. When the concentration-effect relationship is less steep, the correlation of concentration with effect is more continuous.

One very important practical application of this concept is that pharmacokinetic parameters cannot be interpreted in isolation in predicting the duration of drug effect.

Although knowledge of the predicted decline in drug concentration based on pharmacokinetic parameters is helpful, it must be interpreted with knowledge about the drug potency and steepness of the concentration-effect relationship.

For example, in Figure 10-29 (Figure Not Available) , the predicted decline in fentanyl concentration after a steady-state infusion is terminated is plotted versus time. The probability of drug effect is also plotted for two different theoretic concentration-effect relationships; one that is steep (gamma = 10) and another that is not steep (gamma = 2). When the concentration-effect relationship is steep, there is a rapid dissipation in the probability of drug effect with declining drug concentration, whereas when the concentration-effect relationship is not steep, there is a much more gradual decline in the probability of drug effect with falling drug concentration. This notion has been quantified mathematically and has been designated the mean effect time. [719]

The implications of context-sensitive half-time (or 50% decrement time) must thus be interpreted in concert with knowledge of the concentration-effect relationship. Duration of drug effect as predicted by the context-sensitive half-time closely parallels that predicted by the mean effect time when the concentration-effect relationship is steep. When the concentration-effect relationship is less steep, the context-sensitive half-time may be less useful in predicting the time course of drug effect. For alfentanil, a drug whose concentration-effect relationship is steep, the mean effect time and context-sensitive half-time predict a similar time course of drug effect. Conversely, for midazolam, a drug whose concentration-effect relationship is less steep, the mean effect time and context-sensitive half-time predict a different time course of drug effect after termination of an infusion. [719]

The clinical application of these concepts with regard to opioid pharmacology relates to the steepness of the concentration-effect relationship of opioids. Opioids are known to be drugs with relatively steep concentration-effect relationships; that is, the gamma parameter is relatively large. Thus, very small changes in opioid concentration can produce large changes in the degree of drug effect. This means that for patients in whom a typical analgesic regimen fails, sometimes very small increases in dosage can result in adequate analgesia. [720] Figure 10-30 (Figure Not Available) illustrates how small increases in meperidine concentration resulted in an abrupt change from inadequate to good analgesia because of the steepness of the concentration-effect relationship. Patient response to opioids is often binary. Analgesia is either adequate or it is not.

Computerized Delivery Methods in Opioid Research and Clinical Practice

Until recently, the most sophisticated delivery device for the administration of opioids was the calculator pump, a device that enabled an accurate and precise delivery of fluid

---

Figure 10-29 (Figure Not Available) The decline in fentanyl concentration in the plasma after stopping a 60-minute infusion and targeting a concentration of 10 ng/mL versus the probability of drug effect for two concentration-effect relationships, one steep (gamma = 10) and the other less steep (gamma = 2). Note that when the slope of the concentration-effect relationship is steep, the probability of substantial drug effect as a function of concentration is nearly a binary response (see text for complete explanation). *(From Bailey [719])*

per unit of time. Used in both clinical and research settings, the physician operator of these devices simply specifies a delivery rate in terms of milliliters per hour or micrograms per kilogram per minute. The PCA machine is a hybrid of the calculator pump that permits patient control of opioid administration within physician-constrained parameters. The primary limitation of these calculator pumps is that they do not achieve the pharmacokinetic exactness possible with more advanced methods of administration.

Advances in pharmacologic modeling and infusion pump technology have made it possible to administer opioids (and other drugs) via a computer-controlled infusion pump (CCIP). [721] By coding a pharmacokinetic model into a computer program and linking it to an electronic pump modified to accept computerized commands, delivery according to a drug's specific pharmacokinetic parameters can be achieved. The physician operating a CCIP designates a target concentration to achieve rather than specifying an infusion rate. The CCIP then calculates the necessary infusion rates to achieve the targeted concentration. This process is somewhat akin to delivering inhaled anesthetic through the lungs using a vaporizer.

Borrowing from inhalation anesthesia concepts, the CCIP makes progress toward the concept of a "vaporizer" for opioids because they address the fundamental limitation associated with delivering drugs directly into the circulation. Constant

Figure 10-30 (Figure Not Available) Blood meperidine concentration-response curves for three individual patients (A, B, C) illustrating the steepness of the typical opioid concentration-effect relationship. Postoperative patients rated their pain from 0 (no pain) to 2 (severe pain) in response to meperidine therapy. As meperidine concentrations increased, eventually a small increase produced a dramatic improvement in the patient's pain. *(From Austin et al [720])*

---

rate infusions result in continuous drug uptake. The CCIP, in contrast, gradually decreases the rate of infusion based on the drug's pharmacokinetics. Known in its general form as the BET method (i.e., bolus, elimination, and transfer), [722] the dosing scheme determined by a CCIP accounts for the initial concentration after a bolus dose and the subsequent drug distribution and clearance while an infusion is ongoing.

Delivery of an opioid via CCIP requires a different approach by clinicians. Rather than setting an infusion rate based on clinical experience and literature recommendations, the anesthesiologist using a CCIP designates a target concentration, and the CCIP calculates the infusion rates necessary to achieve the concentration over time. The CCIP changes the infusion rates at frequent intervals, sometimes as often as every 10 seconds. Successful use of a CCIP thus requires knowledge of the therapeutic concentrations appropriate for the clinical setting.

Computer-controlled drug delivery is an exciting area with promising potential in anesthesiology and pain management. Available CCIP prototypes typically perform quite well, as exemplified by Figure 10-31 (Figure Not Available) , a fentanyl CCIP application. [723] Pharmacokinetic model-based PCA analgesia is also being developed with optimism. [724] This application of CCIP technology requires the patient to specify whether pain relief is adequate or not. The CCIP raises or lowers the target concentration accordingly.

Surrogate Measures of Opioid Potency

Because a high-resolution measure of analgesia is not available, opioid potencies are usually estimated in terms of some surrogate measure. Surrogate measures are used when the drug effect of clinical interest cannot be directly or conveniently measured. In the case of opioids, although many investigators employ experimental pain models with success, [725] surrogate measures have been extremely useful in providing an accurate and precise measure of potency.

Reduction of the MAC required to produce lack of movement to skin incision (see earlier) has been a frequently utilized surrogate measure in the estimation of opioid potency. [144] [148] [726] [727] Because they quantitate the interaction between opioids and inhaled anesthetics, the estimations of opioid potency determined by MAC reduction methodology have obvious implications for the intraoperative use of opioids, but their application outside the operating room is less clear.

The EEG has been another widely utilized surrogate measure in estimating opioid potency. [141] [142] [152] In contrast to more clinically oriented measures of opioid effect such as respiratory depression or analgesia, the EEG is attractive to investigators seeking to characterize opioid pharmacodynamics because it is an objective, continuous, reproducible, high-resolution signal. The EEG is also advantageous because it can be used as an effect measure when an experimental subject is unconscious or apneic, whereas many of the more clinically oriented measurements require awake, cooperative subjects. The EEG also offers the advantage of relative noninvasiveness. For example, it does not require a skin incision, as MAC reduction studies do, and thus it can be used in volunteer studies.

At relatively high levels, potent mu-receptor opioid agonists produce characteristic changes in the EEG waveform that can be processed into univariate descriptors of drug effect. Figure 10-32 (Figure Not Available) illustrates the changes in the raw EEG that are characteristic of the fentanyl family of opioids. When processed by Fourier spectral analysis, these raw EEG changes translate into a significant decrease in the value of the spectral edge, a parameter that quantitates the frequency

below which a given percentage (usually 95%) of the power in the EEG signal is found. [728]

Figure 10-31 (Figure Not Available) The best, median, and worst performances of a computer-controlled fentanyl delivery device in 21 patients. The line represents the predicted concentration (the computer's target), and the diamonds represent the actual measured concentrations. *(From Shafer et al [723])*

Figure 10-32 (Figure Not Available) The raw electroencephalographic (EEG) changes produced by remifentanil (asleep) compared with the awake state in a representative volunteer. These changes are representative of the EEG effects produced by all the fentanyl congeners. muV, microvolts. *(From Egan et al [703])*

Despite their theoretic appeal, the use of surrogate measures in clinical trials and pharmacodynamic studies is controversial. [729] The obvious concern over surrogate measures is whether or not the surrogate measure actually provides a clinically meaningful representation of what the investigators would really prefer to measure but cannot. Many clinical end points, particularly those that translate into an actual change in patient outcome or cost savings, are extremely difficult to measure. Surrogate measures are obviously useless if no meaningful connection exists between the surrogate measure and the actual clinical effects.

Evidence demonstrates that the EEG as a surrogate measure of opioid effect does, in fact, relate in a proportionally consistent way to clinical measures of opioid potency. [730] Figure 10-33 (Figure Not Available) compares the EEG EC_{50} for three fentanyl congeners with their therapeutic windows measured in numerous clinical studies. Note that each clinical therapeutic window is a relatively constant fraction of the EEG EC_{50} . Thus, although the clinical meaning of the EEG changes produced by opioids is unclear, the opioid potencies estimated using the EEG as a surrogate measure appear to be clinically reliable because they relate to clinically determined potencies in a proportional, reproducible fashion. As illustrated in Figure 10-33 (Figure Not Available) , the same appears to be true for the MAC reduction surrogate measure.

The clinical importance of this surrogate measure issue in anesthesiology is straightforward. For opioids, because the surrogate measures do not always assess the drug effect of clinical interest (e.g., analgesia in the conscious patient), estimations of potency based on surrogate measures must be interpreted with some caution. Because practitioners rely on potency ratios of one drug to another in formulating dosage regimens, it is important to understand how these potencies are estimated and to recognize their limitations.

Figure 10-33 (Figure Not Available) Depiction of the electroencephalographic potency (EC_{50}) versus other clinical measures of potency for the fentanyl congeners. The vertical line in each therapeutic window (horizontal bar) represents the mean value for each window. Note that the therapeutic windows for each fentanyl congener are a relatively constant fraction of its EEG EC_{50} . *(From Egan et al [730])*

For practical purposes, it appears that potency estimates based on the EEG and MAC reduction surrogates are reliable and can be applied clinically.

FACTORS THAT ALTER PHARMACOKINETICS AND PHARMACODYNAMICS

Age

The influence of age on opioid pharmacokinetics and pharmacodynamics has been extensively investigated (Ch. 61) . Unfortunately, conflicting data from these numerous studies make it difficult to draw definitive conclusions. The difficulty in synthesizing this literature is largely a function of methodologic differences among the numerous studies, especially with regard to data analysis techniques. Another limitation is that many studies were simply not sufficiently powerful or relied on historical controls. However, the available data do permit a few generalizations that apply to most opioids.

It is clear that neonates exhibit a reduced rate of elimination of essentially all opioids. [731] This is presumably due to immature metabolic mechanisms, including the cytochrome P-450 system. [732] For example, neonates are known to have poor morphine clearance, resulting in extended elimination half-times. [733] Similarly, the elimination of fentanyl has also been shown to be prolonged in neonates. [367]

The prolonged elimination of opioids observed in the neonatal period quickly normalizes toward adult values within the first year of life. [731] By the end of the first decade of life, maximal opioid metabolic capacity is achieved, and the clearance of most opioids is at least as great as, and often is greater than, in typical adults. [734] For example, clearance of alfentanil in children 1 to 7 years of age is substantially greater than in adults. [735]

With advanced age, although pharmacokinetic changes may play a minor role, pharmacodynamic differences are primarily responsible for the decreased dose requirement in the elderly. In other words, the aging brain is in fact more sensitive to a given concentration of opioid. Scott and Stanski [136] showed that the concentration of fentanyl and alfentanil necessary to produce half of maximal slowing of the EEG (i.e., the EC_{50}) is lower in the elderly compared with younger adults, as illustrated in Figure 10-34 (Figure Not Available) . The hypothesis that pharmacodynamic and not pharmacokinetic differences account for the greater part of the reduced dosage requirement in the elderly is also supported by clinical studies in patients. [736]

However, it is possible to demonstrate pharmacokinetic changes in the disposition of opioids in the elderly. Many studies show a small but significant decrease in opioid clearance. For example, Helmers et al [737] demonstrated that alfentanil clearance was reduced in the elderly. Similar reductions in fentanyl clearance were reported by Bentley et al. [339] Other investigators have shown that the elderly achieve a higher peak concentration after a bolus dose of fentanyl, presumably because of a lower cardiac output that results in a smaller central volume of distribution. [738] Overall, however, the clinical impact of these pharmacokinetic changes is thought to be less important than the pharmacodynamic changes in the elderly (i.e., increased potency of the opioids in the elderly).

Data from studies investigating the pharmacology of remifentanil support the generalization that the elderly exhibit both pharmacokinetic and pharmacodynamic changes in opioid behavior. Minto et al [739] confirmed that age was inversely correlated with remifentanil central volume of distribution, clearance, and potency. When translated into dosage strategy, these combined pharmacokinetic and pharmacodynamic changes mandate a reduction in remifentanil dosage by at least 50 percent or more in the elderly.

Weight

The effect of body weight on opioid pharmacokinetics has not been conclusively investigated, even though opioid dosage regimens are often based on total body weight. Available

Figure 10-34 (Figure Not Available) The relationship of age and opioid potency as measured by the EEG. For both fentanyl and alfentanil, as age increases the concentration required to achieve 50 percent of maximal, brain depression (i.e., the IC_{50}) on the EEG decreases. *(From Scott and Stanski [136])*

literature suggests that opioid pharmacokinetic param-eters are not closely related to total body weight, except perhaps distribution parameters. Instead, many opioid pharmacokinetic parameters, especially clearance, appear to be more closely related to lean body mass. This means that opioid dosage regimens may best be based on lean body mass and not total body weight.

A preliminary report by Bentley et al [740] demonstrated that fentanyl pharmacokinetics is not grossly different in lean versus obese subjects. Schwartz et al [741] reported that sufentanil exhibits more extensive distribution in obese patients, whereas clearance was unchanged. However, this study reported total body weight-normalized pharmacokinetic parameters, and therefore the results must be interpreted with caution because weight-normalized parameters can sometimes achieve a statistically significant difference when none exists. [143] [742] A sophisticated analysis by Maitre et al [743] of a large group of patients who received alfentanil suggests that its volume of the central compartment does correlate with total body weight.

As illustrated by Figure 10-35 (Figure Not Available) , total body weight-based dosing in an obese patient results in much higher remifentanil effect site concentrations than does lean body mass-based dosing. In contrast, for lean patients, the concentrations that result from total body weight-based dosing are not much greater than those based on lean body mass.

The recommendation that opioid dosing be based on lean body mass is consistent with current knowledge regarding the effect of body weight on pharmacokinetics. There is mounting evidence to suggest that lean body mass is a better predictor of metabolic capacity than total body weight. [742] This is probably related to the concept that more than 90 percent of the body's metabolic processes is thought to occur in lean tissue. [744] For practical purposes, because the estimation of lean body mass requires a somewhat cumbersome calculation that is not well suited to the clinical environment, ideal body weight, a parameter closely related to lean body mass and one that is perhaps more easily "guesstimated" by the clinician, is probably an acceptable alternative.

Renal Failure

The impact of renal failure on opioid pharmacokinetics has been extensively evaluated (Ch. 53) . Renal failure has implications of major clinical importance with respect to morphine and meperidine. For the fentanyl congeners, the clinical importance of kidney failure is less marked but is nonetheless measurable. [745]

Morphine is a prototypical example of an opioid with active metabolites that are dependent on renal clearance mechanisms for elimination. Morphine is principally metabolized by conjugation in the liver and is eliminated via renal excretion of water-soluble glucuronides (M3G and M6G). [652] The kidney also plays a role in the conjugation of morphine, accounting for nearly 40 percent of its metabolism. [653] Although the actions of M3G are poorly understood, M6G is a mu-agonist with similar

or greater potency than morphine. [746] Patients with renal failure can develop very high levels of M6G and life-threatening respiratory depression. [747] [748] [749] Figure 10-36 (Figure Not Available) contrasts the morphine and metabolite concentrations that result when morphine is

Figure 10-35 (Figure Not Available) A computer simulation of a typical remifentanil "balanced" anesthetic regimen (i.e., remifentanil in combination with nitrous oxide, inhaled vapor, or propofol) when the dosage is calculated based on lean body mass (LBM) or total body weight (TBW) for lean (57-kg) and obese (159-kg) female patients who are the same height (5 feet, 5 inches). The dosage scheme was 1 mg/kg bolus injection followed by an infusion of 0.5 mug/kg/min for 15 minutes and 0.25 mug/kg/min for an additional 105 minutes. Note that TBW-based dosing in an obese patient results in dramatically higher concentrations. *(From Egan et al [1215])*

Figure 10-36 (Figure Not Available) An example of kidney failure and its effect on the elimination of morphine metabolites. The top panel shows the concentration versus time profile of patients in renal failure who received morphine (0.1 mg/kg) intravenously during arterio-venous fistula surgery. The bottom panel shows the same profile for patients with normal kidney function. Note the prolonged elimination of the morphine glucuronides in the kidney failure group. This delayed elimination is reversed with renal transplantation. *(From Osborne et al [750])*

given to patients in kidney failure who are undergoing arteriovenous fistula procedures compared with subjects with normal renal function. [750] In view of these changes induced by renal failure, morphine may not be a good choice in patients with severely altered renal clearance mechanisms. At the very least, morphine dosages should be decreased, and patients should be carefully monitored.

The clinical pharmacology of meperidine is also significantly altered by renal failure. Like morphine, meperidine is metabolized in the liver to several metabolites that are subsequently rendered soluble by glucuronidation and are eventually excreted by the kidney. Normeperidine, the chief metabolite, has analgesic and CNS excitatory effects. [751] These excitatory effects can range from anxiety and tremulousness to multifocal myoclonus and frank seizures. [752] As with morphine, because the active metabolites are subject to renal excretion, this potential CNS toxicity secondary to normeperidine accumulation is especially a concern in patients in renal failure. [668] Fatal and near fatal CNS toxicities including convulsions and extreme tachycardia and hypertension in patients receiving meperidine who coincidentally developed acute renal failure have been reported. [753] [754] [755] It should be emphasized, however, that the CNS toxicity of meperidine can also be observed in patients with normal renal function. [752]

In contrast to morphine and meperidine, the clinical pharmacology of the fentanyl congeners is not grossly altered by kidney failure, although a decrease in plasma protein binding may potentially alter the free fraction of the fentanyl class of opioids. [745] For example, fentanyl clearance is not altered by renal failure. [756] Although fentanyl metabolites may accumulate, they are thought to be inactive and nontoxic. Patients with renal failure and hyperlipoprotein-emia do, in fact, bind more fentanyl to plasma proteins, but they do not demonstrate a change in clinical effect. [757]

As with fentanyl, sufentanil pharmacokinetics is not altered in any consistent fashion by renal disease, although greater variability exists in its clearance and elimination half-life when patients have impaired renal function. [758] The available data suggest that a substantial dose modification does not appear to be necessary for sufentanil in patients with renal failure. [759] [760]

Two studies have reported alfentanil's pharmacokinetics in patients with renal failure. [761] [762] Both suggested that an increased clinical effect was likely with alfentanil because of a decreased initial volume of distribution and an increased alfentanil free fraction. [761] [762] Discrepancies exist in the results of the two studies, but clearance was unchanged in both. Variations in plasma protein abnormalities (hypoproteinemia, hyperlipoproteinemia, and various accumulated endogenous and exogenous substances) could possibly explain the differing results. Both reports concluded that no delay in recovery after alfentanil should be expected.

Data regarding the effect of renal failure on remifentanil pharmacology suggest that neither the pharmacokinetics nor the pharmacodynamics of remifentanil is altered by impaired renal function. [708] Evidence suggests that the metabolite GI-90291, which is eliminated by the kidney, is at least three orders of magnitude less potent than remifentanil. Levels of GI-90291 that develop during a remifentanil infusion in patients in renal failure are not likely to produce any clinically significant effects. [706] [708]

Hepatic Failure

Even though the liver is the metabolic organ primarily responsible for opioid biotransformation, the degree of liver failure typically observed in perioperative patients, with the exception of patients undergoing liver transplantation, does not have a major impact on the pharmacokinetics of most opioids (Chs. 54 and 55). This reflects the substantial metabolic reserve of the liver, particularly with regard to conjugation reactions (e.g., glucuronidation). [763]

Liver disease can influence opioid pharmacokinetics in a host of ways. In addition to reduced metabolic capacity (i.e., cytochrome P-450 system and conjugation), liver disease may also lead to reductions in hepatic blood flow, hepatocellular mass, and plasma protein binding. The increase in total body water and the edema of advanced liver disease may alter the distribution characteristics of a drug. Finally, enzyme induction such as observed in early alcoholism can actually increase the liver's metabolic capacity. Some of these derangements have opposing pharmacokinetic effects that together may be offsetting.

Because of the numerous mechanisms by which liver disease may alter opioid pharmacokinetics, it can be difficult to predict exactly how an individual patient with liver disease will respond to opioid administration. However, based on the opioid's hepatic extraction ratio and the percent that is protein bound, it is possible to predict the likely impact of liver failure. This notion can be graphically depicted by constructing what is known as the Blaschke triangle, relating hepatic extraction ratio to protein binding. [764] Inspecting the Blaschke triangle makes it possible to categorize drugs according to whether their hepatic metabolism is sensitive to changes in hepatic blood flow, enzyme capacity, or protein binding, as illustrated in Figure 10-37 .

An opioid that is highly extracted by the liver, such as fentanyl or morphine, is substantially influenced by changes in hepatic blood flow, regardless of the amount that is protein bound. Drugs with a low hepatic extraction ratio and low protein binding, such as pancuronium, are especially sensitive to reduced metabolic capacity, but they are not greatly influenced

Figure 10-37 The Blaschke triangle for opioids and other commonly used anesthetics and muscle relaxants. Opioids (and most drugs) can be classified in three general categories with regard to the impact of altered liver function on pharmacokinetics: flow limited, capacity limited-binding insensitive, and capacity limited-binding sensitive. Most, but not all opioids, are flow limited, so that decreased hepatic metabolic capacity does not affect their pharmacokinetics significantly. AL, alfentanil; AT, atracurium; D, diazepam; F, fentanyl; K, ketamine; MID, midazolam; MP, meperidine; MS, morphine; P, pancuronium; S, sufentanil; STP, thiopentone; V, vecuronium.

by reductions in liver blood flow or protein binding. Because none of the common opioids is similar to a drug such as pancuronium in terms of its position on the Blaschke triangle (low protein binding and low hepatic extraction ratio), opioid pharmacology in general is not substantially affected by reduced hepatic metabolic capacity. Opioids such as alfentanil (high protein binding and moderate to low hepatic extraction) are to some extent similar to drugs such as diazepam and thiopentone in that their pharmacokinetics is substantially influenced by changes in protein binding but is relatively unchanged by reductions in hepatic blood flow. Using the Blaschke triangle, opioids can be classified as flow-limited or capacity-limited and binding-sensitive.

In terms of the individual opioids, morphine pharmacokinetics is relatively unchanged by liver failure. [765] This is in part a function of the substantial extrahepatic metabolism of morphine by the kidney. Mazoit et al [766] reported a reduction in morphine clearance in cirrhotic patients, but the pharmacokinetic parameters they reported were similar to those of other investigators in normal subjects. As noted earlier, a reduction in hepatic blood flow would be expected to slow the decline of morphine plasma concentrations.

As an exception to the rule, meperidine is an opioid whose pharmacokinetics is altered by liver failure (perhaps more so than predicted by the Blaschke triangle). Hepatic cirrhosis is associated with reduced clearance and a longer terminal half-time. [767] Other investigators have also documented decreased meperidine

clearance and prolonged elimination half-lives in patients with cirrhosis [768] [769] and acute viral hepatitis. [770] It is not clear how clinically important these changes are.

The disposition of fentanyl is not altered in patients with cirrhosis during general anesthesia. [771] As predicted by the

Blaschke triangle, reductions in liver blood flow that result from either liver disease or some other disorder (e.g., shock) will delay the decline of fentanyl plasma concentrations. Interestingly, although not necessarily related to liver disease, a positive correlation exists between alcohol consumption and the need for fentanyl supplementation during N_2O-O_2-relaxant anesthesia. [772] Up to 70 percent more fentanyl (6.4 versus 3.8 mum
kg
h) was needed in individuals with a mean annual consumption of 31 L pure alcohol.

As with meperidine, alfentanil's pharmacokinetics is also altered by hepatic failure. Ferrier et al [773] reported that patients with alcoholic cirrhosis have reduced alfentanil plasma clearance and prolonged terminal half-times. Thus, an augmented and prolonged alfentanil effect can be anticipated in patients with cirrhosis. Surprisingly, children with cholestatic liver disease who were scheduled to undergo orthotopic liver transplantation showed no changes in alfentanil clearance and volume of distribution at steady state. [774] Although not necessarily related to liver disease, changes in protein binding are thought to account for a substantial proportion of the intersubject pharmacodynamic variability of alfentanil. [775] There is an obvious inverse correlation between unbound alfentanil and the EC_{50} (i.e., the measure of potency). As noted with fentanyl, patients with high alcohol consumption rates require higher plasma alfentanil levels than nondrinking patients. Decreased CNS sensitivity to opioid effects is the likely cause of these pharmacodynamic differences in alcoholics. [776]

Although liver blood flow does not affect the kinetics of alfentanil as much as morphine and fentanyl, decreases in hepatic blood flow can still decrease alfentanil elimination. [689] Major intra-abdominal surgery has been shown to prolong alfentanil effects by reducing clearance from 6.8 to 2.6 mL
min^{-1}
kg^{-1}. [777] Greater elimination half-lives (3.7±2.6 h) have also been observed for alfentanil in patients undergoing abdominal aortic surgery. [778]

As with morphine and fentanyl, sufentanil's pharmacokinetics appears to be minimally changed in cirrhotic patients. [779] However, major intra-abdominal surgery can increase the volume of distribution at steady state and the elimination half-life of sufentanil. [695]

Remifentanil is perhaps the prototype example of an opioid whose pharmacokinetics is completely unchanged by liver disease. Dershwitz et al [707] studied the impact of severe liver disease on remifentanil pharmacokinetics and pharmacodynamics in volunteers. They found no difference in remifentanil pharmacokinetics between the two groups. However, the liver disease cohort appeared to be more sensitive to the respiratory depressive effects of remifentanil. Perhaps the most compelling evidence of no effect of hepatic dysfunction on the pharmacokinetics of remifentanil is that its kinetics does not change during the anhepatic phase of orthotopic liver transplantation. [780]

Cardiopulmonary Bypass

CPB produces significant alterations in the pharmacokinetics of most opioids (Ch. 49) . [755] [781] These alterations are a result of CPB-induced modifications in distribution volumes (secondary to priming), changes in acid-base balance, organ blood flow, plasma protein concentrations, and body temperature. The binding of drugs to components of the bypass circuit is another mechanism by which CPB may alter opioid pharmacokinetics.

There has been little work on the impact of CPB on morphine pharmacokinetics. A single study demonstrated that when morphine is given as a premedicant before cardiac anesthesia, its concentrations decline significantly on initiation of CPB. [782]

Fentanyl pharmacokinetics during CPB has been extensively studied and can serve as a prototype representing the fentanyl family of opioids. Fentanyl pharmacokinetics is extensively altered by CPB. Plasma concentrations of fentanyl decrease by 30 to 60 percent within minutes of starting CPB. This decrease is greater than can be attributed to hemodilution alone. [226] [328] *In vitro* experiments have shown that some of the initial concentration decline after starting CPB can be attributed to sequestration of fentanyl on components of the bypass circuit, especially the oxygenators. [783] [784] Typically, the concentrations of fentanyl during CPB are steady. After termination of CPB, there is usually a rise in fentanyl concentration toward pre-bypass levels. [785] [786] Overall, the elimination of fentanyl is prolonged because of increased distribution and decreased clearance. [226] [785] These changes are attributed to hypothermia, hemodilution, and decreased hepatic blood flow.

Sufentanil's pharmacokinetics during CPB is thought to be very similar to that of fentanyl. Figure 10-38 illustrates the temporal profile of sufentanil concentrations in relation to the CPB events when sufentanil is given in several different doses. [787] Like fentanyl, sufentanil is sequestered in bypass circuit components, although less so. [788] [789] As with fentanyl, sufentanil's elimination is thought to be somewhat prolonged by CPB. [787]

Alfentanil's pharmacokinetics is similarly influenced by CPB. Its elimination is prolonged primarily because of increased distribution. [387] [790] Because the drug's hepatic extraction ratio is relatively low, CPB-induced reductions in liver blood flow do not contribute much to the overall pharmacokinetic changes of CPB. Importantly, the free fraction of alfentanil during CPB remains constant despite complex changes in binding protein concentrations. [791] In contrast to fentanyl, alfentanil is not as likely to be bound by CPB bypass components. [783]

Comparatively little is known about remifentanil's pharmacokinetics during CPB. For example, how much remifentanil is sequestered by the CPB circuit is unknown. It is clear, however, that remifentanil remains a very short-acting drug despite CPB. During the hypothermic portion of CPB, remifentanil's clearance decreases by about 20 percent and then returns to pre-bypass levels after rewarming. [792] Table 10-13 summarizes the pharmacokinetic consequences of CPB.

Acid-Base Changes

The overall clinical impact of acid-base changes on opioid pharmacokinetics is complex, difficult to predict, and incompletely evaluated (Ch. 38) . For example, respiratory acidosis during fentanyl administration has multiple effects including increases in ionization and CBF and decreases in plasma protein binding. [793] [794] [795] How a change in pH can affect opioid kinetics has been described by Lullmann et al. [796]

Figure 10-38 Plasma sufentanil levels after 30-mug/kg bolus (Delta), a 10-mug/kg/min infusion (
), a 20-mug/kg bolus plus a 0.1-mug/kg/min infusion (
), and a 40-mug/kg bolus plus a 0.2-mug/kg/min infusion (
) and the influence of cardiopulmonary bypass.

When mechanical ventilation is abruptly terminated, respiratory acidosis rapidly decreases the pH of the extracellular (blood and interstitial) space. More fentanyl in the interstitial compartment will be ionized, as determined by the Henderson-Hasselbalch equation for weak bases:

More opioid receptors, on cell membranes that interact with ionized fentanyl, are stimulated, producing an enhanced

TABLE 10-13 -- Pharmacokinetic Consequences of CPB

EVENT	CONSEQUENCE
Hemodilution	50% Plasma opioid level; Vd_{ss}
Decreased plasma proteins	Opioid free fraction Vd_{ss}
Hypotension	- Hepatic blood flow - Drug distribution - Opioid clearance
Membrane oxygenator	Plasma opioid levels
Decreased muscle perfusion	Opioid accumulation in muscle
Lung isolation	Opioid trapping
Hypothermia	Opioid potency, need for anesthesia, drug metabolism
Decreased hepatic blood flow, opioid clearance and distribution	Opioid levels constant after initial decrease
Terminating cardiopulmonary by- pass and improved tissue perfusion	Opioid reuptake from tissues and plasma levels
Post-cardiopulmonary bypass	Prolonged $t_{½\ beta}$ persists

$t_{½\ beta}$, elimination half-life; Vd_{ss}, volume of distribution at steady state.

opioid effect (see Fig. 10-20) . Additional respiratory acidosis due to opioid-induced depression of respiratory centers could produce a vicious cycle of ventilatory depression-acidosis-increased ionized fentanyl and increased ventilatory depression. In addition, the acidosis (and shift from free base to ionized fentanyl in the interstitial space) draws un-ionized fentanyl out of the intracellular compartment, where a 13-fold accumulation of fentanyl occurs, further augmenting opioid effects. Finally, increased ionization decreases the amount of fentanyl available for hepatic metabolism or renal excretion. [796] Alfentanil, with a pKa of 6.5, is not as greatly influenced by either pH changes or tissue accumulation. [796]

Intraoperative hyperventilation can also increase the duration of respiratory depression. [326] Brain fentanyl levels are higher with respiratory alkalosis. [355] Alkalosis also increases the lipophilicity (increased octanol/water partition coefficient) of several opioids. Serum and brain levels of morphine are elevated by 10 to 30 percent and 30 to 70 percent, respectively, in hypocapnic, alkalotic dogs. [793] Similar findings have been reported for morphine in rats subjected to alkalosis. [797] Alkalosis favors un-ionized morphine and may enhance brain penetration in spite of decreased CBF and increased plasma protein binding. [793] Nishitateno et al [793] reported a decreased clearance of morphine, and Schwartz et al [798] noted an increased volume of distribution for sufentanil after hyperventilation. Both changes could explain documented increases in elimination half-life and duration of action. Hypercapnia also increases CNS morphine levels in the dog, although to a lesser degree. Hypercapnia also prolongs the removal of morphine from the brain, probably because of CNS acidosis and increased morphine ionization within the brain. Thus, both intraoperative respiration alkalosis

and respiratory acidosis, especially in the immediate postoperative period, can prolong and exacerbate opioid-induced respiratory depression.

ANESTHETIC TECHNIQUES

Sedation and Analgesia

Opioids are frequently used to relieve pain during monitored anesthesia care and regional or general anesthesia (Ch. 65) . For short but painful procedures such as field or retrobulbar nerve blocks, a single bolus injection of an opioid can provide significant relief. Morphine is slow in onset and does not allow rapid titration to effect. Meperidine (50-100 mg IV) produces variable degrees of pain relief and is not always effective in patients with severe pain. [720] IV boluses of fentanyl (1-3 mug/kg), alfentanil (10-20 mug/kg), or sufentanil (0.1-0.3 mug/kg) can produce potent, short-lasting analgesia. For example, the administration of 1 to 2 mL of alfentanil 1 to 2 minutes prior to a short but painful injection or procedure can significantly reduce, if not completely eliminate, associated patient discomfort. Infusion rates range from 0.01 to 0.05 mug
kg^{-1}
min^{-1} for fentanyl, 0.0015 to 0.01 mug
kg^{-1}
min^{-1} for sufentanil, 0.25 to 0.75 mug
kg^{-1}
min^{-1} for alfentanil, and 0.05 to 0.25 mug
kg^{-1}
min^{-1} . Remifentanil can also produce sedation and analgesia at infusion rates of 0.05 to 0.2 mug/kg/min and is approved by the U.S. Food and Drug Administration (FDA) for this indication. Plasma concentrations of these opioids that produce analgesia are detailed in Table 10-14 .

One of the most exciting developments in pain research over the past decade has been the recognition that changes in the excitability of central neurons play an important role in the generation of pain. The neurophysiologic concepts and mechanisms that underlie the concept of preemptive analgesia are complex. [799] Even the definition of preemptive analgesia and the way in which to demonstrate its existence remain confusing, if not controversial. [800] Whether or not preemptive analgesia can be effectively achieved clinically by the early administration of opioids remains uncer-tain. [801] [802] However, reductions in postoperative pain and improved recovery have been attributed to preemptive analgesia with either epidural fentanyl or bupivacaine after radical prostatectomy. [803]

The administration of systemic opioids postoperatively is commonplace. Practice guidelines, developed by the American Society of Anesthesiologists (ASA), help to define important issues surrounding pain management with opioids. [804] PCA with opioids is now a cornerstone of postoperative analgesia. Besides its obvious appeal in providing patients with a sense of control as well as allowing patients to self-titrate pain-relieving medication, PCA with opioids may improve outcome. [805] Nevertheless, pharmacokinetic optimization of opioid treatment in acute pain is a complex matter. [806] For example, PCA therapy with morphine may require an initial loading dose in order to optimize dosing intervals and patient relief. Modern pharmacologic approaches to opioid pain therapy attempt to incorporate the concept that small, frequent doses produce the most stable blood drug concentrations, best relief, and fewest adverse effects. However, without considering effect site drug concentrations over time, the choice of opioid and the amount, method, and frequency of its administration can be suboptimal. [806] Morphine remains a popular and rational choice for PCA therapy. [807]

Balanced Anesthesia

The concept of balanced anesthesia dates back to 1910, when George W. Crile introduced his theory of anociassociation. [808] Crile taught that psychic stimuli associated with operations could be prevented by light general anesthesia, whereas painful stimuli could be blocked by local analgesia. The term "balanced anesthesia" was introduced by Lundy in 1926. [4] Lundy suggested that a balance of agents and techniques (e.g., premedication, regional anesthesia, and general anesthesia with one or more agents) be used to produce the different components of anesthesia (i.e., analgesia, amnesia, muscle relaxation, and abolition of autonomic reflexes with maintenance of homeostasis) [809] (Fig. 10-39) .

Neff et al in 1947 [5] introduced meperidine as a supplement during N_2O anesthesia. Variations of these techniques using meperidine [810] [811] and other opioids were subsequently described [812] [813] and continue to be developed. All the fentanyl congeners have been successfully employed as components of balanced anesthesia.

Which Opioid?

The ideal opioid would permit rapid titration to effect, successfully prevent unwanted responses to noxious stimuli, require little supplementation, not depress cardiovascular function, permit the return of adequate spontaneous ventilation in a timely manner, and produce residual if not complete postoperative analgesia with minimal side effects. Numerous studies have evaluated one or more of these facets for the fentanyl congeners and have compared one opioid

TABLE 10-14 -- Range of Approximate Plasma (or Whole Blood for Remifentanil) Opioid Concentration (ng/mL) Required for Total Intravenous Anesthesia

	FENTANYL	SUFENTANIL	ALFENTANIL	REMIFENTANIL
Predominant agent	15-30	5-10	400-800	--

with another as a component of balanced anesthesia. [814] [815] [816] [817] [818] [819] [820] [821] [822] [823] [824] [825] [826] [827] [828] Fewer studies have compared three or more opioids in balanced anesthesia. [124] [327] [829] Fentanyl and alfentanil have been frequently compared. [815] [820] [827]

Alfentanil and remifentanil provide the greatest ability to titrate opioids rapidly because of their extremely rapid time to onset (1-2 min) of peak effect. The

administration of these two agents can be timed much like anesthetic induction agents.

It is a commonly held perception that all the fentanyl congeners are pharmacodynamically the same. However, differences exist among opioids that can not always be explained by pharmacokinetic characteristics alone. Alfentanil, compared with fentanyl, produces greater decreases in heart rate and blood pressure during induction. [815] [322] [830] Although some investigators reported no significant differences between fentanyl and alfentanil during emergence, [824] most studies have found that alfentanil results in a more rapid recovery and a decreased need for naloxone. [815] [820] [822] [823] [826] [827] In many studies, dose-equivalency and timing of drug administration are confounding factors creating questions about the accuracy of comparisons.

Studies comparing fentanyl and sufentanil indicate that sufentanil provides greater intraoperative hemodynamic stability, [816] [819] more rapid emergence, [817] and less respiratory depression in the immediate postoperative period than fentanyl. [817] [818] Compared with alfentanil, sufentanil provides greater hemodynamic stability and requires less supplementation. [816]

Flacke et al [829] compared morphine, meperidine, fentanyl, and sufentanil in balanced anesthesia for general or orthopedic surgery. Hemodynamic and plasma catecholamine changes were greatest with morphine and meperidine and least with sufentanil. Only patients receiving sufentanil as the opioid component of their anesthetic did not require potent inhalation agent supplementation. Approximately one-third of patients in each other group required such supplementation. Meperidine produced the most side effects, including hypotension, tachycardia, and urticaria, especially during anesthetic induction. On emergence, respiratory depression was greatest with morphine and least with fentanyl and sufentanil. Other investigators [124] have reported similar results in comparisons of these four opioids. These data suggest that fentanyl and sufentanil are preferable to morphine or meperidine in balanced anesthesia. [124] [829]

Sufentanil, alfentanil, and remifentanil are arguably superior to fentanyl in most respects except cost. [18] [687] Onset of action is faster with alfentanil or remifentanil, and thus control is enhanced. Duration of action and time for drug effect to dissipate are shortest and most consistent for remifentanil and are shorter for both alfentanil and sufentanil compared with fentanyl, especially after repeated administration or infusions. Efficacy may be greatest for sufentanil. The ability to administer doses of remifentanil that produce profound opioid action without prolonged effect is unique to this drug. Alfentanil is more easily antagonized with naloxone because of its low receptor affinity. Antagonism of opioid action with naloxone for troublesome respiratory depression is required less frequently after alfentanil and sufentanil compared with fentanyl. Pharmacologic antagonism is rarely required after remifentanil administration.

Currently, fentanyl remains a good choice if the goal of including opioids as part of an anesthetic regimen is to provide basal analgesia and to minimize drug costs. In clinical situations in which a prolonged opioid effect is desired postoperatively, fentanyl is also a rational choice. If opioids are to be employed as "anesthetic" agents, sufentanil, alfentanil, and remifentanil offer significant advantages over fentanyl. Whether or not these advantages translate to benefits that justify their use and increased drug acquisition cost remains unclear.

General Principles

The inclusion of an opioid as a component of balanced anesthesia can reduce preoperative pain and anxiety, decrease somatic and autonomic responses to airway manipulations, improve hemodynamic stability, lower requirements for inhaled anesthetics, and provide immediate postoperative analgesia. [831] [832] [833] Proper anticipation should lead to the administration of any opioid at the right time prior to a stimulus. Fentanyl and sufentanil should be administered for 4 to 6 minutes, and alfentanil and remifentanil should be given 1 to 2 minutes prior to stimulation. Once a stress response is activated and catecholamines are released, opioids are less effective in maintaining hemodynamic stability. [829] In a similar fashion, as mentioned earlier, the administration of an opioid prior to, rather than after, noxious stimulation attenuates physiologic responses.

Opioids interact synergistically and markedly reduce the dose of propofol and other sedative-hypnotics required for loss of consciousness and during noxious stimulation such as skin incision. [834] Opioids can ameliorate or eliminate responses to a rapid sequence induction and other noxious stimuli, [835] [836] [837] controlling changes in heart rate, blood pressure, pulmonary capillary wedge pressure, and other aspects of the stress response that occur during laryngoscopy and intubation. Heart rate response to laryngoscopy is better controlled with an opioid than with esmolol. [833] Frequently,

however, inadequate doses (100 mug) of fentanyl are administered and insufficient time is allowed for effective onset of drug action.

Anesthesia with a single agent can require doses that produce excessive hemodynamic depression. For example, the concentrations of propofol or isoflurane required to eliminate movement after skin incision frequently produce undesirable hypotension prior to such stimulation. [372] [838] Although the intent of combining opioids with sedativehypnotics and/or volatile anesthetics is to produce anesthetic conditions with stable hemodynamics prior to as well as after noxious stimulation, this ideal is not always achieved. For example, combinations of propofol and fentanyl can result in as much or more hypotension than propofol alone prior to tracheal intubation. [839] However, the hypertensive response to intubation is better attenuated with the drug combination than with propofol alone. [840] [841]

The timing, rate of administration, and dose of supplemental opioid should also be tailored to the specific condition of the patient and the expected duration of the operation in order to avoid problems. The duration of action and magnitude of effect of an opioid are determined not only by pharmacokinetic properties but also by timing, dosage, and interaction with other compounds used, as well as patient factors such as age and intensity of pain (see later). Giving a large dose of any opioid shortly before the end of surgery is very likely to result in postoperative respiratory depression or to potentiate and prolong already existing respiratory depression. However, analgesic concentrations of opioids have little effect on the MAC awake of potent inhaled anesthetics. [842] Troublesome opioid-induced respiratory depression needs to be avoided if fentanyl and its congeners are to be optimally employed in most patients. In balanced anesthesia, this means that, at the appropriate time, adequate spontaneous ventilation has returned without the frequent use of opioid antagonists.

Fentanyl

Anesthetic induction is usually achieved by combining a loading dose of fentanyl (2-6 mug kg^{-1}) with a sedativehypnotic, most commonly thiopental or propofol, and a muscle relaxant. The dose of sedative-hypnotic should be significantly reduced. [109] [843] Agents such as etomidate (0.1-0.3 mg/kg) or ketamine (0.5-2.0 mg/kg) are more likely to provide hemodynamic stability compared with thiopental or propofol after fentanyl or other opioids, especially in patients with cardiovascular disease. [837]

Maintenance of anesthesia can be achieved with N_2O (60-70%) in O_2, low concentrations of potent inhalation agents, plus additional fentanyl (intermittent boluses of 25-50 mug every 15 to 30 min or a constant infusion of 0.5-5.0 mug kg 1 h^{-1}). Shorter procedures may require lower bolus doses or infusion rates. [844] Premedication, typically with a benzodiazepine, reduces the need for supplements. Propofol infusions can also be administered as part of balanced anesthesia (see later).

Fentanyl plasma concentrations of 1.0 to 2.0 ng mL^{-1} provide analgesia, [641] but levels of at least 2 to 3 ng mL^{-1} are usually required during surgery (at sea level) if the only inhaled agent is N_2O. Higher plasma opioid concentrations may be necessary at high altitude, where N_2O is less effective. [845] [846] In unpremedicated patients anesthetized with a fentanyl infusion and N_2O in O_2, the CP_{50}* and the CP_{50}-BAR* for fentanyl at skin incision are 3.26 and 4.17 ng/mL, respectively. [847] The MAC of isoflurane at skin incision can be reduced by 50 and 63 percent with plasma fentanyl concentrations of 1.67 and 3.0 ng/mL, respectively [111] (see Table 10-5) (Table Not Available) . Others have reported the fentanyl plasma concentration that reduces the MAC of isoflurane 50 percent to be lower (0.5 ng/mL) but have also noted a wide range of effective concentrations. [144] With greater doses or plasma fentanyl concentrations, further MAC reductions become proportionately less. For example, McEwan et al [111] found that increasing plasma fentanyl concentrations from 3.0 to 10 ng/mL only further reduced the MAC of isoflurane from 63 to 82 percent.

Patient pharmacokinetics varies significantly (up to 5-fold), and predicting plasma levels after a given dose of an opioid can be challenging. Pharmacodynamic actions are also variable; the opioid plasma concentration necessary to block increases in blood pressure and heart rate can be unpredictable. [641] [848] Nevertheless, a balanced technique with fentanyl, titrating the opioid in anticipation of various stimuli and patient responses with pharmacokinetic guidelines in mind, will often result

in a stable hemodynamic course and rapid awakening in a pain-free patient. Low doses of fentanyl (4-8 mug kg^{-1}), followed by a continuous infusion of 2 to 4 mug kg^{-1} h^{-1}, will often result in adequate plasma levels (3-6 ng mL^{-1}) for anesthesia when combined with N_2O.

Repeated doses or continuous infusions of fentanyl are most likely to result in significant depression of spontaneous ventilation. [18] [325] This is especially likely if fentanyl is dosed in an empiric manner without titration to some clinical endpoint. Administering fentanyl boluses toward the latter part of an operation also increases the likelihood of troublesome respiratory actions. Others have reported that fentanyl (1-2 mug/kg), administered at the time of peritoneal closure in women undergoing gynecologic surgery, can significantly attenuate hemodynamic responses to tracheal extubation. [849] A useful clinical approach is to wait for spontaneous ventilation to resume, then administer additional titrated doses (25-50 mug) of fentanyl to produce a respiratory rate of 8 to 12 breaths per minute prior to tracheal extubation. Plasma fentanyl levels associated with adequate analgesia after abdominal surgery have been reported to range 5-fold from 0.23 to at least 1.18 ng/mL. [641]

Sufentanil

Sufentanil (0.25-1.0 mug/kg), administered several minutes prior to induction of anesthesia, effectively prevents significant hemodynamic responses to laryngoscopy and intubation. Marty et al [850] studied 14 patients who were premedicated with lorazepam (2.5 mg) and then anesthetized

* CP_{50} is the steady-state plasma drug concentration that prevents a somatic response in 50 percent of patients.

** CP_{50} -BAR is the steady-state plasma drug concentration that prevents a hemodynamic and autonomic response in 50 percent of patients.

with sufentanil (2-mug/kg bolus plus 0.66-mug kg^{-1} /h infusion). These patients were ventilated with 66 percent N_2O in O_2 and received vecuronium or succinylcholine for muscle relaxation. The mean plasma sufentanil concentration reported to be the CP_{50} for prevention of hemodynamic responses to laryngoscopy and tracheal intubation was 1.08 ng/mL with a range of 0.73 to 2.55 ng/mL.

Maintenance of anesthesia can be achieved with N_2O (60-70%) in O_2 and further sufentanil (intermittent boluses, 0.1-0.25 mug kg^{-1} ; or constant infusion, 0.5-1.5 mug kg^{-1} h^{-1}). The CP_{50} for sufentanil during skin incision is twice as great as that for intubation in unpremedicated patients (2.08±0.62 ng/mL). [145] CP_{50} value ratios at skin incision for sufentanil, fentanyl, and alfentanil in N_2O-O_2 anesthesia are approximately 1:2:150 and represent different and probably more accurate potency ratios than those traditionally published based on drug dose. During surgery, sufentanil plasma levels less than 0.5 ng mL^{-1} can lead to an increased need for supplements. [831]

Sufentanil infusions of less than 1.0 mug/kg/h are associated with fewer postoperative problems than infusions of at least 1.0 mug/kg/h in adults and children. [851] Sufentanil levels less than 0.25 ng mL^{-1} often allow for adequate spontaneous ventilation. [850] Titration of sufentanil to respiratory rate prior to emergence, or minimizing infusion rate to less than 0.25 to 0.5 mug/kg for the last hour of anesthesia are approaches that allow timely emergence.

Alfentanil

Small to moderately large doses (5-50 mug kg^{-1}) of alfentanil used to supplement a sedative-hypnotic induction attenuate or eliminate hemodynamic responses to laryngoscopy and intubation. Because alfentanil penetrates the brain so rapidly, equilibration of alfentanil between the plasma and the CNS can be achieved while plasma alfentanil levels are relatively high compared with sufentanil and fentanyl (Fig. 10-40) (Figure Not Available) . This property, combined with the significant synergism between alfentanil or other opioids and propofol and/or midazolam, [852] [853] explains how low doses (10-30 mug/kg) of alfentanil, administered just before or simultaneously with a sedative-hypnotic, are effective.

Alfentanil (16 mug/kg) is more effective than esmolol (2 mg/kg) in blunting the hemodynamic response to tracheal intubation after induction with propofol (2.5 mg/kg). [854] Alfentanil (25-50 mug/kg IV), followed by small titrated sleep doses of any sedative-hypnotic (e.g., 50-100 mg sodium thiopental), is usually successful in preventing significant hemodynamic stimulation from laryngoscopy and intubation. Indeed, 25 to 35 mug/kg of alfentanil, combined with propofol or etomidate for induction of anesthesia, usually results in good to excellent conditions and allows tracheal intubation without the use of muscle relaxants. [855] [856] Combining alfentanil and propofol can reduce propofol requirements for loss of consciousness by 50 to 75 percent. [839]

Anesthesia is often maintained after such an induction with 60 to 70 percent N_2O in O_2 . Further opioid supplementation can be achieved with an alfentanil infusion (0.5-2.0 mug kg^{-1} min^{-1}) or intermittent boluses of alfentanil (5-10 mug kg^{-1}) for shorter procedures. An alfentanil bolus of 7 mug kg^{-1} will increase plasma alfentanil concentrations

Figure 10-40 (Figure Not Available) Computer-simulated plasma and effect site concentrations for fentanyl, alfentanil, and sufentanil, for the first 10 minutes after a bolus injection, as a percentage of initial plasma concentrations. *(Adapted from Shafer and Varvel [18])*

by 50 ng mL^{-1} (range 20-100 ng mL^{-1}) if a relatively steady plasma level of alfentanil already exists. In balanced anesthetic techniques in which potent inhalation agents are also employed, relatively low plasma alfentanil concentrations (e.g., 29 ng/mL) can reduce the MAC of isoflurane approximately 50 percent. [144]

Failure to institute N_2O and/or an alfentanil infusion may lead to inadequate anesthesia at the time of surgical incision (Fig. 10-41) . The duration of surgery and strength of the surgical stimulus are important influences on alfentanil requirements. Ausems et al [331] determined the plasma concentrations of alfentanil required to supplement N_2O anesthesia for several types of surgery. The CP_{50} , defined as the concentration needed to obtund responses to stimuli adequately in 50 percent

Figure 10-41 Plasma alfentanil levels after three different bolus injections and one bolus plus continuous infusion for 1 hour.

of patients, for several stimuli is listed in Table 10-15 (Table Not Available) . The Cp_{50} for spontaneous ventilation was 223±13 ng mL^{-1} . Interestingly, the more potent the stimulus, the greater the variability in the Cp_{50} . This is depicted in the flatter curve for upper abdominal surgery in Figure 10-42 (Figure Not Available) . These numbers define target plasma concentrations. However, because of considerable variability in effective concentrations, clinicians must still titrate both alfentanil infusions and the frequency and magnitude of boluses to clinical response.

Interestingly, the EC_{50} of alfentanil for various stimuli in patients premedicated with temazepam (10 mg orally) and receiving propofol (plasma concentrations targeted to be 3 mug/mL) was only one-fourth to one-half that required in patients receiving N_2O-O_2 instead of propofol. [857] Balanced anesthesia with a sedative-hypnotic, alfentanil, and N_2O-O_2 in appropriately premedicated patients has been recommended for short and minor operations, [858] as well as for major vascular procedures. [859]

Alfentanil infusions or repeated doses should be minimized 15 to 30 minutes prior to the end of surgery, [331] in order to avoid problematic residual respiratory depression. If no alfentanil is administered toward the latter part of an anesthetic regimen, inadequate analgesia will exist in some patients shortly after they regain consciousness, unless steps

TABLE 10-15 -- Stimuli and Corresponding Cp_{50} for Alfentanil During Alfentanil-Nitrous Oxide Anesthesia

(Not Available)

From Ausems et al [331]

have been taken to ensure analgesia. Although alfentanil infusions should be reduced as permitted during balanced anesthesia, they should not be completely terminated until the operation is nearly finished. Alfentanil plasma concentrations that permit the return of spontaneous ventilation have been reported to be 223±13 ng/mL. [331] Alfentanil infusion rates of 0.5±0.25 mug
kg^{-1}
min^{-1}, administered until surgery is nearly complete, do not usually interfere with the return of adequate spontaneous ventilation and emergence.

Remifentanil

Remifentanil has been administered as a bolus of 1 mug/kg in combination with propofol for induction of anesthesia with favorable results. [860] Combinations of propofol (0.5-1.0- mg/kg

Figure 10-42 (Figure Not Available) Mean alfentanil plasma concentration-effect curves for the intraoperative period in each surgical group of patients during nitrous oxide anesthesia. The mean plasma clearance (Cp_{50}) and slope of these curves were determined by averaging the estimates of individual patients. Bar indicates the standard deviation and Cp_{50}. *(From Ausems and Hug* [1216] *)*

bolus plus a 75-mug/kg/min infusion) and remifentanil (1-mug/kg bolus plus a 0.5-1.0-mug/kg/min infusion) for induction and maintenance of anesthesia can result in hypotension and bradycardia in 10 to 30 percent of healthy patients. [861] It is now recognized that these doses are too high. Remifentanil's very short duration of action mandates that an infusion (0.1-1.0 mug/kg/min) be started prior to or soon after the bolus dose to ensure sustained opioid effect. Another approach is to administer remifentanil only by continuous infusion for induction and maintenance of anesthesia.

Remifentanil maintenance infusion rates range from 0.1 to 1.0 mug/kg/min for balanced anesthesia. Numerous clinical trials, comparing remifentanil with alfentanil or other opioids, document that remifentanil can more reliably suppresses autonomic, hemodynamic, and somatic responses to noxious stimulation and allows the most predictable and rapid trouble-free emergence from anesthesia. [862]

The use of remifentanil as the opioid component of balanced anesthesia should allow a rapid (5-15 min) emergence without troublesome respiratory depression in light of its very short duration of action. [861] Infusion rates of 0.1±0.05 mug/kg/min should permit the return of spontaneous ventilation and responsiveness with maintenance of analgesia. A unique problem associated with emergence from remifentanil anesthesia is the possibility of an excessively rapid dissipation of opioid effect with undesirable consequences. The need for alternative analgesic therapies should be anticipated and administered in a timely fashion, but definitive approaches remain to be determined. [863] Discharge from, or completely bypassing the postanesthetic care unit can also be expedited by the use of remifentanil. Tables 10-14 and 10-16 depict the range of loading and maintenance doses and plasma levels required for fentanyl, alfentanil, sufentanil, and remifentanil in balanced anesthesia.

Neuroleptanalgesia-Anesthesia

In 1949, Laborit and Huygenard [864] introduced the concept of an anesthetic technique that blocked not only cerebrocortical responses but also some cellular, endocrine, and autonomic mechanisms usually activated by surgical stimulation. This state was called "ganglioplegia" or "neuroplegia" (artificial hibernation) and was achieved by the use of a lytic cocktail consisting of chlorpromazine, promethazine, and meperidine. From this idea, De Castro and Mundeleer [865] derived the concept of neuroleptanalgesia, which involved the combination of a major tranquilizer (usually the butyrophenone droperidol) and a potent opioid analgesic (fentanyl) to produce a detached, pain-free state of immobilization and insensitivity to pain. Neuroleptanalgesia is characterized by analgesia, absence of clinically apparent motor activity, suppression of autonomic reflexes, maintenance of cardiovascular stability, and amnesia in most, but not all, patients. The addition of an inhalation agent, usually N_2O, improves amnesia and has been called neuroleptanesthesia.

"Neuroleptic" drugs traditionally include the phenothiazines (e.g., chlorpromazine) and the butyrophenones (e.g., haloperidol and droperidol). The phenothiazines are rarely used as an anesthetic adjuvant in the United States because of associated hypotension. Droperidol can also cause hypotension, but it is usually less severe and transient. Sedation after droperidol, especially after at least 0.1 mg
kg^{-1}, may last much longer than the analgesic used (e.g., fentanyl) and may result in a patient who is apparently calm yet suffering from pain and mental anguish. [866] The commercial preparation of droperidol-fentanyl (Innovar) is frequently the principal component of neuroleptanalgesia for monitored anesthesia care when analgesia and a tranquil patient are desirable. Innovar is also commonly used in a balanced anesthetic technique that usually employs N_2O.

Butyrophenones cause sedation, tranquility, immobility, and antiemesis. One of their side effects includes an extrapyramidal syndrome with face and neck dyskinesia, oculogyric crises, torticollis, agitation, and hallucinations. Droperidol, like other butyrophenones, affects GABA receptors and alters the balance of dopamine and acetylcholine in certain brain sites. Droperidol's effects on dopamine receptors (antidopaminergic) not only account for much of the drug's behavioral effects but also cause its side effects. Administering droperidol alone, without analgesics or other sedatives, often produces feelings of discomfort or dysphoria in patients. The cardiovascular effects of droperidol are most often limited to mild hypotension that is thought to be mediated through alpha-adrenergic blockade. Droperidol has an antiarrhythmic action that is effective during halothane anesthesia or following epinephrineinduced arrhythmias. [867] Droperidol may be of some benefit in patients with Wolff-Parkinson-White syndrome. [868] There is little respiratory depression induced by droperidol, although significant variability exists, and occasional respiratory depression may be noted. Droperidol and other butyrophenones may enhance hypoxic-induced increases in ventilation in humans because of their antidopaminergic effects at the carotid body. [869]

Droperidol can be used as a premedicant (0.025-0.075 mug
kg^{-1} IM), an antiemetic (0.01-0.02 mug
kg^{-1} IV), an adjunct for awake intubations (0.025-0.1 mug
kg^{-1} IV) and as treatment for agitated, belligerent, or psychotic patients (0.05-0.2 mg
kg^{-1} IV or IM). Neuroleptanalgesia with droperidol and an opioid such as fentanyl may still be useful for "monitored anesthesia care" in a variety of clinical circumstances

TABLE 10-16 -- Approximate Opioid Loading (Bolus) Doses, Maintenance Infusion Rates, and Additional Maintenance Doses for Total Intravenous Anesthesia

	LOADING DOSE (mu g/kg)	MAINTENANCE INFUSION RATE	ADDITIONAL BOLUSES
Alfentanil	25-100	0.5-2 mug/kg/min	5-10 g/kg
Sufentanil	0.25-2	0.5-1.5 mug/kg/h	2.5-10 mug

Fentanyl	4-20	2-10 mug/kg/h	25-100 mug
Remifentanil	1-2	0.1-1.0 mug/kg/min	0.1-1.0 mug/kg

including ophthalmic operations, endoscopic and bronchoscopic examinations, neurodiagnostic procedures, and excision of epileptogenic foci. Combining alfentanil (5 mug
kg^{-1} as a bolus and/or an infusion, 1.5 mug
kg^{-1}
min^{-1}) with droperidol and N_2O has been reported to be useful in providing patient comfort for awake craniotomies. More recently, remifentanil, in combination with propofol, has been used successfully as an anesthetic technique for awake craniotomy. [870]

In the past, neuroleptanesthesia with droperidol and fentanyl proved useful in patients undergoing neurologic, cardiac, and general surgical procedures. Neuroleptanesthesia has also been proposed for removal of pheochromocytomas. [871] [872]

Neuroleptanalgesia or neuroleptanesthesia is contraindicated in patients receiving monoamine oxidase inhibitors (MAOI), in those who abuse drugs or alcohol, or those with Parkinson disease. The introduction of newer drugs with superior pharmacologic properties, combined with "fast track" approaches in most surgical patients, has reduced the utility of neuroleptic techniques.

Total Intravenous Anesthesia

TIVA is a natural extension of balanced anesthesia. Newer IV drugs now allow reliable anesthesia to be produced entirely with IV anesthetics and rapid recovery to occur even after long infusions. Additionally, hardware and software also now exist that permit delivery of these agents in a manner superior to manual injection. Although TIVA does not necessarily require an opioid component, especially in minimally stimulating procedures, the fentanyl congeners most often are an important part of TIVA.

Several challenges exist to the successful application of TIVA. Variability in patient drug requirements is significant. [873] The "light" nature of many TIVA techniques often creates an environment with which many anesthesiologists are neither comfortable nor satisfied. Common solutions to this problem are to eliminate the possibility of patient motor responses with the routine use of muscle relaxants. The routine application of muscle relaxants with TIVA predisposes patients to experiencing awareness.

The complexity of delivering TIVA with one, two, and even three simultaneous infusion pumps and programs remains a technical burden compared with the simplicity of modern inhalation agent vaporizers. Most experts agree that continuous infusions are a necessary part of TIVA if benefits are to be maximized and disadvantages minimized. Numerous advantages exist when drugs are administered by infusion (Table 10-17) . [874] [875] [876] [877]

Some researchers and clinicians utilize and recommend the use of population-based or other pharmacokinetic data, [878] software programs, pocket calculator approaches, or other methods to enhance drug infusion accuracy. However, TIVA and drug infusions can be and are most often successfully administered by clinical titration and without mathematic and/or computer-assisted calculations of drug re-quirements. [879] Much progress has been made in the development of pharmacologic models that help us better to understand drug disposition and administration. [687] [712] [713] However, the persistent inability to predict and/or to

TABLE 10-17 -- Potential Advantages of Continuous Infusions over Intermittent Boluses of Opioids in Anesthesia

Decreased total dose
Greater hemodynamic stability
Decreased side effects (e.g., rigidity)
Decreased need for supplementation
More rapid recovery of consciousness
Less respiratory depression and need for antagonists
Less pain in the immediate postoperative period
Decreased discharge time

measure drug levels and effects in individual patients continues to dampen widespread enthusiasm for TIVA techniques. [699] [880]

Another hurdle TIVA enthusiasts must confront is the cost-to-benefit analysis to which many anesthetic regimens are likely to be subjected. Newer, and arguably superior, agents are more expensive by drug acquisition cost analysis. Deciding whether benefits justify the greater costs of these drugs is complex and not always obvious. Potential benefits of new anesthetics include less pain, less nausea and vomiting, and a more rapid recovery and hospital discharge (along with lower resultant overall hospital charges). Benefits more difficult to measure include a decreased use of reversal agents, fewer morbid events, greater patient satisfaction, and a more rapid return of patients to work. [881] Unfortunately, issues such as the superior control of a patient's anesthetic regimen that is provided by the clinician, or the reduced stress on the patient and the anesthesiologist, are largely neglected. [882]

Many different IV compounds can be employed in a number of combinations to provide TIVA. Most commonly, an opioid is combined with another drug more likely to provide hypnosis and amnesia. Propofol-opioid TIVA is popular. For example, both alfentanil and propofol are similarly short-acting agents and have excellent synergism pharmacodynamically. Alfentanil provides analgesia and hemodynamic stability while blunting responses to noxious stimuli. Propofol provides hypnosis and amnesia and is anti-emetic. [603] Profound synergism also exists when more than two agents, such as propofol-alfentanil-midazolam, are combined. [852] [883]

Anesthetic induction with alfentanil (25-50 mug/kg) and propofol (0.5-1.5 mg/kg) followed by infusions of 0.5 to 1.5 mug
kg^{-1}
min^{-1} of alfentanil and 80 to 120 mug
kg^{-1}
min^{-1} of propofol will produce complete anesthesia in patients ventilated with air and O_2 with or without N_2O for a variety of procedures. Although many alternatives to propofol exist, its pharmacokinetic profile and short duration of action, antiemetic properties, and association with a general sense of well-being in patients postoperatively make it popular. Several opioids can be successfully employed, depending on the patient, the proposed operation, and other considerations.

Vuyk et al [883] evaluated the significant synergism between propofol and alfentanil and explored numerous combinations of blood drug concentrations. They proposed that alfentanil concentrations as low as 85 ng/mL, when combined with a blood propofol concentration of 3.5 mug/mL, can produce both optimal anesthetic conditions and speed

of recovery. In an accompanying editorial, Stanski and Shafer [884] suggested that bolus doses and initial infusion rates would be 30 mug/kg and 0.35 mug
kg^{-1}
min^{-1} for alfentanil and 0.7 mg/kg and 180 mug
kg^{-1}
min^{-1} for propofol. Decreasing infusion rates to eventually achieve rates of approximately 0.25 and 100 mug

kg^{-1}
min^{-1} for alfentanil and propofol respectively were also recommended. Recognizing that these calculations were based on EC_{50} data in patients undergoing only moderately painful procedures, clinicians should adjust these doses accordingly. Thus, a plausible infusion regimen would increase the alfentanil infusion rate somewhat in order to enhance suppression of responses to noxious stimuli.

Vuyk et al [885] also determined the optimal propofol-opioid concentrations that ensure adequate anesthesia and rapid emergence with computer modeling for all the modern fentanyl congeners. The optimal propofol concentration decreases in the order of fentanyl > alfentanil > sufentanil >> remifentanil. These conclusions are somewhat intuitive and coincide with ordering based on the context-sensitive half-time of opioids. In essence, a shorter context-sensitive half-time allows the administration of greater amounts of opioid (and less propofol) during anesthesia without creating prolonged opioid effects.

Premedication prior to alfentanil-propofol anesthesia can prolong postoperative recovery and should be avoided if appropriate. [886] [887] Drug infusion devices should be prepared and infusing prior to induction of anesthesia, so that clinician efforts can be appropriately focused on airway management yet anesthesia can be adequately maintained. Induction of anesthesia may proceed with the administration of a defasciculating or priming dose of a nondepolarizing muscle relaxant and alfentanil (10 to 25 mug/kg IV). Additional similar doses of alfentanil may be administered up to a total dose of 25 to 75 mug/kg and immediately followed by a sleep dose of propofol of 0.5 to 1.5 mg/kg. Additional propofol (0.25-1.0 mg/kg) may be required to produce unconsciousness. Lidocaine requirements to reduce pain associated with propofol injection are significantly reduced when propofol is administered after alfentanil. [888] [889]

Figure 10-41 illustrates the plasma alfentanil concentrations over time from four different studies [678] [680] [681] [890] Bolus injections of alfentanil (80-200 mug/kg) produce initial plasma levels proportional to the dose. Although lower doses of alfentanil than illustrated in the figure are frequently administered, the point remains that if alfentanil maintenance infusions are not instituted, plasma drug levels rapidly decline and become subtherapeutic. After 50 mug/kg, plasma levels of alfentanil are less than 300 ng
mL^{-1} within 3 to 5 minutes. [679]

Maintenance infusions vary according to patient condition and surgical stimuli. Propofol (75-125 mug/kg/min) and alfentanil (1.0-2.0 mug/kg/min) are initially recommended. Intraoperatively, propofol and/or alfentanil infusions should be manipulated in an effort to obtain the lowest required rates. Drug infusions should be terminated 10 to 20 minutes prior to end of anesthesia if N_2O is employed in a similar but balanced anesthesia technique. Otherwise, propofol infusions should be terminated 5 to 10 minutes before anticipated patient awakening. Alfentanil infusion rates do not need to be less than 0.25 to 0.5 mug/kg/min until surgery is terminated.

As mentioned earlier, many agents can be used for TIVA. Midazolam-opioid combinations can also provide complete anesthesia. However, midazolam-alfentanil TIVA has not been found to compare favorably to propofol-alfentanil TIVA even with flumazenil reversal of residual benzodiazepine actions. [891] On the other hand, TIVA for major (cardiac) and/or long operations may be effectively achieved with midazolam and sufentanil [892] or midazolam-fentanyl (see later). [893] TIVA with sufentanil and midazolam has also been employed in patients susceptible to malignant hyperthermia [894] and for pheochromocytoma resection. [895] TIVA techniques are especially useful when delivery of inhaled agents is compromised. Examples include patients with significant V/Q abnormalities or requiring one-lung ventilation, as well as patients requiring specialized ventilation techniques such as jet ventilation. The complete description of the application of TIVA techniques is be-yond the scope of this chapter. Nevertheless, by keeping the goals of balanced anesthesia in mind, combining modern opioids and other drugs, utilizing infusion pumps, and employing an increased understanding of pharmacokinetics, clinicians can successfully administer a variety of TIVA techniques.

Continuous Opioid Infusions

The classic pharmacokinetic descriptions of drug disposition have major limitations in anesthesia. [713] The context-sensitive half-time, more modern pharmacokinetic descriptions, and computer simulations have helped clinicians to select opioids in a more rational fashion. [712] [713] [885] The context-sensitive half-time, for example, illustrates how the duration of a drug infusion influences the time needed for dissipation of drug effect (Fig. 10-43) (Figure Not Available) . [18]

Analyses based on effect site concentrations can also be more helpful than those based on plasma concentration. For example, although plasma opioid concentrations over time after a bolus injection of fentanyl, sufentanil, and alfentanil decrease at a similar rate, effect site concentrations both rise and fall faster after alfentanil (see Fig. 10-40) (Figure Not Available) . The more rapid rise in effect site drug concentrations means that more drug will reach the brain because plasma levels will be higher when brain-blood equilibration occurs.

Continuous infusions of fentanyl, sufentanil, and alfentanil have been evaluated as alternatives to intermittent bolus techniques in anesthesia, and the former approach provides many advantages [875] [876] [877] [896] (see Table 10-17) . Some anesthesiologists still prefer to administer large IV boluses of opioids, thus producing high plasma concentrations that are effective for nearly all stimuli. The high therapeutic index of most opioids permits this approach. In addition, in cardiac anesthesia, in which the application of high doses of opioids first achieved popularity, significant postoperative respiratory depression is not a problem because postoperative controlled mechanical ventilation is most often practiced. However, the use of opioids as a key component of anesthesia in many other surgical areas is most often limited by the potential for troublesome postoperative depression of ventilatory drive. For this reason, as well as others reviewed later, some anesthesiologists believe that limiting the dose of opioids, as well as optimizing their use, is better achieved by

Figure 10-43 (Figure Not Available) Computer simulation of recovery curves for fentanyl, alfentanil, and sufentanil describing the time required (Y axis) for 20, 50, and 80 percent decreases in effect site concentrations after intravenous infusions of variable duration (X axis). *(Adapted from Shafer and Varvel [16])*

administering a loading "bolus" dose followed by a continuous infusion (see Tables 10-14 and 10-16) .

Various mathematic models and calculations have been used to predict, establish, and maintain the desired plasma concentration of a drug, but the objective is the same: to achieve a desired plasma and effect site drug concentration and to maintain that state by replacing drug removed by redistribution and metabolism. [722] [897] [899] More recent investigations offer better but more complex regimens [879] or computer-assisted delivery methods. [875] Continuous infusions are often slowed decrementally not only to seek the lowest effective concentration, but also to avoid opioid accumulation when redistribution of the drug declines as the peripheral compartment is filled. The necessity or presumed benefit of invoking complicated pharmacokinetic equations has been questioned as unduly cumbersome and complicated. [685] Titration, based on a dose-response relationship with limited attention to pharmacokinetic equations or concern about "ideal plasma levels," may be equally effective. Nevertheless, computer-assisted continuous infusions that deliver drugs based on population-based pharmacokinetic data and target plasma or effect site concentrations not only are accurate but also are becoming increasingly popular. [699] [900] [901]

Opioid-Based (High-Dose) Anesthesia

Opioids can be administered as the primary or sole anesthetic in opioid-based anesthetic techniques. Several factors have diminished the popularity of high-dose opioid anesthesia, even in cardiac anesthesia, in which it has been most commonly employed. These include the lack of evidence substantiating any significant outcome benefit associated with the use of large doses of opioids, [22] [23] the added drug costs, and the trend toward "fast track" approaches to the cardiac patient that can be impeded by large doses of opioids, especially fentanyl. [21] [902] [903] Anesthesia with an opioid as the sole anesthetic is also less frequently practiced for the same reasons, as well as because such a technique is not consistently reliable. [99] [848] [904]

The concept of a "cardiac" anesthetic has become more, not less, obscure over time. [905] However, the lack of compelling evidence that one anesthetic agent, or combination of anesthetic agents, is not superior or preferred does not negate the need to provide stable intraoperative hemodynamics for patients with cardiac disease. Opioids, particularly when administered by continuous infusion, are still among the most effective anesthetics for patients undergoing cardiac or other extensive operations. In addition, the efficacy of opioid-based anesthesia can be optimized intraoperatively with the administration of moderate drug doses and not result in prolonged postoperative respiratory depression.

Fentanyl

The popularity of high-dose opioid anesthesia was first established with morphine. [8] Problems with intraoperative hemodynamic instability, the need to intervene with vasoactive agents, excessive postoperative respiratory depression, and prolonged emergence have been noted to be more frequent with morphine than with fentanyl or sufentanil. [380] [382] Morphine is not recommended for high-dose opioid anesthesia.

Many different techniques have been used by clinicians and investigators to achieve anesthesia with fentanyl. [9] [10] [101] [129] [240] [252] [374] [380] [482] [786] [848] [902] [906] [907] [908] [909] [910] [911] [912] [913] [914] Rapid or slow bolus injections of fentanyl range from 5 to 75 mug
kg^{-1} . There is little benefit accrued by administering loading bolus doses of more than 5 to 30 mug/kg. These doses will establish sufficient plasma fentanyl concentrations (10-30 ng
mL^{-1}) that are often sufficient to provide stable hemodynamics throughout the induction/intubation sequence

Figure 10-44 (Figure Not Available) The plasma fentanyl concentration and the number of patients with a hypertensive response at each event studied.
, hypertensive; O, normotensive. *(From Wynands et al [374])*

(Fig. 10-44). Continuous infusions of fentanyl for cardiac surgery range from 0.1 to 1.0 (Figure Not Available) mug
kg^{-1}
min^{-1} up to or continuing through CPB (Fig. 10-45) (Figure Not Available) .

Other simple infusion schemes, such as those reported by Hall et al, [915] employing a modified Wagner method, [897] demonstrate that target and anesthetic fentanyl plasma concentrations can be maintained throughout surgery. A priming solution of 2.4 mug/kg/min for 20 minutes in combination with a simultaneously started and maintained infusion of 0.3 mug/kg/min produced fentanyl plasma concentrations between 20 and 27 ng/mL and effectively eliminated the need for supplements.

High dose fentanyl anesthesia has also proved effective and safe in premature infants for repair of patent ductus arteriosus (
50 mug
kg^{-1}) [916] [917] and for pediatric heart surgery (50-100 mug
kg^{-1}). [918] [919] [920] Intraoperative reduction in ventricular fibrillation in neonates undergoing surgery for hypoplastic left heart syndrome has been described as an advantage of high-dose fentanyl anesthesia. [442]

Alfentanil

The induction of anesthesia with large doses of alfentanil has been applied to cardiac surgery. [379] [386] [388] [921] [922] [923] Large doses of alfentanil (150 mug
kg^{-1}) may be used with or without thiopental to induce anesthesia. The loss of verbal response ED_{50} for alfentanil in young unpremedicated adults is 111 mug
kg^{-1} . [114] Other investigators claim that anesthesia cannot be reliably induced with alfentanil alone, at least in young and healthy adults. [904] Continuous infusions of alfentanil (2-12 mug
kg^{-1}
min^{-1}) have been employed to maintain moderate to very high plasma alfentanil concentrations (
3,000 ng
mL^{-1}) during cardiac surgery. [921] [923] Hemodynamic control with alfentanil is more difficult with intermittent bolus techniques. [921] Enthusiasm for high-dose alfentanil anesthesia techniques is limited by the amount (and cost) of drug required and suggestions that alfentanil anesthesia for cardiac surgery is inadequate [388] and is associated with more cardiovascular adverse effects compared with fentanyl and sufentanil. [379]

More modest doses of alfentanil have been successfully administered in combination with sedative-hypnotics such as propofol for cardiac anesthesia. [924] Induction and maintenance of anesthesia with alfentanil (25-75-mug/kg loading dose plus 1-2-mug/kg/min infusion) and propofol (0.25-1.0- mg/kg bolus plus 80-100 mug/kg/min) is reliable and stable.

Sufentanil

Several reports suggest that high doses of sufentanil are superior to fentanyl in anesthesia for cardiac surgery. Purported advantages include more rapid induction, [382] better blunting or elimination of hypertensive episodes, [376] [925]

greater reduction in left ventricular stroke work, [381] with higher cardiac outputs [925] and more stable hemodynamics intraoperatively and/or postoperatively. [382] [925] Patients anesthetized with sufentanil instead of fentanyl also regain consciousness sooner and are extubated earlier. [382] [384] High-dose sufentanil anesthesia may produce lower blood pressures than equivalent doses of fentanyl. [379] Other investigators do not believe clinical differences between the two opioids to be significant. [99] [922] [926]

High doses of sufentanil have been employed in anesthesia for coronary artery and cardiac valvular sur-gery. [138] [376] [496] [922] [927] Induction doses of sufentanil range from 2 to 20 mug
kg^{-1} administered as a bolus or infused over 2 to 10 minutes. Although larger doses are sometimes administered during or early after induction, many anesthesiologists give additional sufentanil in anticipation of provocative stimuli, that is, before skin incision and sternotomy. Total doses of sufentanil employed in high-dose techniques usually range from 15 to 30 mug
kg^{-1} . However, as with other opioids, the trend is to reduce opioid doses and employ drug synergism to advantage. No additional benefit could be demonstrated in terms of hemodynamic control or EEG signs by increasing the dose of sufentanil from 3 to 15 mug/kg for the induction of anesthesia in patients premedicated with lorazepam. [928]

Zurick et al [138] showed that infusions of sufentanil are useful for induction of anesthesia. They found that the total dose of sufentanil needed was less and emergence was faster with an infusion versus a multiple bolus technique. The amount of sufentanil required can be markedly influenced by the supplements employed concomitantly. In a multicenter report of computer-assisted continuous infusion techniques for patients undergoing coronary artery surgery, modest induction (0.4±0.2 mug/kg) and total maintenance (2.4±0.8 mug/kg) doses of sufentanil were used in combination with propofol (1.5±1 mug/kg for induction and 32±12 mg/kg total). [929] Interestingly, sufentanil requirements tripled when midazolam was employed instead of propofol.

Etomidate has been recommended for the induction of anesthesia in patients with significant cardiovascular disease. Etomidate, combined with an opioid, can provide excellent anesthetic conditions with minimal hemodynamic perturbation. [913] Inducing anesthesia with sufentanil (0.5-1.0 mug/kg) plus etomidate (0.1-0.2 mg/kg) frequently confers hemodynamic stability. Maintenance of anesthesia, utilizing an infusion of sufentanil (1.0-2.0 mug/kg/h), in a balanced anesthetic technique, achieves the advantages of an opioid-based anesthetic and avoids prolonged opioid action into the postoperative period.

Remifentanil has been employed in cardiac anesthesia. [792] Insufficient data preclude drawing conclusions about this application of remifentanil. Whether the cost or risks of using an ultrashort-acting opioid would be outweighed by any benefit remains to be seen.

Other Applications of Opioids

New systems and sites for drug delivery have the potential to improve analgesic therapies by improving convenience and patient compliance, reducing pain associated with drug delivery, and increasing drug bioavailability and analgesic efficacy.

Transdermal Drug Delivery

Transdermal drug delivery generally requires high solubility in both water and oil (lipid solubility to pass through the stratum corneum and aqueous solubility to move through the dermis), low molecular weight, high potency (requiring absorption of only small amounts for clinical effect), and little or no skin irritation. Under basal conditions, 450 mL of blood, approximately 10 percent of the cardiac output, passes through the skin. Under thermal stress, skin blood flow can increase as much as 10-fold. Cutaneous vasoconstriction from cold stress can virtually abolish skin blood flow. The transdermal permeability of a drug may vary over different areas of the body. In some formulations, attempts to reduce variability in drug absorption have been made by adding a rate-controlling membrane to the transdermal drug delivery apparatus, which limits the release of drug to a fraction of the uncontrolled rate of absorption of the skin.

Fentanyl is available in a transdermal delivery system. Potential advantages of delivering fentanyl transdermally include no first-pass drug metabolism by the liver, improved patient compliance, convenience and comfort, and consistent analgesia. Other theoretic advantages include its simple, noninvasive nature, reduced nursing efforts, and less interruption of sleep. Transdermal fentanyl is approved by the FDA, but for use only in opioid-tolerant patients. Results of clinical trials utilizing fentanyl for postoperative analgesia have demonstrated a high incidence of significant respiratory depression, and this application is not recommended. [930] [931] [932] The development of other types of fentanyl patches has not eliminated problems with wide variability in fentanyl concentrations produced or in episodes of troublesome respiratory depression. [933] [934]

Doses of transdermal fentanyl include 25, 50, 75, and 100 mug/h and achieve blood levels ranging from less than 1.0 to 2.0 ng/mL, although significant variability exists. Plasma fentanyl levels rise and usually reach a plateau within 8 to 16 hours. Steady-state fentanyl concentrations are achieved by the time a second patch is applied. Fentanyl blood levels fall slowly after patch removal because absorption of drug deposited in the skin continues. [935] The half-life for the decline in fentanyl levels after patch removal is high (17±2.3 h).

Transdermal fentanyl is effective in cancer pain management. Patients should have analgesia provided by fasteracting opioid preparations, then be converted to transdermal fentanyl, with allowances made for drug conversions. Most patients with cancer experience 72 hours of analgesia following application of the patch, but some individuals only obtain about 48 hours of analgesia from each unit. This may be due to tumor fever, a common phenomenon that occurs in about 40 percent of patients with active cancer. Elevated body temperature accelerates either the release of fentanyl from the patch or the distribution from the subcutaneous fat depot.

Because of the difficulties encountered in the passive delivery of drugs through the skin, physical and chemical methods of enhancing transdermal drug delivery are being investigated. [936] Iontophoresis is a technique by which drug passage through the skin is augmented by an external electric current. Morphine HCl has been delivered iontophoretically for postoperative pain control. Patients who received morphine by iontophoresis required fewer additional opioid analgesics than patients receiving a placebo after orthopedic

surgery. [937] After a short delay, plasma morphine levels are directly proportional to the electric current employed in the iontophoretic device. Similar results have been achieved with fentanyl. [938]

Transmucosal Drug Delivery

Similar to transdermal drug delivery, transmucosal delivery through the oropharynx and nasopharynx eliminates hepatic first-pass metabolism (drugs are absorbed directly into the systemic circulation) and improves patient comfort, convenience, and compliance. The oral and nasal cavities are rich in blood vessels and lymphatics; thus, drug absorption is faster and onset of action is more rapid compared with oral (swallowed) and transdermal routes. Possible applications for this mode of administration include premedication, acute postoperative pain relief, and treatment of chronic pain.

Sites for transmucosal delivery in the mouth include sublingual, buccal, and gingival surfaces. Although the sublingual route is easier for patients to use, increased salivary production and swallowing limit systemic availability with this approach.

Buprenorphine, a potent, synthetic morphine analogue with mixed opioid agonist-antagonist properties and a long half-life, is readily absorbed from sublingual mucosal tissues. Buprenorphine is well absorbed across mucosal membranes and is quite suitable for sublingual and buccal administration. The portion of the drug that is swallowed is almost completely metabolized by the liver, and only a small fraction can reach the systemic circulation when swallowed. It has been used successfully for premedication and treatment of postoperative and cancer pain. [939] [940] [941] [942] Sublingual buprenorphine, given 1 hour preoperatively, provides reliable preoperative sedation and postoperative analgesia similar to IM morphine. [941] In several studies, sublingual buprenorphine (0.4 mg) was compared with conventional intramuscular morphine or meperidine and found to provide comparable and satisfactory postoperative analgesia. [942] However, onset of drug effect was slow (3 h) and thus not effective for the immediate postoperative period. [939] [941] Systemic bioavailability after sublingual buprenorphine is approximately 50 percent of that following IV administration. [940] Although the percentage of patients achieving adequate pain relief after cholecystectomy with sublingual buprenorphine alone is high (
80%), other supplemental methods (e.g., PCA) may be required for higher success rates or after more painful operations. [943] Sublingual buprenorphine is not approved for use in the United States.

Initial experience with buccal morphine for postoperative analgesia had been promising. Bell et al [944] demonstrated that buccal morphine has a 50 percent bioavailability. However, subsequent studies by Fisher et al [945] have questioned the reliability and systemic availability of buccal morphine. These investigators showed that IM morphine provided more effective premedication than a buccal tablet of morphine. Furthermore, 81 percent of patients receiving buccal morphine complained of its bitter taste, and plasma drug concentration-time curves were markedly different than those reported by Bell. In addition, peak plasma levels after buccal morphine were lower (9.1 versus 36.0 ng
mL^{-1}), time to peak levels was longer (408 versus 60 min) and bioavailability (area under the curve) was less (1.6 versus 14.8 mug-min
mL^{-1}) than after IM morphine. [944] [945] Reasons for these markedly differing results are unclear, but those offered by Fisher and others [946] include the wide variability in morphine absorption by the buccal route, differences in the pH of the formulation tested and morphine assay methods, and poor adherence and dissolution of the tablet on the buccal mucosa in patients with a dry mouth. [945] In addition, the bitter taste of morphine elicits salivation and swallowing that negate the objective of avoiding first-pass drug metabolism. [946] Bioavailability after sublingual morphine is six times lower than when the same dose is given IM or nebulized and administered intratracheally. [947] Morphine's low lipid solubility makes it an unlikely candidate for effective transmucosal absorption (Fig. 10-46) (Figure Not Available) . Opioids with a high lipid solubility, such as buprenorphine, fentanyl, and methadone are more effectively absorbed sublingually than those with low lipid solubilities such as morphine. [948]

Oral transmucosal fentanyl citrate (OTFC) is a solid dosage form of fentanyl that consists of fentanyl incorporated into a sweetened lozenge on a stick. When consumed, a portion of fentanyl is absorbed through the oral mucosa and the rest is swallowed and absorbed through the GI tract. OTFC gained regulatory approval in 1993 for use as a premedication before surgery and painful procedures (not requiring general anesthesia) in both children and adults. [949] [950] [951] [952] [953]

OTFC is available in 200-, 300-, and 400-mug units. The recommended doses range from 5 to 15 mug/kg, depending on the desired degree of sedation. Patients should be instructed to consume OTFC quickly (within 15 min) because longer consumption times may decrease fentanyl absorption. In addition, OTFC should be administered approximately 30 minutes before surgery (or painful procedure) to obtain peak effect.

Plasma concentrations after OTFC administration peak at 2.0±0.5 ng/mL, 15 to 30 minutes after OTFC administration, then decline to less than 1 ng/mL an hour later (Fig. 10-47) (Figure Not Available) . [954] Plasma concentrations rapidly reach concentrations associated with analgesia (0.63-1.0 ng/mL) during OTFC consumption. The elimination half-life of OTFC is 7.7 hours, similar to the IV route. Unlike transdermal fentanyl, OTFC leaves no significant depot in the mucosal tissues after it is

removed. However, some absorption of fentanyl continues after OTFC is removed or consumed because of the absorption of swallowed fentanyl from the GI tract. Swallowed fentanyl has a low bioavailability because of hepatic first-pass metabolism. The systemic bioavailability of OTFC is 50 percent and reflects both buccal and GI absorption. OTFC bioavailability is similar to that of buprenorphine (55%), but much greater than buccal morphine and other opioids with low lipid solubility.

OTFC was developed because of the need for less painful and frightening methods of obtaining analgesia in children. Because many children do not have IV access, analgesia may be obtained by the transmucosal route. For example, premedication with OTFC can reduce pain in children undergoing lumbar puncture or bone marrow aspiration, and it can also reduce pain associated with laceration repair, dermatologic surgery, and burn dressing changes.

Enthusiasm for OTFC as a premedicant has been tempered by associated side effects, which include perioperative emesis. Decreasing patient activity and timing OTFC

Figure 10-46 (Figure Not Available) The mean absorption (± SE) of the test opioids after 10 minutes in the oral cavity of normal subjects (*n* = 10 for each test condition). administration so that patients are moved to the operating room before the peak effects occur can reduce this side effect. Respiratory depression can also occur, and patients need to be adequately monitored and treated for this side effect.

OTFC is also being evaluated for treatment of acute postoperative analgesia [955] and breakthrough cancer pain. For example, the speed of onset of analgesia with OTFC is equal to that of IV morphine in patients after abdominal hysterectomy. OTFC may be ideally suited to treat breakthrough cancer pain because fentanyl is rapidly absorbed from OTFC and patients can easily self-administer OTFC. Onset of analgesia for breakthrough pain occurs as early as 5 minutes after OTFC administration. Clinical trials examining

Figure 10-47 (Figure Not Available) Plasma concentration of fentanyl (mean ± SEM) after oral transmucosal fentanyl (OTFC) versus oral (swallowed) fentanyl. Total fentanyl administered via each route was 15 mug/kg. OTFC oralets were consumed in 15 minutes, and solutions were swallowed within 10 seconds. Systemic bioavailability was greater for OTFC (0.52±0.1) than for swallowed fentanyl (0.32±0.1) (*P* = .01). *(From Streisand et al [954])*

the safety and efficacy of OTFC in breakthrough cancer pain are completed, and FDA approval is pending. Reviews on OTFC are available. [956]

Delivery of opioids through the nasal mucosa has also been investigated. [957] Although intranasal sufentanil (1.5, 3.0, 4.5 mug kg^{-1}) in children allows easy separation from parents, many of the children cried on drug administration. [958] Side effects of intranasal sufentanil include reduced ventilatory compliance (chest wall rigidity) with higher doses (3.0-4.5 mug kg^{-1}). Intranasal sufentanil (2 mug/kg) in pediatric patients before surgery can cause hypoxemia and impair manual ventilation. [959] Intranasal sufentanil (2 mug/kg) and midazolam (0.2 mg/kg) have been compared as premedicants for pediatric outpatients. [960] Sufentanil provided better conditions during induction and emergence and was associated with less nasal irritation, but more nausea and vomiting postoperatively than intranasal midazolam.

In adults, too, 10 to 15 mug of intranasal sufentanil induces moderate sedation with few side effects 20 to 40 minutes after administration. [961] [962] Plasma sufentanil levels 5 and 10 minutes after intranasal sufentanil are 36 and 56 percent of those after IV dosing respectively. After 30 minutes, plasma levels were the same after both routes. Bioavailability of intranasal sufentanil is 78 percent of IV sufentanil.

Butorphanol, a partial mu- and kappa-agonist, has also been administered nasally. A metered-dose spray pump delivers 1 mg/spray (0.1 mg/mL), the approximate therapeutic dose. Peak blood concentrations occur 15 minutes after administration and bioavailability is relatively high (50-70%). Transnasal butorphanol provides superior and more prolonged analgesia than similar doses given IV for postoperative pain after cesarean section. [963] In human volunteers, transnasal butorphanol (1-2 mg) produced psychomotor, cognitive, and subjective effects for 1 to 3 hours. [964] The application of transnasal butorphanol has proven efficacious after cesarean section, episiotomy, orthopedic surgery in children, and in the emergency room.

Postoperative pain management with self-administered meperidine [965] and PCA with intranasal fentanyl [966] have been demonstrated to be as effective as more traditional pain therapies. Intranasal oxycodone is also rapidly and effectively absorbed, but with significant variability. [967] It appears that further exploration of the transnasal approach to drug delivery for pain management is merited.

Morphine (10 mg) and fentanyl (300 mg) inhalation produces low plasma drug levels (10 and 0.2-0.4 ng/mL, respectively) and analgesia that may be disproportionately greater than expected. [947] [968] Inhaled liposome-encapsulated fentanyl may allow analgesia to be rapidly produced and sustained. [969]

Successful inhalation of any drug requires proper coordination with inspiration, and some devices include strategies toward this goal. One device for the pulmonary administration of morphine (AERx, Aradigm Corp., Hayward, Calif) only releases drug when the correct inhalation pattern is accomplished. Inhaled doses of 2.2, 4.4, and 8.8 mg of morphine, aerosolized in an aqueous solution, provide dosedependent, analgesic blood concentrations of morphine within 5 minutes of administration. Technologic advances in drug delivery are likely to continue to stimulate research in analgesic therapies.

The rectal mucosa is another site for transmucosal drug delivery. Rectal methohexital was frequently used in the past for premedication in young children. Rectal suppositories containing morphine, hydromorphone and oxymorphone, and oxycodone are available.

Morphine is only poorly absorbed from the rectal mucosa of children. [970] However, sustained-release morphine hydrogel suppositories (MHS) may be more promising. [971] Two suppositories have been designed. The first releases a bolus, then a smaller quantity of morphine at a constant rate to achieve initially and then maintain plasma drug concentrations. A second sustained-release-only suppository has also been developed to permit administration for successive 12-hour periods after administration of the first type of rectal morphine. Plasma morphine levels after MHS are lower than after IM morphine, but linear analogue scales for pain were lower, and the incidence of nausea was reduced after rectal sustained-release therapy. [971] The hydrogel formulation of rectal morphine may also be useful for premedication and analgesia in pediatric patients. [972] Although rectal administration of drugs is complicated by interruption of absorption by defecation, mucosal irritation, variable systemic availability (venous drainage of the rectum is in part to the portal system), and poor patient acceptability, further investigation with MHS seems warranted.

Oral Controlled-Release Medications

Despite the high first-pass metabolism of opioid analgesics, morphine has been formulated into an oral, sustained-release tablet (MST) and has been evaluated for premedication, [973] postoperative analgesia [974] [975] and as an analgesic for chronic cancer pain. [976] [977] Early clinical trials have suggested that MST provides unreliable preoperative anxiolysis [973] and postoperative pain relief, [974] [975] possibly because of delayed time to onset of peak effects (3-5 h), which can be increased by impaired gastric emptying and absorption from the small intestine. On the other hand, patients with chronic cancer pain perceived that analgesia was superior and side effects were fewer with MST. [976]

/das/book/view/29494766/875/123.html

OTHER OPIOID AGONISTS

Many other opioid agonists exist (Table 10-18) , but their use in operative anesthesia is usually limited. Some of these agents are used primarily for analgesia. The following is a brief synopsis of many, but not all, available opioid agonists.

Alphaprodine (Nisentil) is a phenylpiperidine derivative that is approximately one-fourth as potent as morphine. Alphaprodine has a rapid onset and a relatively short duration of action (2 h). Some clinicians compare alphaprodine to meperidine but believe the former causes less nausea and vomiting. Alphaprodine has been a popular analgesic for labor pain. [978] Respiratory depression, fetal bradycardia, and depressed progression of labor can occur when the drug is given for analgesia during labor. Murakawa et al, [978] on the other hand, found alphaprodine (39±4 mg IV) to produce no neonatal effects when given to parturients 197±96 minutes prior to delivery.

Codeine (methylmorphine) is one-half as potent as morphine, has a high oral-parenteral potency ratio (2:3) and a plasma half-life of 2 to 3 hours. Codeine has mild to moderate

analgesic but strong cough-suppressant properties after oral administration. Hepatic conversion to morphine (demethylation) is necessary for codeine's activity. Cytochrome P-450 2D6 (CYP2D6) is the enzyme responsible for *O*-demethylation of codeine to morphine. [979] IV codeine produces profound hypotension and is neither approved nor recommended. [980] Its use as a preferred opioid in neurosurgical patients is not substantiated.

Dextromoramide was developed by Janssen Pharmaceutica in 1956. Though unavailable in the United States, dextromoramide is still used in a few European countries. It can be administered orally or parenterally, has a duration of action similar to that of methadone, and is 25 times more potent than morphine. [981]

Etorphine and carfentanil are wild game-immobilizing opioids not available for use in humans and are several thousand times more potent than morphine. [982]

Heroin, diacetylmorphine, is approximately twice as potent as morphine and has a 4- to 5-hour duration of action. Heroin is rapidly hydrolyzed to 6-acetylmorphine and morphine. These metabolites account for a significant portion of heroin's effects. Because of its high solubility and lipophilicity, heroin lends itself to subcutaneous injection. Heroin is excreted in the urine mostly as free and conjugated morphine. Manufacture and importation of heroin is illegal in the United States, but not in the United Kingdom or Canada.

Hydromorphone (dihydromorphinone or Dilaudid) is structurally related to morphine but is approximately five to ten times as potent. The onset and duration of action of hydromorphone is similar to that of morphine. [983] [984] Analgesia after hydromorphone lasts 4 to 5 hours. The effects of hydromorphone are essentially indistinguishable from those of heroin. [985] Hydromorphone does not result in an increase in plasma histamine. [986] It can be administered by oral, rectal, subcutaneous, and other parenteral routes.

Levorphanol is a semisynthetic opioid with a long (12- 16-h) half-life. It is 5 times as potent as morphine with an IM/oral potency ratio of 1:2. Discrepancies between half-life and apparent duration of clinical analgesia (4-6 h) create conditions in which repeated doses may lead to drug accumulation and toxicity. Levorphanol may have particular utility in patients with chronic pain and who demonstrate morphine tolerance, perhaps because of differences in opiate receptor activity.

Methadone (Dolophine) has an equivalent potency but longer duration of action than morphine. [987] Methadone's efficacy is reduced by 50 percent after oral administration, compared with IM delivery. Its major clinical applications are in the prevention of opioid withdrawal symptoms and in the treatment of chronic pain. It can also provide postoperative pain relief. [987] Prolonged and potentially troublesome postoperative respiratory depression can occur, possibly because of the long duration of action of methadone. [988] This may be related to increases in apparent potency that occur with repeated administration. The plasma half-life of methadone is very long and variable (13-100 h). Despite this property, many patients require dosing every 4 to 8 hours to maintain analgesic effects. It is a difficult drug to titrate successfully. Methadone should not be administered subcutaneously because of local skin toxicity.

Oxymorphone (dihydrohydroxymorphinone or Numorphan), also structurally related to morphine, is almost ten times as potent, but has a similar duration of action. Oxymorphone is less likely to cause the release of histamine than morphine and may have particular utility in patients who experience excessive with opioid analgesics.

Pentamorphone, a morphinan derivative, is two to eight times as potent as fentanyl and produces similarly lasting analgesia without hemodynamic disturbances or increases in plasma histamine. [989] Although respiratory depression may be limited with analgesic doses (0.1 mug/kg), greater doses produce typical opioid-induced respiratory depression. [990] Pentamorphone does not appear to offer significant advantages over better-established opioid agents.

Phenoperidine is chemically related to meperidine but is 100 times as potent as an analgesic. Onset of effect is rapid and duration is moderate (2-6 h). Doses of 2 to 5 mg IV produce significant respiratory depression. Metabolism of phenoperidine results in significant levels of meperidine and its metabolites. Phenoperidine has been frequently employed in balanced anesthesia in Europe, but it is unavailable in the United States.

Piritramide, the first 4-amino-piperidine derivative among opioids to be synthesized, is interestingly devoid of emetic activity. In fact, it blocks apomorphine-induced emesis. [981] It is slightly less potent than morphine.

Tramadol is a synthetic 4-phenyl-piperidine analogue of codeine with a dual mechanism of action. [991] [992] Tramadol stimulates the mu-receptor, and to a lesser extent the delta- and kappa-opioid receptors, and like tricyclic antidepressants, it also activates spinal inhibition of pain by decreasing the reuptake of norepinephrine and serotonin. Tramadol is a racemic mixture. It is unlikely to produce troublesome respiratory depression at recommended doses, but it can at greater doses. Tramadol is one-fifth to one-tenth as potent as morphine and can be given by numerous parenteral routes. Recommended dosing ranges from 50 to 100 mg every 4 to 6 hours with a maximum daily dose of 400 mg. A onetime dose of tramadol, 150 mg IV, for immediate postthoracotomy pain can be as effective as thoracic epidural

TABLE 10-19 -- Hemodynamic Effects of Agonist-Antagonist Compounds Compared with Morphine

(Not Available)

From Zola and McLeod [1026]

morphine. [993] Bioavailability of tramadol ranges from 70 to 100 percent. To date, evidence suggests that tramadol has low abuse potential. Analgesic doses of tramadol may produce less respiratory depression in part because of its non-opioid receptor-mediated actions. [994] Other common adverse effects are typical for opioids; however, tramadol may interfere less with GI function. [995] Several warnings should be noted concerning tramadol. Seizures have been reported in patients taking the drug. Caution should be exercised when combining tramadol with MAOI, neuroleptic agents, and other drugs that lower the seizure threshold.

AGONIST-ANTAGONIST COMPOUNDS

The first recorded specific opioid antagonist was developed by Pohl in 1914, who, in an attempt to improve the analgesic properties of codeine, synthesized *N*-allylnorcodeine. [996] This compound mildly antagonized the respiratory depression and sleep produced by morphine. Pohl's discovery went unnoticed for 26 years, until McCawley et al, [997] in a search for a strong analgesic with "built-in" antagonistic action, attempted to prepare *N*-allylmorphine (nalorphine) in 1940. Nalorphine was successfully synthesized by Weijland and Erickson [998] in 1942 and was found to be strongly antagonistic to almost all the properties of morphine. [999] [1000] It was also found to possess fairly strong analgesic properties in humans [1001] and animals. [1002] [1003] Unfortunately, doses of nalorphine sufficient to produce analgesia were accompanied by severe psychotomimetic effects rendering it unsuitable for clinical use as an analgesic. However, nalorphine was used in lower doses as an opioid antagonist.

Agonist-antagonist opioids are usually produced by alkylation of the piperidine nitrogen and addition of a threecarbon side chain such as a propyl, allyl, or methyl allyl to morphine. Changing the side chain to an amyl group restores agonist activity. Currently, there are several agonist-antagonist opioids in use in the United States including pentazocine, butorphanol, nalbuphine, dezocine, and buprenorphine. Buprenorphine is a partial agonist at the mu-receptor. The other compounds are mu-antagonists and full or partial agonists at the kappa-receptors. The differing degrees of interaction at the receptors contribute to the unique hemodynamic and respiratory effects of these compounds (Tables 10-19 (Table Not Available) , 10-20) (Table Not Available) . Buprenorphine has an especially high affinity at the mu-receptor. Its actions at kappa-receptors are probably minimal. Agonist-antagonist opioids are less prone (but not immune) to abuse because they cause less euphoria and are associated with less drug-seeking behavior and physical dependence.

Pentazocine

Pentazocine, a benzomorphan derivative, was the first opioid agonist-antagonist to be widely used in humans. Analgesia produced by pentazocine is primarily related to kappa-receptor stimulation. [1004] [1005] Pentazocine is one-half to one-fourth as potent as morphine. Moderate analgesia results from 10 to 30 mg IV or 50 mg orally. Ceilings to both analgesia and respiratory depression occur after 30 to 70 mg of pentazocine. Although the potential for abuse is less than with morphine, [1005] prolonged use of pentazocine can lead to physical dependence. [1004] [1006] Pentazocine is not particularly useful in reversing the respiratory-depressant effects of fentanyl, [1007] but it can precipitate opioid withdrawal in addicts. [1008] Nalorphine-like dysphoric side effects are common, especially after high doses (>60 mg) of pentazocine in the elderly. The dysphoric effects of pentazocine can be reversed with naloxone. Although the hemodynamic effects of morphine make it a useful analgesic for patients with myocardial failure, ischemia, or infarction, [1009] pentazocine depresses myocardial contractility [1010] and increases arterial blood pressure, heart rate, systemic vascular resistance, pulmonary artery pressure, and left ventricular work index. [1011] [1012] Pentazocine also increases blood catecholamine levels. In Europe, pentazocine (1 mg kg^{-1}) has been used in a general anesthetic technique called "sequential analgesic anesthesia." In this technique, the drug is administered after moderate doses of fentanyl (10-15 mug kg^{-1}). Overall, pentazocine has limited application because it is associated with a high incidence of postoperative nausea and vomiting, it provides limited analgesia, it partially antagonizes other opioids, and it can produce undesirable cardiovascular and psychotomimetic effects.

TABLE 10-20 -- Respiratory Depressant Effects of Agonist-Antagonists Compared with Morphine [a]

(Not Available)

From Zola and McLeod [1026]

[a] Low or moderate naloxone doses readily reverse the respiratory effects produced by therapeutic doses of all drugs listed, except buprenorphine.

Butorphanol

Butorphanol is an agonist at kappa-receptors. Its activity at mu-receptors is either antagonistic or partially agonistic. It is five to eight times as potent as morphine and is only available in parenteral form. After IM injection, onset of effect is rapid, and peak analgesia occurs within 1 hour. Whereas butorphanol's duration of action is similar to morphine, its plasma half-life is only 2 to 3 hours. [1013] Bioavailability after oral administration is only 17 percent of a similar IV dose. Although butorphanol (10 mg IM) causes as much respiratory depression as the same dose of morphine, higher doses reach a ceiling. [1014] Side effects after butorphanol include drowsiness, sweating, nausea, and CNS stimulation. The latter are qualitatively similar but occur less frequently than after pentazocine.

In healthy volunteers, butorphanol (0.03 or 0.06 mg kg^{-1} IV) produces no or minimal cardiovascular changes. [1014] However, in patients with cardiac disease, butorphanol causes significant increases in cardiac index, left ventricular end-diastolic pressure, and pulmonary artery pressure. [1015] These cardiovascular changes are quite similar to those produced by pentazocine. [1011] Thus, butorphanol is not particularly useful in patients with congestive heart failure or at risk for myocardial ischemia.

Butorphanol has been reported to provide adequate analgesia when used as a supplement in N_2O-opioid-O_2 anesthetic or balanced techniques. [1016] [1017] Because butorphanol decreases the MAC for enflurane by only a small fraction (11%), it cannot serve like the fentanyl congeners as an anesthetic agent. [1018] Butorphanol (0.17 mg kg^{-1}) will result in greater immediate postoperative respiratory depression than nalbuphine (0.085 mg kg^{-1}) when used as a supplement with N_2O. [1019] The antagonistic properties of butorphanol at the mu-receptor are weak and do not usually interfere with the use of other opioid agonists in anesthesia. [1020] However, butorphanol does partially antagonize fentanylinduced respiratory depression. [1021] The use of butorphanol as an epidural agent has achieved some popularity, as has its transnasal administration (see earlier).

Butorphanol is subject to less abuse and has less addictive potential than morphine or fentanyl, but it still has some potential for abuse. [1022] Withdrawal symptoms can occur after prolonged use and usually increase in severity for several days. [1023] Hepatic metabolism and urinary and a small amount of biliary excretion account for drug elimination. Acute biliary spasm can occur after butorphanol, but increases in biliary pressure are less than after equipotent doses of fentanyl or morphine. [1024]

Buprenorphine

Buprenorphine is a thebaine derivative, mu-receptor partial agonist, and similar in structure to morphine but approx-imately 33 times more potent. It also binds to delta- and kappa- receptors, but activity at the latter two sites is relatively insignificant. [70] Although buprenorphine is highly lipophilic, its opiate receptor association and dissociation are slow. Whereas fentanyl dissociates rapidly from mu-receptors (half-life of 6.8 min), buprenorphine has a higher affinity and takes much longer (half-life of 166 min). Thus, plasma levels do not parallel CNS effects. [70] Buprenorphine's onset of action is slow, and its peak effect may not occur until 3 hours. Duration of effect is prolonged (
10 h). Metabolism occurs in the liver with biliary excretion of most metabolites. The metabolites of buprenorphine, buprenorphine-3-glucuronide and norbuprenorphine are significantly less potent and have lower affinities for the mu-receptor. Their accumulation in patients with renal failure is unlikely to exert significant pharmacologic activity. [1025] Buprenorphine's volume of distribution is 2.8 L
kg^{-1} and clearance is 20 mL
kg^{-1}
min^{-1} . Recommended initial analgesic doses are 0.3 to 0.4 mg. [1026]

Subjective effects (e.g., euphoria) of buprenorphine are similar to morphine. Buprenorphine produces respiratory depression with a ceiling after 0.15 to 1.2 mg in adults. Higher doses do not produce further respiratory depression and may actually result in increased ventilation (predominance of antagonistic actions). [1027] Respiratory depression can be significant after buprenorphine. Reversal with naloxone is limited by buprenorphine's high affinity for and slow dissociation from the mu-opiate receptor. Very high doses of naloxone and/or doxapram may be required for full reversal. [1026] [1028] Buprenorphine (0.6 mg IV) has been reported to reverse troublesome fentanyl-induced postoperative respiratory depression as well as naloxone (0.4 mg) and to preserve analgesia better. [1029]

Buprenorphine has been successfully used for premedication (0.3 mg IM), [1030] as the analgesic component in balanced anesthesia (4.5 to 12 mug kg^{-1}) [1031] and for postoperative pain control (0.3 mg IM). Sublingual administration (0.4 mg) has also proved effective. [1032] Buprenorphine, like the other agonist-antagonist compounds, is not acceptable as a sole anesthetic, and its receptor kinetic profile restricts its usefulness if other mu-agonists are used. Buprenorphine has been administered via alternate routes (see earlier), epidurally, and it may be of value as an alternative to methadone for maintenance therapy in opiate addicts.

The hemodynamic effects of buprenorphine are similar to those of morphine (see Table 10-19) (Table Not Available) . Opioid withdrawal symptoms develop slowly (5-10 days) after buprenorphine is discontinued following long-term use. In contrast to other agonist-antagonists, buprenorphine produces minimal effects in methadone-maintained opioid abusers. [1033]

Nalbuphine

Nalbuphine is an agonist-antagonist opioid that is structurally related to oxymorphone and naloxone. [1034] Autoradiography studies indicate that nalbuphine binds to mu- receptors as well as to kappa- and delta-receptors. [1035] Nalbuphine acts as an antagonist at the mu-receptor and an agonist at the kappa-receptor. Activation of supraspinal and spinal kappa-receptors results in limited analgesia, respiratory depression, and sedation. [46] [1035] Although 10 mg of nalbuphine produces similar sedation, analgesia, and respiratory depression as 10 mg of morphine, this equivalency does not persist at higher doses. Maximal analgesia occurs after approximately 30

mg
70 kg^{-1} of nalbuphine. Nalbuphine also causes other typical opioid side effects. [1036]

Nalbuphine is only available for parenteral use. Onset of effect is rapid (5 to 10 min), and duration is long (3 to 6 h) because of a long plasma elimination half-life (5 h). Hepatic metabolism and fecal excretion account for most of the drug's elimination. Nalbuphine does not increase plasma histamine levels. Nalbuphine (0.6 mg kg^{-1}) produces no or minimal hemodynamic changes in ASA class I and II patients or those undergoing cardiac catheterization when administered alone. [1037] Premedication with nalbuphine (0.1 mg
kg^{-1}) in patients scheduled for cardiac surgery results in similar sedation, relief of anxiety, and respiratory depression as morphine (0.1 mg
kg), but it causes no significant hemodynamic changes. [1037] In patients experiencing a myocardial infarction, 10 mg of nalbuphine causes small decreases in heart rate (82-72 beats/min) and cardiac index (3.16-2.75 l
min^{-1}
m^{2-1}) and small increases in systemic vascular resistance (1204-1461 dynes
s
cm^{-} [5]). [1038] Changes in systemic, pulmonary arterial, and pulmonary capillary wedge pressures are not significant. [1038]

In addition to occasionally being used as a premedicant, nalbuphine has been administered as an analgesic supplement for conscious sedation or balanced anesthesia and as a analgesic for postoperative and chronic pain problems. Conscious sedation during monitored anesthesia care has also been recommended with combinations of nalbuphine (20-30 mg
70 kg^{-1}) and droperidol (2.5 mg) [1039] or nalbuphine (0.05-0.2 mg
kg^{-1}) and midazolam (0.05 mg
kg^{-1}). [1040] Apnea and/or slow respiratory rates (less than 8) are occasional problems with the latter drug combination. [1040]

Balanced anesthesia with nalbuphine as an IV analgesic supplement is effective for surgical procedures not associated with severe pain. [1041] Postoperative sedation, dreaming, anxiety, and a longer recovery room stay are more common when nalbuphine (0.3 to 0.5 mg
kg^{-1}) is used with N_2O for laparoscopy than when fentanyl (1.5 mug
kg^{-1}) is employed as the opioid. [1041] Other investigators have found that nalbuphine is not as effective as fentanyl in attenuating responses to intubation and surgery, but it provides similar levels of postoperative analgesia with less respiratory depression in women having lower abdominal surgery. [1042] Anesthesia with nalbuphine (3 mg
kg^{-1}), diazepam (0.4 mg
kg^{-1}), and N_2O has been reported to provide hemodynamic stability during cardiac surgery by some investigators, [1043] but not others. [1044] [1045] Nalbuphine's inability to decrease the MAC of potent inhalation agents [1018] (maximum 10-30%) suggests it has little or no role as a sole or primary anesthetic.

Nalbuphine provides good analgesia for mild to moderate, but not severe, postoperative pain. Nalbuphine, like other agonist-antagonist compounds, interferes with the analgesia produced by pure mu-agonists. Addiction, abuse, and withdrawal occur less frequently after nalbuphine than after the pure mu-agonist, but they occur as frequently as after the other agonist-antagonist compounds.

Nalbuphine as an Antagonist of Opioid Drugs

Preservation of analgesia following reversal of opioidinduced respiratory depression has long been a goal of researchers and clinicians. [1046] Although numerous opioid antagonists have been studied in attempts to find the "ideal" compound (including nalorphine, levallorphan, naloxone, and numerous others), none is optimal. Nalbuphine has been extensively evaluated for this purpose. [316] [1047] [1048] [1049] [1050] [1051] [1052] [1053] [1054] Nalbuphine restores normal inspiratory neuronal activity after fentanyl in cats, [316] but respiratory depression induced by oxymorphone (1.5 mg) is only partially reversed by nalbuphine in humans (0.1 mg
kg^{-1}). Nalbuphine (0.21 mg
kg^{-1}) does not reverse and may actually increase respiratory depression after morphine (0.21 mg
kg^{-1}) (Fig. 10-48) (Figure Not Available) . [1052]

Latasch et al [1047] reported that nalbuphine (20 mg IV) adequately reversed respiratory depression but not analgesia in patients who had received 7 mug

kg^{-1} of fentanyl and N_2O for general surgery. Zsigmond et al [1054] found that nalbuphine (0.1 mg kg^{-1}) did not elicit significant cardiovascular changes or pain in patients given fentanyl-N_2O anesthesia for abdominal surgery. Unfortunately, many other investigators have documented the occurrence of significant pain, hypertension, and tachycardia (often requiring pharmacologic intervention) following opioid reversal with nalbuphine. [1049] [1050] [1055] Many of these reports involved patients undergoing cardiovascular procedures (abdominal vascular surgery or coronary artery bypass grafting [1049] [1050] [1054]). Patients at risk for myocardial ischemia or other cardiovascular problems are not good candidates for opioid reversal.

Restoration of spontaneous ventilation using small titrated doses of nalbuphine (2.5 mg q 2-3 min) results in less pain than naloxone (0.08 mg titrated similarly) after fentanyl (mean dose 25 mug kg^{-1}), isoflurane and N_2O anesthesia. [1053] Renarcotization is likely to be less frequent after nalbuphine (Table 10-21) (Table Not Available).

Figure 10-48 (Figure Not Available) Resting end-tidal CO_2 (P_{ECO_2}) at baseline and at 5 and 30 minutes after morphine (0.21 mg/kg IV) and after nalbuphine (0.21 mg/kg IV), naloxone (0.014 mg/kg IV), and saline given 55 minutes after morphine. *(From Bailey et al [1052])*

TABLE 10-21 -- Percentage of Patients Requiring Analgesics and Renarcotizing After Nalbuphine or Naloxone Reversal of Fentanyl

(Not Available)

From Bailey et al [1053]

Dezocine

Dezocine is slightly more potent and faster-acting than morphine, with a similar duration. [1056] It is active at mu-receptors, and side effects are similar to those of morphine. Respiratory depression and analgesia reach a plateau after approximately 0.3 mg kg^{-1}. [1056] Dezocine may prove superior to other agonist-antagonists as an anesthetic supplement because it is more effective in reducing the MAC of potent inhalation agents (50% with cyclopropane or 58% with enflurane) than other agonist-antagonists. [1057] [1058] In addition, dezocine potentiates rather than antagonizes morphine and other pure mu-agonist analgesics. Dezocine is a partial agonist at mu- and probably delta-receptors. [1057] Affinity at mu-receptors is high. Dezocine does not increase plasma histamine and produces less hypotension than morphine or pentazocine in dogs. [1059] Dezocine can be effective for moderate and severe pain, [1060] but it can cause myocardial depression and hypotension.

Meptazinol

Meptazinol is an investigational synthetic analgesic with opioid agonist-antagonist properties. Meptazinol has been reported to cause minimal respiratory depression because of its selectivity for mu_1 - (high-affinity) receptors. [1061] However, other investigators have found significant respiratory depression after meptazinol, as well as significant cholinomimetic effects. [1062] Controversy persists concerning the existence and significance of mu_1 -opiate receptors. Meptazinol has a rapid onset of action that lasts approximately 2 to 4 hours. There are conflicting reports concerning the efficacy of meptazinol as a postoperative analgesic. [1061] [1063] Meptazinol, 120 mg, is equianalgesic to 10 mg of morphine. Side effects (nausea and vomiting) after meptazinol increase with dosage and limit its ability to relieve severe pain. [1061]

OPIOID ANTAGONISTS

Naloxone

Opioid antagonists are essential tools in scientific evaluations of opiates and opiate receptors. [1064] Clinically, opioid antagonists are used to restore spontaneous ventilation in patients who breathe inadequately after opioid overdoses or opioid anesthesia. In addition, opioid antagonists can reduce or reverse opioid-induced nausea and vomiting, pruritus, urinary retention, rigidity, and biliary spasm associated with numerous therapies employing opioids, such as neuraxial analgesic techniques.

The most common side effects of opioids, administered by any route, are nausea, vomiting, and pruritus. These effects can be very disturbing to patients, as well as costly to treat. Numerous strategies utilizing antagonists or mixed agonist-antagonists have been employed in attempts to reduce or eliminate these side effects. In one study, it was suggested that low doses (0.25 mug/kg/h) of naloxone administered via continuous infusion reduced adverse effects associated with PCA analgesia with morphine. In addition, morphine requirements were significantly less in patients receiving naloxone, and the authors of the study concluded that naloxone enhanced analgesia. Proposed possible mechanisms for this apparent paradoxic effect of naloxone include enhanced release of endogenous opiates and opioid receptor upregulation. [26] There is great variability in the requirements and efficacies of opioid reversal agents when they are administered to reduce side effects. [1065]

Reversal of Respiratory Depression

In the early 1950s, nalorphine [1066] and levallorphan [1067] were evaluated as opioid antagonists. They were often found unacceptable because of a high incidence of side effects, as well as incomplete reversal. [1046] Naloxone was introduced into clinical practice in the late 1960s, and numerous studies demonstrated its efficacy as an antagonist of opioid-induced respiratory depression. Reports of side effects (increases in heart rate and blood pressure) and more serious complications (e.g., pulmonary edema) soon followed (Table 10-22) . [1068] [1069] [1070] [1071] [1072] [1073] [1074] [1075] [1076] Initial naloxone dose recommendations ranged from 0.4 to 0.8 mg. These high doses contribute to exaggerated cardiovascular responses after naloxone and are rarely necessary after anesthesia. Initial and required doses of naloxone in emergency room patients who present with possible opiate overdose may be 1 to 2 mg or more. If IV access is not available, naloxone, in doses similar to those

TABLE 10-22 -- Reported Severe Complications Following Naloxone Administration

AUTHOR	NALOXONE DOSE (IV, mg)	COMPLICATION
Azar [1068]	0.4	Hypertension (270/140)
Estilo [1069]	0.4	Hypertension (260/140); cerebrovascular accident
Flacke [1070]	0.4	Pulmonary edema
Tanaka [1071]	0.4	Hypertension (340/150)
Andree [1072]	0.4	Cardiac arrest, death
	0.4	Cardiac arrest, death
Prough [1073]	0.1	Pulmonary edema
	0.2 (+0.3 IM)	Pulmonary edema
Michaelis [1074]	0.1	Ventricular tachycardia, ventricular fibrillation
	0.4	Ventricular fibrillation
Partridge [1075]	0.08	Pulmonary edema
Taff [1076]	0.3	Pulmonary edema

given IV, is effectively absorbed after intratracheal administration. [1077]

Several mechanisms produce increases in arterial blood pressure, heart rate, and other significant hemodynamic alterations after naloxone reversal of opioids. These include pain, rapid awakening, and sympathetic activation not necessarily due to pain. Nausea and vomiting increase when opioid-induced analgesia is antagonized with naloxone. Naloxone administered by itself may not alter mean arterial pressure, heart rate, or plasma catecholamine concentrations in normotensive or hypertensive patients (not treated with clonidine) anesthetized without an opioid. [1078] However, Patschke et al [1079] showed that naloxone reversal of morphine in halothane-anesthetized dogs produces the same hemodynamic changes as it does in unanesthetized animals. These investigators reasoned that pain and awakening did not cause the increases in heart rate, blood pressure, left ventricular dP/dt, O_2 consumption, and coronary artery blood flow that were observed. They postulated that patients with coronary artery disease could be adversely affected by naloxone because of sympathetic activation.

Metabolic stress is also more likely when patients receiving naloxone for opioid agonist reversal are hypothermic. Shivering can occur, and O_2 consumption and minute ventilation can increase 2- to 3-fold. [1080] Such metabolic demands also stress the cardiovascular system, increasing cardiac output. [1081] In addition, greater degrees of hypercapnia at the time of opioid antagonism will result in greater degrees of cardiovascular stimulation because of associated sympathetic stimulation. Often, only modest levels of hypercapnia (P_{CO_2} 46-50 mm Hg) are required to allow for adequate ventilatory drive yet avoid excessive cardiovascular stimulation when opioid antagonism is carefully applied. Opioids decrease sympathetic outflow through their central (brain system and spinal) actions. [393] alpha-Adrenergic agonists (e.g., clonidine) and opioids decrease transmission through the same preganglionic sympathetic neurons. [1082] This mechanism may explain clonidine's effectiveness in blocking hemodynamic stimulation following naloxone reversal of fentanyl. [393] Naloxone also reverses clonidine-induced decreases in potent inhalation agent requirements. [1083] In addition, many hypertensive patients demonstrate reversal of the antihypertensive effects of clonidine by naloxone with concomitant increases in heart rates, peripheral vascular resistance, plasma renin activity, plasma epinephrine, and norepinephrine. [1084] Naloxone may also have a nonspecific analeptic effect through activation of a CNS arousal system. [1085] [1086]

Opioid reversal is perhaps best avoided in patients in whom increases in arterial blood pressure and heart rate could be detrimental. Although naloxone has been used safely in neuroanesthesia, [1087] significant increases in CBF and $CMRO_2$ can occur, [1088] and careful titration is required. Opioid reversal may be particularly

hazardous in patients with pheochromocytoma or chromaffin tissue tumors. [1089]

Onset of action of IV naloxone is rapid (1-2 min), and half-life and duration of effect are short, approximately 30 to 60 minutes. [1090] [1091] Naloxone is primarily metabolized in the liver via glucuronidation. Most often, 1.0 to 2.0 mug
kg^{-1} titrated in 0.5- to 1.0-mug
kg^{-1} boluses every 2 to 3 minutes will restore adequate spontaneous ventilation. [1053] Even smaller doses of naloxone may be adequate after alfentanil. Careful titration of naloxone may obviously not be appropriate if a patient is hypoxic.

Recurrence of respiratory depression after naloxone is due to the agent's short half-life as well as reuptake of opioid from peripheral compartment tissues (e.g., muscle) and other factors (see earlier). Attempts to compensate for naloxone's short duration of action by increasing the size of a single dose risk increasing the incidence and severity of unwanted side effects. "Renarcotization" occurs more frequently after the use of naloxone to reverse longer-acting opioids such as morphine. In these circumstances, an additional IM dose or continuous infusion of naloxone may be helpful. In the immediate postoperative setting, these modes of administering naloxone should not supplant good nursing care and attentive observations of respiratory function. Short-lasting opioids such as alfentanil rarely pose a danger of renarcotization, because of a rapid plasma decay curve, less chance of second plasma peaks due to reuptake of drug from peripheral tissues, and weak opiate receptor binding compared with fentanyl and sufentanil. [1092]

Although other agents (see under nalbuphine) may be somewhat better as antagonists, a rational use of reversal agents includes the following:

1. Use opioids in anesthesia so that reversal agents are rarely necessary.
2. Avoid intraoperative iatrogenic hypocapnia and posthyperventilation-hypoventilation syndrome so that body CO_2 stores are not be depleted and adequate ventilatory drive remains after anesthesia and surgery.
3. Carefully titrate opioid antagonists.
4. Avoid reversal agents in patients with severe or worrisome hypertension or cardiac or cerebrovascular disease.

Naloxone, although active at mu-, delta-, and kappa-receptors, has greatest affinity for mu-receptors, through which most potent opioid effects, including respiratory depression and analgesia, are mediated. Although it is unlikely that analgesia can always be spared following reversal of respiratory depression, careful titration of naloxone often can restore adequate spontaneous ventilation without reversal of adequate analgesia.

Naloxone: Other Applications

The potential roles of opioid receptor antagonists such as naloxone in disorders such as septic and hemorrhagic shock, alcoholism, and other conditions continue to be explored. Naloxone may be useful in the treatment of postanesthetic apnea in infants, even when exogenous opioids have not been administered. [1093] Primary apnea and periodic breathing associated with hypoxemia [1094] may also be ameliorated by naloxone; however, roles for opioid antagonists in other disorders of ventilatory control (e.g., sudden infant death syndrome) await definition. [1095] Naloxone does restore flow-resistive load compensation in patients with chronic obstructive pulmonary disease, [1096] and it may be beneficial in other forms of respiratory failure. [1097]

Alcohol interacts with many neurotransmitter systems, including the endogenous opioid peptide system. The mesolimbic dopamine system is central to drug-induced reward, and it has been suggested that alcohol-opioid system

links may play an important role in alcohol addiction. [1098] The frequency and severity of relapses in alcoholics have been demonstrated to be decreased by treatment with naltrexone, a long-acting opioid antagonist.

Although many conflicting reports and opinions exist, high doses of naloxone may reverse the effects of some nonopioid CNS depressants. [1099] Benzodiazepine reversal has been reported after naloxone and may be related to GABA receptor effects, a nonspecific analeptic effect, or reversal of concomitantly released endogenous opiates. Barbiturate and alcohol reversal have also been reported after naloxone. Certain metabolic products of alcohol (isoquinolines) have opioid-like actions and may account for this interaction. Opioid-GABA receptor interactions could also explain barbiturate antagonism. Naloxone may also partially antagonize ketamine and N_2O analgesia. The MAC of potent inhalational agents is unaffected by naloxone. However, pretreatment of rats with naloxone does counteract halothane-induced depression of sympathetic nerve activity, but interestingly, not halothane-induced analgesia. [1100]

Naloxone increases arterial blood pressure in laboratory animals, primates, and some patients in hypovolemic and septic shock. Purported mechanisms include centrally mediated increases in sympathetic tone and decreases in parasympathetic output and/or antagonism of endogenous opioids. [1101]

Naloxone may ameliorate the neurologic deficit following an ischemic or traumatic neurologic insult in animals. For example, hemorrhage-induced cerebral ischemia and SEP depression in the rat is reversed by naloxone, whereas CBF decreases are not. [1102] Such improvements in neurologic function, attributed to reversal of endogenous opiate effects, may underlie reported benefits. Results have not, however, been consistent, and further research is needed. [1101] Naloxone may also have a therapeutic role in heat stroke disorders, [1103] Alzheimer disease, schizophrenia, intractable pruritus, and thalamic pain syndrome.

Other Opioid Antagonists

New antagonists continue to be developed. [1104] [1105] However, the number of clinically available pure opioid receptor antagonists remains limited.

Naltrexone

Naltrexone is a mu-, delta-, and kappa-opioid receptor antagonist and provides two possible advantages when compared with naloxone. It is longer acting (plasma half-life of 8-12 versus 0.5-1.5 h), and it is active when taken orally. A single oral dose results in a constant plasma concentration for up to 24 hours. Naltrexone is not subject to as much first-pass hepatic metabolism as naloxone. Oral naltrexone (5-10 mg) reduces the frequency and severity of pruritus, nausea, and vomiting associated with epidural morphine without diminishing analgesia. [1106] Abboud et al [1107] found that 6 mg of naltrexone significantly reduces pruritus associated with epidural morphine and better preserves analgesia than 9 mg. Whether or not urinary retention or delayed respiratory depression can also be decreased or eliminated with naltrexone remains to be proven. Higher doses of naltrexone (e.g., 100 mg) are used to prevent opioid activity during maintenance treatment of opioid addicts. Naltrexone, like naloxone, can stimulate the cardiovascular system. [1108]

Nalmefene

Nalmefene is a pure opioid antagonist structurally similar to naloxone and naltrexone. Like naloxone and naltrexone, nalmefene has a greater preference for mu- than delta- or kappa- receptors, as demonstrated by IC_{50} studies. [1109] Nalmefene is long acting after oral (0.5-3.0 mg
kg^{-1}) and parenteral (0.2-2.0 mg
kg^{-1}) administration. It produces little effect when administered by itself. Duration of reversal of fentanyl and morphine-induced respiratory depression is dosedependent. [1110] [1111] Nalmefene is equipotent to naloxone. [1112] Reports of the plasma half-life for nalmefene range from 3 to 8 to 10 hours and reflect differences in doses studied and assay sensitivity. [1112] Bioavailability after oral administration is 40 to 50 percent, and peak plasma concentrations are reached in 1 to 2 hours. The drug undergoes hepatic metabolism and is excreted via the biliary and renal systems. Nalmefene's steady-state volume of distribution and elimination half-life are significantly increased in patients with renal failure because of decreased renal clearance. [1113]

DRUG INTERACTIONS

General Principles

No one drug or agent produces optimal anesthetic conditions. At least two drugs are required. [884] [1114] Opioids are frequently combined with other anesthetic agents toward this end. However, the possibility of adverse drug interactions increases exponentially with the number of drugs a patient receives. In anesthesia, most drugs concomitantly administered interact. Some of these interactions are intentionally sought; others are unwanted and adverse.

There are three general types of mechanisms of drug interactions. [1115] Pharmaceutical-type interactions are chemical in nature, as illustrated when an alkaline solution of thiopental and an acidic solution of succinylcholine precipitate when simultaneously administered IV.

Pharmacokinetic-type interactions are probably commonplace in anesthesia. They occur when the administration of one agent alters the pharmacokinetics or disposition of another. Hemodynamic changes, for example, induced by one agent are likely to alter one or more factors that determine the pharmacokinetics of another agent. Sufentanil, which has a greater hepatic extraction ratio than alfentanil, is more likely to be affected by decreases in hepatic blood flow. Benzodiazepine administration can result in higher opioid plasma levels secondary to the pharmacokinetic consequences of decreased cardiac output. [1116] Opioid plasma levels also increase in the presence of propofol. [1117] Decreased opioid metabolism, by the CYP 3A4 isoform of the cytochrome P-450 enzyme responsible for the oxidative metabolism of more than 50 drugs, may underlie these effects, too. Liver enzyme induction, by substances such as alcohol, antiepileptics, and barbiturates, can also markedly alter the metabolism and disposition

of anesthetic agents, in particular midazolam. Enzyme inhibitors, such as erythromycin, may be more likely to prolong the action of alfentanil than sufentanil. [1115]

A third general mechanism underlying drug interactions is pharmacodynamic. Pharmacodynamic interactions can be adverse, such as when a patient experiences profound hypotension on receiving an opioid and a sedative-hypnotic for the induction of anesthesia. However, understanding and optimally using pharmacodynamic interactions is a cornerstone of clinical practice. Studies have quantified the pharmacodynamic interaction between opioids and inhalation anesthetics with classic MAC reduction evaluations in animals and humans (see earlier). Although marked synergism between opioids and inhalation agents occurs with analgesic doses of opioids, there is a ceiling effect to MAC reduction by opioids. The ceiling to opioid action with opioid- sedative-hypnotic interactions and synergism is much less apparent. Other evaluations of opioid-sedative-hypnotic interactions have focused primarily on suppression of somatic responses to surgery and optimizing recovery, with the aid of computer simulations. [853] [885]

The pharmacodynamic synergism between opioids and sedative-hypnotics such as propofol is profound. Thus, when combined, the amounts administered and the effect site concentrations needed for both agents are significantly reduced. Intuitively, and demonstrated in published studies, choosing an opioid with a short context-sensitive half-life allows greater doses of that opioid to be administered, along with reduced doses of propofol, without compromising the time for recovery from anesthesia. Thus, the optimal plasma level of propofol is estimated to be approximately 30 percent less when it is combined with remifentanil instead of alfentanil. [1117] When a potent opioid effect is sought, the use of remifentanil allows the greatest flexibility in opioid dosing without necessarily prolonging emergence.

Other questions remain to be addressed. For example, what drug dosing regimens and plasma concentrations of an opioid and a sedative-hypnotic will provide optimal hemodynamic control during a range of noxious stimuli? This is of particular interest especially when opioids are employed with the aim of providing hemodynamic control and stability. Complicating our understanding of drug interactions is the observation that the same degree of interaction does not apply across different types of stimuli.

Specific Agents

Sedative-Hypnotics

Benzodiazepines are potent anxiolytics and amnesics, and they produce few significant hemodynamic alterations when administered alone. They are considered by some to be the ideal agents to combine with opioids. Benzodiazepines potentiate the effects of opioids and decrease opioid requirements for loss of consciousness, often in a synergistic fashion. [1118] [1119] Not all benzodiazepine-opioid interactions are synergistic. On the contrary, antinociceptive interaction between these two types of drugs may be less than additive. [1120] [1121] Substantial or convincing proof of this in humans is, however, lacking. [1122] [1123] In addition, many studies reveal benzodiazepine-opioid interactions for many properties other than analgesia to be synergistic (supraadditive). [1124]

As reviewed previously, both the cardiovascular and respiratory actions of opioids can be significantly altered by the concomitant administration of benzodiazepines (Fig. 10-49) (Figure Not Available) . Combinations of benzodiazepines and opioids, although occasionally preserving ventricular function, [1125] can cause significant and occasionally profound decreases in

Figure 10-49 (Figure Not Available) Bar graph of the incidence of hypoxemia (Sp O_2 <90%) and apnea (no spontaneous respiratory effort for 15 sec) in healthy volunteers breathing room air who received 2 mug/kg fentanyl and/or 0.05 mg/kg midazolam intravenously. *(From Bailey et al [343])*

blood pressure, cardiac index, heart rates, and systemic vascular resistances. [9] [217] [1116] [1126] Sudden dramatic hypotension has been reported when midazolam and sufentanil are combined. [1127] [1128] In patients with poor left ventricular function, this drug regimen may be particularly hazardous. Some investigators have found IV lorazepam, if administered after tracheal intubation and high-dose fentanyl anesthesia, to cause less severe hemodynamic changes than other benzodiazepines. [1129] [1130] The slow onset of action of lorazepam may contribute to an apparent reduction of associated adverse hemodynamic effects. Other investigators have suggested that fluid loading may attenuate decreases in blood pressure, ventricular filling, and cardiac output that occur when benzodiazepines are combined with opioids. [1131]

Barbiturates, droperidol, ketamine, etomidate, and propofol are some of the other sedative-hypnotics combined with opioids. Either thiopental or propofol can be employed safely in combination with opioids. However, either drug can potentiate or produce hypotension if too large a dose is administered. This is true in healthy patients as well as in those with coronary artery disease. [1132] Hypotension after barbiturate-opioid combination is due to venodilatation and decreased cardiac filling. Other mechanisms include myo-cardial depression and decreased sympathetic nervous system activity. Attempts to ensure amnesia by combining barbiturates with

opioids can significantly compromise hemodynamic stability. [1132] [1133] Significantly reducing induction doses of barbiturate administered concomitantly with opioids is recommended.

The administration of propofol-opioid combinations is born of the same logic as benzodiazepine-opioid combinations: together they provide unconsciousness and block responses to noxious stimuli, whereas alone neither drug reliably does both. In addition, with the trend toward early tracheal extubation after cardiac surgery, short-acting agents such as propofol can be useful in cardiac anesthesia. Propofol does, however, produce significant cardiovascular depression that may not resolve immediately with decreasing blood drug levels. [1134] Initial reports of hypotension after anesthetic induction with propofol [1135] have been followed by investigations demonstrating minimal changes in blood pressure when propofol is administered via infusion. [1136]

Several clinical studies of cardiac anesthesia with propofol and moderate doses of opioids report favorable outcomes. [902] [924] [1137] [1138] [1139] [1140] [1141] [1142] Propofol-fentanyl [1138] and propofol-sufentanil [1143] anesthesia for coronary artery bypass surgery may provide acceptable conditions, but mean arterial pressure can decrease to levels that may jeopardize coronary perfusion, especially during the induction of anesthesia. [1138] When a propofol infusion is followed by opioid administration, mean arterial pressure and heart rate can decrease by as much as 35 and 16 percent, respectively. [1138] These changes can be associated with similar decreases in systemic vascular resistance and cardiac index. Comparisons of propofol-opioid anesthesia with potent inhaled agent-opioid anesthesia demonstrate that bolus induction doses, but not infusions, of propofol produce greater degrees of hypotension. [1143] [1144]

Other anesthetic induction agents such as etomidate and ketamine can be combined in low doses with opioids with little loss of cardiovascular stability. In patients scheduled for coronary artery bypass grafting, Haessler et al [1145] found etomidate (0.25 mg/kg) plus fentanyl (6 mug/kg) results in less hypotension after induction and intubation than propofol (1 mg/kg) plus fentanyl (6 mug/kg).

Inhaled Anesthetics

Cardiovascular function is frequently preserved during N_2O administration. However, decreases in cardiac output, heart rate and arterial pressure, as well as increases in pulmonary and systemic vascular resistance, can occur. [12] [328] [1146] [1147] Deterioration of cardiac function with N_2O-opioid combinations may be due to increases in afterload (systemic and pulmonary vascular resistance increases), [328] [1148] increases in coronary vascular resistance resulting in impaired coronary blood flow, [1149] lower inspired O_2 concentration associated with the use of N_2O, [1150] or direct myocardial depression. [1151] [1152] [1153] See Chapter 5 .

Other studies demonstrate that N_2O does not exacerbate myocardial ischemia. [1154] [1155] Myocardial dysfunction with N_2O may not be evident with routine monitoring, that is, blood pressure, because of the elevated systemic vascular resistance. [1156] Segmental wall motion abnormalities in areas of marginal myocardial perfusion can be demonstrated in animals when N_2O and opioids are combined. [1156] However, in clinical studies of patients with ischemic cardiac disease, the addition of N_2O to fentanyl or sufentanil is reported not to be associated with any new ST-segment changes or segmental wall motion abnormalities. [1157]

N_2O produces analgesia that is in part mediated through opioidergic systems. [1158] This may explain suggested infra-additive interactions between opioids and N_2O. In addition, N_2O is a weak amnesic, and its use is associated with nausea and vomiting. Combining N_2O with an opioid in a balanced technique may not best employ drug interaction synergism. Although amnesia and intraoperative conditions may be somewhat improved, N_2O does not produce any effects that are not already produced by either an opioid or a sedative-hypnotic. The advent of shorter-acting IV anesthetics, as well as volatile anesthetics with bloodgas partition coefficients equal to that of N_2O, has decreased the popularity of N_2O in balanced anesthesia.

Volatile anesthetics are frequently combined in low doses (one-third to one-half MAC) with opioids in order to ensure amnesia and to promote immobility and hemodynamic stability. Their intrinsic ability to produce cardiovascular depression in a dose-dependent manner often allows their titration toward these goals. [1143] [1159] With the exception of halothane, [1160] low concentrations of volatile anesthetics in combination with opioids are usually well tolerated in patients with normal, as well as compromised, ventricular function. [1159] The newer volatile anesthetics isoflurane, desflurane, and sevoflurane cause only modest myocardial depression at concentrations of less than 1 MAC. Low concentrations of isoflurane have also been effectively and safely used to treat intraoperative hypertension during high-dose sufentanil anesthesia for coronary artery surgery. [1161] [1162]

In general, clinical trials of opioids supplemented with newer volatile anesthetics for cardiac surgery demonstrate well-preserved cardiac output and minimal decreases in mean arterial blood pressure. [1139] [1142] [1163] [1164] The hemodynamic effects of combining opioids with modest doses of

these inhalational agents are usually additive and do not resemble the exaggerated effect on hemodynamics that has been described with agents such as the benzodiazepines. In addition, the added advantage of being able to remove, as well as to introduce, potent inhaled anesthetics results in greater flexibility and perhaps safety.

Myocardial ischemia may not, however, always be ameliorated by approaches that combine opioids with potent inhaled agents in spite of apparent "good" hemodynamic control. [1165] For example, adding halothane to a sufentanil (10-20 mug kg^{-1}) anesthetic to control increases in arterial blood pressure may produce hemodynamic alterations (decreased blood pressure, cardiac output) that exacerbate regional myocardial hypoperfusion and increase lactate production. [1166] In addition, undesirable cardiovascular depression can result from combining these agents. [1165]

Some of the potent inhaled anesthetics can increase sympathetic nervous system activity and may increase the risk of myocardial ischemia in the cardiac patient. For example, the administration of either desflurane or isoflurane can increase heart rate and mean arterial pressure during induction of anesthesia or with rapid increases in drug concentration. [1167] [1168] Theses findings are most pronounced with desflurane, but they can occur with isoflurane. Prior administration of fentanyl, in doses as low as 1.5 mug/kg, can markedly attenuate such responses (Fig. 10-50) (Figure Not Available) . [1167] Alfentanil (10 mug/kg) is also effective in attenuating these effects. [485]

Muscle Relaxants

Autonomic actions of muscle relaxants can alter hemodynamics unfavorably during opioid-based anesthesia (Ch. 12) . Pancuronium bromide has been frequently used for muscle relaxation during high-dose opioid anesthesia and has been reported to provide superior hemodynamics than vecuronium, [1169] metocurine, or metocurine-pancuronium combinations. [1170] The vagolytic actions of pancuronium tend to attenuate opioid-induced bradycardias and to support blood

Figure 10-50 (Figure Not Available) The effect of fentanyl, 1.5 and 4.5 mug/kg, in attenuating the increases in heart rate (HR) and mean arterial pressure (MAP) that are associated with a rapid change in the end-tidal desflurane concentration from 4 to 8 percent. Compared with control (without fentanyl), fentanyl significantly decreases these hyperdynamic responses. *(From Weiskopf et al [1167])*

pressure. [1171] However, other investigators have cautioned against using pancuronium because it can cause significant increases in heart rate and myocardial ischemia. [454] [1172] [1173] [1174] [1175] [1176] One study reported detecting no myocardial ischemia as assessed by transesophageal echocardiography after bolus injections of pancuronium in patients undergoing coronary artery bypass surgery, even though increases in heart rate, blood pressure and cardiac output occurred. [1177] Many factors alter the impact of pancuronium and other muscle relaxants on hemodynamics when combined with opioids: the dose, timing, and rate of administration of each relaxant as well as the premedication, intravascular volume, left ventricular function, and presence of other drugs with autonomic nervous system actions. [1178] For example, beta-adrenergic blockade often attenuates or eliminates significant pancuronium-induced tachycardias. [1172] [1179] [1180] [1181]

Vecuronium can potentiate decreases in heart rate and cardiac index after fentanyl, [1182] [1183] although alone it has minimal cardiovascular side effects. Combinations of vecuronium and high doses of opioids produce negative chronotropic and inotropic effects resulting in decreases in heart rate, cardiac output, and blood pressure

and increases in the need for vasopressor support. [1176] [1184] Stimuli enhancing vagal tone may also predispose patients to bradycardia after vecuronium. [1185]

O'Connor et al [1186] found that, compared with vecuronium (0.15 mg
kg^{-1}), pancuronium (0.15 mg
kg^{-1}) produced tachycardia more often (32 versus 7%) in patients undergoing coronary artery surgery. However, pancuronium-induced tachycardia was easily and rapidly treated and caused no differences in ischemia or perioperative myocardial infarction. Others have found more stable hemodynamics with vecuronium than pancuronium or atracurium during opioid anesthesia. [1175] Still other investigators have found no significant differences in the frequency of intraoperative ischemic events with pancuronium and vecuronium. [1181]

Metocurine (0.5 mg
kg^{-1}) alone has also been reported to produce less hemodynamic fluctuation [1187] than pancuronium during opioid anesthesia, although high doses (>0.3 mg
kg^{-1}) may cause hypotension. [1173] Combining metocurine and pancuronium has several advantages (e.g., increased speed of onset and less tachycardia and hypotension). [1173] [1175] [1188] Doxacurium causes no circulatory changes during sufentanilmidazolam anesthesia effects. [1189] Small decreases in blood pressure and heart rate were observed by Murray et al [1190] in healthy patients receiving doxacurium during balanced anesthesia with fentanyl (2-10 mug/kg). Opioid-based anesthesia does not reduce the ED [95] of doxacurium. [1191]

Pipecuronium, in doses as high as three times the ED [95] , has also been found to be devoid of circulatory actions in patients undergoing coronary artery bypass grafting surgery under midazolam-fentanyl anesthesia. [1192] Starr et al [1193] reported that neither pipecuronium nor vecuronium produced significant hemodynamic changes in such patients who were receiving sufentanil anesthesia. Opioid-based anesthesia does not affect the duration of action of pipecuronium. [1194]

Mivacurium chloride produces modest decreases in blood pressure when larger doses (e.g., twice ED_{95}) are injected rapidly (<30 s). [1195] [1196] This response likely results from histamine release. [1195] Few significant circulatory changes were associated with mivacurium (0.15-0.25 mg/kg over 60 s) in patients undergoing coronary artery bypass grafting surgery and receiving sufentanil-midazolam anesthesia. [1197] These changes were modest and were limited to decreases in heart rate and increases in stroke volume. Opioids do not affect the duration of action of mivacurium. [1198]

Miscellaneous

MAOI can underlie the most serious and potentially fatal opioid-other drug interaction. Although at times this warning was thought to pertain to all opioids, only meperidine is consistently implicated as capable of this severe interaction. [1199] [1200] MAO mediates norepinephrine turnover rate, and treatment with MAOI results in the accumulation of norepinephrine within the CNS. Indirect acting sympa- thomimetics can cause exaggerated norepinephrine release.

Meperidine-MAOI interactions are either excitatory or depressive. The former result in agitation, headache, hemodynamic instability, fever, rigidity, convulsions, and coma. This interaction is thought to be due to excessive central serotoninergic activity. Meperidine, but not morphine, blocks neuronal uptake of serotonin. The depressive form consists of respiratory depression, hypotension, and coma as a result of MAOI inhibition of hepatic microsomal enzymes and meperidine accumulation. [1200]

Treatment of these drug interaction syndromes is supportive. Opioid antagonism may be hazardous, especially in the excitatory form. Suggested therapeutic approaches include administering antipyretics, antihypertensive agents, sedatives, and steroids. [1200]

Although Ca^{2+} entry blockers (CEB) can significantly depress cardiac function and may cause regional wall motion abnormalities during potent inhalation anesthesia, opioid-CEB interactions are usually mild. Mean arterial pressure and cardiac function and conduction have been reported not to change appreciably in dogs when opioids and verapamil are combined. [1201] [1202] Diltiazem-fentanyl interactions in the dog, however, frequently result in hypotension and second-degree heart block. [1203] Regional systolic and diastolic cardiac dysfunction results from verapamil-fentanyl interactions if coronary blood flow is critically limited in the dog. [1204] Fentanyl anesthesia causes minimal decreases in cardiac index and only modest decreases in blood pressure and systemic vascular resistance in patients receiving verapamil. [1205] On the other hand, the presence of beta- adrenergic blockade, the quality of left ventricular function, and the presence of other anesthetics will influence the response to CEB. In addition, CEB have different profiles of effects and can result in persistent hypotension or unpredictable responses when used as an adjunct to opioid anesthesia for controlled hypotension. [1206] *N*-type CEB may also functionally interact with morphine at the level of the spinal cord to influence nociception. [1207]

Nitroglycerin is often used with high-dose opioid anesthesia to treat increases in blood pressure and ischemia. Nitroglycerin infusion during high-dose fentanyl anesthesia for coronary artery surgery has been reported to reduce ischemia by some investigators, [1208] but not others. [1209] These or larger doses of nitroglycerin can result in hypotension, tachycardia, and decreases in ventricular filling pressures.

Erythromycin can inhibit the metabolism of several compounds including theophylline and the histamine $_2$ blockers. It supposedly reduces the oxidizing activity of cytochrome P-450. Alfentanil, but not sufentanil, may have its action prolonged as a result of impaired metabolism in patients receiving erythromycin. [1210] [1211]

Cimetidine can prolong opioid effects by decreasing hepatic blood flow and/or diminishing hepatic metabolism. Ranitidine can also reduce hepatic blood flow but binds less to the cytochrome P-450 system and has less impact on opioid metabolism than cimetidine. [1212] Other drugs that inhibit certain cytochrome systems can increase endogenous morphine production from codeine. [979]
